^bDirect invasion in T4 includes invasion of other segments of the colorectum by way of the serosa, for example, invasion of the sigmoid colon by a carcinoma of the cecum.

^cTumor that is adherent to other organs or structures, macroscopically, is classified R4. However, if no tumor is present in the adhesion, microscopically, the classification should be pT3. The V and L substaging should be used to identify the presence or absence of vascular or lymphatic invasion.

or identifiers for a high risk of an adverse outcome has been confirmed on long-term follow-up.^{29,30} Patients with poor prognostic factors can have local, regional, or systemic spread in 8.5% to 14.4% of cases.³¹ In cases where operative risk is higher (in the elderly), the mortality associated with resection may exceed the risk of residual disease.^{32,33} As laparoscopic techniques for colon resection become more common, it will be important to include the tattooing of suspected malignant polyp sites for identification of the polypectomy site.³⁴ Intraoperative colonoscopy may be an important aid in the identification of the polyp site.³⁵ Most commonly, the issue dictating surgical resection will be an inadequate or questionable margin.³⁶

After colonoscopic removal of the malignant polyp, it is important to document carefully the site of polypectomy in the event that surgical resection is warranted. We commonly perform this procedure using endoscopically placed clips, which are both palpable and evident on abdominal radiographs. Follow-up colonoscopy is generally performed 3 to 6 months after removal of a malignant polyp to assess the polypectomy site for any residual mass. Presence of a mass is an indication for surgical resection. In patients in whom there is no further evidence of residual carcinoma, colonoscopic follow-up can be carried out at 1 year.³⁷

Management of Potentially Curable Colon Cancer

Pretreatment Evaluation

Surgical management is required for most patients with a diagnosis of colon carcinoma. The appropriateness of a surgi-

cal resection will be determined by the extent of disease and comorbidities. In cases of metastatic colorectal carcinoma, surgery may be required for palliation. Some authors have documented an ability to manage colon cancer patients non-operatively in the presence of metastatic disease without significant complications from bleeding, perforation, or obstruction.³⁸

A well-conducted history and physical examination will provide a great deal of information about the patient's extent of disease and suitability for treatment. Specific aspects of the history taking should focus on a personal history of cancer or polyps and family history of colorectal cancer or polyps.

Complete colonic examination not only allows a biopsy of the index lesion but also provides information about the exact location of the lesion. Additionally, it provides information on the presence or absence of synchronous colon cancers, which are present in 1.5% to 7.6% of cases. In addition, significant synchronous polyps can occur in 25% to 40% of patients.³⁹⁻⁴¹ The colon should be endoscopically cleared of these lesions. If polyps cannot be removed endoscopically, they should be included in the planned resection. Preoperative colonoscopy can change the nature of the planned surgical procedures in about 10% to 13% of cases.⁴²⁻⁴⁴

Computed tomography (CT) scanning is used to reveal clinically unapparent liver metastases or local extension to adjacent organs. The negative predictive value of CT scan for synchronous liver metastases has been estimated at 90%.⁴⁵ The argument has been made that a CT scan often does not change management compared to the findings at operation alone.⁴⁶

The value of a chest X-ray for the primary workup of a patient may be in evaluating the patient for comorbid diseases that would have an effect on planning for surgery, as well as to indicate the presence of pulmonary metastases. It is interesting to note that even in patients with liver metastases, when the initial chest X-ray is negative, chest CT is positive in about 30% of patients. However, Kronawitter and associates found that only 5% of high-risk patients had malignant lesions identified.⁴⁷

In those who are curatively treated, there is little prognostic value to preoperative carcinoembryonic antigen (CEA) levels.^{48,49} Preoperative CEA levels have been demonstrated to have prognostic value and to be correlated with stage. CEA levels are increased in 65% to 85% of patients with Dukes' D colorectal cancers.⁵⁰ Among patients with high-risk (i.e., C1 and C2 disease) cancers, high (greater than 5 mg/ml) CEA levels preoperatively correlated with significantly shorter survival. In this retrospective study of 218 patients, CEA was not useful to predict survival in Dukes' A or B patients.⁵¹

The value of preoperative ¹⁸F-fluorodeoxyglucose positron emission tomography (FDG-PET) scanning in the primary evaluation of patients with colorectal cancer has only recently been addressed. In a study of 38 consecutive patients with colorectal primary cancers, PET was compared to CT and sonography. Its accuracy for liver metastases was about 91%, which was similar to CT. In this study, PET is said to have changed the treatment modality in 8% of patients and the extent of surgery in 13%. The studies demonstrated extrahepatic lesions in 4 of 38 patients that could be identified as malignant. Overall, most of the change in therapy (3 of 6 cases) was to avoid operation at all in cases of "generalized malignancy." In 2 of 6 cases, the patient underwent surgery

anyway, and in 1 of 6 of the patients the nature of the surgery was changed to a smaller palliative procedure.⁵² In other single institutional studies, the predictive accuracy in the detection of liver metastases in those with primary colon and rectal cancer is greater than with CT.⁵³ It has yet to be demonstrated in long-term follow-up that clinical management decisions made on the basis of PET scanning will produce either survival or quality of life benefits.

Surgical Management of Carcinoma of the Colon

Radical resection with curative intent is appropriate for 80% to 90% of patients with colon carcinoma.⁵⁴ Surgical resection is the mainstay of treatment for curable colorectal cancer. It is the only treatment required for tumors limited to the bowel wall. Although this is commonly accomplished by palpation and inspection, intraoperative ultrasonography of the liver has increased the rate of detection of small metastases.^{55,56} The findings of exploration in regard to the fixation or extent of the primary tumor, local or regional adenopathy, involvement of adjacent structures, and sites of metastases should be documented in the surgical report.⁵⁷

Extent of Resection

The extent of colonic resection is determined by the blood vessels that must be divided to remove the lymphatic drainage of the tumor-bearing portion of the colon with tumor-free margins.⁵⁸ This is the primary treatment approach in patients with colon carcinoma.⁵⁹ Resection of intermediate and principal nodes requires ligation and division of the main vascular trunks to the affected colon segment.⁶⁰ Tumor-free margins usually are accomplished by resection of at least 5 cm of normal bowel proximal and distal to the tumor.⁶¹ Uncontrolled data exist to demonstrate improvement in outcomes from extending this resection.⁶²

Extent of Lymph Node Resection

Adequate lymphadenectomy is crucial. In addition to its therapeutic benefits of preventing local progression and subsequent development of symptoms caused by mesenteric recurrence, lymphadenectomy is critical in the staging of patients with colon carcinoma.⁶³ In colon cancer, recovery of cancer-bearing lymph nodes is the parameter most often used for adjuvant therapy recommendations in the United States.⁶⁴ Mesenteric resection should be extensive enough to harvest at least 12 lymph nodes for examination to allow for accurate staging.⁶⁵

Controversy exists over the curative efficacy of extensive lymphadenectomy in patients with colon carcinoma. Excellent results have been obtained with wide mesenteric resection.^{66,67} Other studies have found patients with principal node involvement to be incurable.⁶⁸ Slanetz and Grimson⁶⁹ reviewed 2,409 cases of curative resections. They found that specific groups of patients benefited from high ligation of the vascular pedicle; these were the patients with transmural node-negative tumors and those with limited nodal spread. Those in whom the highest nodes were involved did not appear to benefit. A prospective multicenter study was unable to confirm a survival benefit confined by wider mesenteric resection in left colon cancer.⁷⁰

Sentinel Lymph Node Biopsy for Colon Cancer

In an effort to increase the detection of lymphatic metastases in patients undergoing the resection of a colon cancer, sentinel lymph node biopsy has been used. In colon cancer, it is used to stage the patient in a more-sensitive way as opposed to eliminating or minimizing the extent of the lymphatic resection (Table 42.3).

Among patients with node-positive cancers, survival can be affected by the number of positive nodes. Patients with one positive node may have survival rates in the 69% to 75% range whereas 5-year survival for those with four or more positive nodes or metastases along a named vascular trunk are in the 27% to 40% range.⁷¹ Overall, survival rates for patients with node-positive cancers appear to be approximately 40% to 50%. The analysis by Cohen et al.⁷² of node-positive colon cancer patients treated with resection alone showed a significant difference in survival for patients having one to three positive nodes (66% 5-year survival) and those with four or more positive nodes (37% 5-year survival). It has been demonstrated, however, that up to 75% of all positive nodes in resectable colon cancer may be under 2mm in size and therefore gross dissection alone may underestimate nodal status.⁷³

Contiguous Organ Involvement

For tumors that are adherent to adjacent organs, adhesions should not be divided. In one-half of cases, the adherence may be caused by malignant invasion of these adjacent organs.⁷⁴ Separation of sites of adherence can disrupt the tumor, increase recurrence, and reduce survival rates. Adjacent organ involvement should be resected in continuity with the colon and primary tumor. Radical resection may still be curative in 20% to 50% of patients, even if adjacent tissues are invaded by malignant infiltration.⁷⁴ In a review of 25 patients with locally advanced colon cancer requiring en bloc resection, median survival was 38.2 months and 5-year survival was 49%. External-beam and intraoperative therapy was used to obtain these results.⁷⁵

Surgical Technique

Molecular techniques have enhanced the ability to detect cancer cells released into the circulation during operative

manipulation.⁷⁶ A prospective, randomized trial by Wiggers et al.⁷⁷ showed that in patients who underwent preliminary ligation of vessels liver metastases appeared later than in patients who did not undergo this procedure. However, no overall survival benefit was demonstrated.

Possibly because the local recurrence rate for colon cancer approximates 4%, surgical technique for colon resection may be seen as less critical in many cases.^{78,79} Hospital volume seemed to have a greater effect on patient outcome than did individual surgeon volume in a review of a large administrative database.⁸⁰

Laparoscopic Colectomy

Laparoscopic techniques have become widely used in the management of benign and malignant colorectal conditions.⁸¹ With laparoscopic colectomies, there is a theoretical advantage of a shortened hospital stay and a more rapid recovery.⁸²

The overall complications of laparoscopic colorectal surgery were comparable to those of open resection in a large randomized trial of laparoscopic and open colectomy in the United States.⁸³ Data that are available on the extent of lymphadenectomy and resection margins suggest that oncologic laparoscopic resection is comparable to open colectomy for cancer.⁸⁴ Studies have documented estimated recurrence rates in port sites of 1.08% to 3.8% after laparoscopic resection. These recurrence rates are similar to those associated with laparotomy wounds in patients treated by open resection.⁸³

Two prospective, randomized trials have been done to compare the efficacy of laparoscopic colectomy with open colectomy for carcinoma.^{85,86} The COST study involves patients with right, left, or sigmoid colon adenocarcinoma, and patients are randomly assigned to laparoscopically assisted or open colectomy. The primary endpoints of the study are disease-free and overall survival. The secondary endpoints are examinations of morbidity, cost-effectiveness, and quality of life (Table 42.4).

The COST trial demonstrated, in a multiinstitutional trial, that rates of recurrence and overall survival rates were equivalent for open and laparoscopic colectomy.⁸⁵ Wound recurrence rates were less than 1% in both groups. Complication rates were similar in both groups. It is important to recognize that this trial excluded rectal cancer and transverse

TABLE 42.4. Laparoscopic versus open resection for colon cancer.

colon cancer. The authors also had strict controls over the quality of the surgery and the experience of the surgeons before enrolling patients in the study.

In the study by Lacy et al., the criteria for entry were similar; however, it was conducted in a single hospital unit.⁸⁶ This study favors laparoscopic resection in terms of survival and recurrence rates. Lower rates of wound infection and ileus were noted in the laparoscopic resection group, and this was responsible for an overall lower morbidity rate for this group. The cancer-related probability of survival was significantly higher in the laparoscopic resection group.

Prophylactic Oophorectomy

Ovarian metastases and colorectal cancer can occur at the time of presentation in 2% to 8% of patients and as a subsequent site of metastases in 1% to 7% of curatively resected patients. Survival from ovarian metastases is poor in both settings, being 9% with synchronous metastases and 20% with metachronous metastases.⁸⁷

Prophylactic removal of the ovaries at the time of colorectal cancer resection has been considered to reduce the risks of poor survival from metachronous metastases; this is pertinent only for the 1% to 7% of women who develop metachronous metastases, of whom only 6% to 20% have disease confined to the ovaries.

In a study of prophylactic oophorectomy in postmenopausal women by Sielezneck et al.,⁸⁸ the incidence of occult ovarian metastases was 2.4%. The 5-year survival rates in this study were equal, whether or not a prophylactic oophorectomy was performed.⁸⁹ In a preliminary report of a randomized trial of prophylactic oophorectomy in patients with Dukes' stage B and C colorectal cancer treated at the Mayo Clinic, no incidence of gross or microscopic ovarian metastases was found in 77 patients randomized to oophorectomy. No differences were seen in overall survival, whether or not patients were randomized to oophorectomy. A trend was noted toward an improved recurrence-free survival with prophylactic oophorectomy. No selection criteria based on tumor size, grade, or other characteristics exist at this time.⁹⁰

Oncologic Results of Surgical Management

For node-negative patients, survival with surgery alone varies between 75% and 90%.⁷¹ Even in these cancers, such factors as depth of penetration, contiguous organ involvement, lymphatic and vascular invasion, differentiation and perineural invasion, as well as molecular and cellular characteristics, will affect survival.⁹¹

Important issues in surgically resected, apparently node-negative colon cancer are the methods of lymph node evaluation and the detection of occult metastatic disease. Studies have indicated that 12 to 15 lymph nodes should be examined to indicate true nodal negativity.^{65,92,93} Standardizing

node evaluation and using immunohistochemical techniques can identify occult nodal metastases in up to 26% of those whose nodes test negatively by routine techniques.⁹⁴ There is a high likelihood that standard dissection will identify node-negative patients if an adequate number of nodes are examined.⁷³ Some have questioned the relevance of occult micrometastatic disease in patients who have undergone curative resection.⁹⁵ In a group of surgically resected patients with micrometastases in resected nodes and original Dukes' stage A or B colorectal cancer, survival time was 48 months, which equaled the survival time for patients without micrometastases. In a review of 243 cases from NSABP trials that were node negative by standard techniques, immunohistochemical demonstration of nodal micrometastases did not correlate with overall or recurrence-free survival in node-negative patients.⁹⁶

Specific Management Problems

SYNCHRONOUS CANCER

Synchronous cancers are relatively uncommon, having an incidence of 3.4%, as described by Finan et al.⁹⁷ In addition to the presence of another malignancy, there can be up to 30% to 40% incidence of synchronous neoplastic polyps in the colon of a patient with a large bowel carcinoma.⁹⁸

If removal of all polyps cannot be accomplished owing to obstructive lesions or an emergency operation for perforation, the index lesion should be addressed at the time of surgery and subsequent complete colonoscopic examination should be carried out in the early postoperative period.⁹⁹

Passman et al.¹⁰⁰ conducted an 18-year multiinstitutional database study of 4,878 patients with colon cancer. They found a 3.3% incidence of synchronous tumors; they also found that patients with synchronous colon cancers have the same survival rate as patients with solitary colon tumors when the highest stage of the synchronous tumor is considered.¹⁰⁰

OBSTRUCTING CANCERS

Intestinal obstruction is the most common emergency presentation of colorectal carcinoma.¹⁰¹ Poor prognosis is associated with this presentation, even when analyzed stage for stage, with an overall survival rate of 31% at 5 years. Patients who present with this problem are frequently elderly or in poor condition because of dehydration, and operative mortality can approach 28%.¹⁰¹

Staged resection is most useful in elderly persons with multiple comorbidities.¹⁰¹ Further alternatives for obstruction lesions distal to the splenic flexure have been studied. The first is subtotal colectomy, the second is an extended right colectomy to include the obstruction lesion without colonic decompression, and a third is the use of intraopera-

tive colonic lavage and segmental resection. Nyam et al.⁸⁹ reported on a series of 103 patients with obstructing left-side colon carcinomas undergoing an extended right colectomy without colonic decompression or a segmental left colectomy with intraoperative lavage. They found that both procedures had an acceptably low anastomotic leak rate and mortality. Poon et al.¹⁰² studied emergency primary resection and anastomosis with intraoperative colonic lavage for left-sided obstruction. Hospital mortality rate was 5% to 9%; the anastomotic leak rate with this approach was 4%.

The alternative approach of subtotal colectomy with ileorectal anastomosis has been compared with intraoperative lavage in primary colonic anastomosis in a randomized trial.¹⁰³ This trial showed no difference in mortality or morbidity rates. However, patients with subtotal colectomy had a higher postoperative frequency of bowel movements.¹⁰³

PERFORATING CANCERS

Perforation of the colon due to carcinoma can occur either at the site of the colon tumor itself (in approximately 65% to 82% of patients with perforation) or in the bowel proximal to an obstructing tumor (in 18% to 35% of patients).¹⁰⁴ Overall 5-year survival for patients with localized perforation is approximately 44%. This complication occurs in 2% to 8% of all patients with colorectal cancer.

The presence of a perforation or fistula increases cancer recurrence rates. Local recurrence rates of 23% have been reported by Carraro et al.¹⁰⁴ in a study of 83 patients with large bowel perforation and colorectal cancer; this compares with figures of 28% to 44% reported in the literature. Peritoneal seeding is a particularly common failure in patients with perforated colorectal cancers, with carcinomatosis rates of 17% to 18%.

Radiation Therapy for Colon Cancer

The overall component that local failure contributes to the recurrence of resected colon cancer is low. However, it has been possible to demonstrate that those with obstruction or perforation have higher local recurrence rates compared to those without these complications of colon cancer. In a retrospective study of 77 patients with obstruction and 34 patients with perforated colon cancers, the local failure rates were 42% and 44%, respectively, compared with a local failure rate of 14% in other resected patients without these features.¹⁰⁵ From subset analysis of colon cancer adjuvant trials it has been implied that local recurrences can occur in 20% to 27% of resected node-positive patients and that this is not changed by 5-fluorouracil-based chemotherapy. This analysis further concluded that the addition of whole abdominal irradiation reduced local relapse rates to 12% for these high-risk colon cancers.¹⁰⁶

Postoperative irradiation alone was demonstrated to reduce local failure rates compared to historical control rates where doses of 4,300 to 6,300 cGy were delivered to the tumor bed.¹⁰⁷ In another study of postoperative radiation therapy in Astler-Coller stage B2, B3, and C patients, local failure rates were reduced to 8%, 21%, and 31%, respectively, in those receiving radiotherapy compared to 31%, 36%, and 53%, respectively, in those treated with surgery alone.¹⁰⁸ A later follow-up of this series after 5-fluorouracil-based therapy was added to node-positive patients identified Astler-Coller stage

B3 and C3 patients. Tumors associated with abscess or fistula formation and a subset of those with residual gross disease after resection are potential candidates for this approach.¹⁰⁹ Similar results were obtained in B2 and C colon cancer patients when doses of 50 to 55 cGy were given along with fluorouracil. In this study, local control rates dropped from 96% with doses of radiation of 50 to 55 Gy to 76% when less than 45 Gy was given.¹¹⁰ A 10-year retrospective analysis of this approach also confirmed this management in reducing local failure in this group of patients.¹¹¹

Two studies looked at the effect of whole abdominal radiation after the resection of high-risk colon cancer with 5-fluorouracil. In an analysis of 18 patients, local failure was seen in 17%, whereas 28% of patients required treatment breaks of 2 weeks or more and 11% had grade 3 or 4 toxicity.¹¹² In another pilot study, 41 transmural node-negative patients were treated with postoperative 5-fluorouracil, whole abdominal irradiation to 30 Gy, and a boost to the tumor bed. Local control rates compared favorably with similar patients treated with chemotherapy alone. However, 17% of patients had severe toxicity and 7% had life-threatening toxicity. These studies demonstrate positive results with this approach but confirm substantial toxicity for whole abdominal irradiation.¹¹³

On an examination of the role of intraoperative radiation therapy (IORT) in advanced colon cancer where postoperative radiation and chemotherapy were also used, it was found that IORT reduced local failure rate in these with residual disease from 82% to 1%. This result was associated with a 5-year survival improvement for those with residual disease who were treated with IORT compared with external-beam treatment alone.¹¹⁴ For patients with recurrent colon cancer who undergo resection, IORT and external-beam radiation can produce long term survival.¹¹⁵

Chemotherapy for Colon Carcinoma

The treatment of colon carcinoma with curative intent is best achieved in the earliest stages of diagnosis. The estimated 5-year survival of a patient with American Joint Committee on Cancer (AJCC) stage I is approximately 90% with surgery alone. However, the majority of patients present with AJCC stage II/III disease; more than 80% will be rendered disease free following surgical resection but approximately 50% of these patients will develop recurrent disease.¹¹⁶ It is presumed the etiology for the resurgence of colon carcinoma is attributed to microscopic disease that is not self-evident on surgical or radiologic assessment. Therefore, adjuvant chemotherapy is often considered to prevent the manifestation of recurrent tumor that may not be amenable to treatment. Existing heterogeneity in stage II/III patients including surgical technique, the number of lymph nodes involved, colonic obstruction, visceral perforation, histology, age at presentation, coexisting morbidities, and molecular makeup confound the medical oncologist's perspective of what is deemed a simple categorical AJCC stage II or III that can be further subdivided into AJCC subgroups of A, B, or C. For the purposes of this chapter, the discussion of adjuvant chemotherapy is only in reference to surgically resected AJCC stage II (Duke's B2) and III (Dukes' C) patients.

A meta-analysis of 17 randomized adjuvant chemotherapy trials involving 6,791 patients was conducted and published

TABLE 42.5. INT-0035: Adjuvant chemotherapy in Dukes' C colon patients ($n = 929$).

	Observation	Levamisole	5-Fluorouracil (5-FU)/levamisole
Reduction in recurrence	—	NS	41% ($P < 0.0001$)
Decrease in mortality	—	NS	33% ($P = 0.006$)
Overall survival	55%	NS	71% ($P = 0.0064$)

NS, not statistically significant.

in 1988.¹¹⁷ When evaluating all clinical trials published in the English periodical literature through the year 1987, the benefits of adjuvant chemotherapy could not be determined. However, when evaluating 5-fluorouracil (5-FU)-only-containing regimens ($n = 4,700$), the odds of death were 10% lower in comparison to the control arm, and the estimated benefit in 5-year survival was 2.3% to 5.7% higher relative to the control arm, although not statistically significant. If the treatment provided was prolonged for 1 year or more, the absolute 5-year survival benefit was disappointingly less than 5%. Such a small risk-to-benefit ratio in the setting of a patient population that has been surgically cured could not support the use of adjuvant chemotherapy in this setting.

The National Surgical Adjuvant Breast and Bowel Project (NSABP) cooperative group conducted the first large-scale study to evaluate the potential benefits of adjuvant chemotherapy, NSABP C-01.^{118,119} More than 1,100 patients with AJCC stage II and stage III colon cancer were randomized to (a) observation alone, (b) 5-FU, semustine, and vincristine (MOF), or (c) inoculation with the bacillus Calmette–Guerin (BCG) vaccine. The initial use of MOF relative to the control arm indicated a benefit in disease-free survival (DFS) ($P = 0.02$) and overall survival ($P = 0.05$); these findings were not supported after a median follow-up of 8 years ($P = 0.10$ and $P = 0.12$, respectively).¹²⁰ A considerable drawback to the use of the MOF regimen was the development of chemotherapy-related leukemia. There was no survival benefit with the use of BCG.

5-FU/LEVAMISOLE

Immunomodulation of 5-FU with levamisole has been extensively investigated in several randomized trials. Traditionally, levamisole was used as an antihelminthic agent in animals and humans. Its mechanism of action relative to 5-FU is poorly understood but may result in selective stabilization of mRNA.¹²¹ The North Central Cancer Treatment Group (NCCTG) completed the first study to examine the potential immunomodulatory effects of levamisole on 5-FU.¹²² Four hundred eleven Dukes' B2 or C patients following surgical resection were randomized to (a) observation, (b) single-agent levamisole (50mg t.i.d., days 1–3 every 14 days \times 1 year), or (c) 5-FU (450mg/m²/day \times 5 days every 28 days \times 1 year)/levamisole (same schedule and dose as single-agent arm). Patients were followed closely for more than 5 years. It should be noted that two-thirds of patients were Dukes' C colon carcinoma patients; a minority of rectal carcinoma patients were represented. After a median follow-up of 7 years, 5-FU/levamisole versus observation resulted in superiority of disease-

free survival (DFS) ($P = 0.02$) and overall survival (OS) ($P = 0.03$) in Dukes' C patients only; no benefit could be derived in Dukes' B2 patients. The levamisole-alone arm demonstrated a trend in improved DFS and OS but this finding was not statistically significant ($P = 0.06$).

To verify the findings reported in the NCCTG study, Intergroup study, INT-0035, involving members of the NCCTG, Southwest Oncology Group (SWOG) and the Eastern Cooperative Group (ECOG) was completed.¹²³ A total of 1,296 patients were enrolled in this study; three-fourths of the patients were Dukes' C patients. Eligibility criteria were identical to that of the original NCCTG study but rectal carcinoma patients were not included. Preliminary results after a median follow-up of 3.5 years concluded that 5-FU/levamisole provided a significant reduction in recurrence and OS (Table 42.5). Toxicities associated with 5-FU and levamisole were considered to be tolerable. Results of the Dukes' B2 colon carcinoma patients ($n = 318$) were premature and were reported at a later date. This pivotal trial culminated in the Consensus Panel of the National Institute of Health (NIH) recommending 5-FU/levamisole as adjuvant therapy for all node-positive (AJCC stage III/Dukes' C) colon carcinoma patients and became widely accepted as the standard of care in the United States.⁶⁴ The NIH Consensus Panel concluded that Dukes' B2 (AJCC stage II) colon cancer patients are at high risk for recurrence and warrant further evaluation. After a median follow-up of 7 years, the superior benefits of 5-FU/levamisole were confirmed in Dukes' C patients.¹²⁴ Single-agent levamisole failed to provide any clinical benefit in the adjuvant setting.

ALTERING THE PARADIGM OF ADJUVANT CHEMOTHERAPY TO 5-FU/LEUCOVORIN

Whether levamisole provided any true benefit to 5-FU is questionable and may in part be attributed to the large number of patients accrued. An oversight in initial trial design of INT-0035 was to not include an 5-FU-only arm to determine the actual additive benefit of levamisole in this setting.

During the next 5 years, levamisole shortly became replaced by leucovorin (folinic acid), an immunomodulatory agent whose mechanism of action is clearly defined. Leucovorin (LV) biochemically modifies 5-FU by stabilizing the metabolite 5-FdUMP (5-fluorodeoxyuridine monophosphate) to thymidylate synthase (TS), enhancing inhibition of 5-FU on TS. Initial interest in LV in the adjuvant setting developed after a meta-analysis of 18 randomized trials determined superiority in response rate and 1-year overall-survival.¹²⁵ Hence, the adjuvant setting appeared to be the most appropriate for evaluating a survival benefit.

TABLE 42.6. Adjuvant chemotherapy trials of 5-fluorouracil (5-FU)/leucovorin (LV) following surgical resection.

	<i>Adjuvant treatment</i>	<i>N</i>	<i>Three-year DFS</i>	<i>Three-year OS</i>	<i>Reduction in mortality</i>

IMPACT ¹²⁶	Observation	772	62%	78%	—
	5-FU (370–400 mg/m ²)/ LV (200 mg/m ²) daily × 5 days, every 28 days	754	71%	83%	22%

MOF, 5-FU, semustine, and vincristine; DFS, disease-free survival; OS, overall survival.

Multiple trials have since been conducted examining 5-FU/LV in the adjuvant setting (Table 42.6). NSABP C-03 randomized 1,081 patients with Dukes' B2 and C colon cancer between the years of 1987 and 1989 to MOF or 5-FU/LV on the basis of the promising results of NSABP C-01 using MOF as the control arm.¹²⁰ Results from this study clearly designated 5-FU/LV as superior to MOF with an advantage in both DFS (13%) and OS (12%).

Despite the earlier recommendations by the NIH Consensus Panel, doubt in the international community existed regarding the use of adjuvant chemotherapy. A pooled analysis of three cooperative groups, the International Multicentre Pooled Analysis of Colon Cancer Trials (IMPACT), was created randomizing 1,526 patients to 5-FU/LV versus observation only following a surgical resection.¹²⁶ The IMPACT study concluded that the use of 5-FU/LV is an effective adjuvant chemotherapy regimen for Dukes' C colon carcinoma patients (Table 42.7). A subset analysis of Dukes' B2 patients failed to demonstrate any benefit in DFS or OS for patients receiving 5-FU/LV. With the advent of adjuvant chemotherapy in the setting of Dukes' C patients, the optimal schedule and use of levamisole, leucovorin, or the combination of levamisole/leucovorin, with 5-FU remained undefined.

These concerns were addressed by O'Connell and colleagues who conducted an intergroup trial led by the NCCTG with the National Cancer Institute of Canada Clinical Trials Group assessing appropriate duration of treatment.¹²⁷ After a median follow-up of 5.1 years, it was concluded that the doublet 5-FU/levamisole for 1 year was inferior to the triplet combination of 5-FU/levamisole/leucovorin for 6 months (*P* less than 0.01). Greater grade 3–4 gastrointestinal toxicities were observed in the three-drug combination arm (*P* less than 0.0005). This study failed to directly compare 5-FU/LV to 5-FU/levamisole.

Two landmark trials, NSABP C-04 and INT-0089, provided the impetus for the extinction of levamisole in the treatment of colon carcinoma.¹²⁸ NSABP C-04 accrued 2,151 patients in less than 2 years to the doublet regimens of 5-FU/levamisole or LV versus that of the triplet combination of 5-FU/LV/levamisole (see Table 42.7). At the conclusion of this

study, a survival advantage was not detected in any arm. However, superior DFS (*P* = 0.04) was achieved with 5-FU/LV relative to 5-FU/levamisole. The addition of levamisole to 5-FU/LV did not confer any additional benefit in DFS or OS.

INT-0089 is the single largest study created to examine the benefits of adjuvant chemotherapy in Dukes' B2 and C colon carcinoma patients.¹²⁹ Dukes' B2 patients represented 20% of all patients accrued. Patients were randomized to one of four arms: (1) 5-FU/levamisole × 1 year, (2) 8 months of 5-FU/LV (Roswell Park), (3) six cycles of 5-FU/LV (Mayo Clinic), or (4) six cycles of the Mayo regimen of 5-FU/LV + levamisole. Initial results were presented in 1996 and updated in 1998. Final evaluation of the Dukes' B2 patients was reported in a separate study. A subset analysis determined the triplet combination of Mayo Clinic regimen of 5-FU/LV + levamisole was superior in OS relative to 5-FU/levamisole but equivalent to that of the Mayo Clinic regimen alone. The benefits of levamisole were determined to be negligible, and its use could not be advocated. Furthermore, the Roswell Park schedule was equivalent in response and 5-year overall survival to that of the Mayo Clinic regimen (Table 42.8). At the conclusion of the study, 5-FU/LV scheduled in either fashion was recommended as the standard of care in patients with high-risk colon cancer (AJCC stage III/Dukes' C). Remarkably, the final publication regarding this breakthrough study has yet to be published.

NOVEL CHEMOTHERAPEUTICS IN ADJUVANT CHEMOTHERAPY

IRINOTECAN (CPT-11)

For the past four decades, 5-FU has been the sole chemotherapy agent for both the adjuvant and metastatic settings. Other than biomodulation with levamisole or leucovorin, few modifications in this regimen had occurred. The topoisomerase I inhibitor, irinotecan, and the third-generation platinum analogue, oxaliplatin, were to shortly alter the approach to chemotherapy.

Two large Phase III clinical trials conducted both in the United States and Europe provided the foundation for combined chemotherapy with 5-FU/LV in advanced colorectal cancer. Both clinical trials randomized AJCC stage IV advanced colorectal cancer patients to a regimen of weekly bolus irinotecan/5-FU/LV (IFL) versus bolus 5-FU/LV or irinotecan/infusional 5-FU/LV (FOLFIRI) versus infusional 5-FU/LV, respectively (Table 42.9). In short, the combined irinotecan/5-FU/LV arms demonstrated exceptional time to progression, response rate, and OS relative to the 5-FU/LV arms.^{130,131}

The use of infusional 5-FU/LV is commonplace in the European community rather than the bolus 5-FU/LV as in the Mayo Clinic or Roswell Park regimens. Of interest is that pre-

TABLE 42.7. NSABP C-04.

<i>Chemotherapy regimen</i>	<i>N</i>	<i>Five-year DFS</i>	<i>Five-year OS</i>
5-FU/LV	691	65% (<i>P</i> = 0.04)	74% (<i>P</i> = 0.07)
5-FU/levamisole	691	60%	70%
5-FU/levamisole/LV	696	65% (<i>P</i> = 0.67)	74% (<i>P</i> = 0.99)

DFS, disease-free survival; OS, overall survival.

Regimen	Dose and schedule	Five-year OS	Common toxicities
Mayo	5-FU (425 mg/m ²)/LV (20 mg/m ²) daily × 5 days, repeat every 28 days	66%	Stomatitis, leukopenia
Roswell	5-FU (500 mg/m ²)/LV (500 mg/m ²) daily × 5 days, repeat every 28 days	65%	Diarrhea

5-FU, 5-fluorouracil; LV, leucovorin.

vious studies had determined infusional 5-FU/LV resulted in a higher response rate (32.6% versus 14.4%) and progression-free survival (27.6 versus 22 months) when compared to the Mayo Clinic 5-FU/LV but no statistical benefit in overall survival ($P = 0.067$).¹³²

The irinotecan/infusional 5-FU/LV regimen reported by Douillard and colleagues¹³¹ was found to be superior in OS, but the positive results of the IFL regimen reported by Saltz and colleagues¹³⁰ led the U.S. Food and Drug Administration (FDA) to approve weekly bolus irinotecan/5-FU/LV (IFL) as front-line therapy in advanced colorectal cancer. Subsequently, in the year 2000, the weekly bolus IFL regimen became the standard of care for all patients in the United States with advanced stage IV disease unless clinically contraindicated.

Hence, interest in the use of irinotecan/5-FU/LV in the adjuvant setting arose. The largest study to examine the impact of IFL as adjuvant treatment was created by the Cancer and Leukemia Group B (CALGB). CALGB 89803 randomized 1,263 patients with stage III colon carcinoma to either the Roswell Park regimen of 5-FU/LV or to weekly bolus IFL.^{133,134} Paradoxically, a recent interim analysis after a median follow-up of 2.1 years found no difference in time to progression (TTP) or OS between the treatment arms. Thus, the use of weekly bolus IFL cannot be advocated as adjuvant treatment for stage III colon cancer. Whether irinotecan/infusional 5-FU/LV will also be of negative benefit in stage II or III colon cancer is unclear at this time; two Phase III European trials (PETAC 3 and ACCORD02) have completed patient accrual ($N = 1,250$), with final results to be reported at a later date.

OXALIPLATIN

For the past decade, the diamminocyclohexane platinum analogue oxaliplatin (Eloxatin) has been extensively investigated as a single agent and in combination with other chemotherapy agents. Oxaliplatin is the first platinum agent that has demonstrated activity in colorectal cancer and lacks cross-reactivity with other platinum agents. Potential adverse toxicities unique to oxaliplatin compared to other platinum agents may include cold pharyngeal dysesthesia and cumula-

tive reversible peripheral neuropathy. Its activity as a single agent is rather disappointing and is reported 10% at best.¹³⁵ However, when combined with infusional 5-FU/LV synergistic cytotoxic activity is evident.¹³⁶⁻¹³⁸

De Gramont and colleagues proceeded to evaluate oxaliplatin in combination with infusional 5-FU/LV.¹³⁶ Despite a superior difference in relative risk (RR) and TTP, this study was not powered to establish a benefit in OS. Consequently, the Oncologic Drugs Advisory Committee (ODAC) and the FDA did not approve the first-line indication of oxaliplatin in advanced colorectal cancer. Clinical investigators continued to explore its role.

A large, pivotal intergroup study headed by the North Central Cancer Treatment Group, NCCTG 9741, accrued 741 chemotherapy-naïve patients with advanced stage IV colorectal cancer, randomizing them to (a) weekly bolus IFL, (b) oxaliplatin/infusional 5-FU/LV (FOLFOX 4), or (c) oxaliplatin/irinotecan.¹³⁹ The infusional 5-FU/LV (FOLFOX 4) regimen prevailed after a median follow-up of 20.4 months with an impressive median OS of 19.8 months, the longest median overall survival reported to date with standard chemotherapy agents. This study was fraught with questions regarding its clinical trial design for second-line therapy. Sixty percent of patients with progression of disease (PD) while on FOLFOX4 were allowed to receive irinotecan as second-line therapy versus only 24% of patients on the IFL arm who were able to receive oxaliplatin because it was not FDA approved at the time of the study. Regardless, this trial established oxaliplatin as a valuable agent in the armamentarium against advanced colorectal cancer. Its effectiveness as second-line therapy after irinotecan is less than 10% but clearly demonstrates a clinical benefit.¹³⁸ In September 2002, the FDA advocated the use of oxaliplatin/infusional 5-FU/LV as second-line therapy after irinotecan-treated failures. Worldwide, it is accepted as front-line therapy in the treatment of advanced colorectal cancer.

The role of oxaliplatin may not be limited to the advanced disease setting. The multicenter international study of oxaliplatin/5-FU/LV in the adjuvant treatment of colon cancer "MOSAIC" trial has recently reported promising preliminary results from a large randomized Phase III study of FOLFOX4

versus infusional 5-FU/LV as adjuvant therapy. This impressive study accrued 2,246 patients diagnosed with Dukes' B2/Dukes' C colon carcinoma who were subsequently treated for a 6-month duration (Table 42.10).¹⁴⁰ Although the final analysis of this study will be reported at a later date, these encouraging findings may permanently alter the approach to adjuvant therapy. Furthermore, this may be the first study to indicate additional benefit for adjuvant chemotherapy in Dukes' B2 colon carcinoma.

THE CONTROVERSY OF STAGE II/DUKES' B2 PATIENTS

Although a patient with stage II colon cancer has a more favorable prognosis than that of a stage III patient, poor prognostic markers may place the stage II patient at increased risk for local or metastatic disease recurrence.^{105,141-144} Of the four largest clinical studies conducted over the past decade to evaluate this subpopulation of patients, the overwhelming majority of studies have reported no added benefit in OS when adjuvant chemotherapy is administered.

After a median follow-up of 7 years, investigators of INT-0035 substratified the stage II/Dukes' B2 patients ($n = 318$), reporting a trend in reduced recurrence with the use 5-FU/levamisole versus that of observation only (32% decline; $P = 0.10$).¹⁴⁵ The investigators of the International Multicentre Pooled Analysis of Colon Cancer Trials (IMPACT) created a pooled analysis of five separate clinical trials, IMPACT B2, involving 1,016 patients. Patients had been randomized to six adjuvant cycles of 5-FU/LV versus that of observation alone.¹⁴⁶ After a median follow-up of 5.75 years, patients who had received chemotherapy did not experience an improvement in event-free survival (EFS) (76% versus 73%) or OS (82% versus 80%). After a median follow-up of 5 years, Intergroup Study 0089 failed to validate a benefit in OS for Dukes' B2 patients with the use of either leucovorin and/or levamisole when combined with 5-FU, in doublet or triplet combination.¹²⁹ Likely, this study was inadequately powered to evaluate this subgroup with only 20% of all patients accrued with Dukes' B2 disease. Hence, the consideration of adjuvant chemotherapy for a stage II patient was not recommended.

The only positive pooled analysis before to the MOSAIC study¹³⁴ was conducted by the NSABP in Dukes' B2 and C patients. Patients of four separate trials, C-01, C-02, C-03, and C-04, addressed the plausible benefit of not one particular regimen but simply the benefit of 5-FU-based chemotherapy overall. Of the 4,006 patients enrolled, 41% of patients ($n = 1,565$) were diagnosed with a Dukes' B2 carcinoma. In brief, C-01 and C-02 compared 5-FU/LV to observation only, and Studies C-03 and C-04 compared 5-FU/LV with either MOF or the combination of 5-FU/LV/levamisole. When the data of all four studies were combined, a 30% reduction in mortality was determined in Dukes' B2 patients and an 18% reduc-

tion was noted in Dukes' C patients. Despite these positive findings, this study was heavily criticized and not advocated to alter the standard of care at the time the study was conducted as a result of the lack of uniformity among the chemotherapy regimens. In contrast, the recent findings supported by the MOSAIC study may result in a paradigm shift in the consideration of treatment for all Dukes' B2/stage II patients unless contraindicated.¹⁴⁷

MICROSATELLITE INSTABILITY (MSI) ON THE DECISION OF ADJUVANT THERAPY

Significant discussion has recently risen when considering adjuvant chemotherapy for high-frequency microsatellite instability (MSI) patients. MSI results in a defect in DNA mismatch repair as a result of frame-shift mutations and base-pair substitutions found in short, tandemly repeated nucleotide sequences. MSI is associated with familial inherited malignancies as the hereditary nonpolyposis colorectal cancer (HNPCC, or Lynch syndrome) but may be found in approximately 15% of sporadic colorectal carcinomas also as a result of hypermethylation of the promoter region on MLH1.^{148,149} High-frequency MSI has been determined to be an independent prognostic factor and is a positive predictive survival factor.¹⁴⁸ Whether adjuvant chemotherapy provides additional benefit in these patients is unclear. Conflicting results have been reported in both stage II and stage III patients.^{148,150} Ribic and colleagues confirmed that patients with high-frequency MSI had longer OS and DFS but concluded that adjuvant 5-FU/LV was of no benefit in OS ($P = 0.12$) or DFS ($P = 0.06$) for stage II/III patients exhibiting MSI.¹⁵⁰ Elsalem and colleagues have suggested that sex, location, and MSI status may have a bearing on survival following adjuvant 5-FU/LV.¹⁵¹ It is not the intent of this chapter to elaborate in full detail regarding MSI status and outcome but to note that additional clinical studies are warranted to clarify this issue further.

Management Options for Rectal Carcinoma

Improving the management of resectable rectal cancer involves the optimization of patient outcomes through (1) a detailed understanding of the pathology of rectal cancer and its relation to surgical techniques; (2) multidisciplinary management; and (3) organ and function conservation. The goal of the treatment of rectal carcinoma is cure or local control of disease with maintenance of quality of life. The biology of a particular patient's tumor is the most important factor in overall outcome. Adequate surgical removal of the tumor is the major treatment factor affecting local control and cure.¹⁵² Appropriate adjuvant therapies can enhance local

control, reduce systemic recurrence, and increase organ preservation.^{153–155}

The chief reason for this difference between colon cancer and rectal cancer outcomes is related to a difference in local recurrence.¹⁵⁶ Abdominoperineal resection (APR) has been used for management with excellent results. However, APR requires a permanent colostomy, which adversely affects the patient's quality of life.¹⁵⁷ Advances in rectal cancer management and surgical techniques have improved our ability to achieve oncologic control and optimal patient function without APR, even in patients with low rectal cancers.¹⁵⁸ Even in the absence of adjuvant therapy, 79 of 95 patients with T3 N0 rectal cancer had sphincter-preserving procedures with local recurrence rates less than 10%.¹⁵⁹ This study as well as others have continued to demonstrate that there is no difference in local recurrence rates between sphincter-preserving surgery for rectal cancer and APR.¹⁶⁰

Surgical Approaches and Techniques

LOCAL EXCISION

Full-thickness local excision can be effective in the treatment of selected early low rectal cancers. Local excision can be used as curative therapy for patients who have superficial tumors (Table 42.11).

Transanal excision is the most common method of local excision. Selection factors based on tumor size and degree of circumferential involvement predict the potential for a successful transanal excision. The local excision is performed in a full-thickness manner.

Transanal endoscopic microsurgery can be done with success and low complication rates.^{161–163} Whichever method is selected, the full-thickness excision must have at least 1-cm margins of normal tissue surrounding the tumor. An inadequate margin is a predictor of failure.¹⁶⁴ Piecemeal submucosal excision is not considered adequate surgical treatment of invasive rectal cancer. Fragmentation of the tumor is associated with an increased incidence of local recurrence.¹⁶⁵ If the lesion cannot be adequately resected by local excision, then a more standard surgical approach should be used. In a curative case, the patient should be counseled to consider local excision as a form of definitive biopsy, especially when transmural penetration or adverse histologic characteristics are found in the local excision specimen. In a retrospective review of 155 patients it was found that disease-free survival was 94.1% for the group undergoing immediate surgery for adverse findings after local excision, compared to 55% for the delayed salvage group.¹⁶⁵

The criteria used to select patients for local excision are intended to make a negative-margin, full-thickness local excision technically feasible and to ensure a low risk of lymph node metastasis (Table 42.12). The most useful test in this

TABLE 42.12. Indications for the local excision of rectal cancer.

Tumor less than 3 cm in greatest dimension.
Invades only the submucosa or superficial muscularis.
Favorable pathologic grade.

regard has been found to be endorectal ultrasound.¹⁶⁶ Factors that can help identify patients who are at low risk for lymphatic metastasis include small tumors, absence of lymphatic and vascular invasion, well- or moderately differentiated tumor, and absence of clinical or radiologic evidence of enlarged lymph nodes. The assumed low risk in patients treated with local excision alone is accepted because such procedures do not involve resection of the mesorectal lymph nodes.

The major factor predicting patient survival and perirectal lymph node metastasis is the depth of penetration of the primary tumor. In 1966, Morson¹⁶⁷ reported that lymphatic metastasis arose from 10% of tumors confined to the submucosa, 12% of tumors invading the muscularis propria, and 58% of tumors extending beyond the bowel wall. In a study of tumors treated by radical resection, the incidence of lymphatic metastasis was 12% for T1 tumors and 22% for T2 tumors.¹⁶⁸

The incidence of lymph node metastasis in patients with T1 tumors approximates the recurrence rate for T1 cancers treated by local excision alone. Studies describe a 3% to 10% rate of local recurrence after excision alone.¹⁶⁹ Survival rates in patients with T1 rectal carcinomas treated with local excision alone or radical resection are 90% to 100%.¹⁷⁰ Local excision alone is a reasonable treatment for T1 carcinoma of the rectum if the tumor meets the previous selection criteria. A caveat is that blood vessel or lymphatic invasion is a significant predictor of lymph node involvement and poor survival. In such cases, either a standard surgical therapy involving total mesorectal excision or, if the patient refuses or cannot tolerate standard surgical therapy, the use of adjuvant therapy after local excision should be considered.

In patients with T2 rectal carcinomas, the risk of lymph node metastasis is 10% to 30%.^{167,168} Recurrence rates range from 17% to 24% in patients with T2 tumors. Survival rates are 78% to 82% with excision alone.

Many studies, mostly retrospective and single-institution, have examined the results of local excision alone in the management of T1/T2 rectal cancer. Graham et al.¹⁶⁹ found the combined local recurrence rate for T1 lesions to be 5% (range, 0%–12%) and for T2 lesions, 18% (range, 8%–27%). The clinically significant rate of local recurrence, especially compared with lower rates of local recurrence in historical series of similar patients treated with APR (0%–10%),^{170–172} has driven multiple studies examining the use of both postoperative radiotherapy and postoperative chemoradiation after local excision in selected patients.

In one of the first series with an adequately long follow-up, Bailey et al.¹⁷³ reported their experience with local excision between 1978 and 1988. Of the 65 study patients, 34 (54%) received postoperative radiotherapy, and 2 of those (5.9%) had local recurrences. The crude 5-year survival rate in this series was 74.3% and the 5-year disease-specific survival rate was 90.3%. This study provided some of the first

TABLE 42.11. Local excision without adjuvant radiotherapy.

indirect evidence regarding the long-term efficacy of adjuvant radiotherapy.

In a similar report from the Massachusetts General and Emory University Hospitals, 52 patients were treated with local excision alone while 47 patients were given postoperative adjuvant radiotherapy.¹⁷⁴ Although the patients chosen to receive postoperative radiotherapy were at higher risk of local failure because they had higher-stage lesions than the patients treated with local excision alone (70% T2 versus 15% T2, respectively), 5-year local recurrence-free survival (LRFS) and disease-free survival (DFS) rates were significantly better in the patients who received adjuvant therapy (LRFS, 10% versus 28%; DFS, 74% versus 66%). The authors concluded that adjuvant chemoradiation should be offered to all T2 patients undergoing local excision as well as all T1 patients with high-risk histologic features (advanced grade or lymphatic/vascular invasion).

A prospective series from The University of Texas M.D. Anderson Cancer Center reported excellent local control rates for 46 patients treated with local excision and postoperative chemotherapy or radiation therapy.¹⁷⁵ T3 tumors were also treated in this way in patients who were medically compromised or refused standard therapy. All patients underwent negative-margin, full-thickness excisions. The overall survival rate at 3 years was 93%. Table 42.13 shows the pattern of treatment failure by the American Joint Committee on Cancer (AJCC) T stage. Local recurrence-free survival at 3 years was 90%. None of the patients with T1 tumors demonstrated treatment failure. An update of the M.D. Anderson Cancer Center experience with local excision seems to support these findings, with 4-year LRFS rates of 9%, 80%, and 73% for T1, T2, and T3 tumors, respectively.¹⁶⁴

Perhaps the best data regarding the modern-day approach to local excision for T1/T2 rectal cancer come from the initial results of a Cancer and Leukemia Group (CALG) prospective Phase II trial.¹⁷⁶ This study enrolled patients who met the usual criteria for the local excision of distant rectal cancer: mobile tumors confirmed up to the rectal wall (T1/T2), less than 4 cm in size, less than 40% of the bowel wall circumference in size, and with no evidence of lymph node involvement. Patients were registered after a negative-margin, full-thickness local excision. Patients with T1 tumors received no further treatment whereas patients with T2 tumors received adjuvant chemoradiation therapy.

A total of 110 eligible patients completed the study protocol, 59 with T1 tumors and 51 with T2 tumors. The 6-year overall disease-free survival rates were 85% and 78%. Overall, 9 patients (2 with T1 tumors, 7 with T2 tumors) had local recurrence of disease, and 4 of them died of the disease.

Table 42.14 shows the timing of local recurrence in selected large series of patients who did or did not receive

TABLE 42.14. Patterns of local recurrence (LR) following local excision with and without the use of postoperative radiotherapy.

Series	N	LR (n)	LR (n) more than 2 years postoperative
Local excision alone:

Bailey et al. ¹⁷³	34	2	1 (50%)
Willett et al. ³³⁷	26	4	2 (50%)

postoperative radiotherapy. As the data suggest, postoperative radiotherapy seems to result in a shift toward later local failure when compared with local excision alone. In the combined experience of Massachusetts General and Emory University Hospitals, the median time to local recurrence was 13.5 months for patients treated with local excision alone and 55 months for patients treated with postoperative radiotherapy.¹⁷⁴

Results of attempted surgical salvage in patients with local recurrence after local excision (with or without adjuvant therapy) are summarized in Table 42.15. In these combined series comprising 493 patients, 73 patients suffered local failure either alone or in combination with distant disease. In 44 (60%) of these patients, a potentially curative, margin-negative salvage procedure had been performed, most often by APR. Of these 44 patients, 21 (48%) had no evidence of disease at varying lengths of follow-up. Salvage seems to be possible in more than half of patients with isolated local failure after local excision; however, more than 50% of those patients will eventually die of their disease. Therefore, it appears that the argument for a liberal approach to selecting patients for local excision based on good salvage potential in patients whose disease recurs is not supported by the literature.

Baron et al.¹⁷⁷ examined the issue of salvage after local excision at the Memorial Sloan-Kettering Cancer Center. They compared the outcome in 21 patients who had undergone local excision followed by immediate APR or low anterior resection (LAR) for tumors with adverse histologic features with the outcome in 21 patients who underwent local excision followed by LAR or APR at the time of clinical local recurrence. Disease-free survival was significantly improved in the patients undergoing immediate LAR or APR (94.1% versus 55.5%; *P* less than 0.05), a finding that again emphasizes that salvage after local excision does not seem to be an optimal strategy.

Alternative forms of local therapy for T1 and T2 rectal cancer have been reported, including endocavitary irradiation, fulguration, cryosurgery, and Nd:YAG laser therapy.¹⁷⁸ Of these modalities, endocavity irradiation has received the most attention. In Papillon's¹⁷⁹ initial experience with this technique in 1972, the local recurrence rate was 7% and the 5-year overall survival rate was 72% among a selected low-risk group of patients. The potential advantage of endocavitary irradiation over external-beam radiotherapy is the ability to deliver a higher dose of radiation in a more concentrated fashion to the tumor. Both Papillon and others have subse-

quently reported similar results, again among highly selected low-risk patients.¹⁸⁰⁻¹⁸² Birnbaum et al.¹⁸³ identified "ideal" characteristics of rectal lesions for treatment by combination endocavitary and external beam irradiation (Table 42.16). Among 72 patients, they found that recurrence was significantly less likely in those patients with "ideal" tumors than in those with nonideal tumors (15% versus 48%, $P = 0.01$). These authors stressed the importance of careful clinical and endorectal ultrasound staging to identify patients ideally suited to this treatment approach.

Transanal endoscopic microsurgery (TEM), in which either submucosal excision (for adenomas) or full-thickness excision (for invasive carcinomas) is performed through an operating rectoscope, has recently emerged as an option for the local treatment of rectal cancer.^{184,185} In a recent series, local recurrence occurred in 2 of 16 patients (12.5%) with T1 lesions undergoing TEM.¹⁸⁴ However, the authors of this series thought that TEM alone was not appropriate treatment for T2 lesions.

Despretz et al.¹⁸⁶ reported results in 25 patients with rectal cancer treated with preoperative external radiation therapy (35 Gy) followed by local excision and brachytherapy. Local recurrence developed in 5 of the 25 patients. Mohiuddin et al.¹⁸⁷ reported results in 14 patients who underwent preoperative radiation (45 Gy) followed by a full-thickness excision; local recurrence developed in 3 patients. The preoperative use of chemotherapy and radiation therapy to downstage the disease and permit a more satisfactory local excision may be feasible.¹⁸⁸ In a series of 10 patients with T2/T3 primary tumors, such an approach demonstrated an absence of local recurrence and a 78% 2 year survival.¹⁸⁹

Pretreatment Locoregional Staging for Rectal Cancer

Two factors can make pretreatment locoregional staging important in the evaluation of patients with resectable rectal cancer. First is the use of local excision, which could be considered in tumors confined to the bowel wall. Second, and much more common, is the use of preoperative radiation or chemoradiation, which is used in tumors considered to be high risk. This approach has been favored in decision analysis.¹⁹⁰ These are usually tumors that are transmural or those with evidence of metastatic perirectal lymph nodes.

The modalities used for determining the depth of penetration of the primary tumor and enlargement of perirectal lymph nodes are CT, magnetic resonance imaging (MRI), and endorectal ultrasound (EUS) Digital rectal exam (DRE) has been estimated to be a poor selector of patients for preoperative treatment.¹⁹¹ Table 42.17 shows the accuracy of EUS,

MRI, and CT for the T and N staging of rectal cancer preoperatively. Overall, it appears EUS is the most accurate way to stage the depth of penetration.

MRI has been shown to predict the potential for a positive circumferential margin better than DRE or EUS.¹⁹¹ In a treatment algorithm where preoperative treatment was used for those with deep mesorectal invasion or extension of the mesorectal fascia, MRI was the dominant strategy over DRE or EUS in terms of cost-effectiveness.¹⁹¹ In another study of cost-effectiveness, a strategy of CT and EUS dominated CT- and MRI-only approaches when the demonstration of transmural rectal cancer was the prompt for preoperative radiotherapy.¹⁹²

In the staging of patients after neoadjuvant therapy, the dominant component of the lesion seen on EUS is fibrosis. Thus, the technique really stages the extent of fibrosis and not the true residual tumor, which may be microscopic only.¹⁹³ Overall accuracy for pathologic T stage may drop to 48% in preoperatively treated patients who are restaged with EUS. From these data, it appears that EUS is unreliable in evaluating the degree of residual disease after neoadjuvant therapy.¹⁹⁴ CT and MRI suffer from similar limitations in the restaging of irradiated rectal cancers.^{195,196}

When PET scanning is used to stage primary rectal cancer, in a preoperative study where EUS or MRI/CT was also used, 78% of cases had no change in management and in an additional 4% there were changes in treatment independent of the PET results. The management changes appear to result chiefly from the detection or confirmation of metastatic disease.⁵¹ After neoadjuvant chemoradiation, PET has been used to identify tumor response.¹⁹⁷ In a preoperative study of restaging with PET scanning, the degree of rectal cancer response was not able to be differentiated between macroscopic residual disease versus microscopic residual disease after chemoradiation.¹⁹⁸ A prospective study of PET restaging

in 15 resectable high-risk rectal cancer patients found that visual assessment of the response in PET correlated with pathologic response in 60% of cases.¹⁹⁹ Lymph node staging by PET scanning appears to be limited even before changes induced by chemoradiation with a sensitivity of 22% to 29%.⁵²

Locoregional Resection for Rectal Cancer

Patients with stage II or III rectal cancer have tumors that are large and biologically aggressive. Disease at this stage carries a higher risk of local and systemic recurrence after surgical treatment. Accordingly, strategies have been developed to address these issues through locoregional resection and multimodality therapy.²⁰⁰ However, adequate surgical resection and choice of technique are the most critical treatment factors determining patient outcome.^{201,202}

The risk of spread to local lymph nodes and the risk of local recurrence increase as tumor penetration of the rectal wall increases. This understanding has led to the development of operations such as the APR that achieve tumor-free proximal and distal tissue margins and remove the upward pathways of lymphatic spread from rectal cancer.²⁰³ The distal margin has been shown to be adequate when it is 2 cm from the edge of the tumor in unirradiated patients.^{204,205} However, more recently the work of Quirke and others has dramatically demonstrated the importance of lateral tumor spread in the local recurrence of resected rectal cancers.^{206,207}

Among patients with local recurrence, tumor involvement at the circumferential margin of resection has been found in 85% of cases.²⁰⁶ Because of problems in obtaining adequate exposure in the low pelvis and surrounding structures, circumferential margins around rectal cancers can be highly variable and minimal. In this regard, surgeon experience and surgical technique play key roles in the prevention

TABLE 42.18. Importance of distal mesorectal spread in producing an involved radial margin.

of local recurrence.²⁰⁸ Involvement of the circumferential margins can result from direct spread, mesenteric implants, vascular or lymphatic invasion, or cancer-bearing lymph nodes.²⁰⁹ Tumor involvement of the circumferential margins of resection is frequently due to spread in the mesorectum distal to the tumor (Table 42.18).²⁰⁷ The long-term outcome is poor in the presence of a positive circumferential margin.²⁰⁷ Total mesorectal excision has been demonstrated to be effective in the surgical management of rectal cancer.²¹⁰

McAnena and coworkers described the long-term outcome of 57 patients treated by this approach.²¹⁰ The mean follow-up was 4.8 years. Local recurrence was seen in only 3.5% of the patients, and overall 5-year survival rate was 81%. It should also be noted that "serious" postoperative complications occurred in 17% of patients. This effect of the adaptation of total mesorectal excision on complication rates has been confirmed by others.²¹¹ In a subsequent larger review of their experience with total mesorectal excision for rectal cancer, MacFarlane and colleagues²¹² studied 135 patients with Dukes' B and C rectal cancers who were treated with surgery only, by one surgeon over a 13-year period with a mean follow-up of 7.5 years. None of these patients received adjuvant radiation or chemotherapy, yet there was only a 5% local recurrence rate. Further long-term follow-up of a larger group of patients confirmed these findings by finding a 10-year local recurrence rate of 4% and a 10-year disease-free survival rate of 78%.²¹³ These results compare favorably with the results from the North Central Cancer Treatment Group study that form the basis for current recommendations for adjuvant therapy in the United States.²¹⁴

In North America, similar results have been obtained with high rates of local recurrence-free survival when a total mesorectal excision is done by meticulous sharp dissection along the pelvic sidewalls. Enker's report²¹⁵ on this subject called for full rectal mobilization along anatomic planes to obtain complete mesorectal excision. In a series of 42 men who underwent sphincter-preserving surgery for low rectal cancer with this technique, only 1 had local recurrence (median follow-up, 20 months). Moreover, potency was preserved in 88% of the patients.

Wide pelvic lymphadenectomy has been proposed for the treatment of rectal cancer. Although there is little doubt that the presence of metastasis in such lymph nodes is a highly significant negative prognostic factor, there is no evidence to support a therapeutic benefit of the routine addition of extensive lymphadenectomy to standard locoregional procedures.²¹⁶⁻²¹⁸

To address the effect of training and experience in rectal cancer surgery in a region of Sweden where all rectal cancer surgery has been concentrated in one colorectal unit, survival seems to have improved and local recurrence rates have dropped.²¹⁹ Over the past 5 years, several studies have sug-

gested that the surgeon's experience is an important prognostic factor in rectal cancer. In a population-based study of 683 patients, Porter and colleagues²²⁰ found a significant local recurrence and survival advantage among the patients of surgeons with colorectal surgery fellowship training or surgeons with a higher caseload. In addition, a greater rate of sphincter preservation for low rectal cancer was also found to be associated with these surgeon groups. Other studies suggest that hospital volume, hospital type (university versus community), and surgeon experience influence survival and recurrence outcomes.²²¹⁻²²³

In general, three operative procedures can be performed for resectable rectal cancer, all of which conform to the principles of total mesorectal excision: LAR, APR, and total proctectomy with coloanal anastomosis (CAA).^{157,160,224}

Low anterior resection involves the transabdominal resection of the rectum and mesorectum above the level of the levator ani complex. After complete mobilization of the rectum *en bloc* with the mesorectum, the rectum is divided at least 2 cm below the distal edge of the tumor. There is evidence that total mesorectal excision is not required for upper rectal cancers.²²⁵ Reconstruction of the rectum is then carried out between the completely mobilized left colon and the remaining rectal stump. The double-stapled technique has permitted an easier and lower anastomosis, with leak rates (clinical or radiographic) similar to or better than those obtained with hand-sewn techniques.²²⁶⁻²²⁸ Second, although 5 cm was previously thought to be the minimum acceptable distal margin, acceptance of a 2-cm distal margin has allowed lower tumors to be resected by LAR.^{155,205}

Abdominoperineal resection involves a combined transabdominal and perineal approach to complete resection of the rectum, mesorectum, levator muscles, and anus with formation of a permanent colostomy. The rectum and mesorectum are mobilized via an abdominal approach. A perineal approach is used to widely resect the levator complex and anus along with an appropriate margin of perianal skin. A permanent end colostomy is carried out. As sphincter preservation has increased, the overall proportion of rectal cancer patients undergoing APR has decreased.²¹⁹

Proctectomy with CAA has emerged as a well-accepted surgical option in carefully selected patients. This approach can spare patients a permanent colostomy while still producing good functional and cancer-related outcomes. A recent review of 117 patients from the Mayo and Cleveland Clinics provides a perspective on the utility of proctectomy and CAA for patients with low rectal cancer.²²⁹ The patients were treated over a 10-year period (1981-1991). The median distance of the tumor from the anal verge was 6 to 7 cm. The technique that was used required complete mobilization of the rectum to the levators, transanal transaction of the rectum, complete mobilization of the left colon, and endanal anastomosis. The authors recommended loop ileostomy for most patients. The effectiveness of this procedure in preventing local recurrence was demonstrated by the low local recurrence rate of 7%. Fecal continence was satisfactory in 78% of the cases. There were no surgery-related deaths. Early and late complications were related mainly to the anastomosis leaking (10%) and healing with a stricture (21%).

Several groups have reported on patients who had a 6- to 10-cm colonic J-pouch reservoir constructed with no additional risk or compromise of the anastomosis.²³⁰ The forma-

tion of the colon pouch has been compared with the straight CAA in randomized clinical trials.²³¹ Physiologic measures and short-term outcomes seem to be improved with the pouch, although these findings are disputed by some.^{232,233} However, these differences in function may disappear with time.

Major long-term postoperative problems after CAA are related to rectal capacitance and compliance and manifest as urgency and frequency of bowel movements. In a series from the Mayo Clinic described by Drake and colleagues,²³⁴ patients who had a CAA for malignancies had a stool frequency of 2.6 per 24 hours, and only 1 of 19 patients was incontinent. Results from the Mayo and Cleveland Clinics Study are similar to those of others describing proctectomy and CAA for rectal cancer.²³⁵ Even when combined with preoperative irradiation, coloanal anastomosis can result in good to excellent bowel function in 77% of patients. The median number of bowel movements per day was 2 in a Phase I/II trial.²³⁶

In a randomized clinical trial by the Gastrointestinal Tumor Study Group intended to examine the benefit of adjuvant therapy in rectal cancer, patients who underwent APR had a higher recurrence rate than did patients undergoing LAR (*P* less than 0.05),²³⁷ and this has been seen in other studies.²³⁸ However, this probably reflected the presence of larger, more-advanced tumors in the patients undergoing APR. Several other studies involving large numbers of rectal cancer patients have shown no significant differences in local recurrence or survival rates between patients undergoing APR and those undergoing sphincter preservation.²³⁹⁻²⁴² In summary, there is no evidence that, in appropriately selected patients, sphincter-preserving locoregional procedures compromise oncologic outcome.

Adjuvant Radiation and Chemoradiation for Resectable Rectal Cancer

The first adjuvant therapy in rectal cancer to be assessed for efficacy was postoperative radiotherapy. Both the Gastrointestinal Tumor Study Group and the National Adjuvant Breast and Bowel Project performed randomized clinical trials and found decreased local recurrence rates, but not improved survival, in stage II and III rectal cancer patients receiving postoperative radiotherapy compared with patients undergoing surgery alone.^{204,237}

The addition of chemotherapy to postoperative radiotherapy seemed logical in an effort to influence the development of systemic disease and increase the therapeutic effect of radiation. A study conducted by the North Central Cancer Treatment Group was reported in 1991 by Krook and colleagues. This large, randomized trial for high-risk (stage II and III) rectal cancer patients compared postoperative fluorouracil and radiation with postoperative radiation alone.²¹⁴ Reduced local recurrence, systemic recurrence, and cancer-related death as well as improved overall survival were seen in patients randomly assigned to receive chemotherapy in addition to postoperative radiotherapy.

Another major step in adjuvant therapy for rectal cancer came from a report from an Intergroup trial testing the role of protracted or continuous intravenous infusion of fluorouracil combined with radiation therapy as postoperative therapy. The rationale for this protocol was based on *in vitro*

studies indicating that optimal cytotoxicity was obtained by continuous exposure of tumor cells to fluorouracil after irradiation.²⁴³ A study by Rich and coworkers²⁴⁴ showed the regimen to be well tolerated during radiation therapy. In a trial of 680 patients, significant reductions were seen in overall rates of tumor relapse and distant metastasis.²⁴⁵ Survival was significantly increased in those who received the protracted infusion of fluorouracil during irradiation. The National Institutes of Health Consensus Conference has recommended a standard approach widely used in North America for postoperative chemoradiation.⁶⁴

Neoadjuvant Therapy

Although there have been many randomized clinical trials comparing preoperative radiation with surgery alone, most of these trials did not use radiotherapy dosing strategies currently considered appropriate.²⁴⁶⁻²⁴⁸ Local recurrence seemed to be reproducibly reduced with preoperative radiotherapy compared to surgery alone.^{249,250} However, more recently, the Swedish Rectal Cancer Study showed a significant improvement in local recurrence and survival with the use of a short course of radiotherapy versus surgery alone.²⁵¹ Notably, patients in this trial did not receive chemotherapy, and the delivery of radiotherapy (25 Gy, given over 5 days beginning 1 week preoperatively) differed substantially from the delivery strategy traditionally used in North America (45-50 Gy, given over 25-30 days beginning 4-6 weeks preoperatively). A French study that examined the issue of interval between completion of radiotherapy and surgery found that a longer period was beneficial in terms of response and sphincter preservation.²⁵²

In a meta-analysis of the results of 19 randomized trials of preoperative radiotherapy and 9 trials of postoperative radiation therapy by the Colorectal Cancer Collaborative Group, the absolute risks of any recurrence and local recurrence were reduced significantly by the use of radiotherapy either preoperatively or postoperatively. Trials of preoperative radiation therapy appeared to have a greater effect on the reduction of local recurrence at lower radiation doses than did postoperative radiation regimens. Early deaths for noncancer cases appeared to increase when radiation was carried out.²⁵³ The effect of short-course preoperative radiation alone seen in the randomized Swedish Rectal Cancer Trial was to reduce local recurrence rates from 27% to 12% in the group receiving surgery and radiation²⁵⁴; this result indicated that this approach did not result in greater late-term morbidity.²⁵⁵

The improvement in local recurrence rate with preoperative short-course radiation therapy is still seen when modern rectal cancer surgery techniques of total mesorectal excision and quality control of the circumferential margin are carried out.²⁵⁶ The randomized Dutch trial indicates that radiotherapy is helpful along with this technique.^{257,258}

Minsky and colleagues²³⁵ reported on the efficacy and toxicity of preoperative radiation with proctectomy and CAA for low rectal cancer in patients who otherwise would have required an APR. Twenty-two patients with a diagnosis of invasive resectable T2 or T3 primary adenocarcinoma of the distal rectum (median distance from anal verge, 4 cm) were treated. External-beam radiation therapy was given to a total dose of 50.4 Gy. Four to 5 weeks later, resection was performed in 21 of those 22 patients, and 10% of patients had a complete

response. Therapy was well tolerated, and the anastomotic leak rate was only 6%. Eighty-nine percent had a good or excellent functional result. Local failure alone occurred in 5%. These data reveal acceptable local control, survival, and functional results in selected patients treated with preoperative radiation therapy and proctectomy with CAA as an alternative to APR. Outstanding sphincter-preserving results in the treatment of low rectal cancers after preoperative radiation have been described by Marks and coworkers^{258a} at Thomas Jefferson University. They demonstrated long-term adequate sphincter function in 91% of patients, with local recurrence rates of less than 13%. The addition of preoperative endocavitary boost dose to low rectal cancers treated with external-beam radiation improved sphincter preservation rates over external-beam treatment alone.²⁵⁹

Prolonging the interval between radiation and surgery did not appear to significantly change the ability to do sphincter preservation in a randomized trial despite greater tumor response with a longer interval.²⁶⁰ Similar results were seen when chemoradiation was used preoperatively.²⁶¹ Radiation alone has produced complete pathologic response rates of 10% to 17%.^{247,248,262} Concurrent preoperative chemoradiation has produced complete response rates of 20% to 30%.²⁶³ Among patients who had tumors less than 7 cm from the anal verge and who underwent preoperative chemoradiation, Janjan and coworkers²⁶⁴ found a high rate of sphincter preservation in patients who had a complete response compared to those who did not (53% versus 38%).

However, the meaning of a pathologic complete response for a patient in long-term follow-up is unclear, although preliminary evidence suggests that it may be a prognostic factor for improved survival.²⁶⁵ Moreover, the absence of mucosal tumor clearly does not assure a complete response because residual tumor may be found within or beyond the rectal wall or within lymph nodes in the absence of residual mucosal tumor.^{263,265} Among 41 patients with partial or complete primary tumor response to preoperative chemoradiation, 9 (16%) were found to have metastatic disease in mesorectal lymph nodes.²⁶⁵ In a larger series of patients, similar results were seen despite an overall decrease in the number of patients with positive mesorectal nodes.²⁶⁶ Obviously, shrinking the tumor may allow achievement of acceptable negative margins and may facilitate sphincter preservation. In a review of 94 patients from a preoperative database where preoperative chemoradiation was given for low rectal cancers, distal margins of 1 cm or more did not compromise local control rates.²⁶⁷ Although overall these effects tend to produce the ability to perform more sophisticated low rectal cancer operations that preserve sphincter function, they do not appear to support local excision in all but highly selected patients.^{268,269}

Preoperative chemoradiation therapy has been demonstrated to be less toxic than postoperative chemoradiation.²⁷⁰ Minsky et al. reported that when identical chemoradiation regimens were given preoperatively or postoperatively, significantly fewer patients experienced grade 3 or 4 toxic effects when the adjuvant treatment was given preoperatively. In this study,²⁷⁰ 13% of patients treated preoperatively experienced gastrointestinal toxicity, whereas 48% of patients treated postoperatively had grade 3 or 5 gastrointestinal or genitourinary toxic effects.

The addition of chemotherapy to preoperative irradiation for rectal cancer was studied across two different institutions.

In a multivariate analysis of 403 patients, the use of concomitant 5-FU resulted in an increase in sphincter preservation rates for patients with tumors less than 6 cm from the anal verge.²⁷¹ Similar to the results of an endocavitary boost with radiotherapy alone, the use of an external-beam boost dose to the tumor bed increased sphincter preservation for low rectal tumors.²⁷² Even among patients thought to require APR or initial assessment, up to 85% can be treated with sphincter preservation after such regimens.²⁷³

Rich and colleagues²⁷⁴ reported on the outcome of 77 patients treated with preoperative chemoradiation therapy who then underwent resection of low rectal T3 cancers staged by ultrasonography.²⁷⁴ The preoperative treatment given was continuous-infusion fluorouracil (300 mg/m²/day) given with daily irradiation (45 Gy in 25 fractions over 5 weeks). Sphincter preservation was accomplished in 67% of these patients, in whom the mean distance of the tumor from the anal verge was 5 cm. A complete pathologic response was found in 29% and local recurrence in 4% of cases.

There are data comparing preoperative chemoradiation versus postoperative chemoradiation in resectable rectal cancer. This type of regimen given preoperatively can result in high sphincter preservation rates without compromising local recurrence rates, as previously mentioned. A preliminary report of the NSABP R-03 randomized trial of 5-fluorouracil and levocorin and 50.4 Gy given pre- or postoperatively indicated that sphincter preservation was increased from 33% to 50% in the preoperatively treated group. Complications of surgery were similar in both groups.²⁷⁵ In a recently reported trial of a preoperative versus postoperative chemoradiation with continuous infusion 5-FU and standardized surgery with total mesorectal excision (TME), 628 patients with high risks (pT3/4 or N+) cancer were randomized. The trial showed postoperative complications were 12% to 13% in both arms. This result confirmed that neoadjuvant therapy did not carry a higher risk of perioperative morbidity.²⁷⁶ In a later report of this trial with 825 patients randomized and with a median follow-up of 43 months, pelvic and distant recurrence rates were reduced in the preoperative treatment while overall survival rates were similar. Fewer patients were found to have anastomotic stenosis in the preoperative group whereas overall postoperative morbidity was equivalent between the two groups. In a subgroup of patients with low-lying tumors who were randomized, sphincter preservation rates were significantly increased to 39% in the preoperatively treated group, compared to 19% in the other group. This is a major step forward in confirming the value of preoperative conventional dose chemoradiation in the management of high-risk rectal cancer.²⁷⁷

If function is poor after sphincter-preserving surgery, then the patient's quality of life may be impaired more than if a permanent colostomy is present.²⁷⁸ Kollmorgen and coworkers²⁷⁹ studied the long-term effects of chemoradiation therapy on bowel function when this adjuvant therapy was given postoperatively. One hundred patients were studied after extensive exclusions were made to minimize confounding variables affecting outcomes. The group of patients who did not receive postoperative treatment uniformly had fewer problems with bowel function. In contrast, clustering of bowel movements, stool frequency, and fecal soiling were all increased when the reconstructed rectum was postoperatively irradiated (Table 42.19). As is clear from this study, long-term

TABLE 42.19. Long-term effect of postoperative chemoradiation therapy on bowel function in rectal cancer patients.

Postoperative therapy	Median bowel movement per day	Clustering of bowel movements	Percent of patients		
			Occasional	Fecal incontinence Frequent	Urgency
None	2	3%	7%	0%	19%
Chemoradiation	7	42%	39%	17%	17%

Source: From Kollmorgen et al.,²⁷⁹ by permission of *Annals of Surgery*.

detrimental effects on bowel function can result from postoperative chemoradiation. Further support for this conclusion can be drawn from the results of a study by Paty and colleagues on the outcomes of CAA for rectal cancer.²⁸⁰

Sphincter preservation during multivisceral resections for locally advanced rectal cancer can be performed in patients who have involvement of adjacent pelvic organs. Selected patients may benefit from intraoperative radiation therapy or brachytherapy.²⁸¹

Anal Cancer

Anal cancer is an uncommon malignancy in the digestive tract and will be found in about 4,000 patients each year.²⁸² Although a variety of histologic types of cancer can be located in the anal canal, the most common type is squamous cell carcinoma.^{283,284} Basaloid and cloacogenic subtypes of anal cancer have the same survival and treatment responses as squamous cell cancer (SCC).^{284,285} This discussion is limited to the treatment of invasive epidermoid or squamous cell cancer of the anal canal.

The lining of the upper anal canal is the anal transition zone and the lower portion is lined by the nonkeratinized anodermis.²⁸⁶ The dentate line divides these. The lymphatic drainage above the dentate line is primarily to the perirectal and inferior mesenteric nodes and secondary to the internal iliac nodes. Below the dentate line the drainage is primarily to the inguinal lymph nodes and secondarily to the internal iliac nodes.²⁸⁷

Prognosis

The staging of anal cancer is based on tumor size and the presence of nodal and distant metastases.²⁸⁸ Failures of therapy occur more commonly in T3 and T4 tumors than in T1 and T2 cases.^{289,290} Multiple studies have identified positive inguinal or perirectal lymph nodes as a factor that predicts higher rates of cancer death, local failure, and the need for colostomy formation and salvage surgery.^{291–293} Sentinel lymph node biopsy is feasible in these patients and may help to tailor radiation treatment fields.²⁹⁴

Surgery

In an analysis of local excision alone for small and superficially invasive cancers, Boman et al. found that it was successful in 12 of 13 patients so selected. However, in a larger group of patients treated by APR, the recurrence rate was 40% with survival of only 71%. This finding was probably due to

the larger size of tumors selected for APR as a treatment along with the higher likelihood of nodal metastases in such patients. Even in patients undergoing APR, the predominant site of failure was still in the pelvis in 80%.²⁹⁵ This failure pattern has been noted by others and is believed to be attributable to residual pelvic nodal disease after surgical approaches, with positive nodes being seen in surgical specimens in 30% to 60% of patients.²⁹⁶

Radiation Alone

Treatment with external-beam radiation alone can result in high rates of local control for early-stage tumors. When this approach was used for T1 and T2 cancers, local control rates were 100% but the doses were up to 67 Gy.²⁹⁷ When radiation alone was delivered to doses of 60 to 62 Gy, the 5-year survival was noted to be 84% for T1 and T2 tumors but only 58% to 74% for T3 and T4 tumors. Although local control rates were 76%, the overall anal conservation rate was only 62% and normal anal function was maintained in only 55% of patients. The results are indicative of the local toxicity of high-dose external beam irradiation alone for SCC of the anus.²⁹⁸ Total radiation dose was the factor that correlated best with late severe complications of radiation resulting in the need for colostomy formation.²⁸⁹ In an additional series, primary radiation alone resulted in 5-year survivals of 57% with local recurrence rates of 14%.²⁹⁹

Definitive Treatment with Chemoradiation

The initial report of the potential success of definitive chemoradiation was from Nigro et al., who reported complete responses to a preoperative complete responses to a preoperative combination of 30 Gy external-beam radiotherapy and 5-fluorouracil and mitomycin-C in patients then treated with APR.³⁰⁰ A later report by the same group revealed an even more limited role for surgery. Twenty-eight patients were given this combined chemoradiation treatment preoperatively and, of the 12 who underwent APR, 7 had no residual cancer in the specimen while 1 patient had only microscopic disease 4 to 6 weeks after completion of chemoradiation. The reliability of the clinical evaluation of the response to treatment was verified in 14 patients from this series who had a clinical complete response. They had excision of the scar, and none were found to have residual disease. Two additional patients with complete response on clinical examination were followed without biopsy and remained free of disease.³⁰⁰

Single-institution studies showed control of SCC of the anus was improved by the addition of chemotherapy; this was especially true for larger tumors with moderate doses of radi-

ation. Sischy demonstrated a control rate of 89% for SCC of the anus in 29 patients with 5-FU and mitomycin-C.³⁰¹ Leichman et al. reported a complete response rate of 84% in patients treated with this regimen with no recurrence among these patients with a complete response.³⁰² Flam et al. reported even 5- and 10-year treatment with 41.4Gy and 5-FU with mitomycin-C resulted in survival of 92% and 85%, respectively. Grade 3 or 4 late toxicity in this study was limited to 15% of patients, mainly in the form of chronic diarrhea. These excellent results were confirmed in T3–T4 and node-positive patients.³⁰³ Local control rates of 84% with preservation of sphincter function in 80% of patients have been demonstrated with such regimens.³⁰⁴

A retrospective comparison of radiation therapy alone (using a brachytherapy boost) and chemoradiation for anal cancer failed to show a local control, survival, or sphincter preservation advantage to the combined approach.³⁰⁵ However, in a much larger study of 191 patients treated according to sequential protocols of radiation, radiation with 5-FU and mitomycin-C, and radiation with 5-FU, it was found that radiation with both 5-FU and mitomycin-C was superior to the other approaches. The control with 5-FU and mitomycin-C was 86% versus 56% to 60% for the other regimens.²⁹¹ In a comparison of the quality of life in anal cancer survivors treated with or without chemotherapy, there did not appear to be a difference on long-term follow-up.³⁰⁶

The definitive advantage of chemoradiation over radiation alone has been demonstrated in two randomized prospective trials. In the UKCCCR trial involving 585 randomized patients, results were compared between radiation alone and radiation with 5-FU and mitomycin-C. The chief endpoint was local failure. Treatment with chemoradiation reduced local failure rates from 59% to 36%. The risk of death from anal cancer was also significantly reduced, but overall survival was not different in the groups.³⁰⁷ In another trial with 110 randomized patients, the addition of 5-FU and mitomycin-C to 45Gy radiation over 5 weeks with an external beam boost of 15 to 20Gy was studied. In this EORTC study, the addition of chemotherapy increased complete remission rates to 80% from 54%. In this study, significant improvements in local control and colostomy-free survival were found for combined treatment.³⁰⁸

In a Phase III randomized trial, the role of mitomycin-C in addition to 5-FU during chemoradiation was studied in a cooperative group setting. Treatment groups were randomized to radiation and 5-FU or radiation with 5-FU and mitomycin-C. Patients who achieved less than a complete response 4 to 6 weeks after treatment underwent biopsy. If the biopsy revealed residual cancer, an additional 9Gy radiation and cisplatin was given with concurrent 5-FU. Persistence of disease beyond 4 to 6 weeks after treatment was evaluated by biopsy and if confirmed was treated with APR. Patients receiving mitomycin-C had a higher rate of complete response with a corresponding increase in colostomy-free survival. The colostomy rate was lowered from 22% to 9% by the addition of the mitomycin-C. However, the group treated with mitomycin-C had a higher rate of complete response with a corresponding increase in colostomy-free survival. The colostomy rate was lowered from 22% to 9% by the addition of the mitomycin-C. However the group treated with mitomycin-C had a higher rate of grade 4 toxicity and two deaths due to neutropenic sepsis.²⁹³ Because of concerns over this

toxicity, the alternative use of cisplatin has been advocated. The use of 5-FU and cisplatin with radiation has been shown in a retrospective study of 92 patients to produce 5-year survival rates of 85% with colostomy-free survival rates of 82%; this was accomplished with few grade 4 toxicities and moderate (55Gy) doses of radiation.³⁰⁹ Others have demonstrated high complete response rates for this regimen when induction chemotherapy is used followed by chemoradiation with 5-FU and cisplatin. In a Phase II study of this approach, complete response rates of 93% were seen even in poor prognosis tumors.³¹⁰

Management of Persistent or Recurrent Disease

In 8% to 10% of patients, there will be residual disease 4 to 6 weeks after the completion of initial therapy,³⁰⁷ which may be a residual ulcer or a mass. Despite this, regression has been documented more than 3 to 12 months after therapy.²⁹¹ In addition to having concern over being misled by the biopsy of a regressing lesion, there can be concern over poor healing and fibrosis of the anal canal from biopsy in a heavily irradiated field. Excisional biopsy has been correlated with grade 4 long-term morbidity in irradiated patients.³¹¹

Most authors have defined persistent disease as the diagnosis of persistent tumor or recurrent tumor within the first 6 months after multimodality treatment. Recurrent disease has been considered the diagnosis of recurrent tumor at least 6 months after a complete clinical response. The largest series on salvage APR consist of 35 and 38 patients, respectively.^{312,313} The prognosis after failure of primary chemoradiation therapy is dire. Table 42.20 illustrates the selected series that have been published after salvage APR for failure of primary treatment, mainly radiation combined with chemoradiation. The overall 5-year survival has been reported to be between 0% and 60%, and the overall recurrence rate is between 42% and 62%.^{284,312–318}

After salvage APR, the major morbidity is related to the perineal wounds. Perineal wound problems, including infection and nonhealing wounds, have been reported to occur in at least 30% to 60% of the patients after salvage APR.^{312,317} The use of musculocutaneous flaps offers tissue both to obliterate the pelvic defect and for vaginal reconstruction. Tei et al. reported on 14 patients who underwent vertical rectus abdominis musculocutaneous flap reconstruction to cover the perineal defect after salvage APR.³¹⁹

Management of Lymph Node Metastasis

Studies of surgical lymphadenectomy alone can have local failure rates of 20% to 40%.^{295,320} There are reports of a long-term disease-free interval in 60% of patients with inguinal lymph node metastasis managed by limited groin dissection following 45-Gy radiation therapy.³²¹ Others have reported control of clinically abnormal nodes in 71% of patients with high-dose radiation alone. In a review of 270 patients with inguinal lymph node metastases, treatment of synchronous metastases with irradiation and 5-FU with cisplatin resulted in a 5-year survival rate of 54%.³²²

Clinically evident metachronous lymph node metastases will be isolated treatment failures after radiation in approximately 8% of patients. Metachronous lymph node metastasis can be resected with a 5-year survival rate as high as 55%

TABLE 42.20. Results of salvage surgery for persistent or recurrent cancer.

Author	Year	Prior therapy	No. of patients	Procedure	Overall recurrence (%)	Local recurrence (%)	Overall survival (%), 3 years	Overall survival (%), 5 years
Longo ³¹⁴	1994	LE, LE + RT, LE + CRT	17	APR		NS		57

Nilsson ³¹³	2002	RT only, CRT	35	APR	42	93	52	

CRT, chemoradiation; LE, local excision; APR, abdominoperineal resection; PPE, posterior pelvic exenteration; RT, radiotherapy; NS, not significant.

^a Pelvis.

^b Persistent disease.

^c Recurrent disease.

^d Alive and disease free, mean follow-up of 32 months.

^e Local and regional.

^f Five patients pelvis or groin and three patients pelvis and distant.

following lymphadenectomy.³²³ The lymphadenectomy can be accompanied by significant morbidity in terms of wound problems related to seromas or infections.³²⁴ In patients who have received no prior inguinal irradiation for initial therapy, a program of chemoradiation after inguinal dissection achieved a 5-year survival rate of 41%.³²² Ilioinguinal lymph node dissections can be carried out with a higher rate of morbidity from lymphedema, but again with some degree of success.³²⁵

Adenocarcinoma and Other Small Intestinal Malignancies

John H. Donohue

Despite the enormous surface area of the small intestinal mucosa and the rapid turnover of the enterocytes, malignancies of the small bowel are uncommon. Of the more than 250,000 digestive system cancers projected for diagnosis in the United States in 2003, only an estimated 5,300 were small intestinal malignancies.¹ There is a slight predominance of men diagnosed with these tumors. An estimated 1,100 Americans died of small intestinal malignancies in 2003.¹ Because of the low incidence of small bowel cancers and the common occurrence of four distinct histologic types, namely adenocarcinoma, lymphoma, gastrointestinal stromal tumor (GIST), and carcinoid tumor, even major clinical centers have limited experience in treating patients with these diseases. As a result, controlled data evaluating treatment variables and other aspects of small intestinal malignancies are virtually nonexistent.

This chapter reviews what is known about the etiology, diagnosis, treatment, and outcomes for adenocarcinoma, lymphoma, and GIST of the small intestine. Carcinoid tumors are reviewed in Chapter 60.

Etiology

A number of protective factors have been proposed to explain the low incidence of malignant transformation in the small intestinal mucosa, especially when compared to the large bowel. First of all, the liquid chyme is less irritating to the mucosa than solid fecal matter. Both the rapid transit of digesting food through the small intestine and the rapid turnover of enterocytes limit the exposure time of ingested carcinogens to individual mucosal cells. The alkaline pH of the small bowel contents, mucosal hydroxylases, and a several-log-lower concentration of bacteria than that present in the colon all lead to lower rates of carcinogen formation in the small intestine. Last, secretory IgA levels are significantly higher in the small bowel and may provide additional protection against malignant transformation.²

Most patients diagnosed with small bowel malignancies have no apparent underlying predisposition. Evidence for an adenoma–carcinoma sequence similar to that well-documented progression in colon cancers has been reported in the small intestine.³ Facts supporting this theory include these: (1) a third of all small bowel adenomas contain cancer, (2) the

distributions of benign and malignant growths within the small intestine are the same, and (3) the mean age of patients with benign adenomas is lower than that for adenocarcinomas, whereas the gender ratios are identical for both types of tumor.³

Among patients with inherited causes for colorectal cancer, both those with familial adenomatous polyposis (FAP is the result of a mutation of the APC gene)^{4,5} and hereditary nonpolyposis colorectal carcinoma [HNPCC is due mostly to mutations of the mismatch repair (MMR) enzyme genes hMLH1 and hMSH2]^{6,7} are known to have increased risk of small intestinal adenocarcinoma. In FAP patients, the majority of small bowel cancers are duodenal adenocarcinomas, most of which arise in the periampullary area subsequent to total proctocolectomy.⁵ In sharp contrast, small intestinal adenocarcinomas in HNPCC families are more evenly distributed throughout the small bowel and at least half may be the first tumor diagnosed in these kindreds.⁸ In both FAP and HNPCC patients, the lifetime risk of small intestinal adenocarcinoma has been estimated to be more than 100 times that of the normal population.⁸

Peutz–Jeghers syndrome (PJS; the result of a mutation of the LKB1 gene that encodes a serine threonine kinase, STK11) results in the development of multiple hamartomatous polyps of the small intestine.⁹ Although the nonneoplastic nature of the PJS polyps was long believed not to put these patients at increased risk of gastrointestinal malignancy, this hypothesis is now known to be false.^{10,11} PJS patients are estimated to have an 18-fold-increased risk of intestinal cancer.¹¹ Most of the small bowel cancers in PJS appear to arise from hamartomas that transform into adenomas which then follow the usual adenoma–carcinoma sequence.¹² Given the wide distribution of hamartomatous polyps, small intestinal adenocarcinomas in PJS patients appear to be distributed differently than sporadic tumors, although the documentation of this pattern is incomplete.¹³

Several inflammatory conditions of the intestinal tract are also well recognized as risk factors for cancers of the small intestine. Crohn's disease is an idiopathic transmural inflammatory disease that may involve any part of the gastrointestinal tract but most commonly affects the terminal ileum. Although sporadic small bowel carcinomas are most common in the duodenum and rarest in the ileum, approximately two-thirds of adenocarcinomas in patients with Crohn's disease

occur in the ileum, 30% in the jejunum, and rarely in the duodenum.¹⁴ The estimated risk of adenocarcinoma in Crohn's disease has varied significantly because of small sample sizes but is likely more than 100 times that of the normal population.¹⁵ Factors that especially increase the risk of cancer in Crohn's disease include male gender, excluded loops of diseased bowel, long duration of disease, fistula tracts, and multiple strictures.¹⁶ Approximately 10 patients with small intestinal lymphoma in the setting of chronic Crohn's disease have been reported.¹⁷ Although a causal link between these conditions may exist, the rare combination of Crohn's disease and small bowel lymphoma has prevented a quantitative analysis of risk.

Celiac disease, or celiac sprue, is a chronic inflammatory disease of the small intestine caused by exposure to dietary glutes. Patients with celiac disease are at increased risk for both intestinal and extraintestinal malignancies, a predisposition that a gluten-free diet seems to reverse. In a study of 235 celiac disease patients with more than 250 cancers, more than half were malignant lymphomas, incredibly with 80% of these tumors occurring in the small intestine.¹⁸ These tumors are most commonly T-cell lymphomas of the jejunum, whereas sporadic small intestinal lymphomas are predominantly of B-cell origin and occur most often in the ileum. These so-called enteropathy-associated T-cell lymphomas (EATL) presumably arise from intraepithelial-infiltrating lymphocytes, a routine finding in celiac disease patients. Because many patients with mild celiac disease symptoms are not diagnosed, the true prevalence of small intestinal lymphoma in celiac disease is unknown, but risk estimates range from 25 to 120 times that for the general population.¹⁷ The next most common type of malignancy in celiac disease patients is small intestinal adenocarcinoma, occurring at a prevalence 83 times greater than in unaffected patients.¹⁸ The majority of these cancers occur in the jejunum.¹⁷

A small number of patients have been reported with ileal adenocarcinomas after a long-standing Brooke ileostomy,¹⁹ Kock pouch,²⁰ or ileal pouch–anal anastomosis²¹ following total proctocolectomy. Most of these patients had chronic ulcerative colitis as the reason for their proctocolectomy. The patients with both pouch reconstructions had chronic, severe inflammation of the pouch mucosa.^{20,21} In Brooke ileostomy patients, colonic metaplasia and dysplasia have been described as histologic precursors of adenocarcinoma.¹⁹ In patients with FAP and an ileal pouch–anal anastomosis, the probability of an adenomatous polyp in the pouch increases from 7% at 5 years to 75% at 15 years after the operation.²² Because most of these reports have been published in the last 15 years, ileal cancers following proctocolectomy will likely become a more common problem in the future.

Patients with both inherited forms of immunosuppression (e.g., Wiskott–Aldrich syndrome and ataxia telangiectasia) and acquired immunocompromise, including immunosuppressive treatment for solid organ transplantation and human immunodeficiency virus (HIV) infection, are at significantly higher risk of non-Hodgkin's lymphoma. Extranodal sites, including the gastrointestinal tract, are more common than in patients without immunosuppression. Only a small number of these lymphomas, however, originate in the small intestine.²³

Basic Science and Pathology

Adenocarcinoma

Although the duodenum makes up only 4% of the total length of the small intestine, 50% of small bowel adenocarcinomas occur there, and more than half of duodenal carcinomas occur in the periampullary region. Bile exposure has been hypothesized as an explanation for this distribution, but this speculation about bile as a carcinogen has not been proven. The proximal duodenum originates from the foregut, whereas the remainder of the small intestine arises from the midgut. This distinction has been hypothesized as another possible cause for the significant difference in cancer prevalence between these parts of the small bowel.²⁴ Jejunal adenocarcinomas are more common than ileal tumors, but because of similarities between cancers at these two sites and the small numbers at both locations, these malignancies are usually combined in discussions of small bowel carcinoma.

In the colon cancer adenoma–carcinoma sequence, early mutations usually occur in the APC and cyclooxygenase (COX-2) genes, with subsequent mutations in *K-ras*, *SMAD4*, *DCC*, and *P53* genes being commonplace. Another pathway, seen in patients with HNPCC, involves DNA mismatch repair enzyme gene mutations (mismatch repair or MMR phenotype). Many of the later genetic alterations seen in the first pathway also occur in HNPCC patients. The published data on genetic mutations in small bowel carcinomas are sparse because of the rarity of these tumors. A recent summary of published data showed no one mutation present in more than 45% of tumors and some possible differences in the genetic mutation pathways leading to malignant transformation in duodenal and jejunoileal carcinomas²⁴ (Table 43.1). One small study analyzing 12 duodenal cancers found a clear distinction in gene mutations between tumors following the classic adenoma–carcinoma pathway and those with an MMR phenotype,²⁵ but this has not been a consistent finding. In a recent study of 35 small bowel cancers (12 duodenal, 23 jejunal or ileal), 40% overexpressed P53 protein whereas only 9% of tumors had a mutation at codon 12 in

TABLE 43.1. Prevalence of genetic mutations in small bowel adenocarcinomas.

the *K-ras* gene. The latter finding led the authors to conclude that the adenoma–carcinoma sequence was not of great importance in the development of most small bowel tumors.²⁶ Other reports have shown strong COX-2 expression and high levels of other eicosanoid production enzymes in most small bowel cancers²⁷ and frequent 18q chromosomal deletions that result in SMAD4 mutations.²⁸ These findings support a molecular pathway similar to that noted in large bowel tumor development. In another report,²⁹ among 89 small intestine adenocarcinomas studied, 16 (18%) showed microsatellite instability, an indicator of MMR phenotype. MLH1 mutations were the cause of these abnormalities in about half the patients, with MSH2 mutations accounting for most of the remaining MMR mutations in younger patients.²⁹ This prevalence of MMR abnormalities is similar to that found in colorectal cancer patients. We have recently found replication errors to be significantly more common in small bowel adenocarcinomas arising in patients with celiac disease compared to sporadic small intestinal cancers.^{29a} More genetic analyses on larger numbers of tumors are needed to better clarify the prevalence and types of genetic alterations that occur in small intestinal adenocarcinomas.

Lymphoma

The gastrointestinal tract is the most common site of extranodal lymphomas, with the stomach being involved most commonly (approximately two-thirds of primary gastrointestinal lymphomas) and the small intestine and colon having similar numbers of tumors.³⁰ Although many advanced-stage nodal lymphomas involve the gastrointestinal tract, primary intestinal lymphomas can be distinguished by the absence of peripheral or mediastinal adenopathy, a normal peripheral blood smear and bone marrow biopsy, and a primary tumor of the bowel with or without mesenteric nodal involvement.³¹ The majority of intestinal lymphomas in the United States are non-Hodgkin's lymphomas of B-cell origin and occur most commonly in the ileum, less frequently in the jejunum, and least often in the duodenum. This distribution correlates with the amount of mucosal-associated lymphoid tissue (MALT) in the different parts of the small intestine. Table 43.2 outlines the classification system for gastrointestinal non-Hodgkin's lymphomas.³²

The predominant type of small bowel lymphoma differs significantly from one part of the world to another. In the Western world, high-grade MALT lymphomas are the most common histologic type of lymphoma in adults. Although gastric low-grade MALT lymphomas usually occur with *Helicobacter pylori* infestation and regress with treatment that eliminates this bacterium, no link with *H. pylori* infection has been determined for small intestinal lymphoma. In children in both the West and parts of the Middle East, Burkitt's-like lymphomas of the ileocecal region are the most common form of intestinal lymphoma.³² Around the Mediterranean Sea and, less commonly, in the rest of Africa, Eastern Asia, and Latin America, a very different MALT-type lymphoma is the most common intestinal lymphoma. Immunoproliferative small intestinal disease (IPSID) is a disease of younger persons (peak incidences in the second and third decades), usually in poorer socioeconomic classes, that involves the jejunum most often but in later stages causes diffuse disease of the small intestine. Because of the epicenter of the disease

and the usual detection of an alpha heavy-chain protein, IPSID has also been termed Mediterranean lymphoma or alpha heavy-chain disease. In the earliest stage of IPSID, the tumor often responds to treatment with broad-spectrum antibiotics, consistent with a benign immunoproliferative disorder arising in response to bacterial flora antigen(s). Over time, the malignant centrocytic-like cells that are initially confined to the bowel and regional lymph nodes spread to distant sites. Progression of IPSID carries a poorer prognosis and requires chemotherapy for treatment.³³ In countries where celiac disease is common (e.g., the United Kingdom), up to a third of small intestinal lymphomas are of T-cell origin, so-called enteropathy-associated T-cell lymphomas (EATL).³⁴ The link between celiac disease and EATL has long been suspected, but only recently have molecular studies clearly shown these conditions to be related. Patients with celiac disease have a chronic inflammatory infiltration of the small bowel mucosa that generally improves with a gluten-free diet. Patients who no longer respond to a gluten-free diet have refractory sprue, and their involved mucosa contains a monoclonal T-cell population, a finding that is also present in ulcerative jejunitis, another complication of celiac disease. These monoclonal T-cell populations have been shown to be clonally identical to those found in subsequent EATLs.³⁵ Patients with refractory sprue and ulcerative jejunitis require chemotherapy for their neoplastic T-cell disease.

Multiple lymphomatous polyposis (MLP) of the gastrointestinal tract is a rare lymphoma that presents with multiple polyps located anywhere from the stomach to the rectum, with small bowel involvement in almost all patients. A bulky tumor mass is often present and occurs most commonly in the ileocecal region. Given the histologic, immunohistochemical, and molecular characteristics of MLP, it is considered the gastrointestinal form of mantle cell lymphoma, a more indolent form of lymphoma.³⁶ Follicular lymphoma, a common type of non-Hodgkin's nodal lymphoma (NHL), rarely occurs in the small intestine. The distal ileum is the most common site within the bowel. The histologic appearance, surface markers, and molecular changes [increased BCL-2 expression caused by a t(14:18) involving the BCL-2 and immunoglobulin heavy-chain loci] are comparable to nodal follicular lymphomas. The intestinal form of follicular lymphoma rarely spreads to sites away from the gastrointestinal tract. These lymphomas appear to arise from a mucosal population of B cells.^{37,38} Hodgkin's disease is also a common form of nodal lymphoma and the bowel is often involved in

advanced stages of disease; however, primary gastrointestinal Hodgkin's disease is very uncommon. Many intestinal Hodgkin's disease cases have arisen in patients with chronic inflammatory bowel disease treated with immunosuppressive medications. The tumor cells demonstrate infection with Epstein-Barr virus, the likely stimulus for lymphoproliferation in this unusual disease.³⁹

Gastrointestinal Stromal Tumors

Gastrointestinal stromal tumor (GIST) is the most common type of mesenchymal tumor of the small intestine. The prevalence of this neoplasm in the different parts of the small bowel is proportional to the length of these segments, with most occurring in the jejunum, the next largest number in the ileum, and the fewest in the duodenum.⁴⁰ Once classified as smooth muscle tumors and called leiomyomas or leiomyosarcomas depending on whether they histologically appeared benign or malignant, GIST are now thought to arise from the interstitial cell of Cajal (pacemaker cell of the gut) or a pluripotential stem cell.⁴¹ GIST generally express CD117 (KIT, a tyrosine kinase receptor for stem cell factor) and have either a spindle cell or epithelioid histologic pattern. Mutations in exon 11 (and rarely either exon 9 or exon 13) of the *c-kit* gene are common in GIST. These mutations are generally activation mutations and are thought to be the molecular cause for tumorigenesis in GIST.⁴¹ A recent evaluation of nearly 300 GIST revealed differences in surface marker expression between sites in the gastrointestinal tract. CD34 (a hematopoietic progenitor cell antigen) is present in only half of small intestinal GIST but approximately 90% of

gastric GIST. Small bowel GIST are slightly more likely to stain for smooth muscle actin and S100 protein than gastric GIST, but tumor cells at both sites rarely express desmin.⁴² GIST with benign and malignant behavior both have similar DNA losses, including deletions in chromosomes 14q and 22q, but DNA copy gains are seen predominantly in malignant GIST. Specific tumor suppressor gene loss and oncogene activation mutations responsible for GIST development, and different biologic behaviors have as yet not been identified.⁴¹

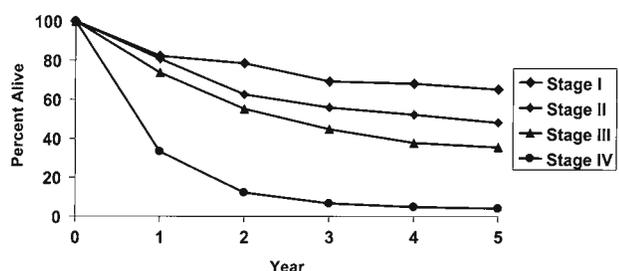

Prognostic Factors

As with most adult cancers, stage is the strongest predictor of survival for small bowel adenocarcinomas. The most recent American Joint Commission on Cancer Staging System for Small Bowel Carcinomas (sixth edition) is shown in Table 43.3.⁴³ The largest reported series of almost 5,000 small bowel adenocarcinomas treated between 1985 and 1995 in the United States was retrieved from the National Cancer Data Base.⁴⁴ In this publication, higher tumor stage, patient age greater than 75 years, and duodenal origin were adverse predictors of disease-specific survival using multivariate analysis. Figure 43.1 shows the survival curves of patients by tumor stage with 5-year disease-specific survivals of 65%, 48%, 35% and 4% for stages I, II, III, and IV, respectively. In Figure 43.2, the outcomes of jejunal and ileal adenocarcinoma patients are seen as essentially identical (both 38% 5-year disease-specific survival) and significantly better than duodenal adenocarcinomas (28% 5-year disease-specific survival; *P* less than 0.0001).⁴⁴ Tumor grade, when comparing poorly dif-

FIGURE 43.2. Patient survival for adenocarcinomas of the duodenum, jejunum, and ileum. The difference in outcome for duodenal cancer patients compared to the other two sites was highly significant ($P < 0.0001$). Data from the NCDB. (From Howe et al.,⁴⁴ by permission of *Cancer*.)

ferentiated tumors with either moderately or well-differentiated adenocarcinomas, revealed a significant survival difference, whereas the latter two tumor grades had similar survivals.⁴⁴ Other much smaller patient series^{45,46} have also found grade to be a significant predictor of patient outcome, but only in univariate analysis. Vascular invasion and incomplete excision have also been reported as adverse prognostic indicators,^{46,47} but these studies lack multivariate analysis and significant patient numbers. No molecular markers have been reported as prognostic indicators for patients with small intestinal adenocarcinomas.

Extranodal lymphomas have traditionally been staged using a modification of the Ann Arbor system.⁴⁸ As reformulated by Musshoff in 1977, this nomenclature included designations for extranodal origin (E) and subcategories of regional nodal involvement for mesenteric and paraortic locations (stages IIE1 and IIE2, respectively).⁴⁹ Within the past decade, a new staging system has been proposed.⁵⁰ These three systems for staging gastrointestinal lymphomas are displayed in Table 43.4.⁴⁸⁻⁵⁰ In the latest staging system, the E designation has returned to the original meaning within the

Ann Arbor classification, namely, extension to an adjacent structure, rather than extranodal disease in general. Stage III has been eliminated and is included with stage IV. The stage of disease at presentation has routinely been found to be a significant prognostic factor for small intestinal lymphomas.^{30,34,51-54}

Other adverse prognostic factors have been described for small intestinal lymphomas. In general, T-cell lymphomas have a worse prognosis than B-cell phenotypes.^{34,49,54} Older patient age,^{52,54} B symptoms,⁵⁴ perforation,^{34,52} and multifocal disease^{34,52} have all been reported as adverse prognostic indicators. Higher-grade lesions have been found to have poorer outcome in some studies,^{34,50} but stage and other variables have not always been accounted for in these analyses.

There is currently no formal staging system for GIST. Because lymph node metastases are very uncommon, GIST presents with either localized disease or distant metastases (most commonly liver, lung, or bone). Not surprisingly, patients with localized GIST have better survival than those who present with metastatic disease. In an effort to classify primary GIST by their risk of metastasis, pathologists sepa-

rate them into low-risk and high-risk categories. The criteria used for this distinction include tumor diameter (less than 5 cm versus 5 cm and more), mitotic rate [fewer than 2 mitoses/10 high-power fields (hpf) versus 2 or more mitoses/hpf], and the proliferation index (10% or less versus more than 10%). Low-risk tumors include those that are less than 5 cm with fewer than 2 mitoses/hpf and tumors that are either 5 cm or more in diameter or have 2 or more mitoses/hpf with a proliferation index of 10% or less. High-risk GIST have both larger size and higher mitotic index, or either of these factors plus a proliferation index greater than 10%.⁵⁵ Tumor size has consistently been a predictor of patient outcome both when evaluating smooth muscle tumors of the gastrointestinal tract^{40,56} and with analysis of only GIST.^{57,58}

Some low-risk GIST do metastasize. Recent findings of activation mutations in the KIT gene seem to correlate with malignant behavior in GIST. About 40% to 50% of GIST, most with a malignant phenotype, have a missense mutation in the juxtamembrane portion of the KIT molecule (exon 11), and the presence of this mutation correlates with poor prognosis.^{59,60} New mutational hot spots have recently been detected in tumors lacking a mutation in exon 11. These mutations localized to exons 9 and 13 of KIT have occurred uncommonly (less than 10%) in the GIST screened and correlate with malignant tumor behavior.⁶¹ Mutations in exon 9 were seen mostly in small bowel GIST in one report,⁶¹ whereas this correlation did not occur in a second study.⁶² The number of DNA sequence copy number changes⁵⁷ and loss of p16^{INK4} protein expression in GIST have also been correlated with poorer patient outcome. Other still undiscovered mutations activating KIT or having another effect on GIST behavior are likely to exist and will impact on tumor biology.

Diagnosis

Small intestinal malignancies do not produce any specific symptoms or signs, with the exception of carcinoid tumors. Because of their insidious presentation and the inability to directly visualize most tumors, the diagnosis of small bowel cancer is often delayed. Compounding this problem is the frequent cessation of the diagnostic evaluation of the gastrointestinal tract once the large bowel, esophagus, and stomach have been deemed normal. In patients with evidence of gastrointestinal blood loss, partial bowel obstruction, or both, the workup is never complete until the small intestine has also been fully evaluated for a source of these abnormalities. The presence of a genetic mutation or inflammatory bowel disease that places a patient at higher risk for these rare tumors (see section on Etiology) should only heighten the clinician's level of suspicion. In FAP patients, the duodenum should be routinely screened for polyps to prevent malignant degeneration and to detect duodenal cancers at an earlier stage.

Abdominal pain, ranging from a vague, dull discomfort to diffuse, acute signs of peritonitis, when a bowel perforation has occurred, is the most common symptom of small bowel malignancy. Up to 30% of small bowel lymphomas present with a surgical emergency. Progressive cramping pain with nausea, vomiting, and change in bowel habits caused by a partial luminal obstruction occurs frequently. Blood loss is

usually occult and chronic in nature, but may be clinically apparent and massive, especially in a patient with a GIST. Symptoms of malabsorption, especially in a patient with celiac disease, may be a sign of lymphoma. Periapillary duodenal cancers, especially adenocarcinomas, may initially present as obstructive jaundice. Jaundice can also occur with extensive hepatic involvement from small intestinal adenocarcinoma or GIST. As with any other primary cancer, weight loss, evidence of malnourishment, and decreased performance status are commonly the result of advanced disease.⁶³

Most duodenal adenocarcinomas occur within the first two portions of the duodenum and are detected during the course of a routine upper endoscopy. All duodenal neoplasms and some proximal jejunal cancers can be visualized with an extended upper endoscopy using a standard endoscope or colonoscope. More extensive direct visualization of the small intestinal mucosa can be accomplished with push or Sonde enteroscopy.^{64,65} Intraoperative or laparoscopic enteroscopy are also options, but most small bowel malignancies are apparent with visual inspection and palpation at laparoscopy or laparotomy, making these diagnostic tools of less value than with benign small bowel pathology. Compared to radiographic studies of the small bowel, endoscopy offers the advantage of pathologic sampling of any abnormality that can be visualized.

A plain film of the abdomen will rarely provide a diagnosis, but findings that may lead to the diagnosis of a small bowel malignancy include air-fluid levels indicative of a partial bowel obstruction plus a proximal or distal location, a mass effect from a large lymphoma or GIST, and calcifications within a GIST. Because many small bowel tumors are inaccessible to endoscopy, contrast radiography continues to have a role in their diagnosis. Standard barium upper gastrointestinal series with small bowel follow-through will detect an abnormality in one-half to three-quarters of malignant tumors, but only 30% to 40% will show direct evidence of the cancer.⁶⁶ Enteroclysis has been shown to have a higher detection rate for several small bowel pathologies, including malignancies. In one comparison of enteroclysis and small bowel follow-through, enteroclysis had a sensitivity of 95% and detection rate of 90% compared to a sensitivity of 61% and tumor detection of 33% for small bowel follow-through.⁶⁷

If a patient has a palpable tumor or evidence of a small bowel malignancy is detected on a contrast study, two-dimensional imaging is usually obtained to better define the site, local extent of the primary neoplasm, and evidence of regional or distant metastases. Although computerized tomography (CT) is more commonly utilized, magnetic resonance imaging (MRI) can be more accurate, especially in patients with a high-grade bowel obstruction where luminal contrast cannot be used. A recent study comparing MRI and helical CT scans in patients with bowel obstruction showed the sensitivity, specificity, and accuracy of MRI (95%, 100%, and 96%, respectively) to be superior to helical CT scan (71%, 71%, and 71%, respectively).⁶⁸

Although not all small intestinal malignancies can be differentiated by their radiographic characteristics, many can be distinguished from one another based on the radiologic findings. Adenocarcinomas most commonly cause a discrete "apple core" lesion on both contrast and cross-sectional imaging studies (Figure 43.3). This stricture is usually rigid, whereas strictures from lymphoma and GIST may alter on

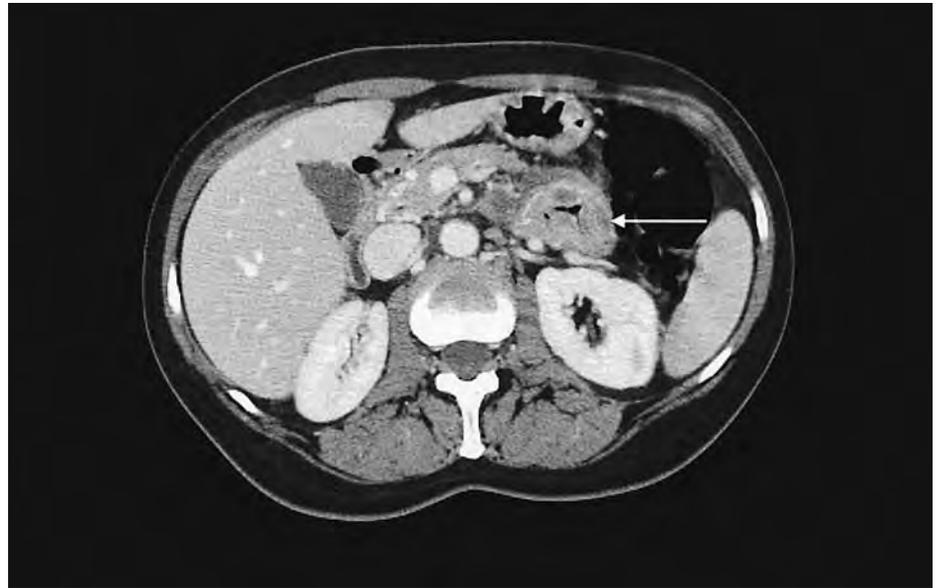

FIGURE 43.3. Computed tomography (CT) image showing tumor mass and luminal narrowing (apple-core lesion) of an adenocarcinoma of the fourth portion of the duodenum.

fluoroscopic imaging with compression. A polypoid intraluminal mass most commonly occurs with a duodenal adenocarcinoma, although more distal polypoid small bowel cancers can present with intussusception. Large high-grade carcinomas may ulcerate and be difficult to distinguish from other small intestinal cancer, especially lymphomas. The cross-sectional images should be assessed for growth into adjacent structures, regional adenopathy, peritoneal seeding, and hepatic metastases. Small bowel lymphomas can be multicentric, but most commonly they present as a segmental infiltrating mass that markedly thickens the bowel wall and often has aneurysmal dilatation of the intestinal lumen (Figure 43.4). Regional lymph nodes are commonly enlarged in lymphoma patients and may form a bulky mass of matted nodes with secondary involvement of small intestinal loops. Small intestinal GIST are generally discrete, round or lobulated, solitary tumors. Larger GIST often have heterogeneous

contrast uptake and may display central necrosis, sometimes with calcifications (Figure 43.5). Large GIST show a predominant exenteric growth pattern, but some GIST have predominantly an endoenteric location. The latter growth pattern causes an eccentric stricture of the bowel lumen with or without ulceration that can frequently be demonstrated on either contrast or cross-sectional images.^{66,69}

Recently, use of a miniature video capsule for diagnosing occult small bowel pathology has been reported.⁷⁰ This technology provides frequent, but not continuous, imaging of the entire bowel. The capsule cannot control its orientation during passage through the gastrointestinal tract. Although this technology will continue to improve and provide a diagnosis in subtle and early-stage small intestinal neoplasms, because most small bowel cancers present at a size amenable to detection with standard imaging, its role may remain a limited one for these tumors.

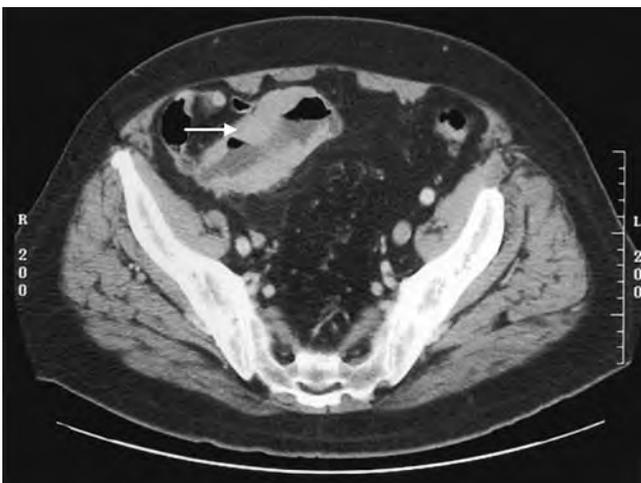

FIGURE 43.4. CT image of an ileal B-cell lymphoma with segmental thickening of bowel wall and aneurysmal dilatation of the bowel lumen.

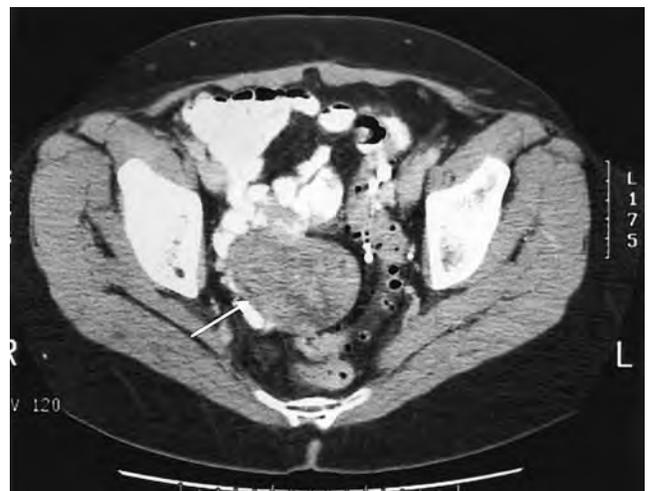

FIGURE 43.5. CT image of jejunal gastrointestinal stromal tumor (GIST) with predominant exenteric growth pattern and heterogeneous vascularity of tumor mass.

Treatment

Adenocarcinoma

Small bowel adenocarcinomas are best treated surgically with a segmental bowel resection and removal of the regional lymph nodes most likely to be involved by metastases (Table 43.5). In the jejunum and all but the terminal ileum, the optimal operative procedure consists of removal of a wide margin (more than 10cm proximally and distally) of adjacent bowel and mesentery with a primary anastomosis. All clinically involved mesenteric lymph nodes should be removed with the cancer, but the proximal mesenteric resection is limited by the superior mesenteric vessels. Any structure adherent to the primary cancer should be resected en bloc when a curative operation is possible. For cancers of the terminal ileum, a right colectomy should be performed to remove the draining lymph nodes along the ileocolic vessels. Among 779 jejunal and 602 ileal carcinomas included in the National Cancer Data Base review, approximately 90% underwent some type of resection (curative operations were not distinguished from noncurative procedures).⁴⁴

Invasive duodenal adenocarcinomas of the periampullary region can only be cured by a pancreaticoduodenectomy. Villous adenomas of the duodenum, especially those presenting with jaundice or other signs of malignancy, are more prone to contain malignancy. The sensitivity of endoscopic biopsy for malignancy in these polyps can be as low as 50%,

making a pancreaticoduodenectomy, especially for periampullary tumors, the best operative choice.^{71,72} For distal duodenal tumors, the lymphatic drainage includes lymph nodes along the superior mesenteric vessels that are not included in a standard pancreaticoduodenectomy. Although several older papers^{73,74} advocated pancreaticoduodenectomy for all duodenal adenocarcinomas, more-recent publications⁷⁵⁻⁷⁸ have found equally good outcomes with segmental duodenectomy for distal duodenal adenocarcinomas. In individual institutional reports of duodenal carcinomas,^{75,76,79-81} the resectability rates of patients surgically explored range from 53% to 87%, and 5-year survivals for curatively resected patients are between 45% and 60%. Data from the National Cancer Data Base for 1,425 duodenal carcinomas indicated only 52% of patients had some type of cancer resection.⁴⁴

At the present time, no adjuvant therapy can be recommended based on objective data for small intestinal adenocarcinomas. Similarities between small and large bowel adenocarcinomas have led some investigators to treat small bowel cancers with chemotherapy regimens of benefit in colon carcinoma, such as 5-fluorouracil and leucovorin. No controlled data exist showing an impact of these treatments in small intestinal cancers. Similarly, patients with duodenal cancers requiring pancreaticoduodenectomy are commonly recommended for adjuvant chemoradiation therapy,⁸² although no significant survival benefit has been apparent in retrospective reports.^{76,81} No major clinical trials looking at adjuvant or palliative treatment in small bowel adenocarci-

TABLE 43.5. Summary of small intestinal cancers.

Small intestinal cancers are rare.

Etiology

Inherited:	Familial adenomatous polyposis (FAP), hereditary nonpolyposis colorectal carcinoma (HNPCC), Peutz-Jeghers—adenocarcinoma
Inflammation:	Crohn's disease—adenocarcinoma (lymphoma) Celiac disease—T-cell lymphoma (adenocarcinoma)
Immunosuppression:	Wiskott-Aldrich syndrome, organ transplantation, human immunodeficiency (HIV) lymphoma

Basic science/pathology

Adenocarcinoma:	Most common in duodenum, least frequent in ileum Adenoma–carcinoma sequence and mismatch repair (MMR) pathways
Lymphoma:	Most common in ileum, least common in duodenum Most B-cell non-Hodgkin's lymphoma (NHL) of mucosal-associated lymphoid tissue (MALT) origin T-cell lymphoma in celiac disease
GIST:	Most common in jejunum, less in ileum, least frequent in duodenum Express CD117 (KIT) and most have c-kit activation mutations

Prognosis

Tumor stage most important	
Adenocarcinoma:	TNM staging, duodenal tumors poorer outcome
Lymphoma:	Modified Ann Arbor and other staging systems T-cell lymphoma poor outcome
GIST:	No definite staging system Metastasis implies poor outcome

Diagnosis

GI source of pathology not excluded without evaluating small bowel
Duodenum, proximal jejunum—extended upper endoscopy
Most jejunum, ileum—enteroclysis, enteroscopy, video capsule
CT/MR scan to stage disease

Treatment

Adenocarcinoma:	Segmental resection of bowel and adjacent lymph nodes (Whipple for periampullary duodenal cancers) Colon carcinoma chemotherapy
Lymphoma:	Resection of primary tumor to prevent complications Combination chemotherapy dependent on histology
GIST:	Resection primary tumor (lymphadenectomy unnecessary) Imatinib for metastatic tumors that express KIT

noma are currently under way, in large part because of the rarity of this condition.

Lymphoma

Because patients with gastrointestinal lymphomas amenable to complete gross resection more often survive than those with unresected lymphoma,^{83,84} many surgeons continue to recommend operative intervention for all early-stage lymphomas.⁸⁵ Experience with gastric lymphomas treated with primary chemotherapy and consolidation radiation therapy, when indicated, provides comparable survival to patients initially treated with resection and later with chemotherapy. Despite concerns about hemorrhage and perforation with primary chemotherapy in gastrointestinal lymphomas, very few patients with gastric lymphoma need any surgical treatment.^{86,87} Because small intestinal lymphomas are even rarer than gastric lymphomas, no controlled or even large-scale uncontrolled data exist comparing primary surgical and neoadjuvant therapy of these cancers. Most recent reports on small intestinal lymphoma⁸⁸⁻⁹⁰ have recommended combination therapy with surgical removal of all disease when feasible and multidrug chemotherapy dependent on the tumor histology. Some data indicate a trend toward treatment without operative intervention. In one study,⁸⁹ a complete remission rate of nearly 50% was noted with chemotherapy in advanced-stage (stage IV) small bowel lymphoma patients, irrespective of whether initial debulking was performed. In another study,⁸⁸ early-stage (stages I and II) patients had similar complete rates of response, survival, and disease-free survival regardless of whether complete resection, limited tumor removal, or no resection was performed.

At present, most clinicians still recommend complete tumor removal in early-stage disease when feasible, to avoid tumor perforation or obstruction, and selective surgical intervention for advanced-stage small intestinal lymphomas. All patients except those with low-grade lymphomas limited to the submucosa should be considered for postoperative combination chemotherapy.⁸⁹ For intermediate- and high-grade lymphomas, CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) remains the treatment of choice. For indolent lymphomas, such as mantle cell and follicular lymphomas, the anti-CD20 antibody rituximab has shown excellent promise in enhancing the response to chemotherapy.⁸⁵ Intestinal T-cell lymphomas are generally unresponsive to traditional combination chemotherapy and have a significantly worse prognosis compared to B-cell non-Hodgkin's lymphomas.⁹¹ Lymphomas associated with HIV infection generally have a poor prognosis due to treatment- and underlying disease-related complications plus low complete response rates with standard chemotherapy.⁹² Although radiation therapy has been recommended for bulky and advanced-stage lymphomas, the incidence of complications is high for gastrointestinal lymphomas,⁸⁵ and many advanced-stage patients do not survive long enough to receive treatment.⁹¹ In general, 5-year disease-free survival for small intestinal lymphomas is approximately 50% to 70% following combination therapy.⁸⁵

Gastrointestinal Stromal Tumors

Complete surgical excision of GIST is the treatment of choice. In most portions of the small intestine, this involves

a segmental bowel resection with en bloc excision of any adherent structures, but not extensive removal of the mesentery, because nodal metastases are uncommon. Duodenal GIST, especially of the proximal duodenum, may require pancreaticoduodenectomy to achieve complete removal, although segmental resection may be feasible if the GIST does not involve the periampullary region and clear margins can be achieved with a less-extensive excision. If all tumor is removed, the 5-year survival rate ranges from 50% to 65%.⁹³ Palliative tumor resection is indicated in metastatic GIST, especially with hemorrhage or perforation.

Following complete tumor removal, local recurrence and peritoneal and hepatic metastases are the most common types of tumor recurrence,⁹⁴ at a median time of 20 months.⁹⁵ Up to one-third of patients with recurrent GIST are amenable to total removal of recurrent tumor, but the median survival following a second operation is only 15 months with no further treatment. Patients with isolated hepatic metastases have the longest survival.⁹⁵ Postoperative intraperitoneal mitoxantrone appears to reduce the prevalence of peritoneal recurrence but has no impact on the development of hepatic metastases following recurrent GIST excision.⁹⁶

GIST have been notoriously resistant to conventional chemotherapy and radiation therapy. In the recent past, imatinib mesylate, a competitive inhibitor of several tyrosine kinases, including *c-kit*, *c-ABL*, and platelet-derived growth factor receptor, has been shown to be an effective treatment for metastatic and unresectable GIST. In a Phase II trial of 147 patients, 38% had a partial tumor response (greater than 50% tumor volume reduction), and the U.S. Food and Drug Administration approved imatinib mesylate for use in the treatment of patients with advanced GIST.⁹⁷ From data presented in two recent publications,^{98,99} it appears that GIST with activating mutations of KIT at exon 11 respond best to imatinib mesylate (83.5% partial response rate, compared to 48% with KIT mutations in exon 9). No responses were seen in 9 patients without detectable KIT or platelet-derived growth factor receptor alpha mutations.⁹⁹ Two Phase III trials evaluating the impact of imitinab in metastatic GIST have been completed, but the results have not been published yet. A third prospective, randomized study of the effect of adjuvant imitinab in high-risk primary GIST following complete resection is currently under way.

and David M. Nagorney

Hepatocellular Carcinoma

Hepatocellular carcinoma (HCC) is the fifth most common neoplasm in the world and the third most common cause of cancer death worldwide.¹ More than 500,000 deaths per year are attributed to HCC, representing 10% of all deaths from cancer. In select areas of Asia and Africa, HCC is the most common cause of death due to cancer. The incidence in Europe and the United States is relatively low but is increasing. In Europe, HCC is now the leading cause of death among patients with cirrhosis.² In the United States, epidemiologic studies have demonstrated a doubling of HCC incidence over the past two decades.³ This increase, which has been attributed to the increasing prevalence of chronic hepatitis C virus (HCV) infection, is expected to continue over the next two decades, given the lag time between the onset of chronic hepatitis and development of HCC.

Etiology

Unique among many other cancers, HCC has well-defined major risk factors. Cirrhosis is the strongest predisposing factor for development of HCC, present in 80% of patients. Chronic viral infection is the most frequent major risk factor for development of HCC. In Asia and Africa, hepatitis B viral (HBV) infection is common, whereas in the West and Japan, hepatitis C virus (HCV) is the main risk factor. The association of HCC and HBV infection is one of the most well recognized etiologic relationships in cancer biology.⁴ In epidemiologic studies, the prevalence of HBV carriers correlates with incidence of HCC. Chronic HBV carriers have a 100-fold relative risk of developing HCC compared with noncarriers.⁵ Up to 40% of HBV carriers who develop HCC do not have evidence of cirrhosis, demonstrating the direct carcinogenic potential of HBV infection.⁶ Prevention of HBV infection reduces the incidence of HCC, as demonstrated in Taiwan, where vaccination of infants reduced the incidence of HBV carriers and simultaneously decreased the incidence of HCC by 60% compared with nonimmunized children.^{7,8} In developed countries, HCC arises in cirrhotic livers as a result of HCV infection or excessive alcohol intake. Approximately 170 million people are infected with HCV.⁹ Vaccination for

prevention of HCV infection is currently not available. Prevention is focused on preventing transmission by transfusion of blood products and in halting the progression of infected individuals to cirrhosis by antiviral regimens such as pegylated interferon and ribavirin. Cirrhosis independent of the etiology is thought in most instances to increase the risk of HCC. The degree of association between cirrhosis and HCC, however, is dependent on the primary condition. Cirrhosis from HCV, HBV, alcohol abuse, and hemochromatosis portends a greater risk for HCC than other conditions such as autoimmune hepatitis, primary biliary cirrhosis, α_1 -antitrypsin deficiency, and Wilson's disease, where HCC is uncommon.¹⁰

The environmental carcinogen aflatoxin B₁ (produced by *Aspergillus flavus*) is a contaminant found in corn, peanuts, and rice that increases the risk of HCC threefold due to a specific mutation on codon 249 of the p53 tumor suppressor gene, leading to unregulated cell growth.¹¹ Aflatoxins do not cause chronic hepatitis, but metabolite intermediates bind selectively to guanine residues in hepatocyte DNA, resulting in mutations of the p53 tumor suppressor gene that lead to unregulated cell proliferation.¹² Clinically, aflatoxins likely act as cocarcinogens in the pathogenesis of HCC in patients with underlying cirrhosis or hepatitis.

Clinical Evaluation

Patients with HCC typically present with either constitutional symptoms or abdominal complaints due to advanced disease. Abdominal pain is present in nearly one-half of patients; anorexia, nausea, weight loss, and fatigue also occur commonly. Presentation may also be related to the degree of cirrhosis and hepatic decompensation manifested by ascites, gastrointestinal hemorrhage, or encephalopathy. Physical examination may be significant only for signs of cirrhosis; however, a discrete mass may be palpable in large tumors.

Serum α -fetoprotein levels are increased in more than 80% of patients with HCC, and this marker provides a sensitivity of 85% and specificity of 90% for detecting the presence of HCC. The presence of a liver mass with an α -fetoprotein level of 500ng/mL or more is virtually diagnostic of HCC. Serum des- γ -carboxyprothrombin, a precursor

of prothrombin, has a sensitivity and specificity similar to α -fetoprotein but is less commonly used.

An accurate assessment of the number, size, and location of HCC is best obtained by using multiple complementary imaging studies. The goals of imaging are to define the number and location of lesions and the relationship of the HCC to major hepatic and portal veins and hepatic ducts and to delineate cirrhosis, splenomegaly, ascites, regional adenopathy, and presence of metastatic disease. Abdominal ultrasonography is a useful initial study in suspected patients based on its noninvasive and cost-effective profile. After the basic characteristics of HCC are defined with ultrasonography, additional imaging with rapid contrast-enhanced computed tomography (CT) is recommended. In addition to confirming ultrasonographic findings, CT further defines evidence for local invasion, vascular invasion, regional and distant metastases, and portal hypertension. It also provides the ability to calculate the resection volume and the expected remnant volume in resection planning, which are essential in determining the functional resectability of HCC, particularly in patients with cirrhosis. Magnetic resonance imaging (MRI) is an accurate method for imaging HCC. It is the single best imaging method to simultaneously evaluate the liver, tumor vascularity, vascular structural relationships, and bile duct anatomy but lacks the clarity of CT for assessment of extrahepatic disease. MRI has largely supplanted the need for angiography in most patients and is the study of choice for patients with impaired renal function. Hepatic angiography in our practice has a decreasing role in diagnostic evaluation, and its primary use is directed in therapy. Hepatic angiography with the contrast agent lipiodol is particularly accurate for the diagnosis of small HCC when CT and MRI are indeterminate. Hepatic angiography with chemoembolization is used to reduce the size of HCC to enhance resectability, as neoadjuvant therapy in patients before transplantation, or as palliative treatment for patients with unresectable disease. Portal vein embolization can be used to increase resectability by inducing hypertrophy of the contralateral lobe when the predicted postresection remnant is small and the risk of hepatic failure is increased.¹³⁻¹⁵

Staging and Prognosis

Prognostic modeling in HCC is complex, because survival is determined not only by the tumor characteristics and metastases but also by the underlying liver function, which in turn affects the applicability of treatment options. HCC is staged according to the tumor, node, and metastases classification of the American Joint Committee on Cancer or the International Union Against Cancer (AJCC-UICC) scheme (Table 44.1). Although improvements in the prognostic value of this staging system have been realized with modifications, accuracy is still limited because of its predominant histopathologic focus and neglect of accounting for underlying liver function. The Okuda classification includes variables related to pathologic staging and liver function and has been used extensively, but it is unable to distinguish between early and advanced stages.¹⁶ Multiple other classifications have been proposed but have not been fully validated or have not received universal acceptance.

TABLE 44.1. American Joint Committee on Cancer (AJCC) staging of hepatocellular carcinoma (HCC) and intrahepatic cholangiocarcinoma.

Stage	Tumor	Node	Metastasis
I	T1	N0	M0
II	T2	N0	M0
IIIA	T3	N0	M0
IIIB	T4	N0	M0
IIIC	Any T	N1	M0
IV	Any T	Any N	M1

T₁, solitary tumor without vascular invasion; T₂, solitary with vascular invasion or multiple tumors less than 5 cm; T₃, multiple tumors greater than 5 cm or tumor involving a major branch of the portal or hepatic vein(s); T₄, tumor(s) with direct invasion of adjacent organs other than the gallbladder or with perforation of visceral peritoneum; N₁, regional lymph node metastases; M₁, distant metastases.

Management

The treatment of HCC is broadly divided into curative and palliative. Curative treatments include resection, liver transplantation, and percutaneous ablation and induce complete responses in a high proportion of patients. Palliative treatments are not aimed at cure but may exhibit partial response rates and even improve survival. In the West, only 30% to 40% of patients undergo curative treatments. In Japan, this percentage is increased to 60% to 90%, which is largely attributed to implementation of surveillance. No level I evidence is currently available evaluating the different methods of curative treatment.

Resection

Hepatic resection aimed at complete extirpation of the tumor is the treatment of choice for HCC in noncirrhotic patients. The treatment of patients with underlying cirrhosis may involve either hepatic resection or transplantation, depending on hepatic function and organ availability. Despite the enthusiasm and theoretical advantages of liver transplantation for HCC patients with cirrhosis, hepatic resection plays a predominant role in the treatment of select patients with well-preserved liver function (Child-Pugh class A) as a result of the lack of organ availability for liver transplantation. There are currently no well-designed controlled trials comparing hepatic resection with transplantation for patients with HCC and cirrhosis.

Hepatic resection is reserved for those patients with HCC grossly limited to the liver and is primarily dependent on the intrahepatic extent of the HCC and the hepatic function. Criteria for resectability are exclusion of extrahepatic metastases, anatomic intrahepatic accessibility of the tumor, and adequate hepatic functional reserve. Major resections in experienced centers can be performed with minimal mortality and excellent outcome. Table 44.2 lists the large contemporary series of hepatic resection in patients with HCC. Overall mortality of hepatic resection is 1% to 15% with an overall 5-year survival of 25% to 50%. Perioperative morbidity and mortality is adversely affected by the presence of cirrhosis,

^c3-year survival data.

which is present in up to 80% of patients. The most frequent serious complications after liver resection in patients with HCC remain perioperative bleeding and liver failure. Several important considerations should be understood when interpreting reports on hepatic resection in patients with HCC. First, each series of patients is highly selected, and overall resectability rate is only 10% of all patients with HCC. Second, the definition of resectability varies widely, with some series excluding patients on the basis of tumor size, vascular invasion, lymph node metastases, and degree of portal hypertension. Third, 75% to 80% of patients who undergo resection have underlying cirrhosis. The degree of hepatic dysfunction, although progressive, may fluctuate and influence perioperative hepatic decompensation and mortality. Moreover, the cause of cirrhosis varies, and the natural history of the underlying liver disease also varies widely. Clearly, there is substantial heterogeneity among patients with resected HCC, and overall comparison of patients frequently neglects these differences.

Tumor recurrence complicates 70% of patients at 5 years, including both true recurrence and de novo tumor.¹⁷ Several predictors of recurrence that have been established include microvascular invasion, poor histologic differentiation, and satellite tumors.^{18,19}

Liver Transplantation

Liver transplantation is a well-established treatment option in cirrhotic patients with HCC. Theoretical advantages include simultaneous cure of the tumor and the underlying cirrhosis. Early reports of transplantation for patients with HCC described poor results, with tumor recurrence rates of 32% to 54% and 5-year survival of less than 40%.²⁰ Careful scrutiny of these reports, however, has enabled identification of optimal candidates for transplantation. With highly selected patients, transplantation has been shown to provide excellent 5-year survival and decreased recurrence rates. Established criteria include patients with one HCC smaller than 5 cm or up to three nodules smaller than 3 cm. With these criteria, 5-year survival of up to 70% and recurrence rates less than 15% have been reported.^{17,21-24} Expansion of these criteria has been proposed but remains to be validated.

A crucial consideration in the role of transplantation for treatment of HCC is organ availability, and thus the waiting time, which can exceed 12 months in many centers, results in a dropout rate of 20% to 50%.^{18,25} However, because of the disparate number of patients with HCC needing liver transplantation compared to the number of available donors, the United Network of Organ Sharing (UNOS) has adapted the model for end-stage liver disease (MELD) to prioritize the waiting list. This model provides consideration for patients with HCC and underlying liver disease. Living donor liver transplantation is emerging as the most feasible alternative to deceased donor liver transplantation. The theoretical unlimited availability of donors is encouraging but is presently unrealized.

Percutaneous Ablation

For patients with HCC who are not operative candidates, percutaneous approaches are the best option for potential curative treatment. Multiple destructive techniques have been described including both chemical (alcohol, acetic acid) and temperature modification (radiofrequency, microwave, and cryoablation). Percutaneous ethanol injection has been extensively evaluated. Advantages are its procedural simplicity, low cost, and minimal adverse effects. Response rates of 90% to 100% in HCC smaller than 2 cm, 70% in those up to 3 cm, and 50% in those up to 5 cm in diameter have been reported.^{26,27} Selected patients with a complete response have been reported to achieve a 5-year survival of 50%.^{26,28} Radiofrequency ablation (RFA) represents an alternative percutaneous treatment option for patients with unresectable HCC. Potential advantages over ethanol injection include fewer treatment sessions and better local tumor control. In one randomized controlled trial comparing percutaneous ethanol injection and radiofrequency ablation, RFA-treated patients were associated with better local tumor control; however, there was no difference in overall survival.²⁹

Arterial Embolization

Arterial embolization is frequently used for treatment for patients with unresectable HCC. Embolization agents, typically gelatin, may be administered alone or in combination

with selective intraarterial chemotherapy (chemoembolization). Arterial embolization achieves partial responses in 15% to 55% of patients and substantially delays tumor progression and vascular invasion.³⁰⁻³³ A meta-analysis of randomized controlled trials comparing arterial embolization or chemoembolization with conservative management demonstrated a survival benefit for chemoembolization.³⁴

Systemic Treatment

The majority of patients presenting with HCC have advanced disease at the time of presentation. It is estimated that only 15% to 30% of patients have potentially resectable disease. However, on further evaluation only about one-half of these patients truly have tumors that are resectable. For patients with unresectable disease confined to the liver, several options of therapy are available, including chemoembolization and alcohol ablation. For patients with disease that has spread beyond the liver, few effective options are available. Despite multiple prior studies of chemotherapy, either as single agents or in combination, only limited benefit for patients with unresectable or metastatic HCC has been observed (Table 44.3).

A variety of studies have assessed single-agent chemotherapy. Anthracyclines, particularly doxorubicin, have often served as the chemotherapy drug of reference. Only level II and III evidence exists for the efficacy of doxorubicin. Objective responses to doxorubicin have generally been about 10% with an associated short median survival.³⁵⁻⁴⁰ Limited data from trials with epirubicin suggest better response rates but not necessarily longer survival.^{41,42} A variety of phase II studies with an anthracycline combined with another agent have not led to a consistent improvement in outcome compared to single-agent studies. However, no phase III trials have been performed.

Fluorouracil (5-FU)- and platinum (CDDP)-based regimens have been evaluated in a large number of clinical trials. All these trials provide level II or III evidence of activity. A combination of 5-FU, CDDP, doxorubicin, and interferon (PIAF) has frequently been cited as an active regimen. Following a complete response to this regimen in a case report,⁴³ a subsequent phase II clinical trial in 50 patients reported a 26% partial response rate and median overall survival rate of 8.9 months.⁴⁴ Although the proportion of patients responding to this regimen was not notably different from that in other platinum-based regimens, 9 of the 13 responding patients were able to undergo surgical resection of previously unresectable tumors. The use of regimens such as PIAF has been limited by the toxicity of the regimens and frequently by the advanced stage of liver dysfunction in most patients with HCC.

Several meta-analyses of published trials have concluded that systemic chemotherapy offers little benefit to patients with HCC.⁴⁵⁻⁴⁷ Given the apparent limited benefit of chemotherapy, other agents have been evaluated, including hormonal therapy.

Preclinical studies have shown varying levels of sex hormone receptors in HCC, leading to an evaluation of hormonal agents in HCC.^{48,49} Several older underpowered phase II trials showed potential benefit with tamoxifen compared to a placebo.^{50,51} Subsequently, a number of randomized multicenter trials of tamoxifen, compared to best supportive care,

have shown no benefit for tamoxifen.⁵²⁻⁵⁵ Phase II trials of other hormonal-based therapies have not clearly shown a benefit,⁵⁶⁻⁵⁹ although several small clinical trials have suggested potential activity that has yet to be confirmed.^{60,61}

Several clinical trials have evaluated the role of adjuvant therapy for patients undergoing surgical resection of HCC. In one of these trials, 49 patients were randomized to receive chemotherapy with epirubicin and mitomycin or observation.⁶² A lower rate of recurrence and better overall survival were observed in patients receiving chemotherapy. The small size of this trial provides only level II evidence of benefit. Most trials have evaluated liver-directed therapy rather than systemic chemotherapy.⁶³ To date, the various approaches assessed have not shown any clear improvement in overall survival or disease-free survival compared to surgery alone.

Cholangiocarcinoma

Cholangiocarcinoma is the second most common primary liver cancer in the world, after the more common hepatocellular carcinoma. The tumor usually occurs over the age of 50 to 60 years and is slightly more frequent in men than in women. In the United States, the annual incidence of cholangiocarcinoma is approximately 7 per million.⁶⁴ Recently, several epidemiologic studies have been published demonstrating an increase in the incidence and mortality of intrahepatic cholangiocarcinoma over the past 30 years in the United States,⁶⁴ as well as in numerous other countries.^{65,66} According to these analyses, the age-adjusted death rates in the United States increased from 0.15 per 100,000 in the 1970s to 0.66 per 100,000 in the 1990s; similar data were reported for many other Western countries, especially England, Wales, and Australia. The reason for the rising incidence and mortality of cholangiocarcinoma is as yet unclear; it may in part be better recognition of the intrahepatic form of this disease, and some authors have suggested that new and not yet defined environmental factors might contribute to a more frequent development of this disease.

Etiology and Pathogenesis

In contrast to hepatocellular carcinoma, cholangiocarcinoma does not develop preferentially in the cirrhotic liver; in some studies only 4% to 7% of cholangiocarcinomas originated from cirrhotic livers.⁶⁷ A number of risk factors have been established, including primary sclerosing cholangitis, liver fluke infestation, Caroli's disease, congenital choledochal cysts, chronic hepatolithiasis, and Thorotrast deposition. However, many patients who are diagnosed with cholangiocarcinoma have none of these factors in their history.

In the United States and Europe, primary sclerosing cholangitis (PSC) is one of the most important risk factors. The estimated risk of a patient with PSC for cholangiocarcinoma is approximately 0.5% to 1.5% per year after diagnosis, and about 10% to 20% of patients with PSC eventually develop cholangiocarcinoma.^{68,69}

Other established risk factors for cholangiocarcinoma include liver flukes (infection with *Clonorchis sinensis* or *Opisthorchis viverrini*), Caroli's disease, congenital choledochal cysts, and chronic hepatolithiasis.⁷⁰ In Japan, hepatitis

PR, partial response; CR, complete response.

C virus infection is frequently found in patients with cholangiocarcinoma,⁷¹ and Kobayashi et al. found that 3.5% of HCV-infected patients developed cholangiocarcinoma within a 10-year observation period.⁷² Moreover, dietary habits have been suggested to contribute to the regional variability in incidence, especially the regular intake of certain salted fish products in Asia, which can contain the bacterial product dimethylnitrosamine.^{73,74}

Most of these risk factors have in common that they are causes of chronic inflammation and/or cholestasis. Thus, as

is the case in many other gastrointestinal tumors, chronic inflammation of the biliary tree appears to be an important factor in the development of cholangiocarcinoma.

A large number of molecular alterations have been found in human cholangiocarcinoma (Table 44.4). However, it must be noted that the most of these alterations have been described in intrahepatic mass-forming cholangiocarcinomas, and their relevance to the ductal-infiltrating and intraductal growth forms as well as extrahepatic tumors is unclear.

TABLE 44.4. Molecular alterations in cholangiocarcinoma.

<i>Molecular finding</i>	<i>Biologic effect</i>
Chronic inflammation/growth factors

Bcl-2 overexpression	Inhibition of apoptosis
Disruption of TGF-beta signaling	Inhibition of apoptosis Loss of cell-cycle control
FasL expression	T-cell apoptosis
Other	
Telomerase reverse transcriptase	Immortalization

As some of the molecular and genetic changes of cholangiocarcinoma can already be detected in preneoplastic inflammatory bile duct lesions, it is generally presumed that chronic inflammation or cholestasis or both cause a sequence of events leading first to hyperplasia and dysplasia of the biliary epithelia, and eventually to the development of carcinoma. Figure 44.1 gives an overview of this hypothesis.

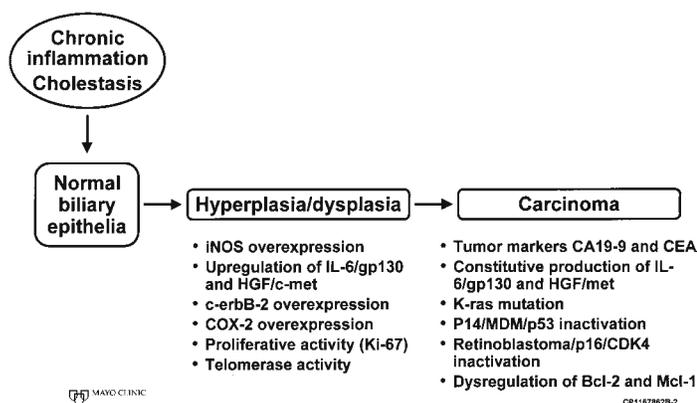

FIGURE 44.1. Molecular alterations in reactive hyper- and dysplasia and in cholangiocarcinoma. Chronic inflammation and cholestasis cause premalignant hyper- and dysplasia of biliary epithelia with distinct molecular alterations such as inducible nitric oxide synthase (iNOS) overexpression, upregulation of growth factors and their receptors, cyclooxygenase (COX)-2 overexpression, increased proliferation, and telomerase activity. With the development of cholangiocarcinoma, malignant cells constitutively express growth factors, mutation of tumor suppressor genes occurs, and oncogenes are observed. There is also dysregulation of antiapoptotic proteins along with expression of classic tumor markers.

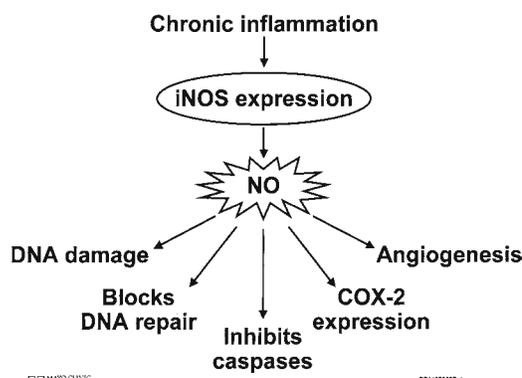

FIGURE 44.2. Nitric oxide in cholangiocarcinogenesis. In chronic inflammation of the bile ducts [e.g., in sclerosing cholangitis (PSC)], cytokines cause biliary epithelia to express iNOS, which in turn generates nitric oxide (NO); NO contributes to carcinogenesis by damaging DNA and inhibiting DNA repair proteins leading to mutation, by inactivating caspases and thus inhibiting apoptosis, by promoting angiogenesis, and by inducing COX-2 expression, which also inhibits apoptosis and triggers angiogenesis.

Chronic Inflammation: DNA Damage

Chronic inflammation is associated with generation of cytokines both by inflammatory cells and by cholangiocytes. A key proinflammatory cytokine is interleukin 6, a strong mitogen for cholangiocytes and cholangiocarcinoma cells. Proinflammatory cytokines including interleukin 6, interleukin 1, interferon- γ , and tumor necrosis factor- α cause cholangiocytes to express the inducible form of nitric oxide synthase (iNOS), a potent generator of nitric oxide (NO). NO itself or NO derivatives (Figure 44.2) can modify or alter DNA bases, resulting in direct DNA damage.⁷⁵ NO may also nitrosylate and inactivate DNA repair proteins, leading to an accumulation of damaged DNA bases, thereby further promoting mutagenesis [76]. In addition, NO has been shown to also disable proapoptotic proteins such as caspases.⁷⁷

Consistent with these data, iNOS expression and generation of NO can often be detected in diseases that predispose to cholangiocarcinoma; for example, cholangiocytes in PSC and cholangiocarcinoma cells have been shown to express iNOS,⁷⁸ and elevated serum nitrate values as a result of iNOS activity can be observed in patients with fluke infections.⁷⁹ Therefore, it has been proposed that iNOS expression and NO generation play an important role in the pathogenesis of cholangiocarcinoma, and that iNOS inhibitors may be chemopreventive in diseases predisposing to the development of cholangiocarcinoma such as PSC, especially because in animal models of intestinal and lung cancer, deletion or inhibition of iNOS can be chemopreventive.^{80,81}

Bile Acids: Regulation of Proliferation and Apoptosis

Cholangiocarcinomas often grow within or along the bile duct lumen, suggesting that they may not only have developed mechanisms to survive the toxic constituents in bile but actually use bile to promote growth and survival. Indeed, cholangiocytes and cholangiocarcinoma cells are resistant to apoptosis when exposed to bile acids in vitro, in contrast to hepatocytes and hepatoma cells, for which most bile acids are toxic. Furthermore, bile acids have been shown to transacti-

vate the epidermal growth factor receptor in cholangiocarcinoma cells and induce expression of cyclooxygenase (COX)-2,⁸² an enzyme that generates prostanooids and can inhibit apoptosis, facilitate growth, and promote angiogenesis in a variety of malignancies.⁸³ In addition to inducing COX-2 expression, bile acids also enhance the cellular protein levels of myeloid cell leukemia protein 1 (Mcl-1), a potent antiapoptotic protein, *in vitro*.⁸⁴ Mcl-1 protein levels are also frequently elevated in human cholangiocarcinoma *in vivo*.⁸⁵

Thus, chronic inflammation as well as the ability to survive and proliferate in the toxic bile milieu appears to contribute to the development of cholangiocarcinoma. It remains to be elucidated whether cholestasis alone, or alterations in bile composition caused by chronic inflammation, or both are responsible for the antiapoptotic and growth-promoting effects of bile on cholangiocarcinoma.

Histology

Histologically, most cholangiocarcinomas are well to moderately differentiated tubular adenocarcinomas, with formation of glands and an abundance of dense desmoplastic stroma; calcification may be present. Mucus, but not bile secretion, is observed in the majority of tumors. The glandular lumens are lined by well-differentiated columnar or cuboidal cells with uniform nuclei and small nucleoli. In poorly differentiated adenocarcinoma, a definite tubular formation is rarely found, and the cells are pleomorphic with irregular nuclei.

In addition to the most common tubular form of cholangiocellular adenocarcinoma, other variants have been described, such as papillary adenocarcinoma, signet-ring carcinoma, squamous cell or mucoepidermoid carcinoma, a spindle cell variant, and a lymphoepithelioma-like form.

Classification

Cholangiocarcinoma is broadly classified as intrahepatic or extrahepatic. Extrahepatic cholangiocarcinoma is further classified as perihilar, midduct, and distal. Major differences in presentation, evaluation, staging, and operative management warrant separate discussion of intrahepatic and extrahepatic cholangiocarcinoma.

Intrahepatic Cholangiocarcinoma

Intrahepatic cholangiocarcinoma (ICC) is the second most common primary liver cancer after HCC, with a prevalence of 10% to 30%.^{86,87} Cholangiocarcinoma of the intrahepatic ducts is far less common than that of the extrahepatic ducts, typically accounting for less than 10% of all cholangiocarcinoma.

Clinical Evaluation

In a review of 61 patients with ICC surgically treated at the Mayo Clinic over a 31-year period, the most common presenting symptom was abdominal pain, followed by signs of weight loss and anorexia. Jaundice is an unusual finding in ICC that is present in only 15%.⁸⁸ The physical examination

is frequently nonspecific for ICC; an abdominal mass is the most common finding but is present in only one-third of patients. Other signs such as ascites, cachexia, and splenomegaly are infrequent and nonspecific. Typically, when patients with ICC present with symptoms, the disease is frequently advanced and the likelihood of a curative resection is low.

Other than mild increases in alkaline phosphatase and aminotransferases, laboratory findings are typically normal in patients with ICC. Tumor markers such as the carcinoembryonic antigen (CEA) and α -fetoprotein are infrequently increased, whereas the carbohydrate antigen 19-9 is more frequently elevated in patients with ICC.

The imaging of ICC is similar to that of HCC. Frequently ultrasonography is the initial diagnostic evaluation that is useful to identify the tumor location and characteristics. As for HCC, CT is an excellent imaging modality to assess the tumor location, extent of invasion, and evidence of extrahepatic disease. Because of the intense fibrosis associated with cholangiocarcinoma, a decreased tumoral vascularity of ICC is frequently noted compared to that of HCC.

Pathology and Staging

The gross appearance of intrahepatic cholangiocarcinomas is of a gray-white scirrhous mass, with an abundance of stroma and mucin secretion, but little vascularization. The masses may be solitary or multinodular and can be relatively well demarcated or infiltrating, growing along the intrahepatic bile ducts.

The Liver Cancer Study Group of Japan has further classified intrahepatic cholangiocarcinoma into three principal types: a mass-forming type that is usually localized with a round shape and distinct borders, a periductal-infiltrating type with diffuse infiltration along the bile ducts, and an intraductal growth type showing intraductal papillary or granular growth.⁸⁹ Among these, the mass-forming type is the most frequent and the intraductal growth type the rarest; overlap, especially between the mass-forming and the periductal-infiltrating type, is very common. This new classification appears to be useful, because the three forms have been shown to differ not only in gross appearance but also in their genetic alterations and prognosis.^{90,91} ICC is staged using the same AJCC tumor, node, and metastases classification as for HCC (see Table 44.1).

Operative Management

Resection remains the only curative treatment in the management of ICC. In our experience, patients with resected ICC are the only long-term survivors, with a 3-year survival of 60% with resection compared to 7% without resection.⁸⁸ Operative mortality and morbidity for resection in patients with ICC are typically less than 2% and 15%, respectively.

Hepatic resection is the standard for intrahepatic cholangiocarcinoma. The extent of resection is determined by the anatomic location of the tumor and by the objective of achieving a complete macroscopic and microscopic (R0) resection. Recent series of outcomes after resection of ICC are shown in Table 44.5. Factors associated with decreased survival are stage, vascular invasion, intrahepatic metastases, and positive lymph nodes. Intrahepatic cholangiocarcinoma spreads along

TABLE 44.5. Hepatic resection for perihepatic cholangiocarcinoma.

^aFor node-negative patients

^bFor patients with curative resection.

^cFor patients with hepatic resection.

Glisson's sheath by way of lymphatics to metastasize to regional lymph nodes. The incidence of lymph node metastases for ICC ranges from 6% to 46%.^{92,93} In an autopsy series of ICC, lymph node metastases were present in up to 72%.⁹⁴ Patients with lymph node metastases have an extremely poor prognosis. Inohue and colleagues evaluated 52 patients with intrahepatic cholangiocarcinoma and reported an overall 5-year survival rate of 36%, but no long-term survivors among 21 patients with lymph node metastases.⁹⁵ Routine lymph node dissection in patients with ICC remains controversial. Currently, there is no strong evidence to suggest that lymph node dissection offers a survival benefit, and no randomized trials have been performed. Additionally, hilar lymphadenectomy does not ensure removal of lymph node metastases because the lymphatic drainage of the liver is not exclusively via the hepatoduodenal ligament but also through the coronary, falciform, and triangular ligaments. The presence of lymph node metastases, however, is an ominous finding and should preclude hepatic resection.^{95,96} Routine lymphadenectomy with frozen section analysis before proceeding to hepatic resection has been advocated.⁹⁶

Extrahepatic Cholangiocarcinoma

Perihilar cholangiocarcinoma (PCC) accounts for approximately 60% of extrahepatic cholangiocarcinomas. Midduct (15%) and distal (20%) cholangiocarcinomas comprise the remainder.

Clinical Evaluation

The majority of patients with extrahepatic cholangiocarcinoma present with progressive, painless jaundice. Biochemical confirmation typically prompts diagnostic ultrasonography. Albeit operator dependent, ultrasonography can demonstrate several salient features of PCC such as tumor morphology, portal vein or hepatic artery obstruction, intrahepatic metastases, and regional lymph node metastases. Because distant disease precludes curative resection and evidence of unresectability will prompt palliative stenting, CT

should precede cholangiographic evaluation. CT provides an excellent overall assessment and can characterize local tumor extension, hepatic lobar atrophy, portal vein compression in invasion, and lymph node and other metastases. The presence of lobar atrophy is frequently associated with ipsilateral portal vein involvement, is a major harbinger of unresectable disease, and should prompt a thorough vascular evaluation.

Cholangiography provides the best evaluation of ductal involvement and extension. Critical in the ductal evaluation is the proximal extent of the disease. Clear delineation of the confluence and proximal biliary system is imperative to correctly classify the tumor and plan surgical resection and reconstruction. Endoscopic retrograde cholangiography (ERC) may not provide sufficient evaluation of the proximal extent of the disease, and percutaneous transhepatic cholangiography may be necessary. The Bismuth–Corlette classification, although not intended to stage PCC, provides a useful conceptualization based on preoperative imaging when considering the extent of resection necessary for a curative intent and communication in reporting (Figure 44.3).

Magnetic resonance imaging (MRI) provides several advantages in the evaluation of cholangiocarcinoma. It provides a noninvasive assessment of the liver, bile ducts, and vessels. Unlike direct cholangiography, however, MRI does not provide equivalent cholangiographic image resolution,

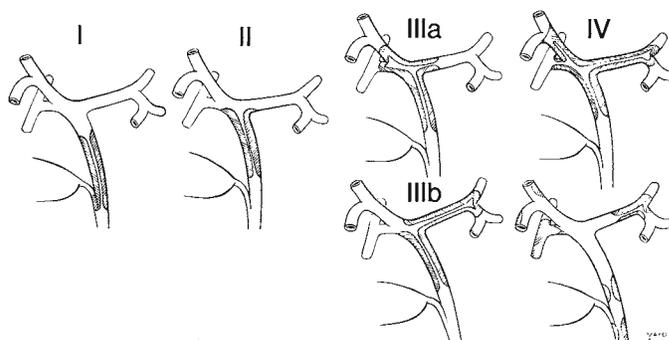

FIGURE 44.3. Bismuth–Corlette classification of perihilar cholangiocarcinoma. (Reprinted by permission of Mayo Foundation for Medical Education and Research.)

access for brush cytology, or the ability of biliary ductal drainage for relief of obstruction and palliation.

A thorough clinical evaluation of the patient's functional status and coexisting medical comorbidities is important before extensive radiographic evaluation. Patients deemed unfit for operative intervention do not need such extensive evaluations, and alternate palliative goals should be considered.

In determining the resectability of PCC, four key issues must be addressed: extent of biliary involvement, vascular (hepatic artery or portal vein) invasion, hepatic atrophy, and metastatic disease. Specific criteria of unresectability have been suggested⁹⁷: these include (1) bilateral ductal extension to the secondary or segmental biliary radicals; (2) encasement or occlusion of the main portal vein proximal to its bifurcation; (3) lobar atrophy with encasement of the contralateral portal vein branch or hepatic artery; (4) lobar atrophy with contralateral involvement of secondary biliary radicals; (5) unilateral segmental ductal extension with contralateral vascular encasement; and (6) distant metastases.

Pathology and Staging

Extrahepatic cholangiocarcinomas have also been subclassified based on their gross appearance as either papillary, nodular, or sclerosing.^{98,99} Sclerosing tumors comprise approximately 70% of hilar cholangiocarcinomas and cause an annular thickening of the bile duct wall with longitudinal and radial tumor infiltration as well as infiltration and fibrosis of the periductal tissue. Nodular tumors are characterized by a firm nodule projecting into the bile duct lumen. Tumors featuring characteristics of both nodular and sclerosing forms are relatively frequent. The papillary variant only accounts for approximately 10% and is most commonly seen in the distal bile duct; its prognosis is generally more favorable than that of the two other forms.^{98,100} Extrahepatic cholangiocarcinoma is staged according to the AJCC-UICC tumor, node, and metastases classification (Table 44.6). Unlike intrahepatic cholangiocarcinoma where staging is combined with other primary liver tumors, the extrahepatic cholangiocarcinoma staging system is unique to cholangiocarcinoma and has undergone significant revisions. Previous editions of the

AJCC staging were criticized for neglect of vascular invasion or hepatic atrophy, which are thought to affect resectability and outcome. Jarnagin and colleagues, in a review of 225 patients with hilar cholangiocarcinoma, proposed a modification of the T staging to include these two factors.¹⁰¹ On univariate analysis, both vascular invasion and hepatic lobar atrophy were prognostic indicators; however, on multivariate analysis they failed to demonstrate prognostic validity. Although both these factors are clinically useful for evaluating resectability and planning resection, the staging system proposed by Jarnagin and colleagues does not appear to have been adapted by others, albeit the *AJCC Cancer Staging Manual, 6th Edition* now includes vascular invasion as part of the tumoral staging.

Operative Management

Complete tumor resection currently offers the only opportunity for cure. As such, all patients with cholangiocarcinoma should be offered an attempt at resection unless specific contraindications exist. Both patient-related factors and tumor-related factors must be considered when assessing patients for potential operative intervention. Clearly, the patient's functional status must be sufficient to tolerate a major operation, and the preoperative tumor assessment must suggest that a curative resection is possible with opportunity for prolonged survival.

The role of preoperative percutaneous or endoscopic biliary drainage in patients with PCC remains an area of controversy. Proponents argue that the improved hepatic function, reduction of cholangitis, and assistance with hilar dissection afforded by biliary drainage warrant its use.^{102,103} Opponents claim that the increased rate of wound infection, bacterobilia, and potential for tumor seeding contraindicate preoperative biliary drainage.¹⁰⁴ Outcome comparisons regarding regeneration after portal vein embolization, hepatic function, and liver failure with or without drainage for hepatic resection in patients with PCC are lacking, and practice guidelines are based on institutional preference.

Patients in whom resection of up to 70% to 75% of the functional liver volume is expected are candidates for portal vein embolization (PVE). The rationale for PVE is to induce hypertrophy and hyperplasia in the anticipated hepatic remnant before resection, theoretically increasing functional capacity and decreasing the risk of postoperative liver failure. In a prospective nonrandomized trial of patients undergoing right hepatectomy for either primary or metastatic liver disease, Farges and colleagues demonstrated a decreased incidence of postoperative complications including liver dysfunction or failure among patients with chronic liver disease who had preoperative PVE.¹³ Similar findings of reduced postoperative liver dysfunction or failure were reported by Hemming and colleagues in patients undergoing extended hepatectomy with PVE compared to those without PVE.¹⁴ No randomized controlled trials have been performed assessing the role and utility of PVE in patients undergoing major hepatic resection. The authors have not employed PVE to treat PCC. Although the potential use of PVE has merit, extended hepatic resections are generally well tolerated if the planned liver remnant is well drained preoperatively and if evidence for adequate hepatic function exists.

TABLE 44.6. American Joint Committee on Cancer (AJCC) staging for extrahepatic cholangiocarcinoma.

Stage	Tumor	Node	Metastasis
0	Tis	N0	M0
IA	T1	N0	M0
IB	T2	N0	M0
IIA	T3	N0	M0
IIB	T1–3	N1	M0
III	T4	Any N	M0
IV	Any T	Any N	M1

T_{is}, carcinoma in situ; T₁, tumor confined to the bile duct histologically; T₂, tumor invades beyond the wall of the bile duct; T₃, tumor invades the liver, gallbladder, pancreas, and/or unilateral branches of the portal vein (right or left) or hepatic artery (right or left); T₄, tumor invades any of the following: main portal vein or its branches bilaterally, common hepatic artery, or other adjacent structures, such as colon, stomach, duodenum, or abdominal wall; N₁, regional lymph node metastases; M₁, distant metastases.

Intraoperative assessment of patients undergoing exploration for potential curative resection includes exclusion of metastases and assessment of the extent of local invasion. Overall resectability among patients undergoing exploration is nearly 65%. The pendulum of operative management of extrahepatic cholangiocarcinoma has swung from a bile-duct-only resection to that of a combined bile duct and hepatic resection. This change is attributed to the recognition of the propensity for intrahepatic ductal extension and hepatic parenchymal invasion as well as the ability to perform hepatic resection with lower morbidity and mortality. With bile duct resection alone, resectability rates of 15% to 20% were reported.¹⁰⁵⁻¹⁰⁷ Multiple reports have confirmed that increases in hepatic resection for PCC correlate with increases in negative margin resections (R0 resection).^{108,109} With hepatic resection rates of 20% to 29%, negative margin rates were achieved in only 15%, compared to a negative margin rate of 60% to 88% with hepatic resection rates of 60% to 89%. Multiple other series have demonstrated that resectability rates parallel hepatic resection rates.¹¹⁰⁻¹¹² Level I data are currently unavailable comparing outcomes of bile-duct-only resection versus that combined with hepatic resection. Outcomes of aggressive hepatic resection for management of PCC are shown in Table 44.5.

Significant consideration has been given to the caudate lobe in the operative management of PCC. Caudate biliary ductal tributaries frequently drain into the posterior aspect of the right or left hepatic ducts near the confluence.^{113,114} Careful histopathologic examination of resected specimens has demonstrated caudate lobe involvement in 42% to 100% of patients.¹¹⁴⁻¹¹⁷ The impact of caudate lobe resection for treatment of PCC is evident by a 20% local recurrence in the caudate lobe when it is not resected.¹¹⁰ In contrast, when the caudate lobe was incorporated into the hepatic resection, local recurrence decreased and 5-year survival increased from 8% to 25%.¹¹¹

Resection of PCC mandates removal of the gallbladder, the extrahepatic duct from the hepatic hilus to the pancreas, regional lymphadenectomy, and Roux-en-Y hepaticojejunostomy. Hepatic resection is generally not required for Bismuth-Corlette type I PCC. Type II and III require resection of caudate and additional segments, dependent on local invasion or ductal extension.

Perioperative mortality and 5-year survival for patients with hepatic resection are shown in Table 44.5. The most frequent serious complications after hepatic resection for PCC are hepatic failure, infection, hemorrhage, and renal or cardiorespiratory failure.

Although no level I data are available comparing outcomes of patients with resected versus nonresected PCC, survival of patients with unresected or advanced-stage PCC has ranged from 6 to 12 months.¹¹⁸ Before acceptance of hepatic resection, 5-year survival was infrequent and only marginally better than patients without resection.¹⁰⁵ In contrast, the 5-year survival in series utilizing hepatic resection ranges from 9% to 45% (see Table 44.5).

Clearly, the major predictor of long-term survival is complete resection with negative margins (R0 resection).^{102,119,120} Existing data suggest that patients with positive margins at resection demonstrate no consistent survival advantage compared to patients without resection.^{101,121} In a recent review of our experience with 46 patients undergoing major hepatic

resection for PCC, an R0 resection was achieved in 80% with an operative mortality rate of 9%. Actual 1-, 3-, and 5-year survival rates were 80%, 39%, and 26%, respectively.¹²² On multivariate analysis, the only predictor of recurrence was tumor grade 3 or 4, whereas negative predictors of survival were history of hepatitis, direct bilirubin at presentation greater than 6.4 mg/dL, blood transfusion requirement greater than 4 units, and male sex. Factors demonstrated to be adversely associated with survival include distant lymph node metastases, vascular invasion, and lobar atrophy.^{102,119,120}

Systemic Treatment

The role of palliative chemotherapy in patients with unresectable hepatobiliary cancer has been assessed in a number of clinical trials. The potential benefit of chemotherapy for this group of cancers is derived primarily from trials providing level II and III evidence (Table 44.7), consisting primarily of phase II and insufficiently powered phase III clinical trials. As such, the standards of therapy for unresectable disease remain uncertain. Even less evidence exists on the potential benefit of either adjuvant or neoadjuvant therapy.

For patients with metastatic disease, chemotherapy remains the primary form of therapy, principally for palliation of symptoms. A randomized trial of chemotherapy [5-fluorouracil (5-FU) and leucovorin (LV) or 5-FU, LV, and etoposide] and best supportive care compared to best supportive care alone in patients with metastatic pancreatic or biliary tract cancers demonstrated improved quality of life and overall survival in those receiving chemotherapy.¹²³

A variety of chemotherapy agents have been evaluated, but in general the response to these agents has been limited (see Table 44.7). Several older studies evaluated 5-FU alone or in combination with other forms of chemotherapy and showed mixed results. Many of these studies were statistically underpowered and combined biliary cancers with pancreatic cancer or hepatocellular carcinoma, making their interpretation difficult. In general, 5-FU as a single agent produces few responses and an overall survival of less than 6 months.^{124,125} However, several recent small trials have suggested high-dose 5-FU or 5-FU in combination with other agents may produce partial responses in up to one-third of patients.¹²⁶⁻¹³⁰ Despite improved response rates, the duration of response is generally short and little increase in overall survival with 5-FU is seen. Only one phase III study has been performed to assess the added benefit of 5-FU combined with other agents to 5-FU alone.¹²⁴ That trial indicated that 5-FU, used alone, was equivalent to or superior to combination therapy. However, this trial provided only level II evidence based on the inadequate sample size.

More recently, trials have focused on gemcitabine as well as other newer agents. Several recent case reports have suggested that gemcitabine may have activity in biliary tract and gallbladder carcinoma.^{131,132} A variety of phase II trials have now been published providing level II evidence for the use of gemcitabine.^{127,133-139} The appropriate dose and schedule of gemcitabine continue to be evaluated. In a phase II trial of gemcitabine in patients with biliary tract or gallbladder carcinoma, two different schedules were evaluated.¹³⁹ Gemcitabine at 1,200 mg/m² given weekly for 3 weeks, followed by a 2-week rest period, resulted in 4 of 24 patients (17%) achieving a partial response. The median survival was

6.8 months and the time to progression was 3.5 months. In the second arm of this study, gemcitabine 2,200 mg/m² was given every 2 weeks, and 4 of 14 patients (29%) achieved a partial response. The median survival with this schedule was 10.5 months and the median time to progression was 4.8 months. In 2002, on review of the available data, the FDA approved a diagnosis of cholangiocarcinoma as an indicator for the use of gemcitabine. Phase III studies to establish the efficacy of gemcitabine have yet to be performed.

Gemcitabine combined with other agents have produced responses ranging from 25% to 64% with median survivals of 10 to 15 months.^{140–142} However, this finding is based on level III and IV evidence and as such is of uncertain value. No phase III trials or appropriately powered phase II trials have been published. It therefore remains unclear if multiagent therapy, using gemcitabine, has any benefit over gemcitabine alone. The potential added toxicity of a second agent has also not been assessed in comparison to gemcitabine.

In addition to 5-FU and gemcitabine, platinum compounds represent the other most commonly evaluated chemotherapy drugs. Most studies have evaluated cisplatin (CDDP) alone or in combination with 5-FU and LV and provide level II or III evidence of activity.^{143–147} There appears to be no justification for the use of single-agent CDDP, with less than 10% of patients having a response and overall survival under 6 months.^{143,144} An improved response rate is seen with the addition of 5-FU and LV. Prolonged infusion of 5-FU appears to increase the response rate to approximately one-

third of patients.¹⁴⁶ However, overall survival does not appear to differ between infusional and bolus regimens of 5-FU.^{145,146} The use of other platinum drugs, such as carboplatin (CBDCA) or oxaliplatin, also does not appear to change response rates or overall survival.^{148,149} Finally, the addition of an anthracycline (doxorubicin or epirubicin) to CDDP and 5-FU does not improve its activity.^{150–152} No level I evidence is currently available to establish the activity of platinum-based regimens in comparison to other regimens or single agents such as gemcitabine.

The activity of several newer chemotherapy drugs has been assessed in phase II trials. These trials have shown no obvious improvement in outcome, based on level II evidence, when the drugs CPT-11, docetaxel, or paclitaxel were used.^{153–156} Clinical trials with novel or targeted agents have not yet been published.

Until recently, no randomized trials had assessed the potential benefit of chemotherapy following resection of gallbladder or biliary tract carcinoma. In a study of resected pancreatic ($n = 173$), bile duct ($n = 135$), gallbladder ($n = 140$), or ampulla of Vater ($n = 56$), patients were randomized to either surgery alone or to adjuvant chemotherapy following surgery.¹⁵⁷ For those randomized to adjuvant chemotherapy, patients were given mitomycin C (MMC) and 5-FU for two cycles followed by oral 5-FU until the time of recurrence. Patients with resected gallbladder cancer who received adjuvant chemotherapy had a significantly better 5-year survival rate if they received chemotherapy (26% versus 14%; $P =$

0.0367). No benefit of adjuvant chemotherapy was seen in patients with resected bile duct cancers. Although this study provides level I evidence for use of adjuvant chemotherapy, at least for resected gallbladder cancer, further studies are needed to confirm the findings of this study and to evaluate the potentially more active chemotherapy drugs including gemcitabine.

The role of adjuvant radiotherapy with or without chemotherapy in combination with hepatic resection for extrahepatic cholangiocarcinoma remains controversial. Although some institutions have demonstrated improved local control and improved overall survival,^{158,159} others have reported no benefit.^{160,161}

An Evidence-Based Approach to the Management of Pancreatic Cancer

Dan Laheru

In 2001, a number of prominent pancreas cancer specialists from the medical community met with industry and pancreatic cancer advocacy partners to make comprehensive formal recommendations for the National Cancer Institute's pancreatic cancer research agenda. They published an executive summary identifying barriers to progress and highlighted research priorities that could lead to real progress for this cancer.¹ As we approach the end of 2004, much has changed, yet much has remained the same for the management of pancreatic cancer. We now have an understanding of how normal duct epithelium progresses to infiltrating cancer at the molecular level.² We finally have available reliable mouse models of early pancreatic ductal lesions³ that will provide unprecedented potential to identify early pancreatic lesions and allow testing of new drugs for prevention and treatment. The technology for pancreatic tumor animal xenografting exists that will allow more efficient testing of new drugs and identifying mechanisms of drug resistance.

Despite reason for optimism that meaningful progress is on the horizon, the current reality is that 5-year survival remains approximately 15% to 20% for resectable disease and 3% for all stages combined.⁴ There remains no current universal standard of care for adjuvant therapy. Gemcitabine still remains the standard of care for metastatic disease.

Therapy for Adjuvant Disease

The current standard of 5-fluorouracil (5-FU)-based combined modality chemoradiotherapy is based on *in vitro* data, animal studies, and a series of human studies, most notable from the Gastrointestinal Tumor Study Group (GITSG). This study utilized split-course irradiation in modest doses with concurrent bolus 5-FU followed by maintenance 5-FU. The study reported a survival advantage for adjuvant chemoradiotherapy in comparison to surgery alone.⁵ While criticized for slow and limited accrual, the GITSG study was the first and only study to document that adjuvant therapy following surgical resection for pancreatic surgery prolonged survival. Additional studies by the GITSG demonstrated the benefit of combined chemoradiotherapy versus chemotherapy alone or radiation therapy alone for patients with resectable disease.⁶

Subsequently, additional groups have further developed this approach⁴⁻²¹ (Table 45.1). The Johns Hopkins Hospital published results of two single-institution prospective but nonrandomized trials that were designed to evaluate survival benefit in patients with pancreatic cancer following surgical resection.¹⁰ This report, involving 174 patients, demonstrated that patients receiving GITSG-style chemoradiotherapy with maintenance 5-FU truncated at 6 months (rather than 2 years), or a more-intensive regimen involving higher doses of irradiation as well as hepatic irradiation administered without interruption and with continuous-infusion 5-FU chemotherapy augmented with leukovorin, did better than patients receiving no postsurgical therapy. The median survival for the more-standard regimen was 21 months, with 1- and 2-year survival at 80% and 44%, respectively. For the intensive regimen, the median survival was 17.5 months with 1- and 2-year survival at 70% and 22%, respectively. For the control arm, the median survival was 13.5 months with 1- and 2-year survival at 54% and 30%, respectively. The intensive therapy had no survival advantage when compared to the standard therapy group, but there was a statistically significant difference between the standard arm versus control with *P* less than 0.002. Multivariate analysis confirmed prognostic factors for disease recurrence including margin and lymph node status, tumor size, and degree of differentiation. This approach, showing the importance of multiple prognostic factors in addition to adjuvant therapy on postsurgical outcomes, has been further refined by Sohn et al.⁴ and Abrams et al.¹² The critical factors appear to be the histologic status of resection margins, lymph node involvement (especially more than three lymph nodes involved), tumor size greater than 3 cm, and the presence of a poorly differentiated component within the tumor. Using these factors, patients can be segregated into high-risk and low-risk groups, with median survival after standard adjuvant therapy being 30.5 months for low-risk patients and 14.0 months for high-risk patients.

In an effort to enhance the activity of chemotherapy in pancreatic cancer, other agents have been examined in combination with 5-FU. Mitomycin-C (MMC) is an antitumor antibiotic with activity in several gastrointestinal cancers including pancreatic cancer. The UCLA group has published

TABLE 45.1. Adjuvant studies in pancreatic cancer.

Adjuvant study	No. of patients	EBRT dose (Gy)	Chemotherapy	MS, months	One-year survival	Two-year survival	Five-year survival
GITSG (1985)	22pts surgery alone	None	None	11	49%	15%	NR

pts, patients; EBRT, external-beam radiation therapy; chemorad, chemoradiation therapy; rad, radiation therapy; 5-FU, 5-fluorouracil; MMC, mitomycin-C; DPM, dipyrindamole; IFN, interferon; CI, continuous infusion; MS, mean survival; NR, no response; est, estimated; N/A, not applicable.

their experience using MMC (10 mg/m² IV q 6 weeks) and 5-FU (200 mg/m²/day administered via continuous infusion), in combination with leukovorin (30 mg/m² weekly) and dipyridamole (75 mg po daily) in 38 patients with locally advanced pancreatic carcinoma.¹¹ There were 14 partial responders with 1 complete response. The median survival for all patients was 15.5 months, which is an improvement over historical data for locoregional advanced disease. This regimen has subsequently been applied to pancreatic cancer in combination with radiotherapy. The Hopkins group recently presented data of 39 patients with pancreatic cancer following surgical resection treated with combined radiotherapy (50 Gy in 25 fractions with planned 2-week break after 25 Gy) and chemotherapy consisting of 5-FU 400 mg/m² days 1–3, MMC 10 mg/m² day 1, leukovorin 20 mg/m² days 1–3, and dipyridamole 75 mg po qid days 0–4 administered on weeks 1 and 4. One month following combined chemoradiotherapy, patients received four additional cycles (4 months) of the same chemotherapy alone. At 12.6 months median follow-up, median survival was 16 months.¹²

Subsequently, the Stanford group published their experience of 52 patients with pancreatic cancer following definitive surgical resection to combined radiotherapy (45 Gy to tumor bed and nodes in 1.8-Gy fractions with boost to total of 54 Gy if surgical margins were positive) and chemotherapy (5-FU 200–250 mg/m²/day administered without break throughout radiation therapy). All patients were able to complete therapy without grade IV toxicities. With median follow-up of 24 months, the median survival was reported at 32 months.¹⁵

The Virginia Mason Medical Center published their experience of 33 patients with resected pancreatic adenocarcinoma who received combined radiotherapy (external beam at a dose of 45–54 Gy in standard fractions, days 1–35) and chemotherapy (5-FU 200 mg/m²/day as continuous infusion, weekly cisplatin 30 mg/m² IV bolus, interferon- α 3 million units SQ every other day) during radiation or GITSG-type chemotherapy with radiation therapy. Following combined modality chemoradiotherapy, chemotherapy alone was administered (5-FU 200 mg/m²/day as continuous infusion) in two 6-week courses during weeks 9–14 and 17–22. Of note, 13 of 17 patients randomized to the interferon-based chemoradiotherapy had positive lymph nodes compared to 7 of 16 patients randomized to the GITSG-based chemoradiotherapy. There were significant grade III/IV gastrointestinal (GI) toxicities including vomiting, mucositis, diarrhea, and GI bleeding in the interferon-based chemotherapy, requiring hospitalization in 35% of patients. However, the majority of patients were still able to receive more than 80% of planned therapy. The median overall survival and 2-year actuarial survival rate were 18.5 months and 54% for patients receiving GITSG-based chemoradiotherapy. In contrast, the median survival and 2-year survival were more than 24 months and 84% for the interferon-based chemoradiotherapy.¹⁶ The Virginia Mason Group has recently presented a follow-up study of 53 patients with resected pancreas cancer treated with similar interferon-based chemoradiotherapy. Toxicities including anorexia, dehydration, diarrhea, mucositis, nausea, and vomiting necessitated hospitalization in 23 of 53 patients. However, the clinical efficacy remains very encouraging, with median survival of 46 months and 2-year survival of 53%.¹⁹ As such, The American College of Surgery Oncol-

ogy Group (ACOSOG) has opened a multiinstitutional Phase II study in patients with pancreatic adenocarcinoma who are candidates for resection.

In July 2002, the Radiation Therapy Oncology Group (RTOG) closed R97-04. This Phase III study of 518 pancreatic cancer patients randomized between 5-FU continuous infusion (250 mg/m²/day for 3 weeks), followed by 5-FU continuous infusion (250 mg/m²/day) during radiation therapy (50.4 Gy in 1.8-Gy fractions), followed by two cycles 5-FU continuous infusion, versus gemcitabine 1,000 mg/m² weekly \times 3, followed by 5-FU continuous infusion during radiation therapy, followed by three cycles gemcitabine alone. The experimental question being asked was whether gemcitabine before and after 5-FU-based chemoradiotherapy would be more efficacious than continuous infusion 5-FU before and after the same 5-FU-based chemoradiotherapy. In 1997, when this study was designed, there was inadequate knowledge regarding how to safely administer gemcitabine concurrently with irradiation to allow for concurrent gemcitabine and radiotherapy. This study was the first North American Co-Operative group trial since the GITSG trial. Although the survival results for this trial will not be known until possibly late 2004, a number of important observations have already been made: neither arm was associated with unacceptable acute toxicity during the trial, accrual was quite rapid (12–14 patients per month), reflecting the support of both the Eastern Co-Operative Oncology Group and the Southwest Oncology Group, and the willingness of patients and their physicians to participate in adjuvant trials for pancreatic cancer.

Despite a growing body of literature supporting the benefit of adjuvant combined modality therapy following potentially definitive resection in patients with high risk for recurrence, adjuvant chemoradiation has not been universally accepted as a standard of care. One of the criticisms has been that none of these studies included an observation-only arm. There have been three studies that have demonstrated contrasting conclusions.

A European Organization for Research and Treatment of Cancer (EORTC) trial randomized 218 patients with pancreatic and nonpancreatic periampullary adenocarcinoma 2 to 8 weeks following potentially curative resection to either observation or to combined radiotherapy (40 Gy using a three- or four-field technique in 2-Gy fractions with 2-week break at midtreatment) and chemotherapy (5-FU administered as a continuous infusion 25 mg/kg/day during the first week of each 2-week radiation therapy module only). No postradiation chemotherapy was administered. Median progression-free survival was 16 months in the observation arm versus 17.4 months in the treatment arm ($P = 0.643$). Median survival was 19 months in the observation group versus 24.5 months in the treatment group, but this was not statistically significant ($P = 0.737$). For the subgroup of patients with pancreatic adenocarcinoma ($n = 114$), the median survival was 12.6 months in the observation group versus 17.1 months in the treatment arm, but this was not statistically significant ($P = 0.099$). Of note, 21 of 104 patients randomized to the treatment arm were not treated. In addition, although the original dose of 5-FU was already modest, 35 patients in the treatment arm received only 3 days of 5-FU during the second module of radiotherapy secondary to grade I/II toxicities. Therefore, this study could be better described as an underpowered positive study.¹³

TABLE 45.2. Active or planned adjuvant or neoadjuvant studies.

Study	Regimen	Study phase
EORTC	Arm I: Gemcitabine weekly $\times 3$ every 4 weeks $\times 2$ cycles followed by Gem/EBRT Arm II: Observation	II/III
ACOSOG	EBRT (50 Gy/5-FU CI/cisplatin/IFN, 5-FU CI) $\times 2$ cycles	II
Johns Hopkins	GM-CSF allo vaccine, 5-FU CI, 5-FU CI/XRT, 5-FU CI $\times 2$ cycles followed by GM-CSF allogeneic vaccine X 4	II
ECOG 1200	Arm A: Gem 500 mg/m ² over 50 min weekly $\times 6$ with EBRT 50.4 followed by surgery, gem 1,000 mg/m ² over 100 min $\times 5$ cycles Arm B: Gem 175 mg/m ² over 30 min days 1, 5, 29, 33/cisplatin 20 mg/m ² days 1–4, 29–33, 5-FU 600 mg/m ² over 21 hours days 1–4, 29–32 followed by EBRT 50.4, surgery, gemcitabine $\times 3$ cycles	II
ESPAC-3	Arm I: Observation Arm II: 5-Fluorouracil/LV days 1–5 $\times 6$ cycles Arm III: Gemcitabine weekly $\times 3$ every 4 weeks $\times 6$ cycles	III

gem, gemcitabine; IFN, interferon-alpha; RTOG, Radiation Therapy Oncology Group; CI, continuous infusion; ACOSOG, American College of Surgery Oncology Group; ECOG, Eastern Cooperative Oncology Group.

The European Study Group for Pancreatic Cancer (ESPAC) randomized 541 patients with pancreatic adenocarcinoma in a four-arm design based on a two-by-two factorial design: (a) observation; (b) concomitant chemoradiotherapy alone (20 Gy in 10 fractions over 2 weeks with 500 mg/m² 5-FU IV bolus during the first 3 days of radiation therapy; the module is repeated after a planned 2-week break) followed by no additional chemotherapy; (c) chemotherapy alone (leukovorin 20 mg/m² bolus followed by 5-FU 425 mg/m² administered for 5 consecutive days repeated every 28 days for six cycles); and (d) chemoradiotherapy followed by chemotherapy.¹⁸ The data set for 289 patients randomized just through the two-by-two design was recently reported.²¹ The four arms were subsequently uniquely combined to make additional comparisons (no chemoradiotherapy versus chemoradiotherapy and no chemotherapy versus chemotherapy). There appeared to be a survival advantage for patients receiving no chemoradiotherapy (17.9 months) versus chemoradiotherapy (15.9 months, $P = 0.05$). In addition, there was a survival advantage for those who received chemotherapy (20.1 months) versus those who did not receive chemotherapy (15.5 months, $P = 0.009$). When the four arms were analyzed individually, there appeared to be a survival benefit for chemotherapy alone (median survival, 21.6 months) versus observation alone (16.9 months), chemoradiotherapy alone (13.9 months), or chemoradiotherapy followed by chemotherapy (19.9 months). However, the study was not powered to examine these arms separately. Multivariate analysis for known prognostic factors including margin status, lymph node involvement, and tumor grade and size did not alter the effect for chemoradiotherapy treatment. The study authors concluded that there was no survival benefit for adjuvant chemoradiotherapy. In addition, the authors concluded that a potential benefit existed for adjuvant chemotherapy alone following surgical resection. Based on these results, the follow-up ESPAC study (ESPAC-3) does not include radiation therapy and is designed as a randomized study of three different chemotherapy schedules (5-FU and leukovorin versus gemcitabine versus observation) following surgery.

Although this was a randomized study consisting of more than 500 patients with a smaller subset of 289 patients included in the two-by-two design, the conclusions of the study should be carefully measured. To encourage maximal patient recruitment, the study was modified in that 68 patients were assigned separately and randomized to either chemoradiotherapy or observation. In addition, 188 patients

were subsequently assigned separately and randomized to either chemotherapy alone or observation. In a sense, three randomizations were possible for inclusion into the same original study design. Also, patients in the additional two randomizations could have received "background chemotherapy or chemotherapy," which was not specifically defined. The background treatment was not known in 82 eligible patients. Of note, these patients were still assigned into an arm of the study despite lack of definitive knowledge of prior therapy. Finally, 25 of the eligible 541 patients refused to accept their randomization and an additional 25 patients withdrew secondary to treatment toxicities.

Although the smaller subset of 289 patients does not include these additional "randomized" patients, other fundamental issues concerning these are patients worthy of comment. First, the absence of a central review of radiotherapy fields and quality control/assurance is essential in such a study design and alone could explain the results of the study. Equally important, the radiation as well as the chemotherapy used in the ESPAC-1 study are not considered contemporary therapy. Doses of radiation therapy integrated with chemotherapy are currently in the range of 45 to 54 Gy. The lower doses of radiation used in ESPAC-1 might explain the high incidence of local recurrence in 109 of 158 patients (62%) with recurrent disease.

As the debate continues, several studies have recently opened or have been proposed by either the cooperative groups or through single institutions. Table 45.2 summarizes open or planned studies in the adjuvant setting. These future studies will be characterized by the addition of multiagent chemotherapy to irradiation at the cooperative group level by the addition of Gemcitabine to the period of chemoradiation and by the use of conformal, three-dimensional (3-D) irradiation planned to patient-specific anatomic and surgical pathologic data.

Future Concepts for Adjuvant Therapy

The identification of overexpressed/underexpressed genes, tumor-dependent growth pathways, and the search for tumor-specific proteins or antigens have for many years been the triple holy grail for oncologists. The impact from such discoveries would potentially not only revolutionize the management of disease but would also have implications for early detection and for monitoring disease. A number of these mol-

ecular targeted drugs (Cetuximab and Bevacizumab) have been approved by the U.S. Food and Drug Administration (FDA) for other malignancies and are currently being tested in combination with Gemcitabine in patients with metastatic pancreatic cancer. To date, no molecular targeted agents have been tested in the adjuvant setting.

Immune-based therapy is a novel therapeutic approach that has the ability to recruit and activate tumor-specific T cells and induce a cytotoxic response. The potential of this approach is attractive for many reasons.²² First, tumor killing by activated tumor-specific T cells occurs via a mechanism that is distinct from chemotherapy or radiation therapy and would represent a noncross-resistant treatment with an entirely different spectrum of toxicities. Second, the immune system is capable of recognizing a broad diversity of potential antigens with selective and specific cytotoxic responses. These features may be essential in recognizing and eliminating a heterogeneous tumor population while avoiding normal tissue toxicity. Third, preclinical animal models using active immunotherapy (vaccines) have been able to eliminate small burdens of established tumors, a situation that corresponds to the state of minimal residual disease commonly found after resection of human tumors. Fourth, there are data to suggest that human tumor-specific antigens can be manipulated to be effectively recognized by the immune system and that these antigens may be shared broadly among tumors of similar histologies.²³ Finally, vaccine cells do not need to be HLA compatible with host immune cells to effectively prime both the CD4⁺ T-cell (regulatory) arm and the CD8⁺ T-cell (cytolytic) arm of the immune response.^{24,25}

Although the use of autologous tumor cells may preserve unique antigens expressed by each patient's cancer, the development of an autologous vaccine has limitations that preclude the use of autologous cellular vaccine for most cancers including pancreatic adenocarcinoma. Recent data support the immunologic rationale for using allogeneic tumor cells rather than autologous cells as the source of antigen used for the vaccination.²⁴ Taken together, the data suggest that relevant tumor antigens can be delivered by an allogeneic tumor and still sufficiently mount an effective immune response.

The Johns Hopkins group has developed allogeneic cell lines from neoplastic tissue harvested from the surgical specimens of patients undergoing pancreaticoduodenectomy at the Johns Hopkins Hospital. All these cell lines have been characterized as 100% epithelial by cytokeratin staining. In addition, all these cell lines carry the same *k-ras* mutation as the original tumor specimen, which supports the conclusion that these lines are derived from malignant pancreatic tumor cells. Two cell lines had been chosen for further testing because they contain the most common *k-ras* mutation at codon 12 found in greater than 90% of pancreatic cancer. These lines were genetically modified to secrete granulocyte-macrophage colony-stimulating factor (GM-CSF). These lines were previously tested for safety in 14 patients with stage 1, 2, or 3 pancreatic adenocarcinoma.²⁶

This study was the first clinical trial to test the hypothesis that allogeneic GM-CSF-secreting pancreatic tumor cell lines can prime a systemic immune response in patients with resected pancreatic adenocarcinoma. Fourteen patients with stage 2 or 3 disease received an initial vaccination 8 weeks following resection; this was a dose escalation study in which 3 patients each received 1×10^7 , 5×10^7 , and 1×10^8 tumor

cells. An additional 5 patients received 5×10^8 vaccine cells. Study patients were jointly enrolled in an adjuvant chemoradiation protocol for 6 months. Following the completion of adjuvant chemoradiation, patients were reassessed, and those who were still in remission were treated with three additional vaccinations given 1 month apart at the same original dose that they received for the first vaccination. Toxicities were limited to grade I/II local reactions at the vaccine site. Postvaccination delayed-type hypersensitivity (DTH) responses to autologous tumor cells have been used in previously reported vaccine studies as a surrogate to identify and characterize specific immune responses that are associated with vaccination. In the pancreatic cancer vaccine trial, postvaccination DTH responses to autologous tumor cells were observed in 1 of 3 patients receiving 1×10^8 and in 2 of 4 patients receiving 5×10^8 vaccine cells.

The major limitation of defined antigen-based vaccines has been the lack of identified pancreatic tumor antigens that are the known targets of the immune response. Thus, current immune-based approaches either target a small group of candidate antigens expressed by the tumor or rely on whole tumor cells as the immunogen. In addition, postvaccination DTH response to autologous tumor provided only indirect evidence of vaccine-derived antitumor immune response. However, with the recent sequencing of the human genome and the development of rapid methods for identifying genes that are differentially expressed by tumor cells,² potential candidate immune targets were expected to be discovered that may serve as immunogens for treatment as well as prevention. Recently, mesothelin, a transmembrane glycoprotein member of the mesothelin/megakaryocyte potentiating factor (MPF) family, was identified by differential gene expression to be overexpressed by most pancreatic adenocarcinomas.²⁷ Mesothelin has been shown to be recognized by vaccinated uncultured CD8⁺ T cells isolated from the three patients who are long-term survivors from the previously described phase I GM-CSF pancreatic cancer vaccine study but not in the other patients who received the vaccine but subsequently relapsed.²⁸ These data suggest that mesothelin may be used as an *in vitro* marker of vaccine-specific T-cell responses to correlate with *in vivo* DTH response to autologous tumors and to clinical responses.

Based on the phase I study, the Johns Hopkins Hospital initiated a 60-patient study, administering a total of five vaccinations integrated around chemoradiotherapy for patients with resected pancreatic adenocarcinoma. The study is planned to complete accrual by the end of 2004.

Role of Neoadjuvant Therapy

Neoadjuvant therapy is a potentially attractive alternative to current standard adjuvant chemoradiation for several reasons: (1) radiation is more effective on well-oxygenated cells that have not been devascularized by surgery, (2) contamination and subsequent seeding of the peritoneum with tumor cells secondary to surgery could theoretically be reduced, (3) patients with metastatic disease on restaging following adjuvant therapy would not need to undergo definitive resection and might benefit from palliative intervention, and (4) the risk of delaying adjuvant therapy would be eliminated because it would be delivered in the neoadjuvant setting. A number of groups have further developed this approach^{1,9,29-41} (Table 45.3).

TABLE 45.3. Neoadjuvant studies in patients with resectable pancreatic cancer.

Study	Evaluable pts	% resected	EBRT (Gy)	Chemotherapy	MS (all pts, months) [N/A]	MS (resected pts, months)	One-year survival	Two-year survival	Five-year survival

The Fox Chase Cancer Center published their experience of 53 patients with localized resectable pancreatic cancer who were treated preoperatively with radiation therapy (5,040 cGy in 180-cGy fractions) and chemotherapy (MMC 10 mg/m² on day 2 with 5-FU 1,000 mg/m²/day by continuous infusion on days 2–5 and 29–32). Forty-one patients subsequently underwent exploratory laparotomy at the conclusion of preoperative chemoradiation. From this group of patients, 17 were not resectable (including 11 patients with hepatic or peritoneal metastases and 6 patients with local extension that precluded resection). Twenty-four patients eventually underwent potentially curative resection. Significant treatment-related hematologic and nonhematologic toxicities were identified, including 1 patient with treatment-related toxicities that precluded reexploration. Median survival for the entire group was 9.7 months and 15.7 months for the group that underwent surgical resection.³¹

The MD Anderson Cancer Center (MDACC) published their experience of 132 patients with localized resectable pancreatic adenocarcinoma who were treated preoperatively with radiation therapy (45–50.4 Gy in standard 1.8-Gy fractions or consisting of 30-Gy rapid fractionation in 3 Gy/fraction) combined with chemotherapy (5-FU continuous infusion 300 mg/m²/day or gemcitabine 400 mg/m²/week or paclitaxel 60 mg/m²/week), followed by surgical resection. There were no surgical delays in the neoadjuvant group but there were noted to be delays in 6 of 25 patients who underwent surgical resection first. At median follow-up of 19 months, no significant differences in survival were noted between treatment groups, with overall median survival of 21 months.³⁷

The Fox Chase group has since published a follow-up study of 30 patients with localized resectable pancreatic cancer of whom 26 received preoperative radiation therapy (50.4 Gy) with 5-FU continuous infusion. Fourteen patients who received preoperative therapy subsequently underwent resection. Median survival was 34 months for the resected group compared to 8 months in the group that could not be resected.³⁹

The MDACC have also used paclitaxel 60 mg/m² over 3 hours weekly with 30-Gy radiation therapy rapid fractionation. Of note, if patients could undergo surgical resection, they could also have received external-beam intraoperative radiation therapy (EB-IORT). Grade III hematologic and nonhematologic toxicities were identified in 16 patients. No delays in surgery were attributable to preoperative therapy. Twenty of 25 patients who underwent exploratory laparotomy underwent surgical resection. There were no histologic complete responders. With median follow-up of 45 months, 3-year survival for those patients following potentially curative resection was 28% with overall median survival of 19 months.⁴¹

Currently, the Eastern Co-operative Oncology Group (ECOG) is planning to open a prospective randomized trial randomizing patients to intensified gemcitabine-based or gemcitabine/5-FU/platinum-based chemoradiotherapy. This trial makes an important distinction between clearly unresectable disease and potentially resectable disease, especially around the issues of partial versus complete encasement of the superior mesenteric artery and length of superior mesenteric vein involved by tumor at initial presentation. To date, the current data demonstrate that although neoadjuvant chemoradiotherapy can be administered safely, there is no

clear advantage to this strategy compared to postoperative therapy. In the realm of marginally resectable patients, it remains to be seen whether there is a meaningful cohort of patients for whom this approach may represent an important therapeutic advantage based on “downstaging” and improved surgical outcomes.

Treatment of Locally Advanced Disease

Pancreatic tumors frequently invade adjacent structures such as superior mesenteric and celiac vascular structures, making curative resection difficult if not impossible. The Memorial Sloan Kettering group recently reviewed their experience of 163 patients with locally advanced pancreas cancer. A number of chemotherapy regimens were integrated with radiation therapy and administered to 87 patients. Only 3 patients had sufficient radiographic response to justify surgical exploration. Of these selected patients, one-third underwent resection for curative intent.⁴² For the approximately 30% to 40% of pancreatic cancer patients who present with such locally advanced, nonmetastatic disease, optimal management is controversial. Palliative surgery, chemoradiation, chemotherapy alone, and locally directed therapies have all been employed in this setting.

Chemoradiation Approaches

Although external-beam radiation therapy (EBRT) alone can improve symptoms associated with locally advanced disease, the high local failure rate and synergy observed when EBRT is combined with chemotherapy have led to trials using both modalities. Chemoradiation approaches have shown improved survival compared to either modality alone, but the improvements are modest, and local control remains a significant challenge. There have been no randomized comparisons of radiation and/or chemotherapy versus supportive care (aside from subset analyses in trials for metastatic disease).

Several prospective randomized trials have shown a benefit with chemoradiation compared to either radiation or chemotherapy alone in the management of locally advanced disease.^{43–49} The first trial was published in 1969 and included patients with different types of gastrointestinal (GI) cancers, 64 of whom had locally unresectable pancreatic cancer randomized to either 5-FU or placebo combined with 35–40 Gy radiation. Median survival in the combined modality arm was significantly higher than in the radiation therapy-only arm (10.4 versus 6.3 months).⁴³ The Gastrointestinal Tumor Study Group (GITSG) randomized 194 locally advanced pancreatic cancer patients to receive split-course EBRT, either alone (60 Gy) or combined (either 40 or 60 Gy) with 5-FU 500 mg/m² on the first 3 days of each 20 Gy of radiation.⁴⁴ The EBRT-alone arm was discontinued after an interim analysis showed improved median time to progression (TTP) and overall survival (OS) in the combined modality arms. There were no significant differences between the high- and low-dose EBRT in the chemoradiation arms, although there were trends favoring the higher-dose arm in time to progression and survival. A second GITSG study compared SMF (streptozotocin, mitomycin, and 5-FU) chemotherapy alone versus SMF combined with EBRT (54 Gy), and showed a significant improvement in

median survival (9.7 versus 7.4 months) for the chemoradiation arm.⁴⁶ In contradistinction to the GITSG studies, a randomized ECOG study of 91 patients comparing 5-FU 600mg/m² weekly with or without EBRT (40Gy, which has been criticized as an insufficient dose) did not find a significant benefit to combined modality therapy over chemotherapy alone.⁴⁵ Thus, three randomized studies have demonstrated a modest survival benefit of combined modality therapy over chemotherapy or EBRT alone, and one ECOG study with a possibly suboptimal dose of EBRT (40Gy) did not show benefit over 5-FU alone.

Several trials have examined the use of different chemotherapy agents with radiation therapy in the locally advanced setting. The first was a Southwest Oncology Group (SWOG) study published in 1980 randomizing 69 patients to mCCNU (methyl lomustine) and 5-FU with or without testolactone, combined with 60Gy of radiation.⁴⁷ There was no significant difference in overall survival, and myelosuppression (87%) and GI toxicity (23%) were common. A GITSG study randomized 143 patients to EBRT with either weekly 5-FU or doxorubicin.⁴⁸ Median survival was similar in both arms (approximately 8 months), but the doxorubicin arm had more frequent severe toxicity. Finally, a randomized Phase II study of 87 patients compared the radiation sensitizer hycanthone to 5-FU, both given with 60Gy of split-course radiation, and found no difference in survival.⁴⁹ Thus, three trials failed to demonstrate a survival advantage of different chemotherapy regimens given with radiation therapy compared to 5-FU, which tended to have less toxicity.

Chemoradiation Using Gemcitabine

There has been considerable interest in combining EBRT with gemcitabine because of its clinical benefit in the metastatic setting and potent radiosensitizing properties. Studies combining radiotherapy with gemcitabine have proceeded cautiously because of this synergy. Early trials were designed to determine the maximal tolerated dose of gemcitabine when delivered weekly and integrated with radiation therapy consisting of 50.4Gy in standard 1.8-Gy fractions. A margin of 3cm around the gross target volume was required for the initial field of 39.6Gy. The margin was subsequently reduced to 2cm for the final 10.8-Gy boost. The starting dose of gemcitabine was 300mg/m². Hematologic and gastrointestinal toxicities were identified as dose limiting at 700mg/m².⁵⁰ Blackstock and colleagues examined, in a Phase I study, gemcitabine (starting at 20mg/m²) twice weekly in combination with radiation therapy (total dose, 50.4Gy in 1.8-Gy fractions) in 19 patients with locally advanced pancreatic adenocarcinoma. Thrombocytopenia, neutropenia, and nausea/vomiting were dose-limiting toxicities. Of the 15 patients assessable for response, 3 partial responses were identified.⁵¹ A dose of 40mg/m² twice weekly in combination with radiotherapy to a total dose of 50.4Gy was subsequently examined by the Cancer and Leukemia Group B (CALGB) in a Phase II study of 38 patients with locally advanced pancreatic cancer. Following chemoradiotherapy, patients without disease progression received Gemcitabine alone at 1,000mg/m² weekly \times 3 every 4 weeks for five additional cycles. Grade III/IV hematologic toxicity was significant and identified in 60% of patients; in addition, grade III/IV GI toxicity was identified

in 42% of patients. With median follow-up of 10 months, median survival was 7.9 months.⁵²

The MD Anderson Cancer Center (MDACC) has since published a corollary phase I study of 18 patients with locally advanced disease using rapid fractionation external-beam radiation. Patients received dose escalation gemcitabine from 350mg/m² to 500mg/m² weekly \times 7 with concurrent rapid fractionation 3,000-cGy external-beam radiation therapy during the first 2 weeks of therapy. Hematologic and nonhematologic toxicities were significant in all three patient cohorts. There were 8 responses (4 minor and 4 partial). One of 2 patients who were subsequently explored had a curative resection. The recommended Phase II testing dose of gemcitabine was 350mg/m².⁵³

These dose-finding studies would suggest that the maximal tolerated dose of gemcitabine when combined with radiation therapy is dependent on the radiation therapy field size. Planned confirmatory studies will follow up on these observations.

The University of Michigan has described an alternative approach by using standard doses of gemcitabine at 1,000mg/m² weekly \times 3 every 4 weeks and administering radiation therapy as dose escalation beginning at 24Gy (1.6-Gy fractions in 15 fractions) in 34 patients with locally advanced disease. The majority of patients received chemotherapy after combined modality treatment at the discretion of the treating physician; 75% of patients received at least 85% of planned gemcitabine. Two of 6 assessable patients experienced dose-limiting toxicity at the final planned radiation dose of 42Gy in 2.8-Gy fractions. An additional 2 patients developed late GI toxicities at this dose level. Six patients were documented to have a partial response, with a complete radiographic response in 2 patients. In addition, 4 patients with documented stable disease at time of study entry experienced objective responses (2 partial and 2 complete responses). Definitive resection was achieved for 1 of 3 surgically explored patients. With median follow-up of 22 months, median survival for the entire group was 11.6 months. The recommended Phase II radiation dose was 36Gy in 2.4-Gy fractions.⁵⁴

Other chemotherapy agents have been added to Gemcitabine combined with radiation therapy. The Eastern Cooperative Oncology Group (ECOG) published a Phase I study of seven patients with locally advanced disease using 5-FU/Gemzar combined with radiation therapy to a maximum 59.4Gy in 1.8-Gy fractions. 5-FU (200mg/m²/day as continuous infusion throughout radiation therapy) was administered with weekly gemcitabine dose escalation beginning at 100mg/m². Because of dose-limiting toxicities seen in two of the first three patients, the study was amended to lower the initial dose of gemcitabine to 50mg/m². However, dose-limiting toxicities were subsequently seen in three of four patients at the 50mg/m² dose. Three of the five dose-limiting toxicities occurred at radiation doses less than 36Gy. The study was subsequently closed.⁵⁵

Gemcitabine has also been combined with cisplatin and radiation in published Phase I trials, following up on promising preclinical synergistic data. A study based at the Mayo clinic gave twice-weekly gemcitabine and cisplatin for 3 weeks during radiation (50.4Gy in 28 fractions). Dose-limiting toxicities consisted of grade 4 nausea and vomiting, and the recommended phase II dose was gemcitabine 30mg/m² and cisplatin 10mg/m².⁵⁶ Another trial used strictly time-

scheduled gemcitabine (days 2, 5, 26, and 33 after a weekly regimen was too toxic) and cisplatin (days 1–5 and 29–33) combined with radiation, with a recommended Phase II dose of 20mg/m² for cisplatin and 300mg/m² for gemcitabine.⁵⁷ The response to chemoradiation allowed 10 of 30 initially unresectable patients to undergo surgery, with a R0 resection in 9 cases and a complete response (CR) in 2 cases.

Given the current published data, would 5-FU or gemcitabine be better suited to be used concurrently with radiation therapy for either resected or locally advanced disease? The MDACC retrospectively examined their database of 114 patients with locally advanced disease treated with combination radiation therapy (rapid fractionation 30Gy in 10 fractions) with either 5-FU by continuous infusion 200–300mg/m² (61 patients) or gemcitabine 250–500mg/m² weekly \times 7 (53 patients). Patients receiving gemcitabine developed a significantly higher incidence of severe acute toxicity, defined as toxicity requiring a hospital stay of more than 5 days, mucosal ulceration with bleeding, more than three dose deletions of gemcitabine or discontinuation of 5-FU, or toxicity resulting in surgical intervention or death, compared with those patients receiving 5-FU (23% versus 2%; *P* less than 0.0001). Five of 53 patients treated with gemcitabine/radiation therapy subsequently underwent surgical resection compared to 1 of 61 patients treated with 5-FU/radiation therapy. However, with short median follow-up, median survival was similar (11 months versus 9 months (*P* = 0.19)).⁵⁸

Chemotherapeutic Approaches

Because the benefit of chemoradiation is relatively modest, and the aforementioned randomized ECOG study showed no benefit to radiation added to 5-FU alone, some oncologists recommend chemotherapy alone for locally advanced disease. Gemcitabine is the most commonly used agent, extrapolating from the metastatic disease setting; this is based on the randomized trial by Burris et al. in which 26% of the study subjects had locally advanced disease. Gemcitabine ameliorated symptoms and modestly improved survival compared to 5-FU, but the results for patients with locally advanced disease were not reported separately.⁵⁹ An ECOG Phase III trial (E4201) comparing gemcitabine (600mg/m² weekly)/radiation (50.4Gy in 28 fractions) followed by weekly gemcitabine (1,000mg/m² weekly, 3 of 4 weeks) versus gemcitabine alone, which opened in April 2003, is examining this issue.

Locally Directed Therapy

Both brachytherapy and intraoperative radiotherapy (IORT) have been employed in the setting of locally advanced disease. Both modalities are aimed at improving locoregional control. Given the propensity of this disease to disseminate, especially into the liver and adjacent peritoneum, what can be achieved overall for patients by the addition of either modality to external-beam irradiation and chemotherapy is not completely clear. Mohiuddin et al. reported on 81 patients with localized unresectable carcinoma of the pancreas managed at Thomas Jefferson using intraoperative iodine-125 implants, external-beam irradiation, and perioperative systemic chemotherapy.⁶⁰ The radioactive iodine implant was designed to deliver a

minimum peripheral dose up to 1,200cGy over 1 year. Patients were also treated with 50 to 55 Gy of external-beam irradiation with systemic chemotherapy consisting of 5-FU, mitomycin, and occasionally CCNU. Implants were performed at laparotomy. There was a 5% mortality rate, and a 34% acute morbidity rate with cholangitis, upper GI bleeding, and gastric outlet obstruction being the most common. In addition, there was a 32% late morbidity rate, with GI bleeding, cholangitis, and radiation enteritis being the most common late developments. Local control was obtained in 39 of 53 (71%) of evaluable patients. Of 14 patients undergoing reexploration more than 6 months following implantation, 86% showed extensive fibrosis and had negative biopsies from the region of the tumor. In 8 patients undergoing autopsy, 5 (63%) were without evidence of locoregional tumor. Nevertheless, 52 of these 81 patients (62%) failed with intraabdominal disease, primarily hepatic and peritoneal. With a minimum follow-up of 2 years at the time of publication, the median survival for the total group was 12 months, the 2-year survival was 21%, and the 5-year survival was 7%. Despite satisfactory local control in several patients, many centers would not be willing to accept this level of therapeutic intensity in a group of patients for whom management is ultimately primarily noncurative.

Nori et al. have reported on a series of 15 patients undergoing similar management but using palladium-103 instead of iodine-125.⁶¹ The implant was designed to provide a matched peripheral dose of 1,100cGy. Patients also received external-beam irradiation of 4,500cGy over 4.5 weeks and chemotherapy with 5-FU and MMC. Median survival was 10 months. The authors concluded that palladium-103 is an alternative to iodine-125 for interstitial brachytherapy for unresectable patients, and that symptom relief appeared to occur somewhat faster. The study did not show any improvement in the median survival as compared to ¹²⁵I. Finally, a note of caution was raised by Raben et al. on the use of palladium brachytherapy for locally unresectable carcinoma of the pancreas. In their series of 11 patients, they found an unacceptably high complication rate including gastric outlet obstruction, duodenal perforation, and sepsis.⁶² They did not find an improvement in median survival over other modalities and did not recommend this approach for further study.

The use of intraoperative radiation therapy (IORT) using single-fraction electron beam treatment has also been extensively studied. In experienced hands, IORT can be given with acceptable morbidity. However, there are occasional reports of unacceptably high complication rates. Generally, IORT has been given in combination with external-beam radiation therapy (EBRT) in the range of 45 to 50.4Gy with 5-FU alone or 5-FU-based combination chemotherapy. The RTOG reported on 51 patients with locally unresected nonmetastatic pancreatic cancer treated with IORT and EBRT/5-FU and found a major postoperative complication rate of 12%. Two patients had major morbidity leading to death.⁶³ A neoadjuvant approach was taken by Garton et al. at the Mayo Clinic, where EBRT (50–54 Gy) with or without 5-FU was given preoperatively, followed by IORT (20Gy).⁶⁴ In 27 patients with unresectable disease because of locoregional considerations, local control was achieved in 78%, although 70% of patients developed distant metastases, including peritoneum and liver. Median survival from diagnosis was 14.9 months. Zerbi et al. have suggested that the use of IORT as an adjuvant to resection decreases the risk of local recurrence.⁶⁵ Mohiuddin

et al. have also reported excellent results with IORT in the management of unresectable pancreatic cancer when combined with postoperative EBRT.⁶⁶ As reviewed by Willett and Warshaw, the dose of intraoperative radiation therapy is generally in the range of 10 to 20 Gy, with some investigators prescribing to the 90% line and others prescribing to the 100% line.⁶⁷

In addition to local radiation delivery, a variety of other techniques and agents are under development for the treatment of locally advanced pancreatic cancer. One example is intratumoral injection via endoscopic ultrasound of ONYX-015, an engineered adenovirus that selective replicates in tumor cells. A Phase I/II trial of this agent combined with gemcitabine in 21 patients showed that the technique was feasible with transgastric injections (2 duodenal perforations occurred early in the trial), and 2 partial responses were seen.⁶⁸ Another novel biologic agent in development is TNFerade, a replication-deficient adenovector carrying a transgene encoding for human tumor necrosis factor- α regulated by a radiation-inducible promoter. Weekly intratumoral injections have been given in combination with chemoradiation (50.4 Gy with continuous infusion 5-FU 200 mg/m² daily).⁶⁹ Two of 17 patients in a Phase I trial converted from unresectable to resectable, and 1 of these had a pathologic CR.

Treatment Recommendation for Locally Advanced Disease

The optimal treatment for locally advanced pancreatic cancer remains controversial. There have been no randomized trials comparing chemoradiation strategies versus best supportive care, or chemotherapy alone (aside from the GITSG trial in which both 5-FU and radiation were added to SMF chemotherapy), and the survival benefit from combined modality therapy for locally advanced disease has been modest in various trials. Nonetheless, most practitioners in the United States employ radiation therapy (typically 54 Gy in 1.8-Gy fractions) with simultaneous chemotherapy, the standard being 5-FU. Although several chemotherapy regimens have been compared to 5-FU in randomized trials, none have proven more efficacious, and these are typically more toxic. Various ways of giving 5-FU have been used in these trials, but most practitioners choose either continuous infusion at 200 mg/m²/day during radiation therapy, or a 500 mg/m² bolus given on the first 3 days and last 3 days of radiation. Studies are under way that will examine the role of gemcitabine (both alone, and combined with radiation) for locally advanced disease. In addition, given the limited success of current treatments, several novel approaches are being actively explored with the aim of allowing patients who present with unresectable disease to undergo curative surgery.

Therapy for Metastatic Disease

Historically, 5-fluorouracil (5-FU)-based chemotherapy has been the most widely studied chemotherapeutic agent for all stages of pancreatic cancer. Despite more recent attempts to modify the delivery of 5-FU, response rates have remained unchanged in the 10% to 20% range, with median survival of 4 to 5 months for patients with stage IV disease.⁷⁰⁻⁷⁴

The Role of Gemcitabine in Metastatic Pancreatic Cancer

Gemcitabine is a prodrug deoxycytidine (2'-deoxy-2',2'-difluorocytidine monohydrochloride) analogue that is metabolized by deoxycytidine kinase to active diphosphate (dFdCDP) and triphosphate (dFdCTP) nucleosides. These metabolites inhibit ribonucleotide reductase with the effect of decreasing intracellular levels of required deoxynucleotide triphosphates for continued DNA synthesis. In addition, gemcitabine triphosphate directly competes with dCTP for incorporation into DNA. Recently, gemcitabine has demonstrated promise as an active agent in treating pancreatic cancer. Casper and colleagues reported the results of a Phase II trial using weekly gemcitabine at 800–1,250 mg/m² in 44 patients with unresectable pancreatic cancer. The response rate was noted to be 11% but with median survival of 5.6 months and a 1-year actuarial survival of 23%.⁷⁵ Subsequently, Burris and colleagues randomized 126 patients with unresectable pancreatic cancer to either gemcitabine (1,000 mg/m² weekly over a 30-minute infusion \times 7 followed by 1 week rest then weekly \times 3 every 4 weeks) or 5-FU (600 mg/m² weekly). Although the primary endpoints were issues related to quality of life, median survival was 5.7 months in the gemcitabine arm compared to 4.4 months in the 5-FU arm. In addition, 1-year survival was 18% in the gemcitabine arm compared to 2% in the 5-FU arm ($P = 0.0025$), with median time to progression also favoring gemcitabine (9 weeks compared to 4 weeks in the 5-FU arm; $P = 0.0002$). Gemcitabine was well tolerated, with the majority of side effects related to grade 3 or 4 neutropenia (26%) without associated infections, low-grade fevers (30%), and nausea and vomiting (9.5% and 3.2%). Gemcitabine has since been approved by the FDA in 1996 as a first-line therapy in metastatic pancreatic cancer.⁵⁹ In addition, Rothenberg and colleagues evaluated gemcitabine (1,000 mg/m² weekly \times 7 with 1 week off then weekly \times 3 with 1 week off) in 63 patients with unresectable disease who had been previously treated with 5-FU. The overall salvage response was 10.5% with median time to progression at 2.5 months and median survival at 3.85 months, with a toxicity profile similar to first-line therapy.⁷⁶ Recent strategies include identifying alternative dosing schedules of gemcitabine that might both enhance drug delivery to tumor cells as well as identifying synergistic combinations with other chemotherapeutic agents. Tempero and colleagues randomized 93 patients to either gemcitabine (2,200 mg/m²) over the standard 30-minute infusion or gemcitabine (1,500 mg/m²) at a rate of 10 mg/m²/min. With analysis completed on 67 patients, the response rate was 17% versus 3% in favor of the longer infusion rate. In addition, median survival (6.1 months versus 4.7 months) and 1-year survival (23% versus 0%) favored the longer infusion rate.⁷⁷

Combination Chemotherapy

Recent efforts have focused on developing strategies that would enhance the efficacy of gemcitabine and ultimately improve median survival. Table 45.4 summarizes the most recent studies.^{59,75-108}

Gemcitabine with 5-Fluorouracil

Preclinical data have also demonstrated a synergistic and non-cross-resistant effect of 5-FU when given with gemcitabine.⁷³

TABLE 45.4. Recent studies in advanced pancreatic cancer.

<i>Study</i>	<i>Patient no.</i>	<i>Chemotherapy</i>	<i>PR/CR rate</i>	<i>Median survival (months)</i>	<i>One-year survival</i>
Casper (1994)	44	Gemcitabine	5 (11%)	5.6	23%

CR, complete response; PR, partial response; NR, no response.

However, the combination of 5-FU and gemcitabine has not consistently resulted in significant improvement over gemcitabine alone.^{79,80,83,84,100} Early studies had designed the use of gemcitabine with bolus infusion of 5-FU with no significant improvement when compared to single-agent gemcitabine.⁷⁹ However, subsequent studies focusing on infusional schedules of 5-FU with gemcitabine suggested a clinical parallel to the data using infusional 5-FU in the therapy of metastatic colorectal cancer. Hidalgo et al. examined the combination of 5-FU administered as a continuous infusion (200 mg/m² throughout the study) with gemcitabine 700–900 mg/m² weekly × 3 repeated every 4 weeks. The reported median survival was 10.3 months.⁸⁰ In addition, Louvet et al. reported a Phase II study of infusional 5-FU and leucovorin (leucovorin 400 mg/m² in a 2-hour infusion followed by 5-FU 400 mg/m² bolus followed by 2–3 g/m² continuous-infusion 5-FU, in a schedule known as LV5FU2) with gemcitabine 1,000 mg/m² on day 3, repeating the cycle every 2 weeks. The reported median survival was 9 months.⁸⁴ However, in a recent study by Hess et al. using gemcitabine (1,000 mg/m², days 1 and 8) and capecitabine (starting 500 mg/m² divided bid × 14 days) in 36 patients with advanced pancreas cancer repeated every 21 days, the median survival was 6.4 months.⁸⁵ A number of modulators of 5-FU have been previously examined, including interferon-alpha and *N*-(phosphonoacetyl)-L-aspartate disodium (PALA), and all have been of no additional benefit. There has been interest in examining other 5-FU formulations, either alone or with gemcitabine, including the multitargeted folate inhibitor pemetrexed that has activity against thymidylate synthase (TS), dihydrofolate reductase (DHFR), and glycinamide ribonucleotide formyltransferase (GARFT).^{81,84}

Gemcitabine with Platinum Chemotherapy

Another potentially synergistic agent that has been used with gemcitabine is cisplatin. This combination is thought to be synergistic either by enhancing dFdCTP incorporation into DNA or via increasing DNA adduct formation.⁷⁸ Early studies identified median survival from 5.6 to 8.2 months.^{82,86,102} This combination has recently been examined in two Phase III studies. Colucci and colleagues treated 107 patients with advanced pancreas cancer with either gemcitabine alone at standard dose and schedule or gemcitabine and cisplatin (25 mg/m² weekly × 3 every 4 weeks). The combination of gemcitabine and cisplatin improved median time to disease progression (2.7 months for gemcitabine alone versus 5 months for combination gemcitabine and cisplatin; *P* = 0.048) with no significant differences in toxicities. However, although the median survival for the gemcitabine group was 5 months compared to 7.5 months for the combination chemotherapy, the *P* value of 0.43 was not statistically significant.⁸⁷ More recently, Heinemann et al. presented the Phase III data of 195 patients randomized to either gemcitabine alone at standard dose and schedule versus gemcitabine and cisplatin (50 mg/m² weekly × 3 repeated every 4 weeks). Although a difference in median survival was noted (6 months for gemcitabine alone versus 8.3 months for the combination), this result was not statistically significant.¹⁰⁴

Gemcitabine with Oxaliplatin

Oxaliplatin is a diaminocyclohexane (DACH) platinum compound that received FDA approval in August 2002 for use in

combination with infusional 5-FU) and leucovorin for the treatment of patients with colorectal cancer whose disease has recurred or become worse following initial therapy with a combination of irinotecan with bolus 5-FU and leucovorin. Based on preclinical data that identified synergistic antitumor activity, oxaliplatin has since also been evaluated in combination with gemcitabine in patients with advanced pancreatic cancer. The French Cooperative group GERCOR examined gemcitabine 1,000 mg/m² as a 10 mg/m²/min prolonged infusion administered on day 1 in combination with oxaliplatin 100 mg/m² as a 2-hour infusion administered on day 2, repeated every 2 weeks, in 64 patients with chemonaive metastatic pancreas cancer. Response rate was noted to be 30.6 % with a clinical benefit response of 40%. Median progression-free survival and overall survival were 5.3 months and 9.2 months, respectively, with 36% 1-year survival. The combination was safe, with reported side effects including grade 3 or 4 neutropenia/thrombocytopenia of 11%, nausea and vomiting of 14%, diarrhea of 6.2%, and peripheral neuropathy of 11%.⁹⁸

The North Central Cancer Treatment Group (NCCTG) completed a Phase I study of gemcitabine and oxaliplatin in 18 patients with metastatic pancreas cancer. Dose-limiting toxicities (DLT) of neutropenia and severe infection were identified at the maximum tolerated dose of gemcitabine, 1,250 mg/m² (day 1 and day 8 every 21 days) and oxaliplatin, 130 mg/m² (day 1 every 21 days).¹⁰³

Louvet et al. recently presented a Phase III study of 308 patients randomized to either gemcitabine or to gemcitabine with oxaliplatin (gemcitabine 1,000 mg/m² as a 10 mg/m²/min prolonged infusion administered on day 1 in combination with oxaliplatin 100 mg/m² as a 2-hour infusion administered on day 2 repeated every 2 weeks) versus gemcitabine alone. Although there was a difference in progression-free survival (4 months for gemcitabine alone versus 6.25 months for combination chemotherapy; *P* = 0.05), the median survival was statistically significant.¹⁰⁶

Gemcitabine with Irinotecan

Rocha Lima et al. completed a Phase II study of 45 patients treated with gemcitabine at 1,000 mg/m² over 30 minutes and irinotecan at 100 mg/m², both weekly × 2 repeated every 3 weeks. Median survival was 5.7 months.⁹⁶ Rocha Lima et al. also presented the follow-up Phase III study recently of 342 patients randomized to either gemcitabine alone or gemcitabine + irinotecan. Although there was a higher response rate for combination gemcitabine and irinotecan (16% versus 4%), the median survival was no different (6.6 months for gemcitabine alone versus 6.3 months for the combination).¹⁰⁵

Gemcitabine with Other Chemotherapy

There has been additional interest based on preclinical data to synergistically combine multiple chemotherapy agents with gemcitabine. Early data suggest that such combinations have similar safety profiles with some of the gemcitabine combinations and are active schedules. Fine and colleagues have published preliminary data with a schedule known as GTX (gemcitabine 750 mg/m² over 2 hours days 4 and 11, Taxotere 30 mg/m² over 30 minutes days 4 and 11, and Xeloda 1,500 mg/m² po divided doses bid days 1–14 repeated every 21 days) in patients with locally advanced and metastatic

disease. Patients without metastatic disease received gemcitabine 200 mg/m² weekly × 6 concurrent with EBRT to 45 to 50 Gy followed by surgery if indicated. Toxicities included 25% grade 3 leukopenia, 20% grade 3 asthenia, 20% grade 3 diarrhea, and 15% erythrodyesthesia. In 9 patients who presented with locally advanced but nonmetastatic disease, 8 patients were resected, with complete response in 6 patients. In patients who presented with metastatic disease, there were partial responses in 12 patients. Median survival for both groups has not been reported.⁹⁷

Kozuch and colleagues treated 34 patients who had been previously treated with gemcitabine either alone or in combination with a schedule known as G-FLIP (day 1: gemcitabine 500 mg/m² over 50 minutes, leukovorin 300 mg over 30 minutes, irinotecan 80 mg/m² over 80 minutes, 5-FU bolus 400 mg/m² over 10 minutes, then 600 mg/m² over 8 hours; day 2: leukovorin 300 mg over 30 minutes, 5-FU bolus 400 mg/m² over 10 minutes, cisplatin 50–75 mg/m² with mannitol over 45 minutes and 5-FU 600 mg/m² over 8 hours). Toxicities were largely hematologic. Median survival for this pretreated group was 10.3 months.⁸⁸

New Drugs in Pancreatic Cancer

During the last few years, an increasing number of new drugs, many of them targeted to specific alterations in malignant cells, have been tested in pancreatic cancer as well as in other tumors. The rationale to develop these drugs in pancreatic cancer comes from the better understanding of the biologic basis of the disease, which has made possible the identification and validation of some of these targets in pancreatic cancer. In addition, the poor prognosis of patients with this disease and the evidence from clinical trials discussed previously that conventional chemotherapy may have reached a plateau in improving outcome have also motivated an aggressive evaluation of new drugs in pancreatic cancer.

Matrix Metalloproteinase Inhibitors

The matrix metalloproteinases (MMPs) are a group of closely related proteases that are dysregulated in the majority of human neoplasms, including pancreatic cancer. The increased activity of these enzymes has been related to the tumor growth, progression, invasion, generation of blood vessels, and metastasis. Several inhibitors of the MMP have been developed as anticancer agents, and two of them, marimastat and BAY12-9566, have been more extensively studied in pancreatic cancer.¹⁰⁹

Marimastat is a hydroxamate peptidomimetic broad-spectrum inhibitor of the MMP family including MMPs 1, 2, and 9. In Phase I studies in pancreatic cancer, doses from 10 to 25 mg orally twice a day were well tolerated. A large Phase II study that enrolled 113 patients, 90% of whom were treated with 25 mg in a once a day dose, reported a 30% decline or stabilization in the tumor marker CA-19-9 and a median survival of 3.8 months, and 51% of the patients had improvement in symptoms. Twenty-nine percent of the patients developed arthralgias, the most common toxicity encountered with marimastat.¹¹⁰ The efficacy and toxicity of marimastat at doses of 5, 10, and 25 mg twice a day was compared to gemcitabine in a Phase III study. Patients treated with gemcitabine had a longer progression-free survival of 3.8 months

versus 1.9 to 2 months for the marimastat-treated group ($P = 0.001$). Overall survival was also better for gemcitabine and significantly worse for patients treated with marimastat at doses of 5 and 10 mg, while no statistically significant differences were observed in overall survival with the 25 mg twice a day dose. A subset analysis in this study showed that the benefit of gemcitabine was restricted to patients with advanced disease and that patients with locally advanced tumors benefited from marimastat, supporting the hypothesis that these drugs may be more active in the situation of early disease.¹¹¹ Finally, the combination of gemcitabine with marimastat was tested against gemcitabine in a randomized Phase III study with no improvement in any parameter of outcome in the combined treatment group.¹¹²

The second MMP inhibitor extensively studied in pancreatic cancer is BAY12-9566, a peptidomimetic inhibitor specific for MMP-2 and MMP-9. The drug was compared in a Phase III study to single-agent gemcitabine in which 270 patients of a planned sample of 350 were enrolled after an interim analysis demonstrated that patients treated with gemcitabine had a significantly better time to tumor progression (3.5 versus 1.6 months; P less than 0.001) and overall survival (6.59 versus 3.74; P less than 0.001). Quality of life analysis also favored gemcitabine.¹¹³ In summary, these studies suggest that current MMP inhibitors do not have relevant antitumor activity in patients with advanced pancreatic cancer. Whether or not these drugs or newer generation analogs would be effective in earlier stages of pancreatic cancer remains to be determined.

Angiogenesis Inhibitors

Pancreatic cancer is not an exception to the rule that tumors require the generation of blood vessels to grow, invade, and metastasize. The drug of this class that appears more promising in pancreatic cancer is bevacizumab, a recombinant human monoclonal antibody against vascular endothelial growth factor (VEGF), a growth factor that has been implicated in pancreatic cancer progression in several preclinical studies. Bevacizumab has been studied in combination with gemcitabine in a Phase II study in patients with pancreatic cancer.¹¹⁴ Patients with advanced or locally advanced pancreatic cancer received gemcitabine 1,000 mg/m² on days 1, 8, and 15 every 28 days and bevacizumab 10 mg/kg intravenously on days 1 and 15. Results on the first 45 evaluable patients have been reported with a response rate of 21%, median survival of 9 months, and an estimated 1-year survival of 37%. Correlative studies suggest that patients with higher baseline levels of VEGF tend to do worse.¹¹⁵ The Cancer and Leukemia Group B (CALGB) is currently leading a phase III study of gemcitabine ± bevacizumab.

Inhibitors of the Oncogene Ras

Mutation in the oncogene Ras is the most frequent genetic abnormality in pancreatic cancer. Because Ras requires to be farnesylated to be active, a posttranslational modification mediated by the enzyme farnesyl transferase, inhibitors of this enzyme have been developed as potential Ras inhibitors.¹¹⁶ Two of these agents, tipifarnib and lonafarnib, have been studied in disease-oriented studies in pancreatic cancer. Tipifarnib was tested in a single-agent Phase II study

in patients with advanced pancreatic cancer administered at a dose of 300mg orally twice a day. Twenty patients were treated with no objective responses and a median survival of less than 5 months. Correlative studies conducted in peripheral blood mononuclear cells demonstrated partial inhibition of the target farnesyl transferase enzyme.¹¹⁷ In parallel to this study, a randomized Phase III study compared the combination of R115777 with gemcitabine against gemcitabine plus placebo in patients with advanced pancreatic cancer. Treatment of 688 patients did not demonstrate any improvement in outcome in patients treated with R115777 and gemcitabine.¹¹⁸ Lonafarnib was evaluated in a randomized Phase II study in comparison to gemcitabine. The 3-month progression-free survival rate for patients treated with lonafarnib was 23% and 31% for gemcitabine, and the median overall survival was 3.3 and 4.4 months, respectively. There were two partial responses in patients treated with lonafarnib and one partial response observed in 1 patient treated with gemcitabine. Overall, lonafarnib was better tolerated than gemcitabine in that study.¹¹⁹

Inhibitors of the EGFR Family of Receptors

The epidermal growth factor receptor (EGFR) family of receptors is formed by four related transmembrane receptors that are composed of an external ligand binding domain, a transmembrane domain, and an intracellular domain with tyrosine kinase (TK) activity. These receptors are frequently dysregulated in cancer and have been associated with the process of tumor growth, invasion, and metastasis, exciting considerable interest in developing these drugs for cancer treatment. Pharmacologically, the inhibitors of the EGFR belong to two broad classes of drugs including monoclonal antibodies against the extracellular domain of the receptor and small molecules inhibitors of the intracellular TK domain.¹²⁰ The studies conducted in pancreatic cancer have mainly tested the combination of these drugs with gemcitabine. Safran and collaborators reported a Phase II study of trastuzumab, a monoclonal antibody that targets the Her-2 receptor, in combination with gemcitabine in patients with pancreatic cancer.¹²⁰ Up to 21% of pancreatic cancers are Her-2 positive, and preclinical studies have shown that inhibition of Her-2 signaling with trastuzumab is associated with antitumor effects in pancreatic cancer models. Patients with Her-2-positive (2 or 3 + as determined by immunohistochemistry) pancreatic cancer received gemcitabine, 1,000mg/m² weekly for 7 consecutive weeks followed by 1 week of rest and then weekly for 3 weeks every 4 weeks, and trastuzumab, 2mg/kg/week following an initial loading dose of 4mg/kg. Data on 23 patients have been reported thus far. Five patients had a partial response (response rate, 24%), and the median survival and 1-year survival were 7.5 months and 24%, respectively. Nine of 18 evaluable patients (50%) have had greater than 50% reduction in CA 19-9. A Phase II study of gemcitabine and cetuximab, a monoclonal antibody against EGFR, in EGFR-positive pancreatic cancer patients was conducted. Forty-one patients were treated in the study. The overall response rate was 12.5% with a median survival of 7.1 months and 1-year survival of 32%.¹²¹ The Southwest Oncology Group (SWOG) is currently leading a Phase III study of gemcitabine ± cetuximab.

The second clinically relevant classes of agents that inhibit the EGFR are small molecule inhibitors of the receptor TK. Several of these agents are currently in clinical development. Two of these compounds, EKB-569 and erlotinib, have been specifically developed in pancreatic cancer. EKB-569, an irreversible inhibitor of EGFR and the Her-2 receptors, has completed a Phase I study in combination with gemcitabine, and a randomized Phase III study through NCI-Canada of gemcitabine plus erlotinib or placebo has completed enrollment.

Future Directions and Conclusions

The principal need to identify more effective therapies to supplement surgical gains in resected patients is unchallenged. What remain unresolved and controversial are the means to this end. Progress in the context of adjuvant trials has been slow. Current controversies may result in part from trial design issues, inadequate consideration of factors other than therapy that may impact on outcomes, and the limited efficacy of single chemotherapeutic agents for pancreatic cancer.

Current efforts are aimed at refining our understanding of the impact of nontherapeutic factors on outcomes (stratification factors for future trials), proceeding to multiagent chemotherapy alone or in combination with irradiation, identifying pancreatic tumor-specific antigens that provide an opportunity for molecular target-based drugs or immunotherapy, and identifying accurate predictors of microscopic disease and of response to therapy.

For metastatic disease, understanding of the molecular pathways that are thought to drive cellular growth is at the heart of the new paradigm of drug development. The utilization of xenografts to rapidly and efficiently screen drugs as well as improved collaboration with industry provide some promise that better therapies are on the horizon.

An Evidence-Based Approach to the Management of Pancreatic Cancer

Dan Laheru

In 2001, a number of prominent pancreas cancer specialists from the medical community met with industry and pancreatic cancer advocacy partners to make comprehensive formal recommendations for the National Cancer Institute's pancreatic cancer research agenda. They published an executive summary identifying barriers to progress and highlighted research priorities that could lead to real progress for this cancer.¹ As we approach the end of 2004, much has changed, yet much has remained the same for the management of pancreatic cancer. We now have an understanding of how normal duct epithelium progresses to infiltrating cancer at the molecular level.² We finally have available reliable mouse models of early pancreatic ductal lesions³ that will provide unprecedented potential to identify early pancreatic lesions and allow testing of new drugs for prevention and treatment. The technology for pancreatic tumor animal xenografting exists that will allow more efficient testing of new drugs and identifying mechanisms of drug resistance.

Despite reason for optimism that meaningful progress is on the horizon, the current reality is that 5-year survival remains approximately 15% to 20% for resectable disease and 3% for all stages combined.⁴ There remains no current universal standard of care for adjuvant therapy. Gemcitabine still remains the standard of care for metastatic disease.

Therapy for Adjuvant Disease

The current standard of 5-fluorouracil (5-FU)-based combined modality chemoradiotherapy is based on *in vitro* data, animal studies, and a series of human studies, most notable from the Gastrointestinal Tumor Study Group (GITSG). This study utilized split-course irradiation in modest doses with concurrent bolus 5-FU followed by maintenance 5-FU. The study reported a survival advantage for adjuvant chemoradiotherapy in comparison to surgery alone.⁵ While criticized for slow and limited accrual, the GITSG study was the first and only study to document that adjuvant therapy following surgical resection for pancreatic surgery prolonged survival. Additional studies by the GITSG demonstrated the benefit of combined chemoradiotherapy versus chemotherapy alone or radiation therapy alone for patients with resectable disease.⁶

Subsequently, additional groups have further developed this approach⁴⁻²¹ (Table 45.1). The Johns Hopkins Hospital published results of two single-institution prospective but nonrandomized trials that were designed to evaluate survival benefit in patients with pancreatic cancer following surgical resection.¹⁰ This report, involving 174 patients, demonstrated that patients receiving GITSG-style chemoradiotherapy with maintenance 5-FU truncated at 6 months (rather than 2 years), or a more-intensive regimen involving higher doses of irradiation as well as hepatic irradiation administered without interruption and with continuous-infusion 5-FU chemotherapy augmented with leukovorin, did better than patients receiving no postsurgical therapy. The median survival for the more-standard regimen was 21 months, with 1- and 2-year survival at 80% and 44%, respectively. For the intensive regimen, the median survival was 17.5 months with 1- and 2-year survival at 70% and 22%, respectively. For the control arm, the median survival was 13.5 months with 1- and 2-year survival at 54% and 30%, respectively. The intensive therapy had no survival advantage when compared to the standard therapy group, but there was a statistically significant difference between the standard arm versus control with *P* less than 0.002. Multivariate analysis confirmed prognostic factors for disease recurrence including margin and lymph node status, tumor size, and degree of differentiation. This approach, showing the importance of multiple prognostic factors in addition to adjuvant therapy on postsurgical outcomes, has been further refined by Sohn et al.⁴ and Abrams et al.¹² The critical factors appear to be the histologic status of resection margins, lymph node involvement (especially more than three lymph nodes involved), tumor size greater than 3 cm, and the presence of a poorly differentiated component within the tumor. Using these factors, patients can be segregated into high-risk and low-risk groups, with median survival after standard adjuvant therapy being 30.5 months for low-risk patients and 14.0 months for high-risk patients.

In an effort to enhance the activity of chemotherapy in pancreatic cancer, other agents have been examined in combination with 5-FU. Mitomycin-C (MMC) is an antitumor antibiotic with activity in several gastrointestinal cancers including pancreatic cancer. The UCLA group has published

TABLE 45.1. Adjuvant studies in pancreatic cancer.

Adjuvant study	No. of patients	EBRT dose (Gy)	Chemotherapy	MS, months	One-year survival	Two-year survival	Five-year survival

pts, patients; EBRT, external-beam radiation therapy; chemorad, chemoradiation therapy; rad, radiation therapy; 5-FU, 5-fluorouracil; MMC, mitomycin-C; DPM, dipyrindamole; IFN, interferon; CI, continuous infusion; MS, mean survival; NR, no response; est, estimated; N/A, not applicable.

their experience using MMC (10 mg/m² IV q 6 weeks) and 5-FU (200 mg/m²/day administered via continuous infusion), in combination with leukovorin (30 mg/m² weekly) and dipyridamole (75 mg po daily) in 38 patients with locally advanced pancreatic carcinoma.¹¹ There were 14 partial responders with 1 complete response. The median survival for all patients was 15.5 months, which is an improvement over historical data for locoregional advanced disease. This regimen has subsequently been applied to pancreatic cancer in combination with radiotherapy. The Hopkins group recently presented data of 39 patients with pancreatic cancer following surgical resection treated with combined radiotherapy (50 Gy in 25 fractions with planned 2-week break after 25 Gy) and chemotherapy consisting of 5-FU 400 mg/m² days 1–3, MMC 10 mg/m² day 1, leukovorin 20 mg/m² days 1–3, and dipyridamole 75 mg po qid days 0–4 administered on weeks 1 and 4. One month following combined chemoradiotherapy, patients received four additional cycles (4 months) of the same chemotherapy alone. At 12.6 months median follow-up, median survival was 16 months.¹²

Subsequently, the Stanford group published their experience of 52 patients with pancreatic cancer following definitive surgical resection to combined radiotherapy (45 Gy to tumor bed and nodes in 1.8-Gy fractions with boost to total of 54 Gy if surgical margins were positive) and chemotherapy (5-FU 200–250 mg/m²/day administered without break throughout radiation therapy). All patients were able to complete therapy without grade IV toxicities. With median follow-up of 24 months, the median survival was reported at 32 months.¹⁵

The Virginia Mason Medical Center published their experience of 33 patients with resected pancreatic adenocarcinoma who received combined radiotherapy (external beam at a dose of 45–54 Gy in standard fractions, days 1–35) and chemotherapy (5-FU 200 mg/m²/day as continuous infusion, weekly cisplatin 30 mg/m² IV bolus, interferon- α 3 million units SQ every other day) during radiation or GITSG-type chemotherapy with radiation therapy. Following combined modality chemoradiotherapy, chemotherapy alone was administered (5-FU 200 mg/m²/day as continuous infusion) in two 6-week courses during weeks 9–14 and 17–22. Of note, 13 of 17 patients randomized to the interferon-based chemoradiotherapy had positive lymph nodes compared to 7 of 16 patients randomized to the GITSG-based chemoradiotherapy. There were significant grade III/IV gastrointestinal (GI) toxicities including vomiting, mucositis, diarrhea, and GI bleeding in the interferon-based chemotherapy, requiring hospitalization in 35% of patients. However, the majority of patients were still able to receive more than 80% of planned therapy. The median overall survival and 2-year actuarial survival rate were 18.5 months and 54% for patients receiving GITSG-based chemoradiotherapy. In contrast, the median survival and 2-year survival were more than 24 months and 84% for the interferon-based chemoradiotherapy.¹⁶ The Virginia Mason Group has recently presented a follow-up study of 53 patients with resected pancreas cancer treated with similar interferon-based chemoradiotherapy. Toxicities including anorexia, dehydration, diarrhea, mucositis, nausea, and vomiting necessitated hospitalization in 23 of 53 patients. However, the clinical efficacy remains very encouraging, with median survival of 46 months and 2-year survival of 53%.¹⁹ As such, The American College of Surgery Oncol-

ogy Group (ACOSOG) has opened a multiinstitutional Phase II study in patients with pancreatic adenocarcinoma who are candidates for resection.

In July 2002, the Radiation Therapy Oncology Group (RTOG) closed R97-04. This Phase III study of 518 pancreatic cancer patients randomized between 5-FU continuous infusion (250 mg/m²/day for 3 weeks), followed by 5-FU continuous infusion (250 mg/m²/day) during radiation therapy (50.4 Gy in 1.8-Gy fractions), followed by two cycles 5-FU continuous infusion, versus gemcitabine 1,000 mg/m² weekly \times 3, followed by 5-FU continuous infusion during radiation therapy, followed by three cycles gemcitabine alone. The experimental question being asked was whether gemcitabine before and after 5-FU-based chemoradiotherapy would be more efficacious than continuous infusion 5-FU before and after the same 5-FU-based chemoradiotherapy. In 1997, when this study was designed, there was inadequate knowledge regarding how to safely administer gemcitabine concurrently with irradiation to allow for concurrent gemcitabine and radiotherapy. This study was the first North American Co-Operative group trial since the GITSG trial. Although the survival results for this trial will not be known until possibly late 2004, a number of important observations have already been made: neither arm was associated with unacceptable acute toxicity during the trial, accrual was quite rapid (12–14 patients per month), reflecting the support of both the Eastern Co-Operative Oncology Group and the Southwest Oncology Group, and the willingness of patients and their physicians to participate in adjuvant trials for pancreatic cancer.

Despite a growing body of literature supporting the benefit of adjuvant combined modality therapy following potentially definitive resection in patients with high risk for recurrence, adjuvant chemoradiation has not been universally accepted as a standard of care. One of the criticisms has been that none of these studies included an observation-only arm. There have been three studies that have demonstrated contrasting conclusions.

A European Organization for Research and Treatment of Cancer (EORTC) trial randomized 218 patients with pancreatic and nonpancreatic periampullary adenocarcinoma 2 to 8 weeks following potentially curative resection to either observation or to combined radiotherapy (40 Gy using a three- or four-field technique in 2-Gy fractions with 2-week break at midtreatment) and chemotherapy (5-FU administered as a continuous infusion 25 mg/kg/day during the first week of each 2-week radiation therapy module only). No postradiation chemotherapy was administered. Median progression-free survival was 16 months in the observation arm versus 17.4 months in the treatment arm ($P = 0.643$). Median survival was 19 months in the observation group versus 24.5 months in the treatment group, but this was not statistically significant ($P = 0.737$). For the subgroup of patients with pancreatic adenocarcinoma ($n = 114$), the median survival was 12.6 months in the observation group versus 17.1 months in the treatment arm, but this was not statistically significant ($P = 0.099$). Of note, 21 of 104 patients randomized to the treatment arm were not treated. In addition, although the original dose of 5-FU was already modest, 35 patients in the treatment arm received only 3 days of 5-FU during the second module of radiotherapy secondary to grade I/II toxicities. Therefore, this study could be better described as an underpowered positive study.¹³

TABLE 45.2. Active or planned adjuvant or neoadjuvant studies.

Study	Regimen	Study phase

The European Study Group for Pancreatic Cancer (ESPAC) randomized 541 patients with pancreatic adenocarcinoma in a four-arm design based on a two-by-two factorial design: (a) observation; (b) concomitant chemoradiotherapy alone (20 Gy in 10 fractions over 2 weeks with 500 mg/m² 5-FU IV bolus during the first 3 days of radiation therapy; the module is repeated after a planned 2-week break) followed by no additional chemotherapy; (c) chemotherapy alone (leukovorin 20 mg/m² bolus followed by 5-FU 425 mg/m² administered for 5 consecutive days repeated every 28 days for six cycles); and (d) chemoradiotherapy followed by chemotherapy.¹⁸ The data set for 289 patients randomized just through the two-by-two design was recently reported.²¹ The four arms were subsequently uniquely combined to make additional comparisons (no chemoradiotherapy versus chemoradiotherapy and no chemotherapy versus chemotherapy). There appeared to be a survival advantage for patients receiving no chemoradiotherapy (17.9 months) versus chemoradiotherapy (15.9 months, $P = 0.05$). In addition, there was a survival advantage for those who received chemotherapy (20.1 months) versus those who did not receive chemotherapy (15.5 months, $P = 0.009$). When the four arms were analyzed individually, there appeared to be a survival benefit for chemotherapy alone (median survival, 21.6 months) versus observation alone (16.9 months), chemoradiotherapy alone (13.9 months), or chemoradiotherapy followed by chemotherapy (19.9 months). However, the study was not powered to examine these arms separately. Multivariate analysis for known prognostic factors including margin status, lymph node involvement, and tumor grade and size did not alter the effect for chemoradiotherapy treatment. The study authors concluded that there was no survival benefit for adjuvant chemoradiotherapy. In addition, the authors concluded that a potential benefit existed for adjuvant chemotherapy alone following surgical resection. Based on these results, the follow-up ESPAC study (ESPAC-3) does not include radiation therapy and is designed as a randomized study of three different chemotherapy schedules (5-FU and leukovorin versus gemcitabine versus observation) following surgery.

Although this was a randomized study consisting of more than 500 patients with a smaller subset of 289 patients included in the two-by-two design, the conclusions of the study should be carefully measured. To encourage maximal patient recruitment, the study was modified in that 68 patients were assigned separately and randomized to either chemoradiotherapy or observation. In addition, 188 patients

were subsequently assigned separately and randomized to either chemotherapy alone or observation. In a sense, three randomizations were possible for inclusion into the same original study design. Also, patients in the additional two randomizations could have received "background chemotherapy or chemotherapy," which was not specifically defined. The background treatment was not known in 82 eligible patients. Of note, these patients were still assigned into an arm of the study despite lack of definitive knowledge of prior therapy. Finally, 25 of the eligible 541 patients refused to accept their randomization and an additional 25 patients withdrew secondary to treatment toxicities.

Although the smaller subset of 289 patients does not include these additional "randomized" patients, other fundamental issues concerning these are patients worthy of comment. First, the absence of a central review of radiotherapy fields and quality control/assurance is essential in such a study design and alone could explain the results of the study. Equally important, the radiation as well as the chemotherapy used in the ESPAC-1 study are not considered contemporary therapy. Doses of radiation therapy integrated with chemotherapy are currently in the range of 45 to 54 Gy. The lower doses of radiation used in ESPAC-1 might explain the high incidence of local recurrence in 109 of 158 patients (62%) with recurrent disease.

As the debate continues, several studies have recently opened or have been proposed by either the cooperative groups or through single institutions. Table 45.2 summarizes open or planned studies in the adjuvant setting. These future studies will be characterized by the addition of multiagent chemotherapy to irradiation at the cooperative group level by the addition of Gemcitabine to the period of chemoradiation and by the use of conformal, three-dimensional (3-D) irradiation planned to patient-specific anatomic and surgical pathologic data.

Future Concepts for Adjuvant Therapy

The identification of overexpressed/underexpressed genes, tumor-dependent growth pathways, and the search for tumor-specific proteins or antigens have for many years been the triple holy grail for oncologists. The impact from such discoveries would potentially not only revolutionize the management of disease but would also have implications for early detection and for monitoring disease. A number of these mol-

ecular targeted drugs (Cetuximab and Bevacizumab) have been approved by the U.S. Food and Drug Administration (FDA) for other malignancies and are currently being tested in combination with Gemcitabine in patients with metastatic pancreatic cancer. To date, no molecular targeted agents have been tested in the adjuvant setting.

Immune-based therapy is a novel therapeutic approach that has the ability to recruit and activate tumor-specific T cells and induce a cytotoxic response. The potential of this approach is attractive for many reasons.²² First, tumor killing by activated tumor-specific T cells occurs via a mechanism that is distinct from chemotherapy or radiation therapy and would represent a noncross-resistant treatment with an entirely different spectrum of toxicities. Second, the immune system is capable of recognizing a broad diversity of potential antigens with selective and specific cytotoxic responses. These features may be essential in recognizing and eliminating a heterogeneous tumor population while avoiding normal tissue toxicity. Third, preclinical animal models using active immunotherapy (vaccines) have been able to eliminate small burdens of established tumors, a situation that corresponds to the state of minimal residual disease commonly found after resection of human tumors. Fourth, there are data to suggest that human tumor-specific antigens can be manipulated to be effectively recognized by the immune system and that these antigens may be shared broadly among tumors of similar histologies.²³ Finally, vaccine cells do not need to be HLA compatible with host immune cells to effectively prime both the CD4⁺ T-cell (regulatory) arm and the CD8⁺ T-cell (cytolytic) arm of the immune response.^{24,25}

Although the use of autologous tumor cells may preserve unique antigens expressed by each patient's cancer, the development of an autologous vaccine has limitations that preclude the use of autologous cellular vaccine for most cancers including pancreatic adenocarcinoma. Recent data support the immunologic rationale for using allogeneic tumor cells rather than autologous cells as the source of antigen used for the vaccination.²⁴ Taken together, the data suggest that relevant tumor antigens can be delivered by an allogeneic tumor and still sufficiently mount an effective immune response.

The Johns Hopkins group has developed allogeneic cell lines from neoplastic tissue harvested from the surgical specimens of patients undergoing pancreaticoduodenectomy at the Johns Hopkins Hospital. All these cell lines have been characterized as 100% epithelial by cytokeratin staining. In addition, all these cell lines carry the same *k-ras* mutation as the original tumor specimen, which supports the conclusion that these lines are derived from malignant pancreatic tumor cells. Two cell lines had been chosen for further testing because they contain the most common *k-ras* mutation at codon 12 found in greater than 90% of pancreatic cancer. These lines were genetically modified to secrete granulocyte-macrophage colony-stimulating factor (GM-CSF). These lines were previously tested for safety in 14 patients with stage 1, 2, or 3 pancreatic adenocarcinoma.²⁶

This study was the first clinical trial to test the hypothesis that allogeneic GM-CSF-secreting pancreatic tumor cell lines can prime a systemic immune response in patients with resected pancreatic adenocarcinoma. Fourteen patients with stage 2 or 3 disease received an initial vaccination 8 weeks following resection; this was a dose escalation study in which 3 patients each received 1×10^7 , 5×10^7 , and 1×10^8 tumor

cells. An additional 5 patients received 5×10^8 vaccine cells. Study patients were jointly enrolled in an adjuvant chemoradiation protocol for 6 months. Following the completion of adjuvant chemoradiation, patients were reassessed, and those who were still in remission were treated with three additional vaccinations given 1 month apart at the same original dose that they received for the first vaccination. Toxicities were limited to grade I/II local reactions at the vaccine site. Postvaccination delayed-type hypersensitivity (DTH) responses to autologous tumor cells have been used in previously reported vaccine studies as a surrogate to identify and characterize specific immune responses that are associated with vaccination. In the pancreatic cancer vaccine trial, postvaccination DTH responses to autologous tumor cells were observed in 1 of 3 patients receiving 1×10^8 and in 2 of 4 patients receiving 5×10^8 vaccine cells.

The major limitation of defined antigen-based vaccines has been the lack of identified pancreatic tumor antigens that are the known targets of the immune response. Thus, current immune-based approaches either target a small group of candidate antigens expressed by the tumor or rely on whole tumor cells as the immunogen. In addition, postvaccination DTH response to autologous tumor provided only indirect evidence of vaccine-derived antitumor immune response. However, with the recent sequencing of the human genome and the development of rapid methods for identifying genes that are differentially expressed by tumor cells,² potential candidate immune targets were expected to be discovered that may serve as immunogens for treatment as well as prevention. Recently, mesothelin, a transmembrane glycoprotein member of the mesothelin/megakaryocyte potentiating factor (MPF) family, was identified by differential gene expression to be overexpressed by most pancreatic adenocarcinomas.²⁷ Mesothelin has been shown to be recognized by vaccinated uncultured CD8⁺ T cells isolated from the three patients who are long-term survivors from the previously described phase I GM-CSF pancreatic cancer vaccine study but not in the other patients who received the vaccine but subsequently relapsed.²⁸ These data suggest that mesothelin may be used as an *in vitro* marker of vaccine-specific T-cell responses to correlate with *in vivo* DTH response to autologous tumors and to clinical responses.

Based on the phase I study, the Johns Hopkins Hospital initiated a 60-patient study, administering a total of five vaccinations integrated around chemoradiotherapy for patients with resected pancreatic adenocarcinoma. The study is planned to complete accrual by the end of 2004.

Role of Neoadjuvant Therapy

Neoadjuvant therapy is a potentially attractive alternative to current standard adjuvant chemoradiation for several reasons: (1) radiation is more effective on well-oxygenated cells that have not been devascularized by surgery, (2) contamination and subsequent seeding of the peritoneum with tumor cells secondary to surgery could theoretically be reduced, (3) patients with metastatic disease on restaging following adjuvant therapy would not need to undergo definitive resection and might benefit from palliative intervention, and (4) the risk of delaying adjuvant therapy would be eliminated because it would be delivered in the neoadjuvant setting. A number of groups have further developed this approach^{1,9,29-41} (Table 45.3).

TABLE 45.3. Neoadjuvant studies in patients with resectable pancreatic cancer.

Study	Evaluable pts	% resected	EBRT (Gy)	Chemotherapy	MS (all pts, months) [N/A]	MS (resected pts, months)	One-year survival	Two-year survival	Five-year survival

The Fox Chase Cancer Center published their experience of 53 patients with localized resectable pancreatic cancer who were treated preoperatively with radiation therapy (5,040 cGy in 180-cGy fractions) and chemotherapy (MMC 10 mg/m² on day 2 with 5-FU 1,000 mg/m²/day by continuous infusion on days 2–5 and 29–32). Forty-one patients subsequently underwent exploratory laparotomy at the conclusion of preoperative chemoradiation. From this group of patients, 17 were not resectable (including 11 patients with hepatic or peritoneal metastases and 6 patients with local extension that precluded resection). Twenty-four patients eventually underwent potentially curative resection. Significant treatment-related hematologic and nonhematologic toxicities were identified, including 1 patient with treatment-related toxicities that precluded reexploration. Median survival for the entire group was 9.7 months and 15.7 months for the group that underwent surgical resection.³¹

The MD Anderson Cancer Center (MDACC) published their experience of 132 patients with localized resectable pancreatic adenocarcinoma who were treated preoperatively with radiation therapy (45–50.4 Gy in standard 1.8-Gy fractions or consisting of 30-Gy rapid fractionation in 3 Gy/fraction) combined with chemotherapy (5-FU continuous infusion 300 mg/m²/day or gemcitabine 400 mg/m²/week or paclitaxel 60 mg/m²/week), followed by surgical resection. There were no surgical delays in the neoadjuvant group but there were noted to be delays in 6 of 25 patients who underwent surgical resection first. At median follow-up of 19 months, no significant differences in survival were noted between treatment groups, with overall median survival of 21 months.³⁷

The Fox Chase group has since published a follow-up study of 30 patients with localized resectable pancreatic cancer of whom 26 received preoperative radiation therapy (50.4 Gy) with 5-FU continuous infusion. Fourteen patients who received preoperative therapy subsequently underwent resection. Median survival was 34 months for the resected group compared to 8 months in the group that could not be resected.³⁹

The MDACC have also used paclitaxel 60 mg/m² over 3 hours weekly with 30-Gy radiation therapy rapid fractionation. Of note, if patients could undergo surgical resection, they could also have received external-beam intraoperative radiation therapy (EB-IORT). Grade III hematologic and nonhematologic toxicities were identified in 16 patients. No delays in surgery were attributable to preoperative therapy. Twenty of 25 patients who underwent exploratory laparotomy underwent surgical resection. There were no histologic complete responders. With median follow-up of 45 months, 3-year survival for those patients following potentially curative resection was 28% with overall median survival of 19 months.⁴¹

Currently, the Eastern Co-operative Oncology Group (ECOG) is planning to open a prospective randomized trial randomizing patients to intensified gemcitabine-based or gemcitabine/5-FU/platinum-based chemoradiotherapy. This trial makes an important distinction between clearly unresectable disease and potentially resectable disease, especially around the issues of partial versus complete encasement of the superior mesenteric artery and length of superior mesenteric vein involved by tumor at initial presentation. To date, the current data demonstrate that although neoadjuvant chemoradiotherapy can be administered safely, there is no

clear advantage to this strategy compared to postoperative therapy. In the realm of marginally resectable patients, it remains to be seen whether there is a meaningful cohort of patients for whom this approach may represent an important therapeutic advantage based on “downstaging” and improved surgical outcomes.

Treatment of Locally Advanced Disease

Pancreatic tumors frequently invade adjacent structures such as superior mesenteric and celiac vascular structures, making curative resection difficult if not impossible. The Memorial Sloan Kettering group recently reviewed their experience of 163 patients with locally advanced pancreas cancer. A number of chemotherapy regimens were integrated with radiation therapy and administered to 87 patients. Only 3 patients had sufficient radiographic response to justify surgical exploration. Of these selected patients, one-third underwent resection for curative intent.⁴² For the approximately 30% to 40% of pancreatic cancer patients who present with such locally advanced, nonmetastatic disease, optimal management is controversial. Palliative surgery, chemoradiation, chemotherapy alone, and locally directed therapies have all been employed in this setting.

Chemoradiation Approaches

Although external-beam radiation therapy (EBRT) alone can improve symptoms associated with locally advanced disease, the high local failure rate and synergy observed when EBRT is combined with chemotherapy have led to trials using both modalities. Chemoradiation approaches have shown improved survival compared to either modality alone, but the improvements are modest, and local control remains a significant challenge. There have been no randomized comparisons of radiation and/or chemotherapy versus supportive care (aside from subset analyses in trials for metastatic disease).

Several prospective randomized trials have shown a benefit with chemoradiation compared to either radiation or chemotherapy alone in the management of locally advanced disease.^{43–49} The first trial was published in 1969 and included patients with different types of gastrointestinal (GI) cancers, 64 of whom had locally unresectable pancreatic cancer randomized to either 5-FU or placebo combined with 35–40 Gy radiation. Median survival in the combined modality arm was significantly higher than in the radiation therapy-only arm (10.4 versus 6.3 months).⁴³ The Gastrointestinal Tumor Study Group (GITSG) randomized 194 locally advanced pancreatic cancer patients to receive split-course EBRT, either alone (60 Gy) or combined (either 40 or 60 Gy) with 5-FU 500 mg/m² on the first 3 days of each 20 Gy of radiation.⁴⁴ The EBRT-alone arm was discontinued after an interim analysis showed improved median time to progression (TTP) and overall survival (OS) in the combined modality arms. There were no significant differences between the high- and low-dose EBRT in the chemoradiation arms, although there were trends favoring the higher-dose arm in time to progression and survival. A second GITSG study compared SMF (streptozotocin, mitomycin, and 5-FU) chemotherapy alone versus SMF combined with EBRT (54 Gy), and showed a significant improvement in

median survival (9.7 versus 7.4 months) for the chemoradiation arm.⁴⁶ In contradistinction to the GITSG studies, a randomized ECOG study of 91 patients comparing 5-FU 600mg/m² weekly with or without EBRT (40Gy, which has been criticized as an insufficient dose) did not find a significant benefit to combined modality therapy over chemotherapy alone.⁴⁵ Thus, three randomized studies have demonstrated a modest survival benefit of combined modality therapy over chemotherapy or EBRT alone, and one ECOG study with a possibly suboptimal dose of EBRT (40Gy) did not show benefit over 5-FU alone.

Several trials have examined the use of different chemotherapy agents with radiation therapy in the locally advanced setting. The first was a Southwest Oncology Group (SWOG) study published in 1980 randomizing 69 patients to mCCNU (methyl lomustine) and 5-FU with or without testolactone, combined with 60Gy of radiation.⁴⁷ There was no significant difference in overall survival, and myelosuppression (87%) and GI toxicity (23%) were common. A GITSG study randomized 143 patients to EBRT with either weekly 5-FU or doxorubicin.⁴⁸ Median survival was similar in both arms (approximately 8 months), but the doxorubicin arm had more frequent severe toxicity. Finally, a randomized Phase II study of 87 patients compared the radiation sensitizer hycanthone to 5-FU, both given with 60Gy of split-course radiation, and found no difference in survival.⁴⁹ Thus, three trials failed to demonstrate a survival advantage of different chemotherapy regimens given with radiation therapy compared to 5-FU, which tended to have less toxicity.

Chemoradiation Using Gemcitabine

There has been considerable interest in combining EBRT with gemcitabine because of its clinical benefit in the metastatic setting and potent radiosensitizing properties. Studies combining radiotherapy with gemcitabine have proceeded cautiously because of this synergy. Early trials were designed to determine the maximal tolerated dose of gemcitabine when delivered weekly and integrated with radiation therapy consisting of 50.4Gy in standard 1.8-Gy fractions. A margin of 3cm around the gross target volume was required for the initial field of 39.6Gy. The margin was subsequently reduced to 2cm for the final 10.8-Gy boost. The starting dose of gemcitabine was 300mg/m². Hematologic and gastrointestinal toxicities were identified as dose limiting at 700mg/m².⁵⁰ Blackstock and colleagues examined, in a Phase I study, gemcitabine (starting at 20mg/m²) twice weekly in combination with radiation therapy (total dose, 50.4Gy in 1.8-Gy fractions) in 19 patients with locally advanced pancreatic adenocarcinoma. Thrombocytopenia, neutropenia, and nausea/vomiting were dose-limiting toxicities. Of the 15 patients assessable for response, 3 partial responses were identified.⁵¹ A dose of 40mg/m² twice weekly in combination with radiotherapy to a total dose of 50.4Gy was subsequently examined by the Cancer and Leukemia Group B (CALGB) in a Phase II study of 38 patients with locally advanced pancreatic cancer. Following chemoradiotherapy, patients without disease progression received Gemcitabine alone at 1,000mg/m² weekly \times 3 every 4 weeks for five additional cycles. Grade III/IV hematologic toxicity was significant and identified in 60% of patients; in addition, grade III/IV GI toxicity was identified

in 42% of patients. With median follow-up of 10 months, median survival was 7.9 months.⁵²

The MD Anderson Cancer Center (MDACC) has since published a corollary phase I study of 18 patients with locally advanced disease using rapid fractionation external-beam radiation. Patients received dose escalation gemcitabine from 350mg/m² to 500mg/m² weekly \times 7 with concurrent rapid fractionation 3,000-cGy external-beam radiation therapy during the first 2 weeks of therapy. Hematologic and nonhematologic toxicities were significant in all three patient cohorts. There were 8 responses (4 minor and 4 partial). One of 2 patients who were subsequently explored had a curative resection. The recommended Phase II testing dose of gemcitabine was 350mg/m².⁵³

These dose-finding studies would suggest that the maximal tolerated dose of gemcitabine when combined with radiation therapy is dependent on the radiation therapy field size. Planned confirmatory studies will follow up on these observations.

The University of Michigan has described an alternative approach by using standard doses of gemcitabine at 1,000mg/m² weekly \times 3 every 4 weeks and administering radiation therapy as dose escalation beginning at 24Gy (1.6-Gy fractions in 15 fractions) in 34 patients with locally advanced disease. The majority of patients received chemotherapy after combined modality treatment at the discretion of the treating physician; 75% of patients received at least 85% of planned gemcitabine. Two of 6 assessable patients experienced dose-limiting toxicity at the final planned radiation dose of 42Gy in 2.8-Gy fractions. An additional 2 patients developed late GI toxicities at this dose level. Six patients were documented to have a partial response, with a complete radiographic response in 2 patients. In addition, 4 patients with documented stable disease at time of study entry experienced objective responses (2 partial and 2 complete responses). Definitive resection was achieved for 1 of 3 surgically explored patients. With median follow-up of 22 months, median survival for the entire group was 11.6 months. The recommended Phase II radiation dose was 36Gy in 2.4-Gy fractions.⁵⁴

Other chemotherapy agents have been added to Gemcitabine combined with radiation therapy. The Eastern Cooperative Oncology Group (ECOG) published a Phase I study of seven patients with locally advanced disease using 5-FU/Gemzar combined with radiation therapy to a maximum 59.4Gy in 1.8-Gy fractions. 5-FU (200mg/m²/day as continuous infusion throughout radiation therapy) was administered with weekly gemcitabine dose escalation beginning at 100mg/m². Because of dose-limiting toxicities seen in two of the first three patients, the study was amended to lower the initial dose of gemcitabine to 50mg/m². However, dose-limiting toxicities were subsequently seen in three of four patients at the 50mg/m² dose. Three of the five dose-limiting toxicities occurred at radiation doses less than 36Gy. The study was subsequently closed.⁵⁵

Gemcitabine has also been combined with cisplatin and radiation in published Phase I trials, following up on promising preclinical synergistic data. A study based at the Mayo clinic gave twice-weekly gemcitabine and cisplatin for 3 weeks during radiation (50.4Gy in 28 fractions). Dose-limiting toxicities consisted of grade 4 nausea and vomiting, and the recommended phase II dose was gemcitabine 30mg/m² and cisplatin 10mg/m².⁵⁶ Another trial used strictly time-

scheduled gemcitabine (days 2, 5, 26, and 33 after a weekly regimen was too toxic) and cisplatin (days 1–5 and 29–33) combined with radiation, with a recommended Phase II dose of 20mg/m² for cisplatin and 300mg/m² for gemcitabine.⁵⁷ The response to chemoradiation allowed 10 of 30 initially unresectable patients to undergo surgery, with a R0 resection in 9 cases and a complete response (CR) in 2 cases.

Given the current published data, would 5-FU or gemcitabine be better suited to be used concurrently with radiation therapy for either resected or locally advanced disease? The MDACC retrospectively examined their database of 114 patients with locally advanced disease treated with combination radiation therapy (rapid fractionation 30Gy in 10 fractions) with either 5-FU by continuous infusion 200–300mg/m² (61 patients) or gemcitabine 250–500mg/m² weekly \times 7 (53 patients). Patients receiving gemcitabine developed a significantly higher incidence of severe acute toxicity, defined as toxicity requiring a hospital stay of more than 5 days, mucosal ulceration with bleeding, more than three dose deletions of gemcitabine or discontinuation of 5-FU, or toxicity resulting in surgical intervention or death, compared with those patients receiving 5-FU (23% versus 2%; *P* less than 0.0001). Five of 53 patients treated with gemcitabine/radiation therapy subsequently underwent surgical resection compared to 1 of 61 patients treated with 5-FU/radiation therapy. However, with short median follow-up, median survival was similar (11 months versus 9 months (*P* = 0.19)).⁵⁸

Chemotherapeutic Approaches

Because the benefit of chemoradiation is relatively modest, and the aforementioned randomized ECOG study showed no benefit to radiation added to 5-FU alone, some oncologists recommend chemotherapy alone for locally advanced disease. Gemcitabine is the most commonly used agent, extrapolating from the metastatic disease setting; this is based on the randomized trial by Burris et al. in which 26% of the study subjects had locally advanced disease. Gemcitabine ameliorated symptoms and modestly improved survival compared to 5-FU, but the results for patients with locally advanced disease were not reported separately.⁵⁹ An ECOG Phase III trial (E4201) comparing gemcitabine (600mg/m² weekly)/radiation (50.4Gy in 28 fractions) followed by weekly gemcitabine (1,000mg/m² weekly, 3 of 4 weeks) versus gemcitabine alone, which opened in April 2003, is examining this issue.

Locally Directed Therapy

Both brachytherapy and intraoperative radiotherapy (IORT) have been employed in the setting of locally advanced disease. Both modalities are aimed at improving locoregional control. Given the propensity of this disease to disseminate, especially into the liver and adjacent peritoneum, what can be achieved overall for patients by the addition of either modality to external-beam irradiation and chemotherapy is not completely clear. Mohiuddin et al. reported on 81 patients with localized unresectable carcinoma of the pancreas managed at Thomas Jefferson using intraoperative iodine-125 implants, external-beam irradiation, and perioperative systemic chemotherapy.⁶⁰ The radioactive iodine implant was designed to deliver a

minimum peripheral dose up to 1,200cGy over 1 year. Patients were also treated with 50 to 55 Gy of external-beam irradiation with systemic chemotherapy consisting of 5-FU, mitomycin, and occasionally CCNU. Implants were performed at laparotomy. There was a 5% mortality rate, and a 34% acute morbidity rate with cholangitis, upper GI bleeding, and gastric outlet obstruction being the most common. In addition, there was a 32% late morbidity rate, with GI bleeding, cholangitis, and radiation enteritis being the most common late developments. Local control was obtained in 39 of 53 (71%) of evaluable patients. Of 14 patients undergoing reexploration more than 6 months following implantation, 86% showed extensive fibrosis and had negative biopsies from the region of the tumor. In 8 patients undergoing autopsy, 5 (63%) were without evidence of locoregional tumor. Nevertheless, 52 of these 81 patients (62%) failed with intraabdominal disease, primarily hepatic and peritoneal. With a minimum follow-up of 2 years at the time of publication, the median survival for the total group was 12 months, the 2-year survival was 21%, and the 5-year survival was 7%. Despite satisfactory local control in several patients, many centers would not be willing to accept this level of therapeutic intensity in a group of patients for whom management is ultimately primarily noncurative.

Nori et al. have reported on a series of 15 patients undergoing similar management but using palladium-103 instead of iodine-125.⁶¹ The implant was designed to provide a matched peripheral dose of 1,100cGy. Patients also received external-beam irradiation of 4,500cGy over 4.5 weeks and chemotherapy with 5-FU and MMC. Median survival was 10 months. The authors concluded that palladium-103 is an alternative to iodine-125 for interstitial brachytherapy for unresectable patients, and that symptom relief appeared to occur somewhat faster. The study did not show any improvement in the median survival as compared to ¹²⁵I. Finally, a note of caution was raised by Raben et al. on the use of palladium brachytherapy for locally unresectable carcinoma of the pancreas. In their series of 11 patients, they found an unacceptably high complication rate including gastric outlet obstruction, duodenal perforation, and sepsis.⁶² They did not find an improvement in median survival over other modalities and did not recommend this approach for further study.

The use of intraoperative radiation therapy (IORT) using single-fraction electron beam treatment has also been extensively studied. In experienced hands, IORT can be given with acceptable morbidity. However, there are occasional reports of unacceptably high complication rates. Generally, IORT has been given in combination with external-beam radiation therapy (EBRT) in the range of 45 to 50.4Gy with 5-FU alone or 5-FU-based combination chemotherapy. The RTOG reported on 51 patients with locally unresected nonmetastatic pancreatic cancer treated with IORT and EBRT/5-FU and found a major postoperative complication rate of 12%. Two patients had major morbidity leading to death.⁶³ A neoadjuvant approach was taken by Garton et al. at the Mayo Clinic, where EBRT (50–54 Gy) with or without 5-FU was given preoperatively, followed by IORT (20Gy).⁶⁴ In 27 patients with unresectable disease because of locoregional considerations, local control was achieved in 78%, although 70% of patients developed distant metastases, including peritoneum and liver. Median survival from diagnosis was 14.9 months. Zerbi et al. have suggested that the use of IORT as an adjuvant to resection decreases the risk of local recurrence.⁶⁵ Mohiuddin

et al. have also reported excellent results with IORT in the management of unresectable pancreatic cancer when combined with postoperative EBRT.⁶⁶ As reviewed by Willett and Warshaw, the dose of intraoperative radiation therapy is generally in the range of 10 to 20 Gy, with some investigators prescribing to the 90% line and others prescribing to the 100% line.⁶⁷

In addition to local radiation delivery, a variety of other techniques and agents are under development for the treatment of locally advanced pancreatic cancer. One example is intratumoral injection via endoscopic ultrasound of ONYX-015, an engineered adenovirus that selectively replicates in tumor cells. A Phase I/II trial of this agent combined with gemcitabine in 21 patients showed that the technique was feasible with transgastric injections (2 duodenal perforations occurred early in the trial), and 2 partial responses were seen.⁶⁸ Another novel biologic agent in development is TNFerade, a replication-deficient adenovector carrying a transgene encoding for human tumor necrosis factor- α regulated by a radiation-inducible promoter. Weekly intratumoral injections have been given in combination with chemoradiation (50.4 Gy with continuous infusion 5-FU 200 mg/m² daily).⁶⁹ Two of 17 patients in a Phase I trial converted from unresectable to resectable, and 1 of these had a pathologic CR.

Treatment Recommendation for Locally Advanced Disease

The optimal treatment for locally advanced pancreatic cancer remains controversial. There have been no randomized trials comparing chemoradiation strategies versus best supportive care, or chemotherapy alone (aside from the GITSG trial in which both 5-FU and radiation were added to SMF chemotherapy), and the survival benefit from combined modality therapy for locally advanced disease has been modest in various trials. Nonetheless, most practitioners in the United States employ radiation therapy (typically 54 Gy in 1.8-Gy fractions) with simultaneous chemotherapy, the standard being 5-FU. Although several chemotherapy regimens have been compared to 5-FU in randomized trials, none have proven more efficacious, and these are typically more toxic. Various ways of giving 5-FU have been used in these trials, but most practitioners choose either continuous infusion at 200 mg/m²/day during radiation therapy, or a 500 mg/m² bolus given on the first 3 days and last 3 days of radiation. Studies are under way that will examine the role of gemcitabine (both alone, and combined with radiation) for locally advanced disease. In addition, given the limited success of current treatments, several novel approaches are being actively explored with the aim of allowing patients who present with unresectable disease to undergo curative surgery.

Therapy for Metastatic Disease

Historically, 5-fluorouracil (5-FU)-based chemotherapy has been the most widely studied chemotherapeutic agent for all stages of pancreatic cancer. Despite more recent attempts to modify the delivery of 5-FU, response rates have remained unchanged in the 10% to 20% range, with median survival of 4 to 5 months for patients with stage IV disease.⁷⁰⁻⁷⁴

The Role of Gemcitabine in Metastatic Pancreatic Cancer

Gemcitabine is a prodrug deoxycytidine (2'-deoxy-2',2'-difluorocytidine monohydrochloride) analogue that is metabolized by deoxycytidine kinase to active diphosphate (dFdCDP) and triphosphate (dFdCTP) nucleosides. These metabolites inhibit ribonucleotide reductase with the effect of decreasing intracellular levels of required deoxynucleotide triphosphates for continued DNA synthesis. In addition, gemcitabine triphosphate directly competes with dCTP for incorporation into DNA. Recently, gemcitabine has demonstrated promise as an active agent in treating pancreatic cancer. Casper and colleagues reported the results of a Phase II trial using weekly gemcitabine at 800–1,250 mg/m² in 44 patients with unresectable pancreatic cancer. The response rate was noted to be 11% but with median survival of 5.6 months and a 1-year actuarial survival of 23%.⁷⁵ Subsequently, Burris and colleagues randomized 126 patients with unresectable pancreatic cancer to either gemcitabine (1,000 mg/m² weekly over a 30-minute infusion \times 7 followed by 1 week rest then weekly \times 3 every 4 weeks) or 5-FU (600 mg/m² weekly). Although the primary endpoints were issues related to quality of life, median survival was 5.7 months in the gemcitabine arm compared to 4.4 months in the 5-FU arm. In addition, 1-year survival was 18% in the gemcitabine arm compared to 2% in the 5-FU arm ($P = 0.0025$), with median time to progression also favoring gemcitabine (9 weeks compared to 4 weeks in the 5-FU arm; $P = 0.0002$). Gemcitabine was well tolerated, with the majority of side effects related to grade 3 or 4 neutropenia (26%) without associated infections, low-grade fevers (30%), and nausea and vomiting (9.5% and 3.2%). Gemcitabine has since been approved by the FDA in 1996 as a first-line therapy in metastatic pancreatic cancer.⁵⁹ In addition, Rothenberg and colleagues evaluated gemcitabine (1,000 mg/m² weekly \times 7 with 1 week off then weekly \times 3 with 1 week off) in 63 patients with unresectable disease who had been previously treated with 5-FU. The overall salvage response was 10.5% with median time to progression at 2.5 months and median survival at 3.85 months, with a toxicity profile similar to first-line therapy.⁷⁶ Recent strategies include identifying alternative dosing schedules of gemcitabine that might both enhance drug delivery to tumor cells as well as identifying synergistic combinations with other chemotherapeutic agents. Tempero and colleagues randomized 93 patients to either gemcitabine (2,200 mg/m²) over the standard 30-minute infusion or gemcitabine (1,500 mg/m²) at a rate of 10 mg/m²/min. With analysis completed on 67 patients, the response rate was 17% versus 3% in favor of the longer infusion rate. In addition, median survival (6.1 months versus 4.7 months) and 1-year survival (23% versus 0%) favored the longer infusion rate.⁷⁷

Combination Chemotherapy

Recent efforts have focused on developing strategies that would enhance the efficacy of gemcitabine and ultimately improve median survival. Table 45.4 summarizes the most recent studies.^{59,75-108}

Gemcitabine with 5-Fluorouracil

Preclinical data have also demonstrated a synergistic and non-cross-resistant effect of 5-FU when given with gemcitabine.⁷³

TABLE 45.4. Recent studies in advanced pancreatic cancer.

<i>Study</i>	<i>Patient no.</i>	<i>Chemotherapy</i>	<i>PR/CR rate</i>	<i>Median survival (months)</i>	<i>One-year survival</i>
Casper (1994)	44	Gemcitabine	5 (11%)	5.6	23%
Burris (1997)	63	5-FU bolus	0 (0%)	4.4	2%
	63	Gemcitabine	3 (5.4%)	5.7 $P = 0.0025$	18%
Rothenberg (1996)	63 (2nd line)	Gemcitabine	6 (10.5%)	3.8	4%
Hidalgo (1999)	26	Gem + 5-FU CI	5 (19.2%)	10.3	40%
Berlin (2000)	36	Gem + 5-FU bolus	5 (14%)	4.4	9%
Miller (2000)	42	Pemetrexed	2 (5.7%)	6.5	28%
Heinemann (2000)	41	Gem + cisplatin	4 (11%)	8.2	27%

	43	Fixed dose Gem	1/17 (5%)	8 ($P = 0.013$)	29%
Kindler (2004)	45	Gem + Avastin	9 (21%)	9	37%
O'Reilly (2004)	340	Gem ± Exatecan	6.3 vs. 8.2	6.3 months vs. 6.7 ($P = 0.52$)	21% vs. 23%
Richards (2004)	565	Gem ± Pemetrexed	9.1 vs. 18.3	6.3 months vs. 6.2 ($P = 0.85$)	21% vs. 20%
Louvet (2004)	313	Gem vs. Gem (FDR) + Oxaliplatin	17.3 vs. 26.8	7.1 vs. $P (P = 0.13)$	28% vs. 35%
Abbruzzese (2004)	41	Gem + Cetuximab	5 (12.2%)	7.1	31.7%

CR, complete response; PR, partial response; NR, no response.

However, the combination of 5-FU and gemcitabine has not consistently resulted in significant improvement over gemcitabine alone.^{79,80,83,84,100} Early studies had designed the use of gemcitabine with bolus infusion of 5-FU with no significant improvement when compared to single-agent gemcitabine.⁷⁹ However, subsequent studies focusing on infusional schedules of 5-FU with gemcitabine suggested a clinical parallel to the data using infusional 5-FU in the therapy of metastatic colorectal cancer. Hidalgo et al. examined the combination of 5-FU administered as a continuous infusion (200 mg/m² throughout the study) with gemcitabine 700–900 mg/m² weekly × 3 repeated every 4 weeks. The reported median survival was 10.3 months.⁸⁰ In addition, Louvet et al. reported a Phase II study of infusional 5-FU and leucovorin (leucovorin 400 mg/m² in a 2-hour infusion followed by 5-FU 400 mg/m² bolus followed by 2–3 g/m² continuous-infusion 5-FU, in a schedule known as LV5FU2) with gemcitabine 1,000 mg/m² on day 3, repeating the cycle every 2 weeks. The reported median survival was 9 months.⁸⁴ However, in a recent study by Hess et al. using gemcitabine (1,000 mg/m², days 1 and 8) and capecitabine (starting 500 mg/m² divided bid × 14 days) in 36 patients with advanced pancreas cancer repeated every 21 days, the median survival was 6.4 months.⁸⁵ A number of modulators of 5-FU have been previously examined, including interferon-alpha and *N*-(phosphonoacetyl)-L-aspartate disodium (PALA), and all have been of no additional benefit. There has been interest in examining other 5-FU formulations, either alone or with gemcitabine, including the multitargeted folate inhibitor pemetrexed that has activity against thymidylate synthase (TS), dihydrofolate reductase (DHFR), and glycinamide ribonucleotide formyltransferase (GARFT).^{81,84}

Gemcitabine with Platinum Chemotherapy

Another potentially synergistic agent that has been used with gemcitabine is cisplatin. This combination is thought to be synergistic either by enhancing dFdCTP incorporation into DNA or via increasing DNA adduct formation.⁷⁸ Early studies identified median survival from 5.6 to 8.2 months.^{82,86,102} This combination has recently been examined in two Phase III studies. Colucci and colleagues treated 107 patients with advanced pancreas cancer with either gemcitabine alone at standard dose and schedule or gemcitabine and cisplatin (25 mg/m² weekly × 3 every 4 weeks). The combination of gemcitabine and cisplatin improved median time to disease progression (2.7 months for gemcitabine alone versus 5 months for combination gemcitabine and cisplatin; *P* = 0.048) with no significant differences in toxicities. However, although the median survival for the gemcitabine group was 5 months compared to 7.5 months for the combination chemotherapy, the *P* value of 0.43 was not statistically significant.⁸⁷ More recently, Heinemann et al. presented the Phase III data of 195 patients randomized to either gemcitabine alone at standard dose and schedule versus gemcitabine and cisplatin (50 mg/m² weekly × 3 repeated every 4 weeks). Although a difference in median survival was noted (6 months for gemcitabine alone versus 8.3 months for the combination), this result was not statistically significant.¹⁰⁴

Gemcitabine with Oxaliplatin

Oxaliplatin is a diaminocyclohexane (DACH) platinum compound that received FDA approval in August 2002 for use in

combination with infusional 5-FU) and leucovorin for the treatment of patients with colorectal cancer whose disease has recurred or become worse following initial therapy with a combination of irinotecan with bolus 5-FU and leucovorin. Based on preclinical data that identified synergistic antitumor activity, oxaliplatin has since also been evaluated in combination with gemcitabine in patients with advanced pancreatic cancer. The French Cooperative group GERCOR examined gemcitabine 1,000 mg/m² as a 10 mg/m²/min prolonged infusion administered on day 1 in combination with oxaliplatin 100 mg/m² as a 2-hour infusion administered on day 2, repeated every 2 weeks, in 64 patients with chemonaive metastatic pancreas cancer. Response rate was noted to be 30.6 % with a clinical benefit response of 40%. Median progression-free survival and overall survival were 5.3 months and 9.2 months, respectively, with 36% 1-year survival. The combination was safe, with reported side effects including grade 3 or 4 neutropenia/thrombocytopenia of 11%, nausea and vomiting of 14%, diarrhea of 6.2%, and peripheral neuropathy of 11%.⁹⁸

The North Central Cancer Treatment Group (NCCTG) completed a Phase I study of gemcitabine and oxaliplatin in 18 patients with metastatic pancreas cancer. Dose-limiting toxicities (DLT) of neutropenia and severe infection were identified at the maximum tolerated dose of gemcitabine, 1,250 mg/m² (day 1 and day 8 every 21 days) and oxaliplatin, 130 mg/m² (day 1 every 21 days).¹⁰³

Louvet et al. recently presented a Phase III study of 308 patients randomized to either gemcitabine or to gemcitabine with oxaliplatin (gemcitabine 1,000 mg/m² as a 10 mg/m²/min prolonged infusion administered on day 1 in combination with oxaliplatin 100 mg/m² as a 2-hour infusion administered on day 2 repeated every 2 weeks) versus gemcitabine alone. Although there was a difference in progression-free survival (4 months for gemcitabine alone versus 6.25 months for combination chemotherapy; *P* = 0.05), the median survival was statistically significant.¹⁰⁶

Gemcitabine with Irinotecan

Rocha Lima et al. completed a Phase II study of 45 patients treated with gemcitabine at 1,000 mg/m² over 30 minutes and irinotecan at 100 mg/m², both weekly × 2 repeated every 3 weeks. Median survival was 5.7 months.⁹⁶ Rocha Lima et al. also presented the follow-up Phase III study recently of 342 patients randomized to either gemcitabine alone or gemcitabine + irinotecan. Although there was a higher response rate for combination gemcitabine and irinotecan (16% versus 4%), the median survival was no different (6.6 months for gemcitabine alone versus 6.3 months for the combination).¹⁰⁵

Gemcitabine with Other Chemotherapy

There has been additional interest based on preclinical data to synergistically combine multiple chemotherapy agents with gemcitabine. Early data suggest that such combinations have similar safety profiles with some of the gemcitabine combinations and are active schedules. Fine and colleagues have published preliminary data with a schedule known as GTX (gemcitabine 750 mg/m² over 2 hours days 4 and 11, Taxotere 30 mg/m² over 30 minutes days 4 and 11, and Xeloda 1,500 mg/m² po divided doses bid days 1–14 repeated every 21 days) in patients with locally advanced and metastatic

disease. Patients without metastatic disease received gemcitabine 200 mg/m² weekly × 6 concurrent with EBRT to 45 to 50 Gy followed by surgery if indicated. Toxicities included 25% grade 3 leukopenia, 20% grade 3 asthenia, 20% grade 3 diarrhea, and 15% erythrocytopenia. In 9 patients who presented with locally advanced but nonmetastatic disease, 8 patients were resected, with complete response in 6 patients. In patients who presented with metastatic disease, there were partial responses in 12 patients. Median survival for both groups has not been reported.⁹⁷

Kozuch and colleagues treated 34 patients who had been previously treated with gemcitabine either alone or in combination with a schedule known as G-FLIP (day 1: gemcitabine 500 mg/m² over 50 minutes, leukovorin 300 mg over 30 minutes, irinotecan 80 mg/m² over 80 minutes, 5-FU bolus 400 mg/m² over 10 minutes, then 600 mg/m² over 8 hours; day 2: leukovorin 300 mg over 30 minutes, 5-FU bolus 400 mg/m² over 10 minutes, cisplatin 50–75 mg/m² with mannitol over 45 minutes and 5-FU 600 mg/m² over 8 hours). Toxicities were largely hematologic. Median survival for this pretreated group was 10.3 months.⁸⁸

New Drugs in Pancreatic Cancer

During the last few years, an increasing number of new drugs, many of them targeted to specific alterations in malignant cells, have been tested in pancreatic cancer as well as in other tumors. The rationale to develop these drugs in pancreatic cancer comes from the better understanding of the biologic basis of the disease, which has made possible the identification and validation of some of these targets in pancreatic cancer. In addition, the poor prognosis of patients with this disease and the evidence from clinical trials discussed previously that conventional chemotherapy may have reached a plateau in improving outcome have also motivated an aggressive evaluation of new drugs in pancreatic cancer.

Matrix Metalloproteinase Inhibitors

The matrix metalloproteinases (MMPs) are a group of closely related proteases that are dysregulated in the majority of human neoplasms, including pancreatic cancer. The increased activity of these enzymes has been related to the tumor growth, progression, invasion, generation of blood vessels, and metastasis. Several inhibitors of the MMP have been developed as anticancer agents, and two of them, marimastat and BAY12-9566, have been more extensively studied in pancreatic cancer.¹⁰⁹

Marimastat is a hydroxamate peptidomimetic broad-spectrum inhibitor of the MMP family including MMPs 1, 2, and 9. In Phase I studies in pancreatic cancer, doses from 10 to 25 mg orally twice a day were well tolerated. A large Phase II study that enrolled 113 patients, 90% of whom were treated with 25 mg in a once a day dose, reported a 30% decline or stabilization in the tumor marker CA-19-9 and a median survival of 3.8 months, and 51% of the patients had improvement in symptoms. Twenty-nine percent of the patients developed arthralgias, the most common toxicity encountered with marimastat.¹¹⁰ The efficacy and toxicity of marimastat at doses of 5, 10, and 25 mg twice a day was compared to gemcitabine in a Phase III study. Patients treated with gemcitabine had a longer progression-free survival of 3.8 months

versus 1.9 to 2 months for the marimastat-treated group ($P = 0.001$). Overall survival was also better for gemcitabine and significantly worse for patients treated with marimastat at doses of 5 and 10 mg, while no statistically significant differences were observed in overall survival with the 25 mg twice a day dose. A subset analysis in this study showed that the benefit of gemcitabine was restricted to patients with advanced disease and that patients with locally advanced tumors benefited from marimastat, supporting the hypothesis that these drugs may be more active in the situation of early disease.¹¹¹ Finally, the combination of gemcitabine with marimastat was tested against gemcitabine in a randomized Phase III study with no improvement in any parameter of outcome in the combined treatment group.¹¹²

The second MMP inhibitor extensively studied in pancreatic cancer is BAY12-9566, a peptidomimetic inhibitor specific for MMP-2 and MMP-9. The drug was compared in a Phase III study to single-agent gemcitabine in which 270 patients of a planned sample of 350 were enrolled after an interim analysis demonstrated that patients treated with gemcitabine had a significantly better time to tumor progression (3.5 versus 1.6 months; P less than 0.001) and overall survival (6.59 versus 3.74; P less than 0.001). Quality of life analysis also favored gemcitabine.¹¹³ In summary, these studies suggest that current MMP inhibitors do not have relevant antitumor activity in patients with advanced pancreatic cancer. Whether or not these drugs or newer generation analogs would be effective in earlier stages of pancreatic cancer remains to be determined.

Angiogenesis Inhibitors

Pancreatic cancer is not an exception to the rule that tumors require the generation of blood vessels to grow, invade, and metastasize. The drug of this class that appears more promising in pancreatic cancer is bevacizumab, a recombinant human monoclonal antibody against vascular endothelial growth factor (VEGF), a growth factor that has been implicated in pancreatic cancer progression in several preclinical studies. Bevacizumab has been studied in combination with gemcitabine in a Phase II study in patients with pancreatic cancer.¹¹⁴ Patients with advanced or locally advanced pancreatic cancer received gemcitabine 1,000 mg/m² on days 1, 8, and 15 every 28 days and bevacizumab 10 mg/kg intravenously on days 1 and 15. Results on the first 45 evaluable patients have been reported with a response rate of 21%, median survival of 9 months, and an estimated 1-year survival of 37%. Correlative studies suggest that patients with higher baseline levels of VEGF tend to do worse.¹¹⁵ The Cancer and Leukemia Group B (CALGB) is currently leading a phase III study of gemcitabine ± bevacizumab.

Inhibitors of the Oncogene Ras

Mutation in the oncogene Ras is the most frequent genetic abnormality in pancreatic cancer. Because Ras requires to be farnesylated to be active, a posttranslational modification mediated by the enzyme farnesyl transferase, inhibitors of this enzyme have been developed as potential Ras inhibitors.¹¹⁶ Two of these agents, tipifarnib and lonafarnib, have been studied in disease-oriented studies in pancreatic cancer. Tipifarnib was tested in a single-agent Phase II study

in patients with advanced pancreatic cancer administered at a dose of 300mg orally twice a day. Twenty patients were treated with no objective responses and a median survival of less than 5 months. Correlative studies conducted in peripheral blood mononuclear cells demonstrated partial inhibition of the target farnesyl transferase enzyme.¹¹⁷ In parallel to this study, a randomized Phase III study compared the combination of R115777 with gemcitabine against gemcitabine plus placebo in patients with advanced pancreatic cancer. Treatment of 688 patients did not demonstrate any improvement in outcome in patients treated with R115777 and gemcitabine.¹¹⁸ Lonafarnib was evaluated in a randomized Phase II study in comparison to gemcitabine. The 3-month progression-free survival rate for patients treated with lonafarnib was 23% and 31% for gemcitabine, and the median overall survival was 3.3 and 4.4 months, respectively. There were two partial responses in patients treated with lonafarnib and one partial response observed in 1 patient treated with gemcitabine. Overall, lonafarnib was better tolerated than gemcitabine in that study.¹¹⁹

Inhibitors of the EGFR Family of Receptors

The epidermal growth factor receptor (EGFR) family of receptors is formed by four related transmembrane receptors that are composed of an external ligand binding domain, a transmembrane domain, and an intracellular domain with tyrosine kinase (TK) activity. These receptors are frequently dysregulated in cancer and have been associated with the process of tumor growth, invasion, and metastasis, exciting considerable interest in developing these drugs for cancer treatment. Pharmacologically, the inhibitors of the EGFR belong to two broad classes of drugs including monoclonal antibodies against the extracellular domain of the receptor and small molecules inhibitors of the intracellular TK domain.¹²⁰ The studies conducted in pancreatic cancer have mainly tested the combination of these drugs with gemcitabine. Safran and collaborators reported a Phase II study of trastuzumab, a monoclonal antibody that targets the Her-2 receptor, in combination with gemcitabine in patients with pancreatic cancer.¹²⁰ Up to 21% of pancreatic cancers are Her-2 positive, and preclinical studies have shown that inhibition of Her-2 signaling with trastuzumab is associated with antitumor effects in pancreatic cancer models. Patients with Her-2-positive (2 or 3 + as determined by immunohistochemistry) pancreatic cancer received gemcitabine, 1,000mg/m² weekly for 7 consecutive weeks followed by 1 week of rest and then weekly for 3 weeks every 4 weeks, and trastuzumab, 2mg/kg/week following an initial loading dose of 4mg/kg. Data on 23 patients have been reported thus far. Five patients had a partial response (response rate, 24%), and the median survival and 1-year survival were 7.5 months and 24%, respectively. Nine of 18 evaluable patients (50%) have had greater than 50% reduction in CA 19-9. A Phase II study of gemcitabine and cetuximab, a monoclonal antibody against EGFR, in EGFR-positive pancreatic cancer patients was conducted. Forty-one patients were treated in the study. The overall response rate was 12.5% with a median survival of 7.1 months and 1-year survival of 32%.¹²¹ The Southwest Oncology Group (SWOG) is currently leading a Phase III study of gemcitabine ± cetuximab.

The second clinically relevant classes of agents that inhibit the EGFR are small molecule inhibitors of the receptor TK. Several of these agents are currently in clinical development. Two of these compounds, EKB-569 and erlotinib, have been specifically developed in pancreatic cancer. EKB-569, an irreversible inhibitor of EGFR and the Her-2 receptors, has completed a Phase I study in combination with gemcitabine, and a randomized Phase III study through NCI-Canada of gemcitabine plus erlotinib or placebo has completed enrollment.

Future Directions and Conclusions

The principal need to identify more effective therapies to supplement surgical gains in resected patients is unchallenged. What remain unresolved and controversial are the means to this end. Progress in the context of adjuvant trials has been slow. Current controversies may result in part from trial design issues, inadequate consideration of factors other than therapy that may impact on outcomes, and the limited efficacy of single chemotherapeutic agents for pancreatic cancer.

Current efforts are aimed at refining our understanding of the impact of nontherapeutic factors on outcomes (stratification factors for future trials), proceeding to multiagent chemotherapy alone or in combination with irradiation, identifying pancreatic tumor-specific antigens that provide an opportunity for molecular target-based drugs or immunotherapy, and identifying accurate predictors of microscopic disease and of response to therapy.

For metastatic disease, understanding of the molecular pathways that are thought to drive cellular growth is at the heart of the new paradigm of drug development. The utilization of xenografts to rapidly and efficiently screen drugs as well as improved collaboration with industry provide some promise that better therapies are on the horizon.

Renal Cell Cancer

Joseph I. Clark, Craig Hofmeister,
Vicki Keedy, and Jeffrey A. Sosman

More than 80% of tumors originating in the kidney are renal cell carcinomas. Tumors of the renal pelvis make up another 10%, and the remaining tumors include a variety of rare lesions such as collecting duct carcinomas, renal sarcomas, or other rare epithelial tumors. This chapter presents evidence-based literature only for renal cell carcinoma and its histologic subtypes.

Epidemiology

Renal cell cancer (RCC) is responsible for approximately 2% of the total incidence and mortality caused by cancer in the United States in 2004.¹ During the past 30 years, based on the Surveillance, Epidemiology, and End Results (SEER) program of the National Cancer Institute (NCI), which covers about 10% of the U.S. population, there has been a rising incidence of renal cell carcinoma.² There will be an estimated 35,700 newly diagnosed cases of renal cancer and another 12,800 deaths during 2004, compared with an incidence of 27,000 and mortality of 10,900 in 1993. The increases over the 20 years in the SEER database (1975–1995) were observed in both genders and in both black and white populations. The upward incidence of advanced RCC with increased mortality is certainly not simply the result of detection of tumors in the presymptomatic stage. The reasons for this rise in RCC are not obvious and are likely multifactorial. The main risk factor for RCC, tobacco abuse, actually decreased in incidence during this time frame. Whether there are other identifiable environmental factors is unknown, but this is significant as understanding may lead to prevention (primary and secondary) strategies for RCC. Last, it is well known that the incidence of RCC in male subjects is twofold that of female subjects. The median age of diagnosis is around 64 years for Caucasians and 58 years for African-Americans. It is unusual to see the occurrence of RCC in individuals below the age of 40 years. The 5-year survival for all RCC is between 50% and 60%. This rate is lowest among African-American men, based on SEER data from 1985 to 1996. Although 5-year survival has improved for Caucasians, this has not been true for African-Americans. The increase in cancer-related mortality due to RCC has been most apparent in the African-American populations.

A number of studies have examined the association of environmental factors and renal cancer. The largest cohort trial involved 363,000 adult men enrolled from 1971 to 1992 in Sweden. The increased risk of RCC has appeared to meet

the required level of significance only for three risk factors: cigarette smoking, obesity, and hypertension (Tables 46.1, 46.2, 46.3).^{3,4} In general, cigarette smoking is a more significant factor in men whereas obesity is more of an important factor for women. Even though there is an increase in risk associated to all three factors, the relative risks are small compared with other cancers (see Table 46.1) (1.2–2.5). For example, cigarette smoking has a greater relative risk in transitional cell cancer of the renal pelvis (greater than 3.5). Smoking has been calculated to account for 20% to 30% of RCC in men but only 10% to 15% of the incidence in women.

Genetic Association

There is a distinct familial or hereditary component in only around 4% of renal cancers (Table 46.4). In general, these renal cancers are distinguishable by their early age of onset, multiplicity, bilaterality, and their equivalent male:female distribution.⁵ The other distinguishing factors include an association with distinct syndromes involving other cancers or other organ abnormalities. The syndromes include von Hippel–Lindau, tuberous sclerosis, and Birt–Hogg–Dube syndrome. All three are autosomal dominant in their transmission.^{5–8} Additionally, familial RCC can manifest itself more restrictively in the kidneys alone, such as hereditary papillary RCC (type I), familial renal oncocytoma, and finally hereditary and familial clear cell RCC (with or without chromosome 3 translocation).^{5,9–11}

von Hippel–Lindau disease (VHL) is an autosomal dominant disease with prevalence in North America or Europe of 1 in 36,000 to 40,000.^{6,12,13} Although clear cell carcinoma of the kidneys is a prominent manifestation in 28% to 45% of the cases, there are a large number of associated characteristics including retinal angiomas, cerebellar and spinal heman-gioblastomas, pheochromocytomas, pancreatic cystic disease (serous cystadenomas), pancreatic neuroendocrine cancers, endolymphatic sac tumors of the labyrinth of the inner ears, epididymal cystadenoma, and renal cystic disease. The VHL gene, mutated in the germ-line VHL patient on chromosome 3p25, is accompanied by the loss of the other allele in the tumor consistent with VHL being a tumor suppressor gene (TSG).^{14,15} This same gene is mutated, deleted, or not expressed in 55% to 85% of sporadic RCC of the clear cell type, emphasizing its importance to the general pathogenesis of clear cell RCC.¹⁴ The protein product of the gene, pVHL, binds to a complex of proteins including elongin B, C, and Cul2 to form an ubiquitin ligase that facilitates ubiquitin-

TABLE 46.1. Cigarette smoking and renal carcinoma.

Reference	Type of study	Number of patients [renal cell carcinoma (RCC)/control]	Relative risk	Association with exposure	Summary	Importance
210	Case-control/ population based	1,732/2,309	1.4 current smokers 1.1–2.1 for <10 to >20 cigarettes/day	Yes	Adjusted for age, gender, body mass index (BMI)	Smoking is responsible for attributable for 24% in men and 9% in women
211	Case-control/ population based	495/697	1.6 ever smoked 1.2–2.3 for <20 to >50 pack-years, men 1.9 ever smoked, women	Yes	More significant risk for men and women	30% in men and 24% in women, attributable risk due to smoking
212	Case control/ population based	518/1,381	2.0 and 2.3 for ever and current smokers, men 1.9 and 2.2 for ever smoked and current smoker, women	No; no trends with amount of smoking	Risk increase after 20 years and decline after stopping for 20 years	No trend with amount of smoking is concerning

TABLE 46.2. Obesity and renal carcinoma.

Reference	Type of study	No. of patients (RCC/control)	Relative risk	Summary	Importance
210	Case-control/ population based	1,732/2,309	1.6 BMI highest quarter, men 2.0 BMI highest quarter, women	Significant trend in women; rate of weight change in women	Important primarily in women; no effect of height or physical activity
212	Case-control/ population based	518/1,381	2.2 BMI highest quarter	Effect in both women and men, with trend; recent weight in women; earlier weight in men	Importance in both genders
3	Cohort study based	102 RCC from 46,827 hospital-discharged patients, 1977–1987, Denmark	2.67 risk obesity in women 1.52 risk obesity in men	Cohort trial: but diagnosis-only based on hospital discharged	Prospective: effect greatest in women

TABLE 46.3. High blood pressure (hypertension) and renal carcinoma.

Reference	Type of study	No. of patients (RCC/control)	Relative risk (RR)	Summary	Importance
210	Case-control/ population based	1,732/2,309	1.7 Hypertension	Antihypertensive effects adjusted for; then 1.4 risk	Diuretics not a risk factor; possible role for beta-blockers
4	Cohort	759 from 363,992 men Sweden	RR approximately 2.0 Almost 70% on diuretics	Cohort trial, significant risk for RCC with hypertension (HTN) Role of drugs to treat	Important based on prospective nature of study; difficult to adjust for other factors
213	Case-control nested in cohort	206/206	RR 2.0 men RR 1.9 women	Diuretic use and beta-blocker use appear to play major role	RR of HTN without anti-HTN agents-only 0.8 Role of drugs more pronounced in women

^aIn addition, balanced translocations between chromosome 3 and other chromosomes have been reported in some families.

^bDerived from linkage analysis of one family with FPTC-PRN.

^cThese two genes account for 70% of cases.

mediated degradation of cellular protein through the proteasome.^{16,17} A key protein that requires this complex for its breakdown and rapid turnover is hypoxia-inducing factor-1 α (HIF-1 α).¹⁸⁻²⁰ When the pVHL is not present or not functioning correctly, the presence of HIF-1 α builds up within the cell, binds to its partner HIF-1 β , crosses into the nucleus, and then as a transcription factor activates a number of downstream genes important to the cellular response to hypoxia. The downstream genes appear critical to mechanisms of oncogenesis in clear cell RCC, including VEGF (vascular endothelial growth factor), EGF (epidermal growth factor), TGF- α (transforming growth factor- α), EGFR (epidermal growth factor receptor), PDGF- α/β (platelet-derived growth factor- α/β), erythropoietin (EPO), GLUT1, and carbonic anhydrase IX (CAIX).²¹⁻²³ HIF-1 α and its activated downstream genes are critical to the pathophysiology of RCC and offer therapeutic targets (discussed later).

Tuberous sclerosis complex (TSC) is an autosomal dominant neurocutaneous syndrome with a high degree of variability in clinical manifestations.^{7,24} The incidence is estimated at 1 in 10,000 based on wide screening. There are a number of cases that are sporadic without a definite family history. Two genes, TSC1 and TSC2, are responsible for the manifestations of the complex.²⁵ These are both considered TSG, with TSC1 located on 9q34 coding for a protein, hamartin, and TSC2 located on 16p13.3 and coding for a protein tuberin. In the kidney, the predominant manifestation of TSC is the development of multiple angiomyolipomas (AML). These *benign* tumors can displace all the functioning kidney and lead to renal failure or cause catastrophic

hemorrhage. Additionally, TSC patients also manifest large renal cysts and finally an increase in renal cell cancers. The histology of these RCC covers a wide spectrum including clear cell, papillary, chromophobe, and even oncocytomas. Renal cell cancer is found in 2.5% to 4.0% of patients with TSC.

Birt-Hogg-Dube (BHD) is an autosomal dominant syndrome associated with inherited internal cancer, primarily renal cancers.^{8,26} The most prominent features of the BHD syndrome are the skin and skin appendage triad of fibrofolliculomas (hair follicle tumors), trichodiscomas, and acrochordons. The renal tumors may vary from chromophobe or mixed chromophobe-oncocytomas, papillary, and clear cell. The mutation has been identified on 17p11.2, and the gene product is known as folliculin. Renal cysts, colonic cancers and polyps, and multiple lipomas have also been associated with BHD.

Hereditary papillary RCC (HPRCC) is a familial cancer syndrome characterized by papillary RCC (type I).²⁷ There are two types of papillary RCC,^{28,29} which are differentiated by their different histologies. Type I contains basophilic, small cells and, in the core of the papillae, foamy macrophages and psammoma bodies. Type II has large, eosinophilic cells lining the papillae. The type I lesions are seen in hereditary papillary RCC. In sporadic cases of papillary RCC, those cancers with type I histology appear less aggressive than those with type II histology. HPRCC is also associated with a number of other cancers including breast, pancreas, lung, skin, and stomach. It has been characterized primarily as showing a gain of function mutation in the oncogene *c-met*.^{9,27} The gene

product is a tyrosine kinase-associated cell-surface receptor for hepatocyte growth factor or scatter factor.

Familial non-VHL clear cell RCC ± chromosomal 3 translocation is a well-recognized syndrome characterized more than 20 years ago.^{9,30} We now know the translocation involves the 3p14, and in one family the FHIT gene is directly involved in the translocation.⁵ The familial CCRCC without chromosomal 3 translocation fails to present at an early age and is rarely bilateral or multiple.

More recently, rare syndromes have been described and genetically mapped. Familial renal hamartomas associated with hyperparathyroidism-jaw tumor (HPT-JT) (1q21–32) is associated with papillary RCC (type I); hereditary leiomyomatosis and renal cell cancer (HLRCC) (1q42–44) are associated with papillary RCC (type 2) and uterine leiomyomas and leiomyosarcomas, breast cancer, and bladder cancer.¹⁰

Pathology

International agreement has been reached on the histologic classification of renal cortical epithelial neoplasms based on light microscopy.³¹ Histologic classifications have subsequently been consistent with the molecular genetics of renal cancer.^{12,31,32} Renal tumor classifications segregate with their observed genetic abnormalities. Some terms previously used to describe certain morphologic features such as granular or cystic have been eliminated, and most are now classified within the major histologic subtypes: clear cell, papillary, and chromophobe. Sarcomatoid remains, not as a separate identity, but instead as a high-grade variant of any histologic subtype.

Oncocytomas represent about 5% of renal cortical neoplasms³³; they are typically large and have a central stellate scar. The histology of these benign tumors includes cells arranged in islands, solid sheets, tubules, or cysts. The tumor cells show a prominent eosinophilic cytoplasm due to the abundance of mitochondria. They are not graded by their benign behavior but must be differentiated from the chromophobe and clear cell renal cancers when providing a differential diagnosis.

Clear cell carcinoma is the conventional neoplasm associated with the renal cortex in adults³⁴ and represents at least 70% of renal cortical neoplasm. Most have a clear cytoplasm but some are either eosinophilic or granular. Some cases have an abundance of cystic structures lined by small clear cells. The *cystic* clear cell renal cancer must be 75% composed of cystic structures to meet the definition; these are usually both low grade and low stage with a generally good prognosis. As stated elsewhere in this chapter, the loss of genes on the 3p chromosome is a frequent finding in sporadic clear cell cancer. The predominant lesions include the loss of the VHL gene, VHL gene mutation, or even VHL gene inactivation through regulatory CpG islands that are hypermethylated.³⁵ One of these processes leads to the loss of functional VHL protein in most (more than 75%) of clear cell renal cancers. A small (5%) number of cases may have sarcomatoid change in areas of the tumor. This feature in itself represents a very high grade tumor with a poor prognosis.

Papillary renal cell carcinoma (PRCC) accounts for 15% of renal cortical cancers and includes those lesions that in the

past would have been called chromophilic.^{28,29} These neoplasms are highly associated with certain cytogenetic changes whether or not papillary architecture is observed. Genetic abnormalities not only include trisomies of 7 and 17 but also abnormalities of 3q, 12, 16, and 20 and loss of Y chromosome.^{11,36} Delahunt and Eble have proposed the existence of two PRCC subtypes, type 1 with papillae covered by a single or double layer of small basophilic cells with scanty cytoplasm and type 2 with papillae covered by cells with abundant eosinophilic cytoplasm, arranged in a pseudostratified or irregularly stratified manner.³⁷ Studies show the tumor stage at diagnosis is significantly higher in type 2 than in type 1 PRCCs, suggesting these subtypes could be clinicopathologic entities with a different prognosis.²⁹ Also, it has been found that the more-common type I variant of papillary renal adenocarcinoma was less vascular on computed tomography (CT) scan, larger in size, and had a lower amount of nuclear pleomorphism as well as decreased expression of cytokeratin 7. The more-aggressive biologic variant, type II, presents in the earlier decades of life, with a smaller but more-vascular cancer with greater nuclear pleomorphism.

Chromophobe renal carcinoma accounts for 5% of the renal cell carcinomas.^{38,39} The cytoplasm is full of a number of microvesicles and stains blue with a colloidal iron stain. Around the nucleus there is a halo caused by cytoplasmic condensation. The major dilemma is differentiating this neoplasm from oncocytoma. Oncocytomas may also stain with the iron stains, but their staining pattern is membranous, not cytoplasmic.

Collecting duct carcinoma is a rare and high-grade neoplasm that represents less than 1% of primary renal cortical neoplasms.⁴⁰ It can be difficult to recognize but usually demonstrates very irregular epithelial-lined channels in the background of extensive fibrosis and stroma. The cells have a hobnail appearance. These tumors can be accompanied by areas of renal parenchyma with dysplastic collecting duct epithelium, the tissue of origin.

Grading of Renal Cell Carcinoma

It has been known for a number of decades that grading of renal cell carcinoma is of great importance to the prognosis and outcome of disease.^{2,34,41} The Fuhrman grading system is the predominant approach to grading done in the United States. Grades I through IV are based on size (10–20 μm) and shape of nuclei, prominence of nucleoli, and admixture of bizarre pleomorphic cells. Grade IV cytology can frequently include polylobulated and spindle-shaped nuclei. There have been difficulties in separating outcome for each individual grade, especially grade II–III. Grade I tumors do quite well whereas grade IV tumors present at an advanced stage and have a very dismal prognosis. The main issues relate to grade I versus II and grade II and III. Survival advantages have been seen with multiple cutoff points; between I and II; between III and IV; or between II and III in various studies. Grading has also been difficult to reproduce even among expert pathologists. It is likely refinement and use of molecular markers will have to occur in the future to make this system more practical and improve our ability to define the significance of each grade.⁴² Other histologic characteristics that have been suggested as helpful in staging include

mitotic rate, microvasculature presence, and microvessel density.

In the future, it is likely that pathologists will characterize RCC not by histologic appearance or even by cytogenetic or specific chromosomal changes, but instead by utilizing gene expression patterns of thousands of genes or even complex arrays of protein expression patterns. The group at the National Cancer Institute (NCI) led by Marston Lineham examined 58 fresh specimens from renal cancers.⁴² They found a set of 45 genes could predict survival outcome as an independent factor. Of this set of genes, only a few genes or gene products appeared critical. VCAM-1 appeared to be the most important gene in predicted outcome.⁴² Upregulation of VCAM-1 was associated with a better prognosis whereas downregulation was associated with a poor prognosis. Other data obtained in a set of clear cell RCC-VHL-expressing cell lines suggest that CXCR4 downregulation was associated with a poor prognosis and regulated by VHL expression.⁴³ Finally, others have shown that global gene expression patterns could accurately predict the histologic subtype of renal cancer.⁴⁴ This approach may ultimately direct us to genes and proteins that may be ideal for molecularly targeted treatment.

Molecular Pathogenesis

Clear Cell Carcinoma

A major breakthrough in renal cancer biology came when the von Hippel-Lindau (VHL) gene was cloned in 1993.¹³ This tumor suppressor gene (TSG) was cloned by positional cloning knowing that the gene had to be within the 3p25–p26 region of the chromosome. Loss of the gene was demonstrated among translocations and deletions, as well as mutations, all consistent with its possible role as a TSG. Even at this early point intragenic mutations were found in cell lines derived from sporadic renal cancer in addition to the cell lines from VHL patients.¹³ Initially, there was little understanding of biology gained from the pVHL structure. It was a gene that was definitely evolutionarily conserved. It was also known that in CCRCC with VHL defects a number of growth factors and their receptors were highly expressed. A critical molecule regulating the expression of these genes or the genes induced by hypoxia was hypoxia-inducing-factor-1 α (HIF-1 α).^{23,45,46} Furthermore, it was known that HIF-1 α was increased in hypoxic situations and in renal cancer cell lines because of an increase in its protein stability. Although in normal cells this increased stability was known to occur only in hypoxic situations, in RCC cells it occurred under normoxic conditions. HIF-1 α was a key component of a very widespread oxygen cellular response mechanism.^{45,46} Ultimately, it was demonstrated that native pVHL binds to HIF-1 α as part of a complex, which led to the ubiquitination of the HIF-1 α protein to allow trafficking to and subsequent destruction by the proteasome. In normal cells with adequate oxygen, the hydroxylation of pVHL allowed for its binding to HIF-1 α , again allowing for rapid degradation of HIF-1 α . This oxygen-sensing and -regulating system is disturbed and dysfunctional in tumors from VHL patients, as well as in a large number of sporadic RCC. The implications are obvious (Figure 46.1): the induction of gene expression for a large number of genes regulated by HIF-

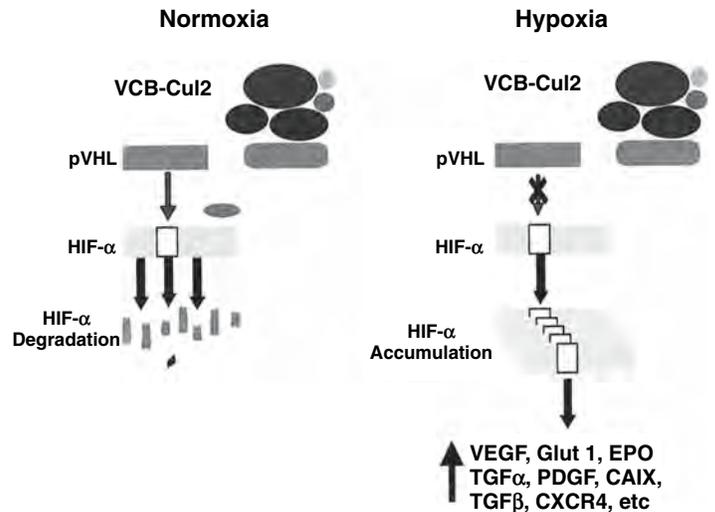

FIGURE 46.1. Von Hippel-Lindau disease (VHL) regulation of hypoxia-inducible factor (HIF)-1 α and the downstream expression of HIF-1 α -controlled genes.

1 α including VEGF, EPO, Glut-1, PDGF α/β , TGF α , TGF β , CRCX4, and CAIX, plus many others. The overexpression of these factors and their receptors leads to many manifestations of clear cell carcinoma of the kidney (CCRCC), including its intense vascularity. The frequency of VHL gene mutation, deletion, or suppression by epigenetic mechanisms in sporadic RCC has been debated but has been estimated to be as high as 85% to 95% and as low as 55%. There may even be prognostic implications to the status of the VHL gene (mutated, deleted, or not expressed through epigenetic changes).⁴⁷

It has been known that, besides VHL, there were other regions in chromosome 3p lost in RCC. A gene deleted (3p21.3) in a number of both clear cell and papillary renal cancer is the RASSF1a (Ras association family 1A gene).⁴⁸ This RASSF1A gene is frequently silenced because of the hypermethylation of its promoter region. RASSF1A has been shown to interact with Ras in its mutated form, potentially mediating some of the downstream effects.⁴⁹

Finally, sporadic papillary renal cancer only rarely has mutations in the *c-met* gene, which is frequently mutated in familial papillary RCC. *c-met* has even been shown to be overexpressed in some of the papillary RCC cases. Therefore, only the RASSF1A gene has been identified consistently in sporadic papillary renal cancer.

Clinical and Laboratory Features

Renal cell cancer is an unpredictable tumor. The minority of patients present with the classic triad of flank pain, hematuria, and a palpable abdominal mass. Paraneoplastic syndromes are well described and some may be secondary to the loss of a functional VHL protein increasing levels of HIF-1 α . Further discoveries in the basic biology of RCC may help explain the myriad of signs and symptoms from which other patients suffer.

Local Symptoms from Primary

The principal presenting complaints of renal cell cancer are hematuria, abdominal pain and mass, and/or symptoms and signs related to invasion of adjacent blood vessels or distant metastases. The classic triad of flank pain, hematuria, and a palpable abdominal mass occurred together in only 9% of patients in a 1971 review of 309 patients⁵⁰ and is likely even less frequent at present. With an increase in incidental diagnoses, it might be better termed the *radiologist's tumor*.

Metastatic Disease

Older series report that approximately 25% of patients present with either distant metastases or advanced locoregional disease. Historically, metastatic disease often presented with a wide array of symptoms and laboratory abnormalities such that renal cell carcinoma was termed "the internist's tumor."

Frequent sites of metastases include the lung, bone, lymph nodes, pleura, brain, ipsilateral adrenal gland, and liver.

Paraneoplastic Syndromes

A large amount has been written about paraneoplastic syndromes despite little knowledge of these syndromes or their etiologies.⁵¹ Still, a minority of patients with renal cell carcinoma develop paraneoplastic syndromes.

Without bony metastases, hypercalcemia is one of the most common of the paraneoplastic syndromes, affecting up to 20% of patients via increased production of parathyroid hormone-related peptide, osteoclast-activating factor, transforming growth factor- α , and/or tumor necrosis factor.⁵² The main hypercalcemic factor identified in patients with solid malignancies and hypercalcemia has been parathyroid hormone-related protein. Metastatic renal cell carcinoma complicated by hypercalcemia has been found to shorten survival, and it represents one of the five poor prognostic factors incorporated into Motzer's model (see following).^{53,54}

Renal cell carcinoma can be associated with increased production of inflammatory cytokines,⁵⁵ and the subsequent inflammation leads to a number of signs and symptoms. Fever is usually intermittent and is frequently accompanied by night sweats, anorexia, weight loss, fatigue, and cachexia. Anemia of chronic inflammatory disease can frequently precede the diagnosis of renal cell carcinoma by a number of months.

An often-discussed but not very often seen paraneoplastic manifestation is erythrocytosis. The loss of the protein product of the VHL gene, pVHL, is common in sporadic clear-cell renal carcinomas. Therefore HIF-1 α accumulates and activates the transcription of hypoxia-inducible genes, including erythropoietin. The overproduction of erythropoietin accounts for the association of paraneoplastic erythrocytosis with kidney cancer and hemangioblastoma.⁵⁶ The much less frequent overproduction of a soluble VEGF receptor may lead to the paraneoplastic hypertension and proteinuria.^{56,57}

A recognized syndrome of hepatic dysfunction in the absence of liver metastases (Stauffer's syndrome)⁵⁸ has been

reported to occur in up to 20% of patients with renal carcinoma. Hepatosplenomegaly, fever, elevated alkaline phosphatase levels, prolonged partial thromboplastin time, and elevated serum haptoglobin levels characterize this idiopathic syndrome. As an example among 365 patients in one report, 77 (21%) had a paraneoplastic elevation in the serum level of alkaline phosphatase. When present, it is frequently observed in association with fever, weight loss, and fatigue.⁵⁹

Staging

Computed tomography (CT) scan of the abdomen is generally the first noninvasive staging tool used in renal cell carcinoma. The urologist in planning the surgical approach often uses magnetic resonance imaging (MRI) to evaluate renal vein and inferior vena cava (IVC) involvement.⁶⁰ For staging, it is required to evaluate the extent of vascular invasion from the tumor when present. Preoperative staging may or may not include a CT of the chest. A bone scan should only be considered in patients with bone pain or an elevated serum alkaline phosphatase.⁶¹

Systems

Tumor stage, which reflects the anatomic spread and involvement of disease, is recognized as the most important prognostic factor for the clinical behavior and outcome of RCC.⁶² The Robson's classification, which includes consideration of vascular involvement, is often cited in the literature and can be compared with the tumor, nodes, and metastasis (TNM) staging system proposed by the International Union Against Cancer in Table 46.5.⁶³

Initially, the Robson staging system was widely used; however, it was subsequently demonstrated to correlate poorly with prognosis.⁶⁴ Patients with renal vein involvement (Robson stage IIIa) but with cancer confined to the kidney had similar survival rates when compared with patients whose disease were confined to the renal capsule (stage I) or Gerota's fascia (stage II). In contrast, the TNM system emphasized local growth, nodal spread, and distant metastasis and therefore more accurately classifies the extent of tumor involvement.⁶⁴ The 2002 TNM classification system⁶⁵ is summarized in Table 46.6.

TABLE 46.5. Robson staging compared to the 1997 TNM staging: tumor stage for renal cell carcinoma.

<i>Robson stage</i>	<i>TNM (1997)</i>	<i>Disease extent</i>
I	T1-2N0M0	Organ confined
II	T3aN0M0	Perinephric fat or adrenal involvement
IIIa	T3b-cN0M0	Venous involvement
IIIb	TxN+M0	Lymphatic involvement
IVa	T4N0M0	Locally advanced
IVb	TxNxM+	Systemic metastases

Nephrectomy for Primary Therapy

Renal cell carcinoma is not the only malignant lesion in the kidney. In addition, any number of benign cysts, adenomas, and lipomas can arise from the renal parenchyma and are frequently seen incidentally on radiographic imaging. Malignant renal tumors in children include Wilms' tumors, neuroblastomas, and rhabdomyosarcomas, whereas sarcomas, lymphomas, metastatic lesions, renal pelvis transitional cell cancer, and renal cell carcinomas account for most adult kidney cancers.

The surgical approach and the extent of resection should be based primarily on the size of the primary tumor. Patients with T1 tumors should be considered for partial nephrectomy.

Any tumor T2 or above by preoperative staging should undergo a radical nephrectomy, if feasible by the least invasive method possible. Those with radiologic evidence of abdominal lymphadenopathy should still be offered a radical nephrectomy as suspicious nodes are often enlarged because of reactive inflammation.

Radical Nephrectomy

The results from a retrospective study by Robson et al.⁶³ of 88 cases operated on from 1949 to 1964 set the standard for oncologic care from simple to radical nephrectomy. Simple nephrectomy is performed through the lumbar approach. Perinephric tissue is removed only if the tumor extends visually beyond the renal capsule and the adrenal gland is removed only if there was an upper pole lesion. Radical nephrectomy begins with a thoracoabdominal, extrapleural supracostal, or anterior transabdominal approach to the medial border of the tumor, followed by dissection of the renal vein and artery. These vessels are then ligated early to prevent putative tumor emboli, the kidney is removed without incising Gerota's fascia to theoretically reduce the risk of tumor seeding, the ipsilateral adrenal gland is removed, and the paraaortic and paracaval nodes are dissected. Dr. Robson reported tumors isolated to the kidney in 33 patients, to the perirenal fat in 15, and spread to the vessels or lymphatics in 27, and distant metastases present in 12 patients, with 5-year survivals at 66%, 64%, 42%, and 11%, respectively. Dr. Robson reported the superiority of the overall 52% 5-year survival compared with the 40% to 50% survival of simple nephrectomy in four other published reports from 1939 to 1966. His retrospective study was later supported⁶⁶ and disputed^{50,67} by other retrospective studies, a prospective randomized study was never published, and radical nephrectomy became the standard of care mostly for theoretical reasons.

Since the publication by Robson et al. in 1969, the procedure for radical nephrectomy has been significantly refined with regard to removing the adrenal gland, dissecting regional lymph nodes, and in evaluating and removing tumor thrombus. Adrenalectomy is now limited to patients with large upper pole tumors, those with solitary metastasis identified by preoperative staging to the ipsilateral adrenal gland, or when the adrenal gland is displaced or not identified on preoperative imaging. A normal-appearing adrenal gland visualized preoperatively by CT essentially rules out neoplastic adrenal involvement.⁶⁸ Renal cell carcinoma that has spread to local lymph nodes not only defines a higher stage but also may be indicative of a tumor that is less likely to respond to therapy. In fact, there is some evidence that patients with regional nodal metastases have a shorter survival than those with distant metastases without regional node disease.⁶⁹ Lymphadenectomy at the time of nephrectomy may improve response to subsequent immunotherapy⁷⁰ but is rarely a part of a curative procedure.⁷¹ Finally, renal cell carcinoma is complicated by tumor thrombus involving the inferior vena cava or right atrium in 5% to 10% of cases.⁷² Small studies support the use of MRI to evaluate the presence and extent of associated tumor thrombi.⁶⁰ Simple thrombectomy may suffice for patients with thrombus extending below the major hepatic veins, whereas for thrombi located above the major hepatic veins, cardiopulmonary bypass and hypothermic circulatory arrest may be required for complete resection.⁷³

Partial Nephrectomy

Since Robson et al. published their landmark papers^{74,75} proposing radical nephrectomy as the new standard for renal cell carcinoma, the incidence of incidentally discovered tumors has increased,⁷⁶ along with technologic advances allowing partial nephrectomies with less risk of renal insufficiency⁷⁷ and laparoscopic surgeries with shorter hospital stays and less pain than standard laparotomies.⁷⁸

Partial nephrectomy is performed with a close eye on reducing damage to the uninvolved kidney while performing an oncologically sound procedure. Generally an extraperitoneal flank incision through the bed of the 11th or 12th rib is performed, the kidney is mobilized within Gerota's fascia while leaving the perirenal fat intact, and the renal artery is interrupted. The renal vein remains patent to reduce ischemic damage. The kidney is then cooled with ice slush for 10 to 15 minutes and the tumor is excised. Campbell et al.⁷⁹ have previously shown that intraoperative ultrasound can assist in delineating the limit of intrarenal tumors, show collecting system structures, and overall help avoid inadvertent entry into the renal sinus. In patients with sarcomatoid histology on frozen section or with renal vessel invasion, surgery should be extended when possible to a radical nephrectomy as these patients have a higher risk of recurrence and incomplete resection. Although not supported by any prospective studies, retrospective reviews support the notion that the width of the targeted resection margin should be greater than or equal to 3 mm with negative microscopic margins.^{80,81}

The performance of a partial nephrectomy has been the standard of care for select patients with renal cell carcinoma involving an isolated kidney or in patients at high risk of cancer involving the contralateral kidney. However, concerns that such a procedure might put the patient at higher risk for recurrence have hindered its widespread use.

Partial nephrectomy should be considered in the following clinical situations:

1. Renal masses less than 4 cm (T1) or those located within the cortex where up to 23% have been reported to be benign.⁸² Several groups have recommended that tumors less than 4 cm be considered for partial nephrectomy as the chance for disease-free survival is greater than 95%.^{82,83}
2. Mass in a patient with a single kidney or with compromised renal function.⁸⁴
3. Synchronous bilateral renal tumors or patients with von Hippel–Lindau syndrome at high risk of renal cell cancer in the contralateral kidney.⁸⁵ One prospective study in 96 patients with von Hippel–Lindau disease or hereditary papillary renal cancer recommended a maximum size of 3 cm by preoperative staging for patients sent for partial nephrectomy to minimize the need for more-frequent surgery.

Partial nephrectomy is not without potential complications: one study reported urinary fistula, acute tubular necrosis, need for temporary dialysis, and the requirement of permanent dialysis in 7.4%, 6.3%, 4.9%, and 1.9%, respectively. The risk of worsened renal insufficiency or failure is approximately 5% in an elective partial nephrectomy and may increase to 15% to 20% or more in symptomatic tumors, T2 or larger lesions, lesions that involve excision of more

than 50% of the parenchyma, and when the ischemia time is greater than 1 hour.⁸⁶

The risk of urinary fistula has been reported to range from 2% to 21%. The risk is decreased among subjects undergoing elective surgery after 1988 when the routine injection of methylene blue was initiated to identify anastomotic leaks and for smaller lesions. There is an increased risk in those with tumors larger than 4 cm, central or hilar lesions, and surgery involving reconstruction of the collecting system.⁸⁷

Overall partial nephrectomies should be performed on patients with small tumors, those with impaired renal function, or those with an inherited risk of subsequent renal carcinomas such as von Hippel–Lindau. The approach should be via a standard laparotomy until the laparoscopic technique is proven to be safe.

Laparoscopic Nephrectomy

Laparoscopic nephrectomy, first performed in 1990, represents a reasonable alternative to open radical nephrectomy for patients with renal cell cancers less than 10 cm.⁸⁸ The three laparoscopic approaches to radical nephrectomy are transperitoneal, retroperitoneal, and hand-assisted. The transperitoneal approach provides ample working space, and multiple landmarks are available to guide the surgeon, but it does require reflection of multiple abdominal structures to gain access to the kidney, intracorporeal placement of the specimen in a bag is required, and removing large renal specimens is cumbersome. The retroperitoneal approach is generally a shorter procedure but is technically more difficult and is generally not suited for large renal tumors.⁸⁹ There is no difference in blood loss, complications, pain, or length of stay when compared with the transperitoneal approach⁹⁰ (Table 46.7). The hand-assisted approach involves placing the nondominant hand into the abdomen via an incision below the umbilicus; this may be technically easier than a transperitoneal approach, with an associated shorter operative time,⁹¹ but still requires reflection of multiple abdominal structures and is ill suited for small, thin patients.

Destroying the renal tumor, termed morcellation, before removal allows for a smaller incision, improves cosmesis, and is thought to result in less pain. Meticulous care must be taken to avoid tumor contamination during morcellation; at least one patient with a T3 lesion developed a port site recurrence at 25 months.⁹² One of the disadvantages of morcellation is that the tumor size cannot be determined pathologically although the histology, grade, and stage are still accurate.⁹³ Because of the prolonged operative times, increased expense, risk of tumor contamination, and no proven benefits beyond a smaller incision, intact specimen removal is the more-prudent route.

Laparoscopic nephrectomy has demonstrated similar recurrence rates in retrospective reviews,^{78,94} but no prospective trials have been published. This technique is becoming more popular as the advantages of decreased postoperative analgesia and pain, shorter hospital stays, and improved cosmesis are published and more technical experience is gained with this method.

The maximum tumor size limit for laparoscopic nephrectomy has not been specifically studied, although the maximum tumor diameter generally ranges from 12 to 14 cm in published reports.^{78,95,96} Laparoscopy was initially reserved

TABLE 46.7. Complications of laparoscopic nephrectomy.

Reference	No. (years), indication	Major operative complications
Gill ⁹⁷	185 (1990–1993): 153 benign 32 malignant	6 (3%): 4 bleeding, 1 pneumothorax, 1 small bowel cutaneous fistula Conversion to open in 3 patients due to complications and in 7 because of difficult dissection
Rassweiler ⁸⁸	482 (1992–1996): 444 benign 38 malignant	29 (6%): 22 bleeding, 3 bowel injury, 2 hypercarbia, pleural injury in 1, pulmonary embolism in 1 Conversion to open in 26 patients due to complications and in 20 because of difficult dissection
Ono ²⁰²	60 (1992–1998): All malignant	6 (10%): duodenal injury was treated by open duodenojejunostomy Left renal artery injury, splenic injury, adrenal injury, and periureteral injury were treated laparoscopically One pulmonary embolism
Dunn ²⁰⁹	61 (1990–1999): 46 malignant 15 benign	2 (3%): superior mesenteric artery ligation, renal vein incomplete ligation leading to conversion to open procedure
Chan ⁹⁶	67 (1991–1999) All malignant	3 (4%): bowel injury during morcellation, small bowel obstruction due to an incisional hernia, pulmonary embolus
Kim ²⁰³	114 (1998–2002): 35 radical (LRN) 79 partial (LPN) All malignant	LRN: 4 (11%): 1 mesenteric injury, 1 liver injury, and 2 serosal tear LPN: 3 (4%): 1 lumbar vein tear, 1 splenic capsule tear, 1 ureteral injury

for clinical stage T1–T2 tumors, but pathologic T3 tumors have also been removed laparoscopically.⁷⁸

Tumor Ablation

Cryoablation, radiofrequency ablation, and high-intensity focused ultrasound are three newer, less-invasive strategies that have been developed for small tumors in patients who are not operative candidates. The goal of energy-based tissue ablative procedures is to achieve targeted destruction of a predetermined volume of tissue that would otherwise be excised during a traditional partial nephrectomy, that is, the tumor itself and a surrounding margin of healthy parenchyma.

Cryotherapy-induced cytonecrosis is a sequential two-step process involving the rapid intracellular formation of ice followed by delayed microcirculatory failure, rendering the area necrotic due to ischemia. The most commonly used reagents include liquid nitrogen or argon. Limited experience with cryoablation suggests that it is effective in more than 90% of T1 renal cell cancers, but only limited follow-up data are available.^{97,98}

Radiofrequency ablation utilizes a high-frequency electrical current to create molecular friction, denaturation of cellular protein, and cell membrane disintegration. The threshold temperature necessary for tissue thermal destruction ranges from 40° to 70°C. The use of radiofrequency ablation for kidney tumors is emerging as a viable technique,^{99,100} but this procedure can often be complicated by perinephric hematomas, and viable tumor unfortunately was shown to remain in every patient in one trial.¹⁰¹

High-intensity focused ultrasound is the least invasive ablative technique. Ultrasound frequency beams are generated by a cylindrical piezoelectric element, then focused by a paraboloid reflector. Similar to extracorporeal shockwave lithotripsy, this beam is focused on a lesion to cause localized hemorrhage, coagulative necrosis, and chronic inflammatory infiltration. The size and configuration of the radiolesion are related to ablation time, the amount of delivered energy, the

electrolyte content of the targeted tissue, and the surface area of the electrode. High-intensity focused ultrasound may become an effective technique once the technical problems of protecting against superficial skin burns and incomplete ablation have been solved.¹⁰²

Adjuvant Therapy for High-Risk Renal Cell Cancer

Adjuvant therapy in solid tumors is based on the concept that chemotherapy after a cytoreductive surgery will serve to eliminate micrometastatic disease at a time when the tumor is growing rapidly and is therefore most susceptible to incorporating chemotherapeutic toxins. Unfortunately, no proven adjuvant therapy exists for renal cell carcinoma; in fact, trials using immunotherapy have shown distant metastasis as the most common site of relapse, suggesting that nonselective immune stimulators such as interferons or interleukins are ineffective in micrometastatic disease. Recent trials using autologous tumor cell vaccines provide hope that reeducating the body's immune system to attack this cancer is possible.

Characteristics of High-Risk Tumors

Tumors at high risk of recurrence are generally thought to be ideal candidates for adjuvant therapy. Unfortunately, a number of trials performed to date in renal cell carcinoma have shown no benefit to adjuvant chemotherapy or immunotherapy despite well-done studies on populations at high risk of recurrence (Table 46.8).

Characteristics of high-risk disease are based generally on tumor size and Fuhrman histologic grade, extent of local invasion, ipsilateral adrenal gland involvement, or nodal positivity. Three centers have reviewed their large retrospective database of patients who have undergone nephrectomy as primary curative therapy: Mayo Clinic, Memorial Sloan Kettering Cancer Center (MSKCC), and UCLA (University of

California at Los Angeles).¹⁰³⁻¹⁰⁵ The largest experience reported is that of the Mayo Clinic based on surgery performed from 1970 to 2000.¹⁰³ Their 1,671 clear cell carcinoma patients presented with symptomatic primary disease in more than 70% of the cases. The factors of greatest importance were tumor stage, lymph node status, tumor size (cutoff of 5 or 10 cm), nuclear grade (1-4), and histologic tumor necrosis. All were very significant in a multivariate analysis. By assigning points from 0 to 4 for these characteristics, a prognostic model was developed. Ten-year metastases-free survival could be predicted for three cohorts with low (0-2 points), intermediate (3-5 points), and high (6 points or more) at 92%, 64%, and 24%, respectively. These factors in this model were called the SSIGN score. For T1 lesions alone, both size (0-5 or 5-7 cm) and histologic grade were predictive of recurrence. The MSKCC group reviewed 601 patients who had undergone a nephrectomy from 1989 to 1998 for primary RCC.¹⁰⁴ A normogram was constructed with the factors that were significant by multivariate analysis. The entire groups were generally at an earlier stage than the Mayo study. More than two-thirds of the patients had disease found incidentally without even local symptoms. The normogram included symptoms (none, local, or systemic), histology (chromophobe, papillary, or clear cell), tumor size, and tumor stage including T1, T2, T3a, and T3b/c. Only 66 of the 601 patients had recurred at this time of the analysis, compared with the Mayo database in which 479 of 1,671 patients had recurred. Finally, the UCLA Urology Group has created a prognostic model called UISS.¹⁰⁵ This model has been made applicable for any patient undergoing nephrectomy, whether metastatic or only primary disease. The factors of most significance were included in a multivariate model based on 661 patients undergoing nephrectomy from 1989 to 1999. The overall model included nuclear grade, tumor stage, number of symptoms, nodes involved, and immunotherapy received. However, for primary disease alone, only nuclear grade (0-4) and performance status (0 versus 1 or more) were predictive of survival.

Although trials to detect the benefits of adjuvant therapy for resected renal cell carcinoma have traditionally based their eligibility criteria on tumor size, T3-T4, and the presence of nodal involvement, better indicators for patients who will respond to adjuvant therapy are being developed.

Role for Postoperative Radiation

In the past 20 years, only two poorly designed studies of postoperative radiation therapy after nephrectomy have been pub-

lished, both describing treatment failures similar to previously reported data.¹⁰⁶ Although the more-recent trial¹⁰⁷ suggests that modern radiation therapy is likely safe, no trials have been published to detect its possible benefit, if any, in an adjuvant setting. In addition, studies have shown that patients who relapse after nephrectomy rarely have isolated renal bed lesions and that disseminated disease is the predominant problem.

Adjuvant Immunotherapy

Two adjuvant studies with interferon^{108,109} and one with high-dose interleukin-2 (IL-2)¹¹⁰ have all failed to show any benefit. The most recent controlled trial was conducted by the Cytokine Working Group¹¹⁰ comparing observation to the treatment arm using high-dose IL-2, usually in an intensive care unit to monitor and treat for IL-2-induced capillary leak syndrome. Unfortunately, this trial's statistical power to detect a benefit from adjuvant therapy was hindered by slow accrual and an ambitious predicted clinical benefit using high-dose IL-2. When the study was designed, it was estimated that the 2-year disease-free survival (DFS) after resection of locally advanced RCCa was 40%.¹¹¹ With an estimated accrual of 68 patients with locally advanced RCCa, the goal was to detect an absolute increase in DFS from 40% to 70%. Between September 1997 and June 2002, 69 patients were accrued. At a predefined interim analysis, 16 of 21 patients with locally advanced disease receiving IL-2 experienced relapse, compared with 15 of 23 patients in the observation arm ($P = 0.73$) (Figure 46.2). The study was therefore closed early when the Data Safety and Monitoring Board concluded that the anticipated improvement in 2-year DFS was unattainable even if full accrual occurred.

The largest and most well designed trial to date tested lymphoblastoid interferon in patients who had undergone radical nephrectomy and were found to have unilateral, locally advanced (pathologic stage T3-T4), and/or node-positive renal cell carcinoma conducted under the Eastern Cooperative Oncology Group (ECOG) from May 1987 to April 1992.¹⁰⁹ Two hundred ninety-four patients were randomly assigned to receive up to 12 cycles of interferon- α (IFN- α)-NL or observation until recurrence or progression. Only 70% in the treatment group received completed normal lymphoblastoid therapy, with the remainder withdrawing because of grade 3-4 toxicities. No benefit was seen for disease-free or overall survival. At a median follow-up of 10.4 years, median survival was 5.1 years in the treatment arm and

7.4 years in the observation arm. In patients who recurred, 71% had distant metastases alone, arguing against a significant antitumor effect against micrometastatic disease.

The second trial with interferon, a multicenter Italian trial, began in February 1990 and enrolled 247 patients who had undergone a radical nephrectomy finding pathologic staged T3a/bN0M0 or T2/3N1-M0.¹⁰⁸ One hundred twenty-three patients were treated with 6 million IU IFN α -2b intramuscularly three times per week for 6 months starting within 1 month of surgery. After a median follow-up period of 62 months, relapses occurred in 38 (31%) of the 124 controls and in 51 (41%) of the 123 treated patients. The overall survival probability at 5 years was 67% for controls and 66% for treated patients.

Adjuvant Vaccine Therapy

There are three published large clinical trials using autologous tumor lysate vaccines¹¹²⁻¹¹⁴ after nephrectomy. In a randomized placebo-controlled trial of 120 patients with stage I-III renal cell carcinoma from January 1987 to December 1991,¹¹² 4 weeks after complete resection, patients were randomized to receive three intradermal injections of 10^7 autologous irradiated tumor cells or placebo. The first two injections were mixed with 10^7 viable bacillus Calmette-Guèrin organisms in hopes of boosting the host's immune response. Delayed cutaneous hypersensitivity reactions to autologous tumor cells were demonstrated in 70% of treated patients: 25 of 44 patients at 6 months and 16 of 28 patients at 12 months. Unfortunately, with a median follow-up of 61 months, the probability of 5-year disease-free survival was 63% for treated patients and 72% for control patients, with an overall survival of 69% and 78%, respectively.

From data presented in January 2002 at the 11th International Hamburg Symposium on Tumor Markers, Dr. Rüdiger Repmann¹¹³ reported on a nonrandomized prospective controlled study of 360 patients accrued between 1990 and 1995 who underwent a radical nephrectomy. The study was limited to the 236 patients who were found to have T2N0M0 or

T3N0M0 renal cell carcinoma. Of this group, 148 received a median of 13 adjuvant injections of autologous tumor cell lysates every 4 weeks. The 5-year overall survival was 71.4% in the control group compared with 86% in the vaccine group ($P = 0.0059$). A prospective randomized multicenter Phase III trial was started in 1997 to confirm these results is described next.¹¹⁴

A recent trial of an autologous cancer vaccine was published in 2004 in *Lancet*¹¹⁴; this was a randomized non-placebo-controlled trial of patients with T2 or T3 RCC with endpoints of progression-free survival (PFS). The randomization took place preoperatively for which the rationale was unclear. There was a very large loss of patients following surgery because of incorrect stage, incorrect diagnosis, and a number of other factors. Therefore, of the 558 patients enrolled only 379 were analyzed and continued therapy. The trial did seem to offer an improved PFS at 5 years and 70 months. The effect was predominantly seen in those patients with T2 disease RCC. The overall survival is not discussed in the article.

In summary, there is little evidence to support adjuvant immunotherapy up to the present time. There is good evidence to support withholding adjuvant interferon interleukin-2 for high-risk renal cell carcinoma, and there is a suggestion that tumor lysate vaccine therapy may have a future role.

Follow-Up

Any recommendations for follow-up after nephrectomy for RCCa should bear in mind the patterns of relapse and whether any follow-up protocol has led to a survival benefit in a disease where recurrence is notoriously difficult to treat. Unfortunately, there are only a handful of studies documenting sites of recurrence, no prospective trials that used a uniform follow-up protocol, and no trials to show that any type of follow-up improves survival.¹¹⁵⁻¹¹⁸

Overview of Therapy of Metastatic Renal Cell Cancer

Prognostic Factors in Metastatic Renal Cell Cancer

Although therapy of metastatic disease has progressed at a painfully slow pace, the development of models to accurately predict prognosis and survival have allowed for much better counseling of patients regarding their prognosis. These studies are summarized in Table 46.9.¹¹⁹⁻¹²³ It is critical that these prognostic factors be used to better understand the meaning of Phase II trials and better cohort balance through stratification with these factors in large Phase III trials. Overall time from diagnosis to metastases, poor performance status or number of symptoms, lack of nephrectomy, and elevated serum lactic dehydrogenase (LDH) have been poor prognostic factors in a number of clinical databases and must be taken into consideration when discussing prognosis and designing and evaluating outcomes from clinical trials.

TABLE 46.9. Independent prognostic factors identified in previous studies including different populations of patients with metastatic renal cell carcinoma.

Surgery in the Metastatic Setting

DEBULKING NEPHRECTOMY

There are several accepted reasons to excise the primary renal cell carcinoma in the presence of metastatic disease. Palliative nephrectomy for severe pain, hemorrhage, and endocrinopathy appears to be justified in the patient who is expected to live at least 6 months. Angioinfarction is another option in patients with intractable pain or hematuria from inoperable local disease.

The role of debulking nephrectomy in the presence of metastatic disease stems from the unique biology of renal cell carcinoma. There is a rare phenomenon of spontaneous regression of metastatic disease following nephrectomy. Although single centers have published extensively on the benefits of cytoreductive nephrectomy before immune therapy,^{124–128} two prospective studies provide the only randomized data.^{129,130} The European Organization for Research and Treatment of Cancer (EORTC) Genitourinary Group trial 30–947 was a Phase III study of 85 patients with metastatic renal cell carcinoma who were randomized to either IFN- α -2b alone or nephrectomy followed by interferon.¹²⁹ Nephrectomy was performed on 42 patients with only 6 perioperative complications requiring that 1 patient not receive immunotherapy. They reported no significant difference in the response rates to systemic therapy between the two groups (19% versus 12%; $P = 0.38$) but did note a pro-

longed time to progression (5 months versus 3 months; $P = 0.04$) and overall survival benefit (17 months versus 7 months, respectively; $P = 0.03$).

The Southwest Oncology Group (SWOG) trial 8949 examined the role of cytoreductive nephrectomy in combination with IFN- α -2b therapy in 241 patients with metastatic renal cell carcinoma as part of a multicenter randomized phase III trial performed in the United States.¹³⁰ There were 121 patients in the interferon-alone arm and 120 patients in the nephrectomy-plus-interferon arm. In this clinical trial, there was 1 perioperative death, 5 major surgical complications, and 16 mild to moderate surgical complications. Despite the complications, 98% of the patients in the surgery arm were able to receive interferon. Again, this study reported no difference in response rates to systemic interferon therapy in the two groups, 3.3% in the nephrectomy arm versus 3.6% in the immunotherapy-alone arm. Despite the low overall response rates, the study demonstrated a significant survival advantage for patients who underwent cytoreductive nephrectomy and immunotherapy when compared with patients who received immunotherapy alone (12.5 months versus 8.1 months, respectively; $P = 0.012$).

Table 46.10 summarizes results from the SWOG and EORTC trials as well as the largest single-institution retrospective from the NCI describing their 11-year experience with 195 patients who underwent nephrectomy with an overall 13% surgical complication rate.^{98,99} One hundred twenty-one (62%) patients who underwent nephrectomy in the NCI series went on to receive immunotherapy. Only 18 (9%) patients missed systemic treatment because of surgical complications. The NCI's 37.9% failure to receive immunotherapy likely indicates the rate of off-protocol adjuvant therapy rather than the 2% seen in the SWOG and EORTC trials.

Based on these results from these two randomized studies, debulking nephrectomy in those patients with distant metastatic disease is indicated in those patients with a good performance status deemed capable of proceeding on to systemic immunotherapy.

Metastatectomy

Approximately 25% to 59% of patients with renal cell carcinoma already have multiple distant metastases at tumor diagnosis, including the lungs (55%), lymph nodes (38%), liver (35%), or bones (33%). Moreover, metachronous metastatic disease may develop in approximately 50% of patients who have undergone seemingly curative radical nephrectomy.¹³¹ In the rare patient with a solitary synchronous metastasis, radical nephrectomy and excision of the solitary metastasis provide a 5-year survival rate of 23 to 35%.¹³²

TABLE 46.10. Trials of nephrectomy in metastatic disease followed by immunotherapy.

Trial	N	Mortality (%)	% that missed immunotherapy	Immunotherapy response rate (%)
NCI ²	195	1.0	37.9	17.8

EORTC ¹²⁹	42	0	2.4	19.0

n, number of patients enrolled on trial.

Memorial Sloan Kettering¹³³ retrospectively reviewed 278 patients with recurrent renal cell carcinoma from 1980 to 1993. They stated that 141 patients underwent a curative resection for their first recurrence with an overall 44% 5-year survival. Those who underwent noncurative surgery or who were treated nonsurgically had 14% and 11% 5-year survival rates, respectively. Favorable features included a disease-free interval greater than 12 months, solitary metastasis, and age less than 60 years. Of the 94 patients with solitary metastasis, 50 patients had a single pulmonary lesion resected, leading to a 54% 5-year survival rate compared with 11 patients with a solitary brain metastasis with an 18% 5-year survival rate. Their conclusion was that patients with a single site of recurrence and/or a long disease-free interval will have a good chance at long-term survival with curative resection of disease. Surgical resection of solitary metastases should be considered standard of care when feasible.

Chemotherapy-Based Treatment of Renal Cell Cancer

Many single-agent chemotherapeutic agents have been studied in metastatic RCC. These trials have not shown any single chemotherapeutic agent to have significant efficacy in renal cell carcinoma. In 1988, Bergerat et al. found a 42% response rate in patients treated with combination interferon and vinblastine, leading to hopes that vinblastine would prove to be an effective agent.¹³⁴ Unfortunately, subsequent randomized trials have been less promising.¹³⁵ In a study of 160 patients treated with IFN-2 α plus vinblastine versus vinblastine alone, the vinblastine arm showed only a 2.5% response rate.¹³⁵ Similarly, early Phase II studies also showed promising results for 5-fluorouracil (5-FU)^{136,137}; however, Negrier et al., comparing IFN- α plus IL-2 with or without 5-FU, showed no added benefit from chemotherapy in survival and a very poor response rate in both arms.¹³⁸

Similarly, combination therapies have not been proven effective in randomized controlled trials. Many studies have concentrated on platinum- fluorouracil-, and gemcitabine-based therapies, all in Phase II trials of various size populations.^{139,140} A single-arm Phase II trial by Rini et al. of gemcitabine with continuous 5-FU showed a 17% objective response rate.¹⁴¹

In the past few years, newer chemotherapeutic drugs have been studied. A large number of Phase II studies of newer chemotherapeutic drugs have shown no improvement in survival or significant response rates but have occasionally suggested a prolonged stable disease.¹⁴²⁻¹⁴⁹ Therapies that have been studied include bryostatin-1, a protein kinase C inhibitor; flavopiridol, a cyclin-dependent kinase inhibitor; troxacitabine, a nucleoside analogue; iriflavin, which covalently binds to DNA, inhibits DNA synthesis, and induces apoptosis; the 5-fluorouracil, folinic acid, and oxaliplatin (FOLFOX-4 regimen); arsenic trioxide (As₂O₃); razoxane, an antiangiogenic topoisomerase II inhibitor; and most recently, PS-341, a proteasome inhibitor, to name a few. In general, chemotherapy has failed to improve or even match the objective responses seen with cytokine therapy, and none has shown improvement in survival.

TABLE 46.11. Hormone therapy in advanced renal cell carcinoma.

Therapy	Patients (n)	% response (range)
Progestational agents	695	5 (0-17)
Androgenic agents	190	3 (0-14)
Hormonal responses by year of reporting		
1967-1971	228	17
1971-1976	415	2

Hormonal Therapy of Advanced Renal Cell Cancer

Numerous trials have explored the role of hormonal therapy in treatment of patients with metastatic renal cell carcinoma (Table 46.11). These studies were prompted by preclinical studies in which progesterone was shown to be effective in inhibiting both tumor development and tumor growth.^{150,151} Progestins have been the most actively studied clinically as well and have produced response rates ranging from 0% up to 20%. More recent studies using standard defined response criteria have produced response rates of only 1% to 5%.¹⁵² In reviewing the data on medroxyprogesterone,¹⁵⁰ it was concluded that irrespective of dose or schedule, human renal cell carcinoma is neither hormone dependent nor hormone responsive. Nonetheless, patients with severe anorexia and weight loss may occasionally derive significant symptomatic relief from the administration of medroxyprogesterone, even in the absence of any direct antitumor effect.

Cytokine-Based Therapy of Renal Cell Cancer

Although there have been innumerable trials examining a number of biologic agents in treatment of advanced RCC, few have provided strong evidence for the clear benefit of one treatment over another. The majority of studies have been focused on the clinical effects of two cytokines: interleukin (IL)-2 and interferon-alpha. These have been extensively studied alone and in combination in Phase I and II trials; surprisingly few trials have compared the two treatments in a randomized Phase III design.^{138,153-155} Other cytokines have been tested in numerous phase I and II settings including IL-4, IL-6, IL-12, Flt3L, and others without any real suggestion of significant activity in trials of small cohorts of patients.¹⁵⁶⁻¹⁶¹ The cytokine therapy of RCC suffers greatly from an abundance of relatively small unconfirmed Phase II trials and very few properly sized and statistically sound Phase III trials.

INTERFERON-ALPHA (IFN- α)

There is an extensive literature examining single agent IFN- α in the treatment of advanced RCC.¹⁶²⁻¹⁶⁶ In the early studies, a number of different and noncloned interferons were utilized and RCC was chosen as a target disease. In numerous trials, antitumor activity in terms of tumor regression and disease stabilization was observed. Additionally, it has been suggested that the objective rules we use to evaluate complete and partial responses do not capture the ability of IFN- α to extend survival without objective disease regression. Meta-

analyses encompassing a large number of trials and patients with RCC in the 1980s supported the following results.

1. The various interferons, that is, lymphoblastoid, leukocyte, IFN- α 2a, and IFN- α 2b, all demonstrated similar results with complete responses between 1% and 4% and partial responses as high as 10% and 15% and as low as 5% in other trials.¹⁶⁴

2. Doses between 3 and 10 MIU/day appear as active as and less toxic than higher doses.¹⁶⁴⁻¹⁶⁷

3. SC or IM was the most effective route, and other IFNs such as IFN- β and IFN- γ had lower activity than IFN- α .¹⁶⁸⁻¹⁷²

Several important Phase III trials have tried to determine whether the combination of other agents with IFN- α could improve therapy in RCC. Several Phase I and II trials combining IFN- α with vinblastine, an agent initially approved for advanced RCC but rarely applied to the disease, reported promising results with objective response rates exceeding 20% to 25% and median survivals up to 70 weeks (16+ months).¹⁷³ This finding led to a Phase III trial that selected vinblastine (Vbl) as control and IFN- α plus Vbl as the experimental arm,¹³⁴ with a total of 160 patients enrolled. For those in the Vbl arm alone, the median survival was only 37.8 weeks, with an objective response rate of 2.5% (2 patients). This result compared poorly to Vbl plus IFN- α patients,¹⁷⁴ who demonstrated a 16.5% response rate ($P = 0.0025$) and median survival of 67.6 weeks ($P = 0.0049$). One obvious conclusion is that Vbl alone has no value as a single agent in advanced RCC. The benefit of the combined arm was likely totally the result of the contribution of IFN- α .

Another attempt to improve the effects of IFN α in RCC was led by Motzer at MSKCC. Based upon a Phase II trial combining IFN- α with 13-*cis*-retinoic acid (CRA),¹⁷⁵ a Phase III trial was then conducted at multiple centers through ECOG and MSKCC and enrolled 284 patients with advanced RCC in slightly more than 2 years.¹⁶⁹ In the 139 patients on IFN- α plus CRA, there were 16 responses [5 complete responses (CRs) and 11 partial responses (PRs)] for a response rate of 12%, compared with 9 (1 CR and 8 PRs) (6%) among the 145 patients receiving only IFN- α ($P = 0.14$). The duration of the responses was long in both cohorts but longer ($P = 0.03$) in those receiving IFN- α plus CRA (33 versus 22 months). The median survival for all patients, 15 months, was not significantly different between the groups ($P = 0.26$). The quality of life of patients receiving both IFN- α and CRA was decreased.

Smaller but definitive studies have shown that IFN- γ , when added to IFN- α , did not increase the response rate.¹⁷¹ In fact, among the 102 patients enrolled, 7 of 53 responded to IFN- α alone, whereas only 2 of 45 responded to IFN- α plus IFN- γ . Finally, two randomized control trials examined the role of nephrectomy in patients with advanced RCC who followed surgical intervention with systemic therapy such as IFN- α .¹⁷⁰ An EORTC trial of 85 patients and a SWOG Intergroup trial both showed an improved outcome for both survival and progression-free survival when patients treated with IFN- α had nephrectomy before surgery,^{129,130} although the objective response rate to IFN- α in the 85-patient EORTC trial was 19% and 12% ($P = 0.38$), respectively, for patients with and without nephrectomy. On the other hand, among the 246 patients enrolled on the SWOG trial, of those with measurable disease only 3% to 4% of patients had evidence

for objective responses whether or not they had undergone prior nephrectomy. This finding implied that the statistically significant improvement in overall survival was not completely dependent on improving the number and quality of tumor regressions induced by IFN- α .¹³⁰

INTERLEUKIN-2 (IL-2)

Since its rapid translation from animal models to clinical trials back in the mid-1980s, IL-2 has been the focus of both great excitement and great disappointment^{176,177} (Table 46.12). Initially, trials of a high-dose bolus regimen administered at 600,000–720,000 units/kg intravenously (IV) every 8 hours for 14 doses (maximum) on days 1–5 and 15–19 of every 8–12 weeks with ex vivo IL-2-activated peripheral blood mononuclear cells (LAK cells) demonstrated response rates as high as 30% to 40% in patients with advanced RCC.¹⁷⁶ These trial included highly selected groups of patients.^{176,178} Later, it became clear that ex vivo LAK cells were not essential and very costly.^{179,180} Additionally, it became apparent that the response rate was lower (15%–25%); however, the durability of the responses persisted as the most impressive finding. These findings culminated in the 1995 publication by Fyfe et al. of 255 patients with advanced RCC who had been entered on seven Phase II clinical trials from 21 different institutions.¹⁸¹ This database included all patients with advanced RCC treated with high-dose bolus IL-2 as a single agent. As in many high-dose IL-2 trials that were subsequently reported, the patients were selected for excellent organ function (cardiac, respiratory, renal, hematologic), no evidence of brain metastases, and excellent performance score (PS) of 0–1 or Karnofsky 70–100. Eighty-five percent had prior nephrectomy, 65% had a PS = 0 or certainly Karnofsky PS above 80, whereas 44% had initial diagnosis with 12 months of IL-2 therapy. No data were available on the number of patients with elevated serum LDH, elevated serum calcium, or anemia (Motzer prognostic factors). Of the 255 patients, 36 (14%) demonstrated objective evidence of response, 12 CRs and 24 PRs.¹⁸¹ Most impressive was the duration of the responses, 19 months for PRs and 8 of 12 ongoing responses in the CR patients (5+ to 62+). Responses were observed in patients with bulky disease (larger than 25 cm²). As expected, toxicity was quite impressive, with grade 3–4 hypotension in nearly 75% of patients and grade 3–4 mental status changes in nearly 30% of patients. Oliguria/anuria and symptoms such as nausea, vomiting, diarrhea, and fever were severe (grade 3–4) in 24% to 46% of patients. In this group of patients, many were treated before a full understanding of toxicity management, and therefore treatment-related mortality was 4% (11 patients). An additional follow-up report more than 12 months later on the same cohort of 255 RCC patients showed even better durability, with very rare if any late relapses among any of the objective responders.¹⁸²

The year 2003 saw a completed Phase III trial (actually two Phase III trials combined) published in the *Journal of Clinical Oncology*.^{154,155} From 1991 to 2001, 306 patients were randomized between high-dose bolus IL-2 (720,000 U/kg/dose) versus low-dose bolus IL-2 (72,000 U/kg/dose). Another 94 patients were randomized to outpatient subcutaneous IL-2 from 1993 to 2001. The trial began as a two-arm trial, and after the initial 117 patients were accrued, the trial was modified into a three-arm Phase III with an additional

IFN, interferon.

283 patients then randomized. When all results were combined, high-dose bolus IL-2 was associated with a 21% response rate among 155 evaluable patients (11 CRs and 22 PRs) versus 13% for low-dose bolus IL-2 (6 CRs and 13 PRs) ($P = 0.048$ by chi-square test). The patients receiving subcutaneous IL-2 as outpatients had a response rate of 10%, with 2 CRs and 7 PRs among the 93 patients. Compared with the IL-2 high-dose bolus randomized simultaneously, the statistical difference favored high-dose IL-2 ($P = 0.033$ by χ^2 testing), although the study did not show a definitive overall survival advantage for those receiving high-dose IL-2. Overall, the responses to high-dose IL-2 were more durable; in fact, the responding patients getting high-dose IL-2 had a better survival than responders in the low-dose IL-2 bolus arm ($P = 0.04$). Responses were more frequent and the responses were apparently more durable.

In another trial conducted by the Cytokine Working Group, 193 patients with advanced RCC were randomized between high-dose bolus IL-2 and outpatient subcutaneous IL-2 plus IFN- α based on the Atzpodien regimen.¹⁵⁵ This trial accrued patients from 1997 through 2000 with 96 patients accrued to each arm and eligible. Similar to the NCI randomized trial, high-dose IL-2 had a significantly better response rate versus IL-2/IFN- α outpatients (23 versus 9%; $P = 0.018$). Again, the response duration was greater with high-dose IL-2 (14 versus 7 months). Finally, only 2 of the 9 IL-2/IFN- α responders were progression free at 17+ and 35+ months, whereas 9 of 22 high-dose IL-2 responders remained progression free at 22+ to 44+ months. Together, these trials support high-dose bolus IL-2 as the preferred treatment of metastatic RCC at centers where experience and clinical support exist. On the other hand, only approximately 10% of patients ultimately obtain very meaningful benefit with high-dose IL-2 and far more do not get a major benefit.

THALIDOMIDE

Based on the in vitro antiangiogenic activity of thalidomide, it has attracted much interest for the treatment of RCC.^{183–187}

A number of Phase II studies have been performed demonstrating partial responses ranging from 0% to 8% and stable disease at 6 months of 23% to 30% (Table 46.13).^{183–187} A randomized ECOG Phase III study was recently reported in abstract form¹⁸⁸; it compared treatment with IFN- α alone to IFN- α in combination with thalidomide and enrolled 353 patients, of whom 342 were eligible, with a median age of 59 years (range, 24–84), including 227 men and 115 females with a median ECOG PS 1. Of these, 254 patients had undergone a prior nephrectomy and 236 had a disease-free interval of 1 year or less. Treatment consisted of IFN- α , 1 million IU SC bid alone or in combination with thalidomide (inpatient dose escalation from 200 mg/day to 1,000 mg/day maximum). The study was designed to detect an improvement in progression-free survival (PFS) at 6 months of 35% compared with 20% in the “standard IFN- α ” arm and a 50% improvement in median overall survival (OS) from 12 to 18 months. Fatigue, myelosuppression, and thrombotic events (12 versus 4) were greater in the thalidomide + IFN- α arm. There was no difference in response rates or overall survival, although PFS was longer, and the difference was significant statistically, in the IFN + thalidomide arm (Table 46.14). Quality of life and fatigue scores were worse on the IFN + thalidomide arm. The addition of thalidomide to this IFN regimen modestly improves PFS but not OS and worsens quality of life in RCC patients.

Other Therapies Applied to Renal Cell Cancer

ADOPTIVE CELLULAR THERAPY

Transfer of immune cells for the treatment of renal cancer has been an integral component of research over the years in RCC. There was an interest in the role of LAK cells in the setting of high-dose interleukin-2, and this was presumed to be a critical component of the IL-2 therapy. However, a randomized trial revealed that it added little in terms of response rate and overall survival. The results may have trended toward an advantage with cellular therapy, but it was certainly not worth the labor, cost, and added toxicity.^{179,180}

TABLE 46.14. Thalidomide contribution to RCC treatment.

	CR (%)	PR (%)	RR (%)	6-month PFS	Median PFS	Median OS
IFN alone	0	2	2.2	26%	2.8 months	12.2 months
IFN + T	2	4	6.5	29.3%	3.8 months $P = 0.04$	10.8 months $P = 0.93$

T, thalidomide 100 mg/day po escalating to 1,000 mg; IFN, interferon 1 mm/BID sq daily.

Probably the most ambitious effort was led by the investigators at UCLA. Over a number of years the group treated 55 patients with autologous CD8 selected tumor-infiltrating (TIL) cells from prior resection specimens; an additional 7 patients could not undergo the therapy. There were 5 complete responses and 14 partial remissions for an overall response rate of 35%. The patients also received IL-2 but at doses that rarely induced a response rate greater than 10%. The responses were durable, with a median of 14 months. These data were the impetus for a Phase III trial of the same schedule and dose of IL-2 with or without CD8+ selected TIL cells in which 178 patients were enrolled and 160 patients were randomized.¹⁸⁹ Twenty additional patients did not receive any therapy because of postoperative complications, mortality, or simply inability to tolerate the IL-2 therapy. Of 72 patients designated to receive CD8+ TIL cells, 33 did not have adequate cells generated. In the end, with intent to treat, the responses in both groups were around 10% and 1-year survival was similar at approximately 50%. This experience showed the difficulty in exporting highly technical cellular approaches into a large multicenter trial. The need for a single-institution commitment cannot easily be recreated in a multicenter trial.

Vaccination strategies in RCC have differed from melanoma primarily because of the lack of obvious tumor antigens that appeared to be recognized by T cells.^{190,191} This finding may have changed recently as a result of the expression pattern of some enzymes associated with VHL mutations such as CAIX,¹⁹² which has led to efforts using the antigens from tumor cells without specific knowledge of what they are or having to isolate them. The first approach explored the use of tumor cell-autologous tumor hybrids. An initial report from Kugler et al. in Germany included 17 patients with advanced renal cancer.¹⁹¹ Of the 17 patients, 7 had objective responses with 4 CRs, 2 PRs, and 1 mixed response. Two other patients had prolonged stable disease for more than 12 months each. Although this report was quite promising, it was retracted later with a great deal of suspicion about the validity of any of the findings. Others have not reported this approach in RCC, primarily because of technical difficulties with the fusion and growth culturing procedures.¹⁹³ More recently, the group at Duke led by Vieweg and Gilboa have attempted a slightly different strategy of isolating RNA from the RCC specimens and then transfecting the RNA into autologous dendritic cells (DC).¹⁹⁴ This approach appeared to be successful at inducing CTL activity by ELISPOT assays in most patients of the 10 treated. These immune responses included those directed to specific antigens, telomerase, G250, RNA tumor-loaded DC, and oncofetal antigens. None of the 10 patients had obvious tumor regression; however, 7 of the 10 remain alive with a median follow-up of almost 20 months. This result could represent a significant effect of the treatment or simply a matter of patient selection and the presence of only good prognosis patients.

NONMYELOABLATIVE HLA-MATCHED SIBLING STEM CELL TRANSPLANTS AS A FORM OF IMMUNOTHERAPY

A new paradigm for treating renal cancer appeared in 1998–2000 when Childs and his colleagues at the NCI and National Institutes of Health (NIH) reported on the use of

allogeneic stem cells transplants utilizing nonmyeloablative chemotherapy regimens in the treatment of RCC.¹¹¹ The approach was based on the well-known association of graft-versus-host disease with improved clinical outcome and even clinical regressions in hematologic malignancies. The hope was for a graft-versus-tumor (GVT) effect. Ten of the first 19 patients with RCC who underwent the procedure had a clinical remission after failing cytokine therapy.¹¹¹ Three complete responses remained ongoing at 16+ to 27+ months. Regression of disease was frequently delayed up to 4 to 6 months after the allogeneic stem cell therapy. In a number of cases the patient did not demonstrate chimerism, a sign of the engraftment of donor cells. In these cases, frequently additional donor lymphocytes were infused to enhance the potential for a GVT effect. The risk and importance of graft-versus-host disease (GVHD) was emphasized. GVHD occurred in 10 of the patients at grade II–IV, being associated with transplant mortality in 2 patients (Table 46.15).

Although overall this approach to RCC therapy is exciting and scientifically of great interest,^{195–197} it is far from established, is associated with great toxicity, and should only be performed as part of a clinical trial. The center where it is performed must be truly committed to optimally studying these patients and understanding how to improve the efficacy and diminishing the toxicity.

Novel Therapy of Advanced Clear Cell RCC Based on Its Cancer Biology

As reviewed, the cloning of the VHL gene, the understanding of its role in HIF-1 α stability and activity, and the large number of HIF-1 α -regulated genes that are expressed in RCC. These genes appear to have uncovered numerous molecular targets for therapeutic intervention, which include VEGF, PDGF, TGF- α , EGFR, and carbonic anhydrase IX, and appear important to the behavior of this malignancy.¹⁹⁸ Small molecule kinase inhibitors and/or antibodies have been developed to either selectively block many of these pathways or inhibit a number of pathways on their own. These agents have now entered clinical trials at the Phase I/II/III stage (Table 46.16).

The data as published in peer-reviewed journals so far are most compelling for a humanized antibody to VEGF (anti-VEGF; Avastin, Bevacizumab). In a randomized, double-blinded Phase II trial of placebo versus anti-VEGF at 3 mg/kg/2 weeks versus 10 mg/kg/2 weeks in which 50 patients were to be enrolled into each arm, RCC patients were followed for the primary endpoint of time to progression (TTP), as well as objective clinical responses and overall survival.¹⁹⁹ All patients either had prior interleukin-2 or were unable to receive it. Most patients had previously undergone nephrectomy. The trial was terminated at the enrollment of the 116th patient because “the difference in outcome in the three arms mandated closure by the DSMB.” There were only 4 responses (all PR) among 39 [confidence interval (CI) at 95%, 2.9%–24.2% relative risk (RR)] patients treated with the high dose of anti-VEGF (10 mg/kg). There were no other responses among the other 74 patients. At the time of unblinding, the median TTP was 4.8 months for the high-dose anti-VEGF versus 2.5 months for placebo [P less than 0.001; hazard ratio (HR) = 2.55]. The difference in median TTP for those receiv-

ing low-dose anti-VEGF versus placebo nearly reached statistical significance ($P = 0.053$; HR = 1.26). The percent that were progression free on each of the arms at 4 and 8 months are shown in Table 46.17.

There was crossover allowed for those progressing patients to receive the anti-VEGF at the high dose (10 mg/kg) if they were initially in the placebo or 3 mg/kg arm of anti-VEGF. This choice likely made the overall survival evaluation impossible. Nevertheless, the excitement generated by these results has led to a number of other trials including a

large multicenter trial of IFN- α versus IFN- α plus anti-VEGF, Phase II trials of combination blockade with anti-VEGF and EGFR tyrosine kinase inhibitors. The later trial of anti-VEGF and an EGFR inhibitor was very promising. The combination produced a 21% objective response rate in a group of 58 evaluable patients with advanced RCC. An additional 45% of patients had stable disease/minor response for 6 months or more.²⁰⁰ More recently, Phase II and III trials of a number of agents look especially promising via inhibition of VEGF, PDGF, Raf, and mTOR signaling.²¹⁷⁻²²⁰

TABLE 46.16. Clinical trials of novel therapies for clear cell RCC.

Therapeutic agent	Mechanism of action	Target molecule(s)	Advantages	Disadvantages	Clinical status
Anti-VEGF	Humanized antibody to VEGF	VEGF	Specificity	Intravenous	Phase II/III
SU5416	Tyrosine kinase inhibitor	VEGFR1 and VEGFR2		Toxicities	Program closed
PTK787	Tyrosine kinase inhibitor	VEGFR2 and PDGFR	Oral		Phase II/III

Ureter, Bladder, Penis, and Urethra

Cheryl T. Lee, Brent Hollenbeck,
and David P. Wood, Jr.

Evidence-based clinical medicine has been proven to produce the best outcomes.¹ Unfortunately, many tumor sites do not have adequate randomized clinical trials to provide the necessary data to reach treatment and diagnostic consensus. The ureter, bladder, penis, and urethra fall into this category. There are several reasons for a lack of randomized clinical trials in these sites, but the primary reason is the relatively low incidence of each tumor. Of these tumors, bladder cancer has the highest incidence (16 per 100,000 people), followed by ureteral cancer (10 per 100,000) and subsequently penis and urethra (less than 2 per 100,000)²; this is in contrast to prostate cancer, which has an incidence of 75 per 100,000 men.² Despite the limited randomized clinical trials in these sites, there are excellent Phase II clinical and historical trials that can shed light on management of these rare tumors.

In this chapter we describe the etiology, basic science, pathology, prognostic factors, screening tests, diagnostic tests, and treatment for cancer of the ureter, bladder, penis, and urethra. The ureter, bladder, and urethra are discussed as one tumor type as they are all components of transitional cell carcinoma (TCCa). Penile cancer is considered separately.

Ureter, Bladder, and Urethra

Etiology

Many data suggest that bladder cancers are carcinogen induced.³ Factors reported to be causally related to bladder cancer include occupational chemicals, tobacco, coffee, analgesic abuse, artificial sweeteners, bladder calculi, pelvic irradiation, and certain types of chemotherapeutic agents. Inhaled or ingested carcinogens are filtered by the kidney and concentrated in the urine where they are stored in the bladder for prolonged periods of time before excretion. Repeated exposure of the urothelium to these carcinogens can lead to genetic alteration and tumor formation. Multiple lesions or genetic mutations are likely required to cause malignant transformation of the urothelium, as evidenced by the multitude of chromosomal abnormalities recorded in TCCa.^{4,5}

The most common environmental exposure that promotes bladder cancer is tobacco.⁶ Cigarette smokers have a fourfold higher incidence of bladder cancer than nonsmokers do. The risk correlates with the number of cigarettes smoked,

the duration of smoking, and the degree of inhalation. Although males are more commonly affected with TCCa than females (3 to 1 ratio), this ratio has decreased as women have increased their tobacco use. An estimated one-third of bladder cancer cases may be caused by cigarette smoking. The specific chemical carcinogen is unknown; however, nitrosamine has been implicated. Occupational exposures also increase the risk of urothelial malignancies. Aniline dyes containing xenylamine and benzidine, for example, are known urothelial carcinogens in humans and in animals.⁷

Genetic mutations appear to play an important role in formation of TCCa.⁴ Figure 47.1 illustrates consensus genetic changes that occur in bladder cancer.^{4,8} Bladder cancer is typically stratified into superficial and invasive tumors. Superficial tumors have a high recurrence rate but invade and metastasize in a minority of cases. Conversely, invasive TCCa has a highly metastatic potential. Genetic mutations appear different in the two tumor types. Superficial bladder cancers are typically associated with loss of 9q, ink4A, and p16; invasive tumors have loss of p53, Rb, p14, and p16. Several monoclonal tests have been developed to detect these markers in urine, but the reproducibility is unclear.

Pathology

As with many tumors, pathologic evaluation of TCCa is critical in determining appropriate therapy. The pathology description for TCCa is divided into grade (1 to 3) and stage (Tis to T4).⁹ Grade is associated with the aggressiveness of the disease, whereas stage is a reflection of the time the tumor has been present and its ability to metastasize. Tumor staging is generally based on the TNM system (Table 47.1). The T stage is defined by the depth of invasion into the bladder, ureteral, or urethral wall. Nodal disease is based on number as well as location of metastatic lymph nodes. Metastatic sites most commonly involve lung, bone, and liver. *Clinically, the precise TNM stage is used rather than the overall stage.* Recently, the World Health Organization (WHO) has reclassified superficial bladder cancer from grades 1 to 3 to low malignant potential tumors to high malignant tumors.¹⁰ Low malignant potential TCCa has a high recurrence rate (60% to 80%) but a low rate of invasion (less than 10%). Conversely, high malignant potential superficial bladder cancer has a high risk of recurrence and invasion (70%). Treatment decisions are highly predicated on the pathology.

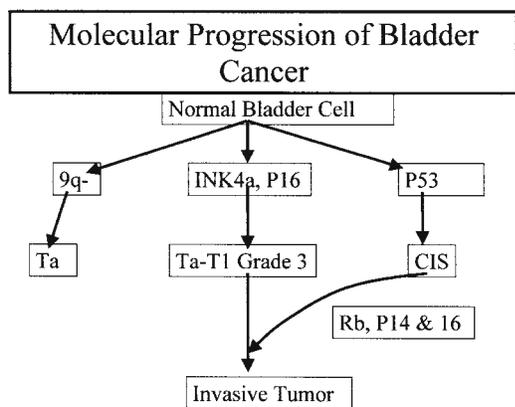

FIGURE 47.1. Bladder cancer progression.

Prognostic Factors

Multiple factors may influence the prognosis of bladder cancer. Pathologic parameters have been studied in great depth and have traditionally been the primary means of predicting prognosis. More recently, an increased study of molecular alterations and disease outcome has led to novel approaches to therapy and methods for patient stratification.

Pathologic Factors

Although grade and presence of vascular invasion have been proposed as predictors of adverse outcome,¹¹ pathologic stage is the most powerful predictor of survival outcome. Increased stage, particularly extravesical disease and nodal or visceral involvement, results in diminished survival when compared to organ-confined disease.¹²⁻¹⁴ Despite the excellent 87% to 97% local control provided by radical cystectomy, metastatic recurrence in patients with extravesical disease is common.^{12,15} The respective 10-year overall survival (OS) of 54%, 22%, 22%, and 23% for organ-confined, pT3, pT4a, and N+ disease has been demonstrated in a large retrospective series of 1,054 patients.¹² Pretreatment clinical predictors of extravesical disease include hydronephrosis and a palpable mass on bimanual examination. Unilateral and bilateral hydronephrosis are associated with T3-T4, N- disease in 33% and 36%, and metastatic disease in 34% and 55%, respectively.¹⁶ Although bimanual examination is believed to correlate with extravesical or unresectable tumors, there remains a paucity of data confirming its sensitivity and specificity apart from other clinical staging.^{17,18}

For earlier-stage cT1 disease, the depth of penetration is also an important predictor of progression and death from bladder cancer. In a prospective, nonrandomized study of 121 patients with cT1 disease, tumor penetration of the muscularis mucosa (T1b) was associated with a 53% risk of

TABLE 47.1. The 2002 American Joint Committee on Cancer (AJCC) staging of bladder cancer: TNM definitions.

Primary tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Ta	Noninvasive papillary carcinoma
Tis	Carcinoma in situ: "flat tumor"
T1	Tumor invades subepithelial connective tissue
T2	Tumor invades muscle
pT2a	Tumor invades superficial muscle (inner half)
pT2b	Tumor invades deep muscle (outer half)
T3	Tumor invades perivesical tissue
pT3a	Microscopically
pT3b	Macroscopically (extravesical mass)
T4	Tumor invades any of the following: prostate, uterus, vagina, pelvic wall, or abdominal wall
T4a	Tumor invades the prostate, uterus, vagina
T4b	Tumor invades the pelvic wall, abdominal wall
Regional lymph nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node, 2 cm or less in greatest dimension
N2	Metastasis in a single lymph node, more than 2 cm but not more than 5 cm in greatest dimension; or multiple lymph nodes, none more than 5 cm in greatest dimension
N3	Metastasis in a lymph node, more than 5 cm in greatest dimension
Distant metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

progression compared with a 31% risk with superficial penetration (T1a) of the lamina propria (P less than 0.05).¹⁹ At a minimum of 5 years of follow-up, death from bladder cancer occurred in 44% of T1a and 23% of T1b patients (P less than 0.05).

Molecular Markers

p53

In an effort to complement prognostic information obtained from pathologic and imaging criteria, several molecules important in cancer biology have been explored. The most extensively studied marker in bladder cancer is the tumor suppressor gene *p53*. Upregulation of *p53* protein induces cell-cycle arrest, which allows repair of damaged DNA. Mutations result in accumulation of abnormal protein in the cell nucleus. The suspected importance of this gene began with observations of *p53* mutations in a high proportion of bladder cancers.²⁰ Detection of nuclear *p53* staining by immunohistochemistry has been independently associated with diminished survival after cystectomy or systemic chemotherapy.^{21–23} Other studies have demonstrated a correlation between nuclear accumulation of *p53* protein and bladder cancer progression and an increased risk of disease recurrence and decreased overall survival (OS).^{24,25} These findings have provided the rationale for a randomized study from the University of Southern California for patients with organ-confined bladder cancer (stage pT1–pT2) and *p53* mutations. Patients with *p53*-positive tumors are randomized to three cycles of MVAC (methotrexate, vinblastine, doxorubicin, cisplatin) or observation after radical cystectomy.

EPIDERMAL GROWTH FACTOR RECEPTOR

Epidermal growth factor receptor (EGFR) is a transmembrane receptor tyrosine kinase that is overexpressed in bladder

cancer. EGFR activation influences cellular proliferation and the cell cycle, and affects other cellular processes, including angiogenesis, apoptosis, motility, adhesion, invasion, and metastasis.²⁶ Bladder tumors that overexpress EGFR are more likely to recur, progress to muscle-invasion, and have diminished survival.^{27,28} In other reports, however, EGFR expression has not been associated with tumor progression or survival.²⁹

HER2-NEU

The HER-2/neu proto-oncogene encodes a transmembrane receptor kinase. Overexpression of HER2, seen in 30% of bladder tumors,³⁰ has been correlated with increased tumor grade and is an independent prognostic factor of tumor-specific survival.³¹ Further, overexpression of HER2 in primary tumors is predictive of increased HER2 expression in metastases.³⁰ Currently, however, it is unclear whether HER2 expression levels provide any additional prognostic information over tumor stage and grade for bladder cancer.^{32,33} The availability of therapeutic antibodies to the HER2 protein has resulted in several ongoing clinical trials to determine the efficacy of these agents in advanced bladder cancer patients.

Other markers outlined in Table 47.2 may have potential prognostic benefit in bladder cancer. A great deal of preclinical investigation continues to delineate the impact of alteration of these markers and the resultant clinical implication. Unfortunately, none of these molecular prognostic markers has been confirmed to be useful for clinical decision making at this time.³⁴ With the continued development of relevant therapeutics, patient benefit will be assessed through neoadjuvant studies in surgical patients and treatment trials in the advanced disease state.

TABLE 47.2. Prognostic markers of bladder cancer.

Marker	Biological function	Potential prognostic value
T138	Tumor-associated antigen	Association with progression and metastasis, diagnostic marker
ABO	Blood group antigens	Diagnostic marker, association with progression in secretory individuals
<i>c-H-ras</i> , <i>c-myc</i> , <i>c-erb-B2</i> , <i>mdm-2</i>	Oncogenes	Prognosticators of disease recurrence (<i>ras</i>) or survival (<i>erb</i>), correlation with tumor grade (<i>erb</i> , <i>myc</i>) or metastasis (<i>erb</i>)
Rb, <i>p53</i> , <i>p21</i> , <i>p27</i>	Cell-cycle regulators	Correlation with progression/survival (Rb), markers of progression (<i>p53</i>) or recurrence and survival (<i>p21</i> , <i>p53</i>), association with tumor grade and survival (<i>p27</i>)
Ki-67, PCNA, MCM	Proliferation-associated antigens	Markers of recurrence, progression, and survival (Ki-67), correlation with recurrence (PCNA) and grade (MCM)
Vessel density, thrombospondin-1	Angiogenesis and inhibitors of angiogenesis	Markers of progression (V.d.), recurrence (Thromb-1) and survival (V.d., Thromb-1)
Cadherins, integrins, Ig-super family	Cell adhesion molecules	Association with metastasis, tumor grade and stage (E-cadherin) and survival (E-cadherin, integrins)
Laminin-P1, cathepsin D, U-PA, matrix-metalloproteases and -inhibitors	Extracellular matrix proteases	Correlation with tumor size and number (laminin), association with survival (Cathepsin D) or metastasis (u-PA), correlation with tumor stage, grade, and survival (MMPs)
EGFR	Growth factor receptors	Correlation with recurrence and progression
EGF, FGF, TGF- α , TGF- β , VEGF	Peptide growth factors	Correlation with survival (EGF, TGF- α), or tumor stage, grade and recurrence (FGF, VEGF)
Bcl2, Bax, Fas, Fas-L, survivin	Markers of apoptosis	Correlation with recurrence (survivin, bcl-2/bax) or survival (Fas)
CD44	Cell-cell/matrix interactions	Correlation with survival, diagnostic value

TABLE 47.3. Selected diagnostic urinary tests.

	Sensitivity (%)	Specificity (%)
BTA	41–83	72–95
BTA trak	54–78	95–97
BTA stat	75–90	72–95
BTF	80	75
FDP	82	86–96
FISH	81	>95
HA/HAase	86–92	84–92
ImmunoCyt	86–95	90
Microsatellite DNA (ex. MAUS)	89	100
NMP-22	47–100	60–90
TRAP (telomerase)	50–100	80–90
Urine cytology	20–58	>95

BTA, bladder tumor antigen; BTF, bladder tumor fibronectin; FDP, fibrin degradation product; FISH, fluorescent in situ hybridization; HA, hyaluronic acid; HAase, hyaluronidase; MAUS, microsatellite analysis of urinary sediment; NMP22, nuclear matrix protein 22; TRAP, telomeric repeat amplification protocol.

Screening

Although cystoscopy remains the “gold standard” for diagnosis, it is not a good tool for general bladder cancer screening because it is invasive and expensive. Urine cytology uses a morphologic assessment to evaluate cells shed in the urine. The very favorable 97% to 99% specificity is offset by its lack of sensitivity, particularly suboptimal for low-grade tumors, and also limits its use as a general screening tool. Several non-invasive tests have been developed to augment the sensitivity of urine cytology while maintaining the specificity (Table 47.3). Although several of these tests have been investigated for general screening, the use has primarily been in screening for tumor recurrence in patients with a prior diagnosis of bladder cancer. Currently, there is not a clear consensus on the clinical utility of many of these markers.

FLUORESCENT IN SITU HYBRIDIZATION

Fluorescent in situ hybridization (FISH) uses fluorescently labeled centromeric and locus-specific DNA probes to detect chromosomal abnormalities in exfoliated cells in the urine, specifically looking at chromosomes 17, 3, 7, and 9p21. The specificity rivals urine cytology at 96%.³⁵ The sensitivity for Ta tumors is 65%, for Tis is 100%, and for T1–T4 is 95%. This technique is much more sensitive at picking up invasive disease as nearly all tumors of T1 or above have multiple chromosomal alterations. FISH may also allow earlier detection of tumors than urine cytology.

BTA STAT

The BTA Stat test is a qualitative test performed on voided urine. It measures “bladder tumor antigen” complement factor H-related proteins and is relatively easy to interpret, although weak positive results can be difficult. BTA has a higher sensitivity than urine cytology and a similar specificity.¹

FIBRIN/FIBRINOGEN DEGRADATION PRODUCT (FDP)

Fibrin/fibrinogen degradation product (FDP) was introduced for the detection of occult and rapidly recurring disease after

transurethral resection of bladder tumor (TURBT). FDP assesses fibronectin fragments excreted in urine.³⁷ These fibrin products are widely distributed on cells involved in the mechanism of human bladder cancer cell invasion.

NUCLEAR MATRIX PROTEIN (NMP)

Nuclear matrix protein (NMP) is a quantitative test that measures tumor-related proteins in urine. Nuclear matrix proteins make up portions of the nuclear structure, organize chromatin, regulate critical aspects of mitosis, and are elevated in patients with active TCCa of bladder.³⁸

MICROSATELLITE ANALYSIS OF URINARY SEDIMENT (MAUS)

Although not currently approved for surveillance in bladder cancer, microsatellite analysis of urinary sediment (MAUS) markers may be useful as clonal markers for the detection of human cancer. Microsatellite analysis can detect loss of heterozygosity and may reveal genetic instability marked by areas of increased repetition of DNA sequences. The test is based on the detection of exfoliated urothelial cells with genetic alterations consistent with specifically identified microsatellite regions common in TCCa.³⁹ It, too, may provide early tumor detection by examining the DNA of urinary sediment.

TELOMERIC REPEAT AMPLIFICATION PROTOCOL (TRAP)

Telomeric repeat amplification protocol (TRAP) detects telomerase activity. Telomerase plays an important role in cellular immortalization and oncogenesis, is a marker for carcinogenesis, and has increased expression in bladder cancer patients. It has a higher sensitivity in bladder washings than in voided urines⁴⁰ and is a promising tool.

Diagnosis

The majority of patients diagnosed with bladder cancer have signs or symptoms. Typically, gross painless hematuria is present but may be associated with urgency, frequency, and dysuria, all signs of bladder cancer, particularly carcinoma in situ (CIS). The signs associated with advanced TCCa are a palpable mass in the abdomen, a urethral mass, urethral spotting, or bone pain. The tumor site may be suggested by the timing of gross hematuria. Initial gross hematuria is likely associated with a urethral abnormality, whereas midstream hematuria is associated with a bladder abnormality, and finally late or terminal hematuria may be associated with a ureteral lesion.

The evaluation required to make the diagnosis of TCCa is a combination of endoscopic and radiologic techniques. For patients with gross or microscopic hematuria, imaging of the upper urinary tracts and the bladder is required. The American Urological Association recently published a summary of the best practice policies for the evaluation of symptomatic microscopic hematuria.⁴¹ Upper tract imaging with an intravenous pyelogram (IVP) or computerized tomography (CT) scan is recommended. An office cystoscopy to evaluate the bladder mucosa and a urine cytology to detect malignant cells complete the evaluation. For patients with invasive tumors, appropriate metastatic evaluation consists of a chest X-ray,

CT scan of abdomen and pelvis, and a bone scan, if the serum alkaline phosphatase is elevated or bone symptoms exist.

Upper tract abnormalities on imaging studies should prompt retrograde pyelography and ureteroscopic evaluation with ureteral cytology and washings as well as biopsy of suspicious areas. The endoscopic evaluation may provide valuable clarification of tumor histology, grade, and, potentially, stage; however, ureteroscopic biopsy can be hampered by small fragments that leave one relying on visual inspection. Transurethral resection of bladder tumor (TURBT), performed under general or regional anesthesia, is mandatory to obtain pathologic diagnosis and staging of any bladder lesion identified on cystoscopy. It should include an examination under anesthesia (EUA) and sampling of the bladder muscular wall to fully assess depth of invasion. It may also be appropriate to biopsy multiple areas of mucosa to identify multifocal CIS.

Treatment of Bladder Cancer

The treatment of bladder cancer can be complex and frequently involves a combination of surgery and chemotherapy/immunotherapy or radiation. Treatment approach is essentially a reflection of tumor behavior patterns, which are commonly stage specific. For nonmetastatic disease, the goals of therapy include complete tumor resection followed by adjuvant treatments, when appropriate, that will diminish the risk of tumor recurrence and progression.

EARLY-STAGE DISEASE: TA/TIS/T1

TRANSURETHRAL RESECTION

The initial treatment of all bladder tumors generally begins with TURBT. Resection of all visible tumor, when possible, is performed, with care taken to assess detrusor muscle below the lesion. For extensive but clearly well-differentiated papillary tumors, staged endoscopic resections may be necessary for complete tumor excision. Large or bulky tumors may not be feasible to remove with TURBT, and thus deep biopsies are taken for purposes of staging.

Restaging TURBT within 2 to 6 weeks is recommended in the patient with incomplete, undersampled, or uncertain resection. This repeat is especially important in the patient with Tis, Ta, or T1 disease, as well as the patient with suspected T2 disease who is being considered for a bladder preservation treatment strategy. Up to 29% of patients thought to have superficial or early-stage disease may be upstaged and 22% of individuals believed to have muscle-invasive disease may be downstaged, ultimately altering treatment in 33% of patients.⁴² Rates of residual tumor detected by the second TURBT are 55% to 76% for all stages sampled.⁴³ For cT1 disease, a 33% to 78% residual tumor rate is detected if muscle is present in the sample for evaluation; up to 28% of these patients are upstaged to muscle-invasive disease. If muscle is absent, up to 83% will be upstaged on the restaging TURBT when muscle is ultimately sampled.

Disease recurrence rates of superficial and early invasive bladder cancer after TURBT range from 50% to 70%, and progression rates range from 5% to 40%.⁴⁴ Thus, TURBT is limited as the sole treatment for early-stage disease. Patients at increased risk of both disease recurrence and progression include those with (1) invasion into the lamina propria (cT1), (2) high-grade disease, (3) multifocal tumors, and (4) associ-

ated CIS. Adjuvant treatments are generally applied to high-risk patients or low-risk patients with recurrent disease.

INTRAVESICAL THERAPY

Intravesical treatments are the primary adjunctive strategies aimed at reducing recurrence and possibly progression after TURBT (Table 47.4). Intravesical treatment is desirable as the risk of systemic absorption is generally low; however, local side effects can result in significant irritative symptoms. Intravesical chemotherapy used in conjunction with TURBT can reduce the risk of recurrence by 44% to 73% in patients with primary Ta and T1 tumors and by 38% to 65% in patients with recurrent Ta, T1, and Tis tumors when compared to TURBT alone.^{45,46}

Bacillus Calmette-Guérin (BCG) is an attenuated strain of *Mycobacterium bovis* that has stimulatory effects on immune responses.⁴⁷ Intravesical immunotherapy using BCG provides a significant reduction in recurrence that is greater than 50% in patients with superficial and early invasive disease and may also improve progression.^{48,49} Several randomized Phase III studies support the use of BCG as a first-line intravesical agent (see Table 47.4). The Southwest Oncology Group studied intravesical and percutaneous BCG versus intravesical doxorubicin in patients with rapidly recurrent Ta, Tis, and T1 disease.⁵⁰ This study demonstrated a significantly improved 5-year disease-free survival (DFS) for patients treated with BCG as compared to doxorubicin. The 45% DFS in patients with CIS was quite encouraging and was confirmed in another prospective randomized study in which BCG was found to be superior to doxorubicin and thiotepa in DFS and progression-free survival for superficial tumors.⁵¹ A subsequent randomized Phase III study by the EORTC demonstrated the superiority of intravesical BCG over epirubicin.⁵² The addition of percutaneous BCG to intravesical therapy does not increase treatment efficacy, and its use has been abandoned.⁵³

Despite improved rates of DFS, standard induction courses of intravesical chemotherapy and immunotherapy do not improve disease-specific survival (DSS) and therefore may not have long-term impact on the evolution of early-stage bladder cancer.^{54,55} However, when an induction course of BCG is followed by a series of maintenance doses consisting of weekly BCG given for 3 weeks at 3, 6, 12, 18, 24, 30, and 36 months after induction, DFS can be prolonged.⁵⁶ Median DFS for the maintenance group was 76.8 months, whereas DFS for the induction therapy alone was 35.7 months (*P* less than 0.0001). Overall 5-year survival was 78% in the no-maintenance arm compared with 83% in the maintenance arm. For patients who fail an initial or maintenance course of intravesical therapy, it may be reasonable to try another agent, such as MMC, doxorubicin, interferon-alpha, or gemcitabine as these agents may salvage 20% to 50% of patients with early-stage disease who fail to respond to BCG.⁵⁷⁻⁵⁹

Mitomycin C is an antitumor antibiotic that has been used in the treatment of patients with superficial bladder cancer intravesically since the early 1960s.⁶⁰ Although mitomycin C is inferior to BCG in patients with Ta/T1 and Tis tumors,⁶¹ its use in the immediate perioperative period provides a unique clinical application. A single dose of MMC administered immediately after TURBT can improve the rate of tumor recurrence of low-grade superficial tumors.⁶² In this study of 452 eligible patients, 1 dose of perioperative MMC

TABLE 47.4. Randomized trials of intravesical treatments for superficial and early-invasive bladder cancer.

Trial	Reference	Accrual years	Patient no.	Stage	Intervention/design	Median follow-up (F/U), months	DFS	Result
SWOG	50	1983–1985	262	Ta, T1 or CIS	BCG vs. Doxorubicin	65	5-year Ta/T1: 37% vs. 17% ($P = 0.015$) CIS: 45% vs. 18%	BCG superior to Doxorubicin
Martinez-Pineiro	51	1980–1988	176	Ta/T1	BCG vs. Doxorubicin vs. Thiotepa	36	3-year: 87% vs. 57% ($P = 0.002$) vs. 64% ($P = 0.004$)	BCG superior to both drugs Doxorubicin similar to Thiotepa
EORTC	52	1992–1997	837	Int-high risk Ta/T1	Epirubicin vs. BCG vs. BCG + INH	41	3-year: 49% vs. 65% vs. 64%; ($P = 0.0001$)	BCG better than Epirubicin INH offers no benefit

SWOG	61	1988–1992	447	Ta/T1	BCG vs. MMC	30	Median DFS: 44 vs. 22 months ($P = 0.017$)	BCG superior to mitomycin
MRC	62	1984–1986	452	Ta/T1	TUR vs. TUR ± MMC × 1 vs. TUR ± MMC × 5	84	40% vs. 55% ($P = 0.010$) vs. 63% ($P = 0.0001$)	TURBT + MMC × 1 is superior No benefit to MMC × 5 vs. × 1

DFS, disease-free survival; INH, Isoniazid; TUR, transurethral resection; MMC, mitomycin C; BCG, bacillus Calmette–Guérin.

(40 mg/40 mL) given within 24 hours of TURBT decreased the risk of recurrence by 34% when compared to TURBT alone.

MUSCLE-INVASIVE DISEASE: T2

TRANSURETHRAL RESECTION

TURBT is generally not effective in the treatment of cT2 disease; however, this modality may be of benefit in selected patients. Herr reported 10-year outcome of TURBT in 151 patients with cT2 bladder cancer who were downstaged to T0 or T1 after a restaging TURBT.⁶³ Of these 151 patients, 99 received definitive TURBT and 52 had immediate cystectomy. The 10-year DSS was 76% in the 99 patients treated with TURBT; 57% had their bladder preserved. The 52 treated with immediate cystectomy had a 71% DSS ($P = 0.3$). Thirty-four patients (34%) treated with definitive TURBT relapsed in the bladder; 18 were salvaged with cystectomy, but 16 died of disease. Radical TURBT may thus be of benefit, particularly in those ineligible for radical surgery or chemotherapy. However, this technique is best augmented with radiotherapy.

PARTIAL CYSTECTOMY

Because of the risk of recurrent tumors, indications for partial cystectomy are limited and generally apply to isolated tumors or those within diverticula. The 5-year survival rates range from 25% to 50%, with local recurrence ranging from 40% to 80%. Candidates should have unifocal lesions amenable to a resection with a 2-cm margin, and still have a reasonable remaining bladder capacity. Classic teaching suggests that

patients with CIS should not be candidates, although the use of intravesical BCG to treat CIS may broaden this teaching.

RADICAL CYSTECTOMY

Radical cystectomy remains the standard of care for patients with muscle-invasive disease and is the most effective means of cancer control of nonmetastatic TCCa of the bladder, with a 10-year DFS rate of 66%. The broad indication for cystectomy is a superficial, early-stage, or invasive tumor that is refractory to or unlikely to be controlled by transurethral resection and intravesical therapy. Local control in the pelvis is achieved in 93% of cases.¹²

The standard technique of radical cystectomy in men requires resection of the bladder and surrounding prostate and seminal vesicles because of the risk of prostatic urethral invasion and incidental prostate cancer.⁶⁴ In women, anterior pelvic exenteration may be required for high-volume disease, necessitating removal of portions of neighboring reproductive and sex organs at risk for direct extension. A complete total pelvic lymphadenectomy provides staging information and also treatment benefit. Although node-positive patients have a significantly shortened survival when compared to node-negative patients, 30% DFS at 5 and 10 years is still achievable despite extravesical disease in the primary specimen.¹² Recently, extended node dissection has been advocated because a 27% improved 5-year survival has been observed in patients who receive a standard node dissection when compared to those who have no dissection.⁶⁵ At least 11 to 14

nodes are necessary to define node-negative status accurately and to optimize cure by surgery in node-positive cases.

Patients with muscle-invasive bladder cancer are at risk for distant relapse after cystectomy; recurrence typically occurs within 2 years after treatment. This finding partly relates to the 30% to 40% understaging rate of preoperative assessment. Modern pelvic imaging tools such as CT and magnetic resonance imaging (MRI) are often unable to detect low-volume perivesical invasion; thus, many patients are upstaged at the time of cystectomy.

BLADDER PRESERVATION

A feasible alternative to radical surgery for selected patients with limited cT2 disease is radical radiotherapy. This modality has been of benefit for patients who are ineligible for or refuse radical surgery or those who desire organ preservation. Aggressive TURBT is followed by radiotherapy, which offers an improved rate of survival when performed in conjunction with chemotherapy.⁶⁶ A 5-year DSS rate of 20% to 40% is expected in patients with preserved bladders, with the best overall survival outcome in younger patients with lower-stage tumors without lymphovascular or nodal invasion.^{66,67} Superficial or early-stage recurrence approaches 50%, but it can be managed with TURBT with or without intravesical chemotherapy, although salvage cystectomy must be heavily considered. Because of the high local recurrence rate and low survival rate, it is accepted that radical cystectomy provides superior local control and more-efficacious survival for muscle-invasive disease and is therefore the preferred local therapy. A competing treatment strategy for those patients desiring bladder preservation has been early cystectomy and orthotopic neobladder diversion, which is able to simulate a natural voiding pattern, has very acceptable rates of continence, and avoids an external appliance.⁶⁸

To improve the efficacy of radical radiotherapy, neoadjuvant and concomitant chemotherapy has been applied. The Radiation Therapy Oncology Group (RTOG) performed a series of Phase II studies and ultimately a randomized Phase III study that examined the efficacy of peritreatment chemotherapy. In RTOG 85-12, aggressive TURBT was followed by concurrent radiotherapy and cisplatin, a treatment regimen that offered a 64% 4-year survival rate for patients with cT2 disease and 24% for patients with cT3–T4 disease.⁶⁹ RTOG 89-03, a Phase III study, assessed the effect of cisplatin/methotrexate/vinblastine (CMV) as a neoadjuvant to concurrent radiotherapy and cisplatin.⁷⁰ The primary objective was survival, although secondary objectives included bladder preservation, tolerance, and toxicity. Poor patient tolerance to the CMV regimen was demonstrated despite a 5-year survival of 49% in the 123 patients who were entered into the trial.⁷¹ Toxicity resulted in 3 treatment-related deaths, primarily due to neutropenia and severe sepsis. No difference in survival or bladder preservation was observed in patients who did or did not receive neoadjuvant CMV. Radiation sensitizers, such as gemcitabine and taxol, are currently being investigated.⁷⁰

EXTRAVESICAL DISEASE: T3/T4/N+

Patients with clinical evidence of extravesical tumor have a 5-year overall survival (OS) rate as high as 30% to 40% after cystectomy.^{12,15} As tumor recurrence is common in this

population, perioperative systemic chemotherapy has been advocated. Both neoadjuvant and adjuvant chemotherapy offer advantages and disadvantages to the patient. Adjuvant therapy has several benefits: (1) pathologic staging is the best prognostic indicator and will be known after surgical treatment; (2) low-risk patients are spared unnecessary treatment and toxicity if their staging is favorable; (3) no delay in surgery exists; (4) chance of cure for patients with chemoresistant disease is maximized; and (5) the lower toxicity of newer combination chemotherapy is likely to improve tolerance of and compliance with postoperative therapy. Neoadjuvant therapy also has several benefits: (1) prognostic information can be obtained from response to therapy of the primary lesion; (2) chemotherapy is not delayed, thus treating chemosensitive microscopic metastases immediately; (3) bladder preservation may be considered in complete responders; (4) patients may be downstaged increasing the opportunity for complete surgical resection; and (5) the presurgical patient is more likely to tolerate and be compliant with treatment.

NEOADJUVANT CHEMOTHERAPY

Neoadjuvant chemotherapy is increasingly being advocated for patients with muscle-invasive disease who will undergo radical cystectomy. Table 47.5 outlines several randomized trials that examined the survival effect of neoadjuvant chemotherapy.^{72–78} Most recently, an Intergroup study initiated by the SWOG lent further support for the use of neoadjuvant chemotherapy before radical cystectomy in patients with muscle-invasive disease.⁷⁸ In this study, 307 patients were randomized to receive three cycles of methotrexate, vinblastine, adriamycin, and cisplatin (MVAC) chemotherapy before cystectomy or cystectomy alone. With a median follow-up over 8 years, survival in the MVAC arm was significantly superior to survival in the no-MVAC arm, with a hazard ratio of 0.74 and estimated median survival times of 6.2 and 3.8 years, respectively. The improved median DSS and decreased total number of deaths was most pronounced in the patients with T3 and T4 disease. An added benefit in the chemotherapy arm was the downstaging of patients to pT0, confirmed at cystectomy. Criticisms regarding the study's methodology and lengthy accrual period of 11 years have led to some controversy.⁷⁹ Although a statistically significant improvement in DFS and median survival was appreciated, the overall survival benefit of the neoadjuvant cohort was relatively modest (less than 6%), and the toxicity from the treatment was significant.

The results of the SWOG-led study have contrasted those of the largest trial of neoadjuvant chemotherapy. The international intergroup trial initiated by the MRC and EORTC of CMV before cystectomy or radiotherapy enrolled 976 patients from 106 institutions in 5.5 years.⁸⁰ The trial, powered to detect a 10% improvement in survival, observed a 15% reduction in the risk of death in the chemotherapy arm, which translated into a 3-year survival benefit of 5.5% (50% in the no-chemotherapy arm and 55% in the chemotherapy arm.) The median length of follow-up for patients who were still alive was 4 years. The significance of these results have been debated, and follow-up analyses at 7 years suggest a possible significant survival benefit for the chemotherapy arm. Although interpretation of these randomized trials (see Table 47.5) has been difficult, it is clear that long term survival rates after cystectomy alone are poor for cT3 and T4 disease, and so a perioperative chemotherapy strategy makes sense.

TABLE 47.5. Randomized trials of neoadjuvant chemotherapy for invasive bladder cancer.

<i>Trial</i>	<i>Reference</i>	<i>Accrual years</i>	<i>Patient no./evaluable Patients</i>	<i>Stage</i>	<i>Neoadjuvant regimen</i>	<i>Median F/U (years)</i>	<i>Survival (chemo + Cx) vs. (Cx alone)</i>	<i>Chemo benefit</i>

ADJUVANT CHEMOTHERAPY

Four randomized studies have evaluated the benefit of adjuvant chemotherapy after cystectomy (Table 47.6).^{81–85} Two of these trials did not show a benefit when adjuvant treatment was compared with observation.^{83,84} The study by Studer⁸³ and colleagues has been criticized for using an inferior regimen, single-agent cisplatin, when a cisplatin-based multidrug regimen such as MVAC was known to be more efficacious at that time.⁸⁶ The study by Freiha et al.⁸⁴ has been criticized for being underpowered.

In the Skinner study,⁸¹ patients with stage T3–T4 or node-positive disease were randomized to observation or four cycles of adjuvant CAP (cyclophosphamide, adriamycin, cisplatin). A significant delay in recurrence was observed in the adjuvant chemotherapy group when compared to those treated with cystectomy alone (70% versus 46% 3-year-DFS, respectively). A significant improvement in OS (4.3 versus 2.4 years) was also observed. This study was criticized for the small number of

patients (91), flawed statistical methods, premature termination, and the use of nonstandardized chemotherapy. Moreover, chemotherapy compliance was poor; only 70% of patients in the chemotherapy group received any treatment and only 62% received the planned number of cycles.

In the study by Stockle et al.,⁸² 49 patients with stage pT3a–pT4a or node-positive TCCa were randomized to MVAC, MVEC, or observation. Patients in the observation group did not receive chemotherapy at relapse. A significant reduction in the risk of tumor recurrence was observed in the chemotherapy arm: 3 (17%) of 18 patients who received chemotherapy relapsed compared with 18 (82%) of 23 untreated patients. This study also faced poor chemotherapy compliance, with only 75% of patients in the chemotherapy group receiving any treatment and only 48% receiving the planned number of cycles. Unfortunately, both the Skinner and Stockle trials ended prematurely based on interim analyses favoring adjuvant chemotherapy.

TABLE 47.6. Randomized trials of adjuvant chemotherapy for invasive bladder cancer.

<i>Trial</i>	<i>Reference</i>	<i>Accrual period</i>	<i>No. of patients</i>	<i>Stage</i>	<i>Adjuvant regimen</i>	<i>Median F/U, months</i>	<i>Survival</i>	<i>Chemo benefit</i>

Stockle	82	1987–1990	49	pT3, pT4 N+	MVAC/MVEC	>12	DFS in 73% (Cx/chemo) vs. 18% (Cx); <i>P</i> = 0.0012	Yes for DFS
Studer	83	1984–1989	77	pT1–4 N0–2	Cisplatin	69	5-year OS: 57% (Cx/Cis) vs. 54% (Cx); <i>P</i> = 0.65	No for OS
Freiha	84	1986–1993	50	pT3b, pT4 N0–1	CMV	62	Median OS: 63 (Cx/CMV) vs. 36 months (Cx); <i>P</i> = 0.32	No for OS

CISCA, cisplatin, methotrexate, vinblastine; CMV, cisplatin or carboplatin, methotrexate, vinblastine; MVAC, methotrexate, vinblastine, doxorubicin, cisplatin; MVEC, methotrexate, vinblastine, epirubicin, cisplatin; DFS, disease-free survival; OS, overall survival; Cx, cystectomy alone.

Despite criticisms of adjuvant treatment trials, there is a suggested survival benefit for patients with extravesical or nodal extension or extension to neighboring viscera. Currently, a large international Intergroup study is under way to determine whether adjuvant chemotherapy is effective.⁸⁷ This randomized study will compare delayed versus immediate chemotherapy (gemcitabine plus cisplatin, MVAC or high-dose MVAC plus granulocyte colony-stimulating factor) after radical cystectomy for pT3–pT4 or node-positive, but M0 TCCa, of the bladder.

DISTANT UROTHELIAL METASTASES: M+

There have been several randomized clinical trials evaluating chemotherapeutic regimens for the treatment of metastatic TCCA (Table 47.7).^{88–98} Although chemotherapeutic regimens can result in response rates as high as 65%, the median survival is at best 12 to 15 months. The most active chemotherapeutic regimen for TCCA is MVAC.^{93,94} Its use has been limited by its significant toxicity, including an associated 3% to 4% treatment mortality rate.^{94,96,97} Gemcitabine/cisplatin has similar survival but an improved toxicity profile, and in many respects it has become the standard therapy for metastatic TCCA.⁹⁶ Variants of the traditional MVAC dosing may also make the regimen more tolerable while maintaining survival rates.⁹⁷

Newer Phase I and Phase II studies using a combination of monoclonal antibodies and chemotherapy are under way at single institutions. Some of these studies have shown promise, particularly the use of Herceptin in the treatment of patients with tumors that express Her-2/neu. Although TCCA appears to be responsive to chemotherapy, the number of complete long-term responders is low, and the development

of additional chemotherapeutic regimens will be necessary to make an advance in this disease.

Treatment of Ureteral Cancer

When the diagnosis of upper tract urothelial cancer is well established, it is critical to consider multiple tumor and patient factors when making a treatment decision. Tumor size, grade, stage, and location all guide treatment strategy, but tumor stage remains the most important prognostic factor for recurrence and DSS.⁹⁹ Apart from stage, one must also weigh the value of renal preservation against the reality of tumor threat. Organ preservation is entertained if a patient has a solitary functioning kidney, multifocal urothelial tumors, or an abnormal or threatened contralateral kidney. This strategy is considered in view of the significant mortality of dialysis, with a 5-year survival rate of 19% in patients between 65 and 74 years of age.¹⁰⁰ Modern endoscopic strategies have also permitted a wider application of conservative treatment options.

ENDOSCOPIC OPTIONS

Endoscopic treatment of low-grade, low-volume, noninvasive renal pelvic and ureteral tumors is now possible with improved instrumentation in ureteroscopy and enhanced experience with percutaneous techniques. Figure 47.2 demonstrates a typical papillary ureteral tumor visualized during ureteral imaging (Figure 47.2A) and through a ureteroscope (Figure 47.2B). Retrograde ureteroscopic tumor biopsy and treatment may be accomplished using flexible instrumentation of an accessible ureteral orifice. Electrocautery and the holmium and neodymium YAG lasers have all been used

TABLE 47.7. Randomized trials of chemotherapeutic intervention for metastatic bladder cancer.

<i>Trial</i>	<i>Reference</i>	<i>Accrual</i>	<i>No. of evaluable patients</i>	<i>Chemotherapy regimen</i>	<i>RR (%)</i>	<i>CR (%)</i>	<i>Median survival</i>	<i>Treatment mortality (%)</i>	<i>Outcome</i>

successfully for primary upper tract tumor ablation. Small working endoscopic channels with decreased irrigant flow can compromise the visual field, however, and can limit the therapeutic applications. Percutaneous management, a better approach to selected renal pelvic tumors, has the benefit of larger working channels that can accommodate resections and cautery instruments, permitting more complete biopsy, fulguration, and staging. However, percutaneous management has the potential risk of extravasation of cancer cells when obtaining renal access and dilating the nephrostomy tract. The authors do not recommend elective endoscopic or percutaneous management of T1 disease in the patient with a normal contralateral kidney in view of the 20% to 55% progression rates experienced for grade II/III primary tumors.¹⁰¹

Tumor recurrence remains the most serious consequence of conservative treatments. With any conservative approach, one must ensure that salvage therapy is available for failures. When surveyed closely, most patients are still candidates for open resection if they fail endoscopic approaches. Recurrence rates of renal pelvic and ureteral tumors treated with ureteroscopy are 33% to 35% and 31% to 32%, respectively. Tumor grade and size do impact recurrence, with a rate of 26% for grade I, 44% for grade II, and 25% for lesions less than 1.5 cm compared with 50% for tumors larger than 1.5 cm.^{101,102} A reasonable initial approach to the small (less than 1.5 cm) low-grade ureteral or renal pelvic tumor would be ureteroscopic ablation. Multiple or large low-grade renal pelvic tumors in the patient who is a poor candidate for nephroureterectomy would likely benefit from initial percutaneous management.

UPPER TRACT CHEMOTHERAPY OR IMMUNOTHERAPY

Carcinoma in situ presents a much greater treatment challenge than low-grade superficial disease, in part because of its often multifocal nature; this is reflected in the higher recurrence and progression rates of high-grade superficial disease treated endoscopically or percutaneously.¹⁰¹ Upper tract immunotherapy and chemotherapy have been used as adjuvant strategies for Ta and CIS. Logistic problems often arise relative to delivering adequate drug dosage whether by ante-

grade or retrograde techniques. There is limited experience with all agents, with only few reports describing the use of BCG, thiotepa, and mitomycin C; the efficacy of these agents remains unclear.^{101,102} Although BCG delivery can be cumbersome, a recent study of 41 renal units treated in 37 patients with primary Ta or Tis disease demonstrated that percutaneous BCG can be delivered without seeding the nephrostomy tract and without undue morbidity; acceptable 3% and 5% rates of BCG inflammation and septicemia, respectively, were observed.¹⁰³ The median recurrence free and progression free survival was 21 and 34 months at 42 months of follow-up.

SEGMENTAL OR DISTAL URETERECTOMY

The best results with preservative procedures for upper tract urothelial tumors are seen in the treatment of isolated tumors of the lower third of the ureter. Complete distal ureterectomy with reimplantation of the ureter can yield results very similar to those obtained with a nephroureterectomy if appropriate cases are chosen, particularly for low-grade noninvasive tumors. The proximal margin of the ureter must be examined intraoperatively. Using this approach in the patient with high-grade and invasive disease must be done with caution as a significant number of these patients will die of recurrent disease.⁹⁹ The temptation of segmental ureterectomy for midureteral lesions should be avoided in the patient without renal compromise in view of the 30% recurrence rate within the ureter distal to the initial lesion.¹⁰⁴

NEPHROURETERECTOMY

Nephroureterectomy with bladder cuff excision continues to be the standard treatment for organ-confined invasive or recurrent superficial upper tract TCCa, particularly in the mid- to upper ureter and renal pelvis. Partial nephrectomy and pyelotomy with tumor excision are undesirable but are considered in the presence of a solitary kidney, diminished renal function, or bilateral disease. The major concern after conservative procedures is tumor spillage and local recurrence, which can approach 62% for open renal pelvic procedures.¹⁰⁵ Excision of the entire ureter with a small cuff of bladder ensures total removal of the intramural ureter and

avoids unnecessary recurrence. Historically, recurrence of 48% was reported after nephrectomy alone, 32% after nephrectomy and partial ureterectomy, 24% with nephrectomy and subtotal ureterectomy, and only 12% after total nephroureterectomy, illustrating the importance of total ureterectomy.¹⁰⁴ An incomplete ureterectomy also leaves an ipsilateral ureteral stump that is difficult to survey for recurrent disease. Laparoscopic nephroureterectomy has several benefits over open nephroureterectomy for primary upper tract tumors including more rapid recovery, shorter hospital stay, and less requirement of pain medication. Rates of recurrence, local control, and disease-specific survival are comparable to open nephroureterectomy, and consequently laparoscopic nephroureterectomy has become standard treatment in many centers.¹⁰⁶ Success of upper tract treatments is heavily reliant on tumor stage. Five-year DSS is 100% for Ta/CIS, 92% for T1, 73% for T2, 41% for T3, and 0% for T4.⁹⁹ Median DSS for T4 patients is 6 months.

Treatment of Urethral Cancer

Treatment of urethral cancer is complex and often requires a multidisciplinary approach. Patients often present at a later stage requiring radical surgery with adjuvant chemotherapy or radiation.¹⁰⁷ Because of the uncommon nature of the disease, there is a lack of uniform treatment. In women, because of the short urethra, fewer conservative treatment strategies exist. Therapy for superficial low-grade tumors may be treated endoscopically; however, one risks disrupting the continence sphincteric mechanism. For invasive disease, total urethrectomy is performed along with cystectomy and, depending on the tumor bulk and age of the patient, partial resection of neighboring sexual and reproductive organs. Urinary diversion is then required.

URETHRAL CANCER IN WOMEN

In a retrospective case series from Memorial Sloan Kettering, 72 women with urethral cancer were followed for a median of 84 months; 68% presented with cT2–cT4 tumors.¹⁰⁷ Forty (56%) underwent major or radical surgery including anterior or total pelvic exenteration, urethrectomy, cystectomy, or diverticulectomy; 10 of those undergoing anterior pelvic exenteration received preoperative radiotherapy. A total of 25 patients (35%) were treated with external-beam radiotherapy with or without brachytherapy. The 5-year DFS and DSS were 46% for the entire cohort, 83% to 89% for low-stage women, and 33% for high-stage patients. In a multivariate analysis, primary stage, nodal status, and site of disease were independent predictors of survival. Primary treatment with either surgery or radiation resulted in similar DFS and DSS; however, preoperative radiotherapy significantly improved DFS.

Organ preservation may be achieved with the use of brachytherapy and radiotherapy.¹⁰⁸ In a retrospective case series of 34 women treated with external-beam radiotherapy with or without brachytherapy, brachytherapy reduced the risk of local recurrence by a factor of 4.2. Its effect was most prominently seen in patients with bulky primary disease. Large tumor size was the only independent adverse predictor of DFS and DSS. The 7-year DSS was 45%.

URETHRAL CANCER IN MEN

In men, the location and stage of the tumor dictates the treatment. Small or low-grade superficial tumors may be treated endoscopically throughout the urethra. However, bulkier tumors require surgical resection and often adjuvant chemoradiation. Tumors in the distal or anterior male urethra may be treated with subtotal urethrectomy with or without partial penectomy depending upon tumor extension. More proximal disease in the prostatic or pendulous urethra may require cystoprostatectomy with urethrectomy and urinary diversion.

Dalbagni et al. retrospectively reviewed the Memorial Sloan Kettering experience over a 38-year period during which 46 men were treated for primary urethral cancer.¹⁰⁹ The majority (70%) presented with locally advanced or nodal disease, with a median interval of 7.5 months from the onset of symptoms to diagnosis. The infrequent nature of the disease led to nonstandard treatment with conservative (endoscopy, partial urethrectomy, partial penectomy) and radical (total urethrectomy, total penectomy, cystectomy, pelvic exenteration) surgery. Six patients received preoperative radiation, although no benefit in local recurrence-free survival was observed in this group. At a median follow-up of 125 months, the 5-year DSS and OS were 50% and 42%, respectively. Tumors in the bulbar (proximal) urethra had a worse prognosis when compared to those in the anterior (distal) urethra (26% versus 69% OS, respectively). In view of the low disease incidence, evidence-based treatments will only be realized through national cooperative group studies.

Penis

Etiology

Carcinoma of the penis is an uncommon malignancy, with an estimated 1,400 new cases in 2003.¹¹⁰ Epidemiologic evidence suggests that penile cancer has several similarities with other anogenital malignancies. Specifically, these tumors occur more commonly among those of lower social class and those who are separated or divorced. Furthermore, these cancers occur infrequently in Jewish populations.¹¹¹ Although potential risk factors of penile cancer have been studied extensively, a true etiology remains unclear.

Human papilloma virus (HPV) is a sexually transmitted virus that has been associated with anogenital infections in men and women.¹¹² The prevalence of HPV infection in penile cancers is variable (22%–71%),^{113–115} and less prevalent than in genital warts,¹¹³ suggesting distinct pathogenesis of these conditions. Historically, penile carcinomas were thought to arise from cellular atypia or intraepithelial neoplasia¹¹⁶ associated with HPV infection.¹¹⁷ Two case-control studies detected an increased risk (4.5 to 5.9 times) of penile cancer in men with genital warts, implicating HPV as a potential causal agent.^{114,118} Because of the variable association of HPV with carcinoma of the penis, however, its oncogenicity is likely additive to other causal factors.

Other risk factors commonly associated with invasive or in situ carcinoma of the penis include tobacco use/exposure, phimosis, penile injury, poor hygiene, physical inactivity, and history of genital rash.^{114,118,119} Men with prolonged exposure to ultraviolet A and B radiation in the treatment of psoriasis, prospectively followed for 12 years, demonstrated a 59-fold-

FIGURE 47.3. Photograph of a penile cancer on the shaft of the penis.

increased risk of developing invasive or in situ penile cancer when compared to unexposed men.¹²⁰ This risk was strongly dose dependent, suggesting a high susceptibility of the genitalia to the carcinogenic effects of ultraviolet radiation.

Although newborn circumcision is not routinely recommended by the American Academy of Pediatrics or the American College of Obstetrics and Gynecology,¹²¹ there is some evidence to suggest that newborn circumcision may prevent the development of penile cancer.¹¹⁴ It is unclear whether this effect is mediated by improved hygiene¹¹⁹ or prevention of complications related to phimosis.^{118,119} However, the incidence of penile cancer among American circumcised men is essentially nonexistent, with a lifetime risk of developing penile cancer of 1 in 600.¹²²

Pathology

Most penile cancers are of squamous cell origin, resembling those malignancies that develop in nongenital skin (Figure 47.3). Because of the implications of pathogenesis and morphology on prognosis, squamous cell carcinoma (SCCa) of the penis has been classified into three histologic subtypes.^{113,123,124} The most common subtype is typical SCCa. Other subtypes—warty and basaloid—correspond to those found in vulvar malignancies. Warty SCCa of the penis morphologically resembles other verruciform lesions of the penis such as giant condyloma and verrucous carcinoma.¹²⁴ Unlike the latter two lesions, warty carcinoma is uniformly associated with HPV infection¹¹⁴ and has the ability to metastasize.^{124,125} The association of basaloid carcinomas with HPV infection (80% of cases)⁵ is similar to that of the warty subtype, whereas the most common variant, typical SCCa, is infrequently associated with this viral infection (35% of cases).¹¹³ In contradistinction to the warty subtype, the basaloid variant is commonly associated with deeper invasion and diminished survival.¹²³ Collectively, these data suggest that these subtypes of penile carcinoma may have distinct pathogenesis and pathophysiology. The frequent association of basaloid and warty subtypes with HPV DNA may also provide a molecular basis for a viral etiology in their development. Staging of penile cancers is based on that of the American Joint Committee on Cancer TNM staging system

(Table 47.8).¹²⁶ *Clinically, the precise TNM stage is used rather than the overall stage.*

Prognostic Factors

Clinical variables (e.g., palpable adenopathy) and primary tumor factors (e.g., vascular invasion) associated with regional lymph node metastasis have been described as prognostic factors (Table 47.9). To date, there have been no randomized clinical trials in the management of inguinal lymph nodes in patients with or without palpable adenopathy. Consequently, the current evidence is based on multiple, single-institutional case series. Despite these limitations, these data, in conjunction with the pathologic stage of the regional lymph nodes, have been useful in defining various measures of survival (see Table 47.9).

REGIONAL LYMPH NODES

The morbidity of a modified inguinal lymph node dissection (ILND), including lymphedema, flap necrosis, deep venous thrombosis, and wound infection, precludes its routine use in the treatment of patients with penile cancer.^{127,128} Consequently, factors predictive of lymph node involvement have been sought.

LYMPHATIC AND VASCULAR INVASION

Multiple studies^{129–131} have demonstrated the importance of vascular invasion in the penile specimen as an independent predictor of subsequent lymph node metastasis. Among 82 patients treated with penectomy and bilateral ILND between 1953 and 1992, those with lymphatic embolization of tumor cells in the penile specimen were nine times more likely to have positive lymph nodes compared to those without lymphatic invasion.

TABLE 47.8. The TNM staging system for carcinoma of the penis.

<i>Primary tumor (T)</i>	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Ta	Noninvasive verrucous carcinoma
T1	Tumor invades subepithelial connective tissue
T2	Tumor invades corpus spongiosum or cavernosum
T3	Tumor invades urethra or prostate
T4	Tumor invades other adjacent structures
<i>Regional lymph nodes (N)</i>	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in single superficial, inguinal lymph node involvement
N2	Metastasis in multiple or bilateral inguinal lymph nodes
N3	Metastasis in deep inguinal or pelvic lymph node(s) unilateral or bilateral
<i>Distant metastasis (M)</i>	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

ACCUMULATION OF p53

Inactivation of the tumor suppressor gene, p53, has been associated with pathogenesis and progression of multiple malignancies. In penile cancer, lymph node metastasis has been associated with nuclear accumulation of dysfunctional p53 protein.^{129,132}

PATHOLOGIC STAGE/GRADE OF PRIMARY TUMOR

Pathologic stage of the primary tumor is also associated with lymph node involvement.^{131,132} Invasion of the corpus spongiosum or cavernosum (pT2 or greater) independently portends increased risk for nodal involvement.¹³¹ Poorly differentiated primary tumors also offer increased risk of

lymph node metastasis.¹³¹ These data highlight the importance of careful pathologic analysis of the primary tumor.

Disease Progression and Survival

NODAL STATUS

The presence of inguinal lymph node metastasis at the time of ILND is the single greatest predictor of overall^{1129,130,133} and disease-specific^{134,135} survival among patients with penile cancer. In one series, patients with lymph node involvement were 8.3 times more likely to die of penile cancer than those patients without nodal disease. Moreover,

bilateral lymph node metastasis portends a worse prognosis than unilateral disease, with 5-year DSS decreasing to 9% from 56%, respectively.³⁶ Involvement of the deep inguinal or pelvic lymph nodes heralds aggressive disease with 5-year survival of less than 18%.^{29,33,36} The number of lymph nodes involved at the time of ILND is also associated with survival. Specifically, the presence of metastasis in more than two lymph nodes results in significant declines in 5-year survival.¹³⁶ Moreover, the likelihood of pelvic metastasis rises as the number of involved inguinal lymph nodes increases.^{136,137}

AGE

Not surprisingly, older age (classified as more than 50 to 60 years of age) has been associated with a decline in overall survival among patients with penile cancer.^{129,130} However, advanced age has also been shown to be independently associated with lower DSS.¹³⁴ In fact, men over the age of 60 were 3.4 times more likely to die of penile cancer than younger men.

TUMOR GRADE

Patients with high-grade or poorly differentiated cancers are more likely to succumb to their disease or have progressive disease than those with low-grade tumors.^{134,138,139} Multiple other factors have been associated with diminished OS (eosinophilic infiltrate on pathologic examination,¹³⁰ corporal involvement,¹⁴⁰ and p53 immunoreactivity¹³²), DSS (ulcerative tumors),¹³⁴ and tumor progression (pathologic stage, depth of invasion, and vascular invasion).¹³⁹

Diagnosis

The diagnosis of penile cancer is made by excisional, incisional, or punch or needle biopsy methods depending on the location of the tumor. Once the diagnosis is confirmed, subsequent local treatment (e.g., partial or total penectomy, laser surgery, or Moh's micrographic surgery) can be undertaken based on biopsy results and extent of the primary tumor (see Treatment: Local). Additional staging may be performed with a chest radiograph, an abdominal-pelvic CT scan (to assess for pelvic adenopathy), and a bone scan (in patients with extensive disease, bone pain, or abnormal serum chemistries, such as alkaline phosphatase, calcium).

Evaluation of the regional (superficial and deep inguinal) lymph nodes poses a greater problem because of the lack of sensitivity of various imaging modalities and the potential for significant morbidity associated with ILND.^{128,141} Multiple attempts have been made to clarify the accuracy of the various staging modalities. Horenblas and colleagues¹³⁸ described their experience with staging techniques among 118 patients with cancer of the penis. The investigators noted that the sensitivities for physical examination, lymphangiography, computed tomography, and fine-needle aspiration were 90%, 31%, 36%, and 71%, respectively. The respective specificities for these tests were 21%, 100%, 100%, and 100%. The authors concluded that imaging is useful in determining the management of the regional lymph nodes: negative findings are essentially meaningless. Rather, imaging may be helpful in the context of evaluating the pelvic lymph nodes and in determining the extent of disease.

Invasive techniques for assessing the inguinal lymph nodes include modified ILND, dynamic sentinel lymph node biopsy, and fine-needle aspiration. Some investigators have demonstrated improved postoperative recovery following the saphenous vein-sparing modified ILND with transient lymphedema and scrotal edema in 20% of patients and no long-term complications.^{127,142} Morbidity with this procedure appears to be greater when performed as a palliative procedure rather than prophylactically in the setting of clinically negative nodes.¹²⁸ Although the modified dissection is perhaps the most popular form of lymphadenectomy currently utilized, some investigators advocate a more-extensive dissection because of its worrisome local recurrence rates (up to 15%).¹⁴¹

The use of fine-needle aspirations has also proven problematic because of false-negative rates of at least 10%.¹⁴³ Among 20 patients who underwent extensive fine-needle biopsy using lymphangiographic and fluoroscopic guidance, 2 patients (10%) were found to have false-negative results at the time of ILND. Attempts to improve upon the sensitivity of needle biopsy and morbidity of ILND resulted in the use of dynamic sentinel lymph node biopsy.^{144,145} Initial findings of high false-negative rates as manifested by subsequent progression or the presence of metastasis at the time of ILND¹⁴⁶⁻¹⁴⁸ have prompted technique modification. Recent efforts employing preoperative lymphoscintigraphy, vital blue dye, and gamma-ray detection probes have made considerable inroads into improving technique sensitivity. However, current results reiterate that sentinel node sampling continues to be imperfect¹⁴⁹ and results in false-negative rates of at least 20%.¹⁵⁰ Despite this, recent evidence suggests that universal application of this technique in cT2-cT3 patients can improve DSS at 3 years when compared to surveillance. These findings highlight the importance of early treatment of the inguinal lymph nodes in those with nodal involvement.¹⁵¹

Therapy

Carcinoma of the penis typically follows a stepwise progression in which the disease proceeds from the penis to regional inguinal lymph nodes to distant sites. Because of this predictable pattern of spread, the extent of radical surgery is often measured against the high probability of surgical-related morbidity. Consequently, less-deforming modalities of therapy have been utilized to strike a balance between therapy and morbidity.

LOCAL

Excisional biopsy encompassing normal neighboring skin is the initial local treatment for small superficial penile cancers. Lesions confined to the preputial skin can successfully be managed with circumcision alone.¹⁵² For more-extensive cancers involving the glans, the shaft, and other local structures (e.g., prostate), the standard treatment includes either partial or total penectomy, depending on the extent of the primary tumor.^{137,153} Partial penectomy is indicated when an adequate 2-cm tumor margin¹⁵⁴ can be achieved while maintaining sufficient penile length for upright micturition. Margins less than 2 cm may also provide adequate local control, because penile cancers are focal and do not spread in

a discontinuous fashion.¹⁵³ Several studies have documented the efficacy of margins less than 1 cm when performing partial penectomy, thus increasing the eligible patient population for the procedure.^{153,155}

Because of the morbidity of total or partial penectomy, less-disfiguring treatments have been implemented in select patients including laser therapy,¹⁵⁶ Moh's micrographic surgery,¹⁵⁷ and multimodality regimens that incorporate conservative surgery, radiation (external beam or brachytherapy), and systemic chemotherapy.¹⁵⁸⁻¹⁶² The aggregate of data suggest that responses to these modalities are highly variable and that local recurrence rates for these less-invasive treatments is higher than for extirpative surgery. Consequently, these conservative modalities should be reserved for selected patients with smaller, well-differentiated disease.¹⁶²

REGIONAL

Standard treatment for documented inguinal lymph node metastasis is ILND. Certainly, despite its modifications,¹⁴² the ILND is commonly associated with postoperative morbidity,¹²⁸ excluding its routine use in all patients with carcinoma of the penis. Historically, patients with palpable inguinal lymph nodes at the time of primary treatment were initially managed with a 6-week course of antibiotics to treat adenopathy related to infection or inflammation.¹⁵² Persistent adenopathy following antimicrobial therapy was associated with tumor invasion in at least 70% of patients.^{136,137} Likewise, development of palpable inguinal nodes after treatment of the primary tumor generally represents tumor extension rather than inflammation.¹⁵²

Early or prophylactic ILND provides improved cancer control^{131,136,163} and less morbidity than lymphadenectomy performed in the presence of known lymph node metastasis (therapeutic) or for palliation.¹²⁸ Selected patients eligible for observation instead of ILND include those with low grade (grades 1-2), low stage (Ta, Tis, T1) tumors without vascular invasion. In this setting, close surveillance is critical as delayed ILND may result in increased tumor burden manifested by extranodal disease, pelvic lymph node metastasis or contralateral inguinal spread.¹⁵¹

Controversial issues in the management of the regional lymph nodes include whether or not to perform a bilateral dissection and the utility of a pelvic lymphadenectomy in the setting of positive inguinal lymph nodes. The lymphatic drainage of the penis to both the right and left inguinal lymph nodes is well documented.^{150,164} Hence, bilateral ILND would seem warranted in the setting of prophylactic dissection. This methodology is further substantiated by the aforementioned benefits of an early ILND. The indication for pelvic lymphadenectomy is less clear because the presence of pelvic nodal metastases portends a poor prognosis with a 5-year survival of 10%.¹⁵² Consequently, pelvic lymphadenectomy is rarely curative, and patients with demonstrable pelvic nodes may receive more benefit from neoadjuvant systemic therapy.

DISTANT

Patients uncommonly present with distant disease (less than 3%).¹⁶⁵ Table 47.10 summarizes the efficacy of single-agent and combination chemotherapy in the setting of advanced penile cancer.

TABLE 47.10. Selected chemotherapeutic studies directed at the treatment of advanced penile carcinoma.

Reference	Year of study	No. of patients	Design	Stages	Treatment regimen	Median survival (months)	Conclusions
Hussein ¹⁷¹	—	5	Phase II	Regional, bone metastasis	Cisplatin + 5-fluorouracil	15	All had clinical PR, all received subsequent XRT
Haas ¹⁷⁰	1986-1994	40	Phase II	Locally advanced or metastatic disease	Cisplatin + methotrexate + bleomycin	28 (progression-free survival, 14 weeks)	CR 12.5% PR 20% Treatment-related death in 12.5% 15% life-threatening toxicities
Sklaroff ¹⁶⁶	1970s	11	Phase II	Regional	Cisplatin Prior treatments: 50% ILND 63% XRT 88% chemo		OR 33% 1 patient had CR of 7 months
Ahmed ¹⁶⁷	—	39	Phase II	Advanced disease	Methotrexate 13 Bleomycin 14 Cisplatin 12	2 to 8 (nonresponders vs. responders)	Median response (in months): Methotrexate 3 Bleomycin 3 Cisplatin 8
Dexeus ¹⁷³	1987-1989	12	Phase II	Advanced; 93% nodal disease	Cisplatin + methotrexate + bleomycin	10	OR 72% CR 14% PR 57%
Sklaroff ¹⁶⁸	1970s	8	Phase I	Advanced 88% nodal, 38% liver, 50% pulmonary	Methotrexate Prior treatments: 75% ILND 38% XRT 25% chemo		OR 38% lasting 2-11 months
Shammas ¹⁷²	1985-1990	8	Phase II	Metastatic disease/inoperable	Cisplatin + 5-fluorouracil	12	PR 25% Response facilitated subsequent surgery
Edsmyr ¹⁵⁹	1971-1984	42	Case series	T1 36 T2 45 T3 19	Group 1 45 Gy + bleomycin Group II 58 Gy + bleomycin	77% 5-year survival	Group I CR 86% Group II CR 94% Local recurrence 10%

Large, multiinstitutional trials are uncommon in penile cancer, largely because of its low incidence. Single-agent cisplatin,^{166,167} methotrexate,^{167,168} and bleomycin^{159,167} have all demonstrated treatment efficacy, with partial responses occurring in 14% to 53% of patients. However, complete and durable responses following single-agent chemotherapy are rare, occurring in 7% to 8% of patients.¹⁶⁷ A multiinstitutional SWOG study treated 26 chemotherapy-naïve patients with cisplatin. The investigators noted a modest response of 15% with 1 to 3 months durability.¹⁶⁹

Suboptimal responses with single-agent chemotherapy prompted the use of multidrug regimens. A Phase II intergroup study, SWOG 8520, treated 40 patients with locally advanced or metastatic disease with cisplatin, bleomycin, and methotrexate. The median overall and progression-free survival in this population was 28 months and 14 weeks, respectively.¹⁷⁰ The overall response rate in this cohort of patients was 33%. However, the toxicity of the regimen was prohibitive, with treatment-related deaths occurring in 13% and life-threatening grade 4 toxicity in 15%.

Because of its squamous cell origin, established regimens utilized in the management of head and neck cancers have been tested in advanced penile cancer. The combination of cisplatin and 5-fluorouracil has demonstrated promising results, with median survival of 15 to 57 months in responders.^{171,172} Moreover, this regimen has documented efficacy in improving the feasibility of salvage surgery. Its use may be limited by toxicity because only 38% of patients received more than two cycles. Other regimens have provided modest responses in advanced disease.¹⁷³

In summary, combination chemotherapy appears to offer the best efficacy in the treatment of advanced/nonsurgical carcinoma of the penis. Current regimens offer a modest response rate and may facilitate subsequent surgery, although the role of this methodology is evolving and the effectiveness is uncertain. Certainly, the use of novel agents and drug combinations is warranted in this disease.

Prostate Cancer

Richard Whittington and David J. Vaughn

Prostate cancer presents one of the most controversial challenges to clinicians today. Where controversies may exist as to how best to treat many diseases, the controversies in prostate cancer start with the question, "Should we even try to diagnose this disease before it becomes clinically evident?" When the disease is found, the next question is whether the disease should be treated and whether the cure is worse than the disease. The next set of controversies revolve around how to most effectively treat the tumor. If a decision is made to proceed with radiation, the final controversies revolve around radiation fields and techniques. Each of these decision points can provoke heated discussions among recognized authorities in the field. This chapter attempts to discuss the controversies with the data supporting each point. It is likely that partisans of any argument will find support for their position, but it is also likely that a disinterested observer will see logic in each position. Before reviewing the controversies, it is necessary to develop a common foundation for the discussion.

Prostate cancer is the second leading cause of cancer death in the United States, second only to lung cancer, with an estimated 221,000 new cases in 2003 with an expected 28,900 deaths. It represents nearly one-third of all cancers diagnosed in men but only 10% of the deaths. The age-adjusted incidence of prostate cancer has increased by 70% in the past 25 years but is still 25% lower than values from 1993. There is a disequilibrium in the racial distribution of prostate cancer, with a very high incidence in African-Americans and a lower incidence in Asian-Americans (Table 48.1).¹

The staging of prostate cancer has also been modified twice in recent years, which confuses staging. Initially, stage B tumors (palpable nodule) were divided into B1(n), a nodule smaller than 1 cm entirely surrounded by normal prostate stroma; B1, which was a larger or peripheral unilateral nodule; and B2, representing a bilateral nodule. This scheme was modified shortly after prostate-specific antigen (PSA) screening became available to describe B1 as a nodule encompassing half of one lobe and B2 as a unilateral nodule encompassing more than one-half of a lobe. B3 tumors were palpable bilaterally. This system also introduced the T1c tumor, which is not palpable but is diagnosed based on a biopsy for an elevated PSA or ultrasound abnormality. In 2001, this system was again revised to classify B1 tumors as unilateral and B2 as bilateral nodules. In the current system, T1 tumors are nonpalpable and T2 tumors are palpable and organ confined, whereas T3 tumors have palpable extraprostatic disease and T4 tumors invade adjacent structures.

The problem with this system is that T1a tumors represent incidental tumors found at transurethral resection (TUR) of the prostate for obstructive symptoms. The patient has less than 5% of the chips involved and a Gleason score less than 7. T1b tumors represent more-extensive disease or poorly differentiated tumors found at TUR, and T1c tumors are tumors discovered through PSA screening. T1b tumors may involve 6% or 90% of the chips or be very aggressive; this includes a wide range of tumors, as a T1c tumor may have one positive screening biopsy up to all biopsies involved. These more-extensive T1b and T1c tumors actually are more similar to T2b or T3 tumors and are more likely to have nodal metastases whereas the T1c tumor with 1 positive core of 12 to 24 is more similar to T1a tumors. This approach makes any conclusions based on an analysis of results based on stage highly uncertain. Nodal staging is based on the absence (N0) or presence (N1) of pelvic nodal metastases. Stage classification sets stage I as T1a N0 tumors, T2 includes any T1b/c N0 or T2 N0 tumor, stage III includes all T3 N0 tumors, and stage IV includes all T4 or N1 or M1 tumors.

Utility of Prostate-Specific Antigen as a Screening Tool

The availability of serum PSA determination has dramatically increased the number of cases of prostate cancer diagnosed in the United States. Although the American Urologic Association and the American Society of Therapeutic Radiology and Oncology argue that this finding supports the widespread availability of screening, the American College of Physicians–American Society of Internal Medicine argues that the tumors identified are not clinically significant and that they are less likely to alter the quantitative or qualitative survival. The incidence of subclinical prostate cancer in a contemporary autopsy series in an unscreened population is shown in Table 48.2.² Older publications have reported a higher incidence of subclinical cancers, as high as 50% at age 60 and 80% at age 80, although many of these studies date from the 1950s when PIN was not a defined entity and many of these lesions may have been interpreted as carcinoma. The incidence, mortality, and age distribution of prostate cancer and breast cancer are similar and yet there is controversy over the need to screen men for prostate cancer and little discussion of the need for screening mammography.³ The difference is largely due to the perceived effect of both tumor and treatment on lifestyle and the effectiveness of available treat-

TABLE 48.1. Incidence and mortality caused by prostate cancer in the United States, 2003.

<i>Ethnic group</i>	<i>Incidence^a</i>	<i>Mortality^a</i>

ments. Whether this distinction is justified is beyond the scope of this chapter.

Several studies have reviewed large screened populations for the incidence of occult prostate cancer. PSA is a serine protease inhibitor produced by both normal and malignant prostate. The malignant prostate will leak more of this protein into the circulation than normal prostate. The malignant prostate also allows a larger protein, a serine protease inhibitor, into the blood as well. These two proteins circulate in the blood as a complex that is detected by the PSA assay along with the free PSA. The picture is complicated by the fact that the infected, inflamed, and traumatized prostate gland also leaks increased quantities of PSA into the blood. Kane also reported that increased prostate volume will produce higher serum PSA levels. Using the accepted cutoff of 4.0, 95% of men with prostates smaller than 35 cm³ have a normal PSA whereas only 75% of men with prostates larger than 45 cc³ will have a normal value.

The normal value of 4.0 was established in studies reported by Catalona et al. and Brawer et al. of men undergoing digital rectal exam, transrectal ultrasound, and biopsy.^{4,5} They found that this value found prostate cancer in 2.2% and 2.6% of asymptomatic men, respectively. In Catalona's series, the sensitivity of the PSA cutoff of 4.0 was 79% with a specificity of 59%; the predictive value of a positive test was 40% and the predictive value of a negative test was 89% for an overall accuracy of 64%. Subsequent investigations have tried to use PSA density (serum PSA/prostate volume), PSA velocity (dPSA/dt), and free PSA level to improve the specificity of the test and reduce the number of negative biopsies, without notable success.⁶ The current sensitivity and specificity data would suggest that only 15% to 25% of men with PSAs between 4.0 and 7.0 have prostate cancer on biopsy.

TABLE 48.2. Incidence of prostate cancer in an autopsy series of unscreened patients.

<i>Age (years)</i>	<i>Incidence of cancer (%)</i>	<i>Incidence of high-grade (PIN)</i>
20–30	3.6	7.1

Natural History of Untreated Prostate Cancer

There are a number of reviews of patients managed expectantly with localized prostate cancer with conflicting results. There are a number of reasons for this. Some series include men with incidental disease found at TUR, which has a low risk of progression to clinically significant disease, whereas other series allow men and their physicians to select treatment if they believe the risks of tumor progression outweigh the risks of treatment. Some studies observed men and selected men who did not show progression over an interval but excluded men with progression during that interval. The unknown value is the annual probability that a clinically occult tumor will progress to become clinically evident with either local tumor manifesting as a palpable nodule, bladder invasion, or outlet obstruction. This is the key value that must be applied to decisions regarding screening. As in other issues in prostate cancer, the value probably depends upon the Gleason score and other tumor characteristics.

The Veterans Administration trials in prostate cancer during the 1950s provide the basis for the Gleason scoring system for prostate cancer.⁷ This was the first and is still the most important factor used to estimate the risk of metastatic disease and death. This study was confined to men with clinical stage T2–T4 Nx M0 so that it is not strictly applicable to patients seen today with T1c prostate cancers due to the lead time bias caused by the application of PSA screening. Table 48.3 shows the annual cancer-specific mortality reported in their review and the projected 15-year survival based on the mortality observed. In evaluating a patient with a newly diagnosed prostate cancer, it is necessary to balance an estimate of the cancer-specific morbidity and mortality against the mortality of competing conditions. In making these considerations, it is necessary to factor in life expectancy. The most useful estimate may come from the Internal Revenue Service, given the relationship between death and taxes. They calculate the median survival at age 60 is 24.2 years, at age 70, 16 years, and at age 80, 9.5 years.

A number of series have reviewed the survival of men electing a course of watchful waiting instead of potentially curative treatment. The most famous of these series is the series reported and updated by Johansson et al. from Uppsala.^{8–10} This study is not strictly applicable, because among men with T1–T2 tumors 72 of the 223 patients appear to have had T1a tumors. They report a progression-free

survival at 5 years of 72% and a cancer-specific survival of 94%; the figures were 53% and 87% at 10 years and 31% and 81% at 15 years, respectively. Of concern in this series, however, is that there is substantial morbidity in this population. Specific complications reported at 10 years are listed in Table 48.4. Fifty-three percent of the men had a major complication in the first 10 years, and it must be remembered that 32% of the men had T1a tumors that would not have been treated with any therapy and had only a 14% risk of progression. This finding would indicate that 72% of the men experienced a significant cancer-related effect on quality of life as well as the reported 13% mortality. Adolfsson reported a similar series from Stockholm restricted to men with well or moderately differentiated tumors and T1 or T2 tumors. At 10 years, it was found that 55% of the patients had progressed to T3 tumors, 28% had developed metastatic disease, and 16% had died.

In the United States, Whitmore et al. reported a series of 75 patients that has been cited extensively.¹¹ The concern with this study is that it included only men with clinical T2 tumors who were evaluated on two occasions more than one year apart without any evidence of clinical progression. The progression-free survival is then back-dated to the date of the first evaluation. There are no data available on how many men were lost to follow-up or treated for progressive disease before the second evaluation.

The concept of early diagnosis and treatment is supported by the work of Hugosson and Aus, who reviewed the results of expectant management in 490 men in Goteborg.¹² They included deaths caused by underlying conditions exacerbated by prostate cancer as well as those men dying of conditions caused by prostate cancer as cancer-related deaths. They did not include deaths due to cardiac events in men on estrogen therapy. They reported that the cause-specific survival was 43% at 15 years in T2 lesions, 23% in grade 2 and 3 tumors, and 60% in grade I lesions. They found that prostate cancer comprised 4 of 11 deaths in the first 5 years but increased to 15 of 28 deaths between 5 and 10 years and 24 of 32 deaths occurring after the 10th year.¹³

It is clear that the only solution is a randomized clinical trial, although these are difficult to construct and complete. There are questions as to whether to include patients with very early stage tumors (T1c) and those with advanced tumors (T3), because the one group may have tumors that would not be discovered in other settings and the latter group has a tumor that has already demonstrated biologic aggressiveness by extending beyond the prostate. Similarly, the study must stratify patients by tumor grade and must be able to estimate the global state of patient health to estimate the anticipated survival, which is necessary to estimate the anticipated

benefit. Any study also needs to include a quality of life assessment because both tumor and treatment may affect bowel and bladder function as well as performance status. Finally, it is necessary to decide whether to study expectant management or noncurative treatment, as many men will insist on androgen deprivation at some time due to changes in PSA or prostate palpation. As well, there are differential effects of hormones and no therapy on tumor and quality of life.

Holmberg et al. reported a comparison of expectant management versus radical prostatectomy.¹⁴ Although the early follow-up demonstrates no improvement in 8-year survival with a relative risk of death in the prostatectomy group of 0.83 [95% confidence interval (CI), 0.57–1.2; $P = 0.31$], there was a significant reduction in prostate cancer deaths with a relative risk of 0.50 (95% CI, 0.27–0.91; $P = 0.02$). Similarly, there was a reduction in the relative risk of metastatic disease with a relative risk of 0.63 (95% CI, 0.41–0.96; $P = 0.03$). This study needs longer follow-up to determine if there is a significant difference in outcome between the two groups.

A second randomized trial has been completed by Moon et al. randomizing men to radical prostatectomy or conservative therapy including early hormonal therapy in asymptomatic men.¹⁵ This study will likely require an additional 10 to 12 years to mature. Until we have a definitive answer from these trials, the clinician is left to estimate the prostate cancer mortality and competing mortalities, factoring in the tumor stage and grade as well as the extent of prostate involvement, and balance that against the patient's coexistent medical problems to determine whether the risks of treatment outweigh the risk of tumor progression and the probability of tumor-related death.

Local Therapy: Radical Prostatectomy Versus Radiation Therapy

Although the decision to treat or observe is controversial, the question of best therapy of limited disease is perhaps more controversial. This problem reflects the fact that there are two specialties that can effectively treat prostate cancer, although time required, the side effects, and quality-of-life effects are distinctly different. The controversy is accentuated by the fact that the patients who are not treated successfully are frequently referred to the other specialty for palliative care. Patients initially treated with surgery may develop metastatic disease and are referred for palliative radiation, where a radiation oncologist is more likely to note incontinence and pelvic pain while being less cognizant of the rectal effects of radiation. Similarly, the management of local recurrences after surgery is generally left to the radiation oncologist, who may be inclined to question the wisdom of surgery in high-risk patients.

Radiation oncologists do not consider the problems with subsequent pelvic surgery for vascular disease, diverticulitis, and colon polyps or neoplasms to be complications of treatment. Bladder neck contracture, urethral stricture, and hematuria all subsequent to radiation are urologic problems managed by urology. Radiation oncologists also generally lose track of patients with local recurrences and bladder invasion after radiation, as their problems are managed by urologists. Each specialty sees more of its own successes and the failures

of the other specialty. The resultant competitive atmosphere in many institutions reflects the biblical observation that it is easier to note the splinter in our brother's eye while being oblivious to the board in our own eye.

Radical Prostatectomy

Radical prostatectomy has been a widely practiced effective approach to men with organ-confined prostate cancer since the perineal approach was described by Young in 1905.¹⁶ Millen first reported the retropubic approach in 1945 in a paper republished as a classic paper in urology.¹⁷ Both these papers describe the complete anatomic removal of the prostate and its capsule with urethral-vesical anastomosis to control the tumor. Retropubic prostatectomy will also try to remove portions of the proximal seminal vesicle that cannot always be achieved with the perineal approach. Neither treatment gained widespread popularity because of the problems with bleeding, incontinence, and impotence and a relatively low cure rate. This latter was largely related to the frequent diagnosis of the tumor after extracapsular extension had occurred. Relapse rates were high, and there was not a clear advantage over expectant management because of the long natural history of the disease. Two advances have made radical prostatectomy a safe, effective, and attractive treatment option for prostate cancer. The first is the description by Walsh of the nerve-sparing anatomic radical prostatectomy that preserved potency in a high percentage of men without incontinence.¹⁸ A better understanding of the pelvic anatomy with an improved understanding of the patterns of tumor extension and spread has led to better surgical planning and more complete tumor excision. The second advance was the development of a radioimmunoassay for serum prostate-specific antigen (PSA) for screening large populations of men at risk for prostate cancer¹⁹; this has changed the spectrum of disease presenting to the clinician. The prevalent wisdom in 1970 was the rule of four; one-fourth of patients presented with metastatic disease, one-fourth with extraprostatic disease confined to the pelvis (T3 or N+), one-fourth with organ-confined disease, and one-fourth with subclinical disease (T1a–T1b). Today, in regions of the country where PSA screening is prevalent, more than 50% of the patients present with nonpalpable disease detected by screening PSA (T1c). A review of the technique for radical retropubic and perineal prostatectomy is beyond the scope of this chapter. For a full description and illustration of the procedure, the reader is referred to *Campbell's Textbook of Urology*.^{21,22}

As large numbers of men have undergone radical prostatectomy and been followed, a number of factors have been identified that will predict the risk of biochemical recurrence. Initially it was noted that extracapsular extension, positive

surgical margins and seminal vesicle involvement are associated with local recurrence after surgery. Roach developed formulae to predict the risk of occult nodal involvement and seminal vesicle involvement.²³ Many series have reported the results of treatment in large numbers of men with reasonably long follow-up.^{24–26} Four large recently reported series are reported by Partin and Walsh from Johns Hopkins,²⁷ D'Amico from the University of Pennsylvania and Harvard,²⁸ Bauer, et al. from Walter Reed Army Medical Center,²⁹ and Iselin and Paulson from Duke.³⁰ In the first three series patients underwent retropubic prostatectomy and the Duke patients underwent perineal prostatectomy. The characteristics of the four series are reported in Table 48.5.

The groups are not comparable due to differences in the distribution of PSA and Gleason scores in the different populations, with Iselin's group having a higher Gleason score and not reporting PSA values in a number of patients operated on in the pre-PSA era.³⁰ Two-thirds of the patients from Duke University had PSA follow-up, and their data demonstrate that nearly all biochemical recurrences occur in the first 5 years after surgery. Median time to recurrence was less than 2 years in men with Gleason score 8–10 tumors and was more than 3 years in men with Gleason score 7 tumors. Men with Gleason scores of 6 or lower had a lower recurrence rate and a median time to recurrence that was longer still (Table 48.6). They do show that patients with extracapsular extension have a higher recurrence rate and among men dying of prostate cancer the survival is shorter, confirming that histologic factors correlate with biologic aggressiveness of the tumors.

Bauer et al. reviewed a group of 378 men undergoing radical prostatectomy at Walter Reed Army Medical Center between 1985 and 1995 and identified race, PSA, surgical Gleason score, and capsular transgression as critical parameters affecting recurrence risk.²⁹ The model required a sigmoid transformation of the PSA value and assigned a value of 1 for race = African-American and 0 for race = other. The value was 0 for organ-confined tumors and 1 for extracapsular extension or positive surgical margins. The formula was relative risk (RR) = $\exp[(0.51 \times \text{race}) + (0.12 \times \text{PSA}_{\text{ST}}) + (0.25 \times \text{postopera-}$

tive Gleason sum) + (0.89 × organ confinement)]. Using this method, it was possible to separate the population into three groups with low (less than 10%) risk of recurrence versus intermediate (10% to 30%) versus high risk (more than 30%). The utility is limited because it does not lend itself to easy grouping of clinical risk.

Partin reported that there were four prognostic groups identified based on Gleason score, pathologic stage, and surgical margins.²⁷ He was able to derive a similar equation based on a multivariate analysis of the patients undergoing radical prostatectomy at Johns Hopkins and was then able to separate the population into four groups with different risk of recurrence (Table 48.7). This is the first effort to quantitate the risk of recurrence and separate patients into risk groups based on easily identified pathologic characteristics.

The preferred method of evaluation would be to predict the risk of local recurrence based on preoperative tumor characteristics. D'Amico identified clinical tumor characteristics associated with biochemical recurrence including Gleason score, preoperative PSA, and findings on magnetic resonance imaging (MRI) with an endorectal coil.²⁴ Partin at the same time created a series of tables predicting the risk of organ-confined and specimen-confined tumors based on the clinical stage and Gleason score.²⁵ Both Partin and D'Amico have shown that the factors associated with the risk of biochemical recurrence include Gleason score.

D'Amico has developed a prognostic system based on the preoperative clinical and pathologic findings. He identified a low-risk group based on a Gleason score of 6 or less and a preoperative PSA 10.0 or less. The high-risk population included men with Gleason score of 8 or more and PSA of 20.0 or more. The intermediate-risk group with Gleason score of 7 and PSA between 10.0 and 20.0 were further divided by D'Amico based on the percentage of biopsies containing tumor, showing that men with 17% or less of the biopsies containing cancer had a lower risk of biochemical recurrence and those with more than 50% positive biopsies had a high risk of recurrence. For the intermediate-risk patients, MRI was useful in identifying clinically significant extracapsular extension and seminal vesicle involvement.²⁶ The risk of biochemical recurrence in the low-risk population was less than 20% at 3 years, whereas the risk of biochemical recurrence was greater than 50% in the high-risk population. A description of the three populations is shown in Table 48.8.

The morbidity of radical prostatectomy is difficult to define and will vary according to the experience of individual surgeons. Begg et al.³¹ reviewed the results from six metropolitan areas in five states using the Surveillance, Epidemi-

ology, and End Results (SEER)–Medicare database using a consistent assessment method. They demonstrated that the risk of incontinence rises with increasing age. They also demonstrated that increasing the annual number of procedures per surgeon reduced the risk of postoperative complications, late urinary complications, corrective procedures, and incontinence. The most common late urinary complication was anastomotic stricture, which comprised 70% of the complications. The frequency of complications based on age and surgical volume is shown in Table 48.9. Although no relationship was found between age and mortality or urinary complications, there was a strong association with the severity of comorbidities (*P* less than 0.002). The study clearly shows that the risk of stricture, incontinence, and other morbidities is lower in younger patients who are undergoing surgery by surgeons who perform more procedures.

Radiation Therapy

Paralleling the development of surgery was the development of radiation therapy as a specialty with the ability to effectively treat prostate cancer. Because the prostate is situated deep within the pelvis, treatment developed slowly because of difficulty delivering an effective dose of radiation to the tumor without injuring the adjacent bladder and rectum. Localization of the prostate gland was also difficult until the development of cross-sectional imaging, first with computed tomography (CT) and later MRI. The earliest use of megavoltage radiation to treat prostate cancer in a substantial number of men was reported in 1965 by Bagshaw et al.²⁰ Tech-

niques have been improved since that time with the development of CT-based computerized treatment planning, three-dimensional conformal radiation, and intensity-modulated radiation therapy to allow the delivery of higher doses of radiation to the prostate with better sparing of the adjacent normal tissues, which produces higher control rates with less morbidity. Brachytherapy has also been shown to be an effective treatment option. There are still a number of major questions that produce controversy. What is the optimal dose of radiation? Is there any benefit to treating the lymph nodes? Is there any benefit to adding external radiation to brachytherapy? Who benefits from adjuvant hormonal therapy? How long should hormonal therapy last? Is androgen deprivation as effective as combined androgen blockade?

The definition of the target in prostate radiation depends on the stage and grade of the tumor. It is easiest to think in terms of expanding and infiltrating tumors. Low-grade and early-stage tumors are generally assumed to be confined to the prostate and limited by the prostate capsule. As the tumor proliferates, these tumors with limited invasive potential are more likely to remain confined within the prostate, so as the tumor proliferates the prostate expands. In these cases the clinical target volume (CTV) includes only the prostate. Advanced-stage and high-grade tumors may extend grossly or subclinically beyond the capsule to invade adjacent structures. In this situation of infiltrating tumor the CTV will extend further beyond the prostate to encompass these areas at risk for subclinical infiltration.

How much radiation is enough?

To answer this question is difficult because prostate cancer is more difficult to assess on follow-up than many tumors because the low proliferative activity of many tumors causes nodules to regress slowly, and postradiation fibrosis may make it difficult to assess the local control status of many tumors. Bone scans are sensitive, but lack specificity as a follow-up tool, and the utility of acid phosphatase is limited by its lack of both sensitivity and specificity. The development of PSA testing has improved the follow-up of patients treated in the last 10 years, but the incidence of late

clinical failures complicates the follow-up because there is no accurate correlation of biochemical recurrence with clinical failure and progression to metastatic disease and death.

The largest series of men with clinically localized tumors treated with conventional radiation techniques with consistent long-term follow-up is the group reported by Bagshaw et al. from Stanford.³² These patients were treated to doses of 70 Gy using multiple shaped fields and in most cases received adjuvant radiation to the pelvic lymph nodes.

To try to achieve an earlier indication of local control, many institutions have biopsied men following radiation with the idea that a negative biopsy may predict local control and cure. This is difficult to accomplish because postradiation atypia may mimic prostate cancer. Similarly, because radiation causes a lethal injury that is expressed at mitosis, well-differentiated tumors that have low growth fractions and prolonged doubling times may regress slowly, although ultimately are controlled. Crook et al.³³ performed serial biopsies every 6 months and demonstrated that a minimum follow-up of 24 to 30 months is necessary to assess the histologic local control.

A group of institutions reported the biochemical disease-free survival in a group of patients with a minimum biochemical follow-up of 2 years (median, 4 years) and found four groups with distinct survival curves.³⁴ Patients with PSA values of 9.2 or less had a 5-year biochemical disease-free survival of 81%, whereas patients with PSA values higher than 9.2 but less than 19.7 had a bNED (no evidence of biochemical disease) survival of 69%. Patients with PSAs higher than 19.7 were divided into those with Gleason score of 6 or less, who had a 47% 5-year bNED survival, whereas those with Gleason scores of 7 or more had a 29% bNED survival. A substantial number of patients were followed for up to 8 years, and the biochemical relapse rate after 5 years was 5%.³⁴ They used strict criteria for diagnosing recurrences that included all patients with three consecutive rises in PSA at least 1 month apart with failure back-dated to the date halfway between the last nonincreasing PSA and the first increasing PSA. The institutions used a number of dose levels in this

study, so one cannot use the bNED survival rates as reflecting the results of radiation; they do, however, suggest that early PSA results may be a useful marker of cure rate (Table 48.10).

Because of the higher local recurrence rate in patients treated with conventional radiation therapy, many institutions have investigated the utility of increased radiation dose. In a recursive partitioning analysis, Horowitz et al.³⁵ identified four risk groups and studied the effect of dose on bNED survival (Table 48.11). While the results are complicated, they demonstrate that higher T stage and higher PSA require higher doses of radiation to produce local control.

Investigators at M.D. Anderson began a randomized trial in 1993 to assess the value of dose-escalated radiation in managing prostate cancer.³⁶ Patients with stage T1 to T3 prostate cancer were randomly assigned to doses of 70 or 78 Gy over 7 to 8 weeks. There was a longer time to treatment failure in the group treated by 78 Gy, but on subset analysis, the group that benefited from the higher dose were men with pretreatment PSA values greater than 10.0.

Many clinicians are concerned about the tolerance of the adjacent bladder and rectum and worry that doses of 75 to 80 Gy may not be safely delivered. A number of trials have been reported in men at risk for occult metastatic disease

TABLE 48.11. Recursive partition analysis of results of radiation for prostate cancer.

treated with radiation and hormones. Some have questioned whether hormones could be combined with lower doses of radiation to achieve the same effect as higher doses of radiation with reduced morbidity and comparable local control. It would appear logical that hormonal therapy would reduce the intraprostatic tumor burden by two to three logs, which would lower the tumor control dose. Nguyen et al.³⁷ reported the results of a comparison of two cohorts from the Fox Chase series. Men with high-risk prostate cancer (PSA greater than 20.0, Gleason 8–10 or T3–T4) treated with doses less than 75 Gy (62–75 Gy; median, 71.8 Gy) and 2 to 6 months of androgen deprivation were compared with those who received doses greater than 75 Gy (75–80 Gy; median, 75.8 Gy) without hormones. Median follow-up was 52 months in the high-dose radiotherapy (RT) group and 69 months in the androgen deprivation group. The 5-year bNED survival was 36% in the adjuvant hormone group and 55% in the high-dose RT group. In a multivariate analysis, there was no evidence that short-term androgen deprivation reduced the risk of local recurrence or distant metastases.³⁷ There was also no survival benefit noted.

The major current controversy in external-beam radiation concerns the safest method of delivering an effective dose of radiation with the least morbidity. Before 1990, most patients were treated with conventional radiation with shaped fields or rotational techniques. Patients underwent simulation to the prostate region as defined by bony landmarks with or without contrast. It was known that the prostate lay posterior to the symphysis pubis, inferior to the bladder, anterior to the rectum, and superior to the urogenital diaphragm. The structures were located using the lateral pelvic film with contrast in the bladder and rectum. The inferior margin could be located by performing a urethrogram to find the cone-shaped tapering of the urethra as it passed through the diaphragm or by using a Foley catheter, because the posteriormost extension of the urethra is where it passes through the urogenital diaphragm and this can be seen on a lateral radiograph. The lateral margins were arbitrarily assigned based on the clinician's perception of the prostate width on palpation, although some centers would include data from the ultrasound or CT scan. Lymph nodes may or may not have been treated, although the benefit of lymph node irradiation may have been related to the dose of radiation delivered to the periprostatic structures and perhaps even to more complete coverage of the prostate. Lymph nodes routinely included in the target volume included the obturator and external and internal (hypogastric) lymph nodes, and may also have included the common iliac lymph nodes. Lymph nodes were generally treated with two or four fixed shaped fields.

Since 1990, three-dimensional conformal radiation (3-D CRT) has been developed as CT data became more routinely available in radiation oncology departments and computer programs were developed to use the images from the CT scan to create digitally reconstructed radiographs. The target size and location was defined in three dimensions from a treatment planning study and transferred to the treatment planning computer to develop a plan using shaped fields to treat the target volume defined by the clinician. The locations of the rectum and bladder were also defined, and the treatment plan was developed to deliver the maximum dose of radiation to the target while minimizing the dose to the bladder, rectum, and femoral heads. In general, four to six treatment

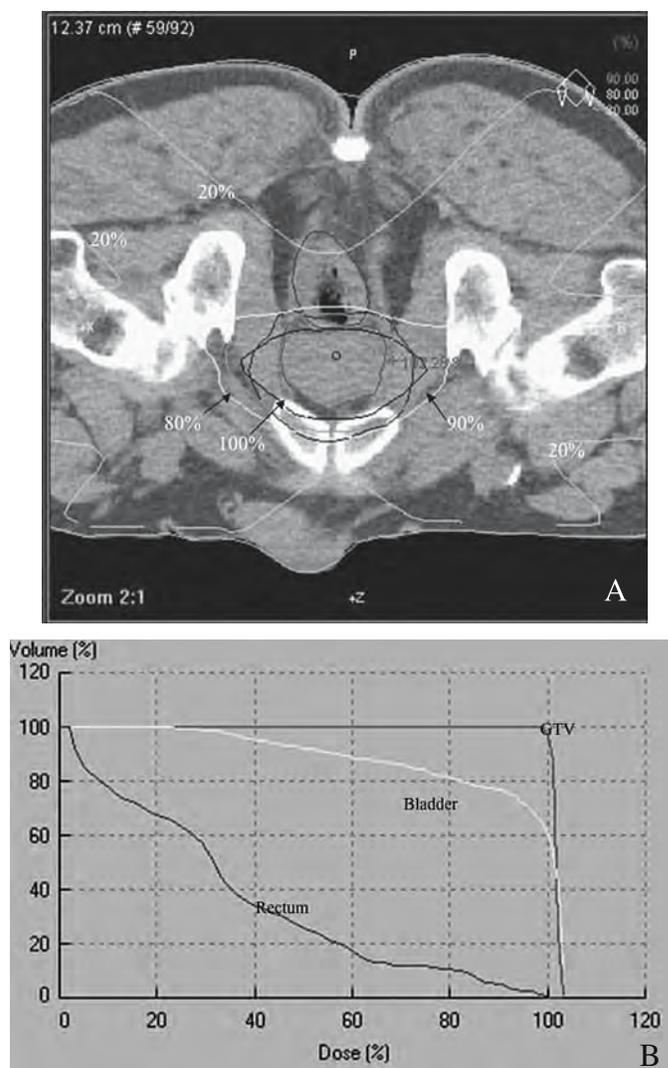

Figure 48.1. (A) Distribution of typical six-field technique on prone patient: 50% of dose delivered with two lateral fields and 50% delivered with four oblique fields. (B) Dose–volume histogram for six-field prone technique: dose to tumor, 78 Gy with inhomogeneity of +2% to –4% (95% volume \pm 2%); dose to rectum, median 35 Gy with 82% less than 50 Gy and 90% less than 65 Gy; dose to bladder, median 78 Gy with 20% less than 65 Gy and maximum dose of 78 Gy.

fields are used, although arc techniques with variable collimation have been explored and are used in some institutions. A sample treatment plan using a six-field technique is shown in Figure 48.1.

Within the last 5 to 6 years, intensity-modulated radiation therapy (IMRT) has been used for prostate cancer. Intensity-modulated radiation therapy uses an inverse treatment planning methodology to define the desired dose to the target volume and the tolerable dose to normal structures. IMRT uses more fields, frequently five to nine, to treat the target, and the shape of each field is changed several times during each treatment. The treatment is optimized to minimize the radiation dose to the surrounding normal tissue, which is done by treating individual segments of each field so that each segment treats a portion of the tumor and maximizes the shielding of the normal tissue. The total number of segments is usually between 50 and 90 with each segment receiving a

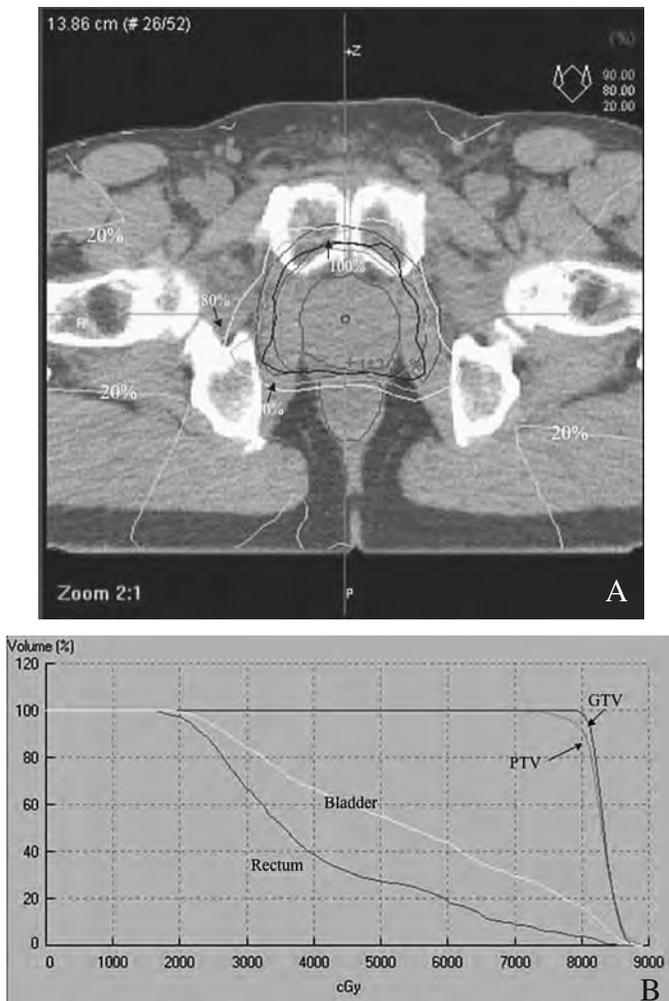

Figure 48.2. (A) Dose distribution of typical intensity-modulated radiation therapy (IMRT) plan on same volume. Note that 70% volume is somewhat smaller whereas 10% and 20% lines cover more of the volume; this is the additional region receiving 8–16 Gy. (B) Dose–volume histogram for plan shown in (A). Prostate dose, 78 Gy with inhomogeneity of +10% to 10% (95% volume +8% to –4%); dose to rectum, median 32 Gy with 68% less than 50 Gy and 90% less than 71 Gy; dose to Bladder, median 52 Gy with 65% less than 65 Gy and maximum dose of 87 Gy.

very small dose of radiation. When the cumulative dose is calculated, the tumor has received the prescribed daily dose, usually 1.80 to 2.0 Gy, but the maximum dose to the adjacent normal tissue is reduced. A sample treatment plan for prostate cancer using IMRT techniques is shown in Figure 48.2.

The difference in dose distribution between 3-D CRT and IMRT is that the dose homogeneity is somewhat better with 3-DCRT but the maximum dose to the adjacent normal tissue, especially the bladder, is higher. With IMRT, the maximum tumor dose is higher but the minimum target dose may be lower, and the maximum dose to adjacent normal tissues is lower, although a somewhat larger volume of tissue is treated to a low or moderate dose. Whether one technique is superior is unknown as there have been no randomized trials to compare the methods. Although some institutions have reported that higher doses can be delivered to the prostate with reduced morbidity, it is not clear that the long-

term control will be similar. Because multiple segments are used and it is necessary to interrupt the treatment many times to change the collimator settings to alter the field shape, the treatment takes longer. A significant proportion of the damage caused to the tumor is through the accumulation of short-lived intermediate compounds, DNA strand breaks, and free radicals. Because the effective dose rate with IMRT is frequently 20% to 25% of the dose rate with 3-D conformal radiation, it is not clear whether there is reduced efficacy. Many authors claim that the complication rate is reduced with the use of IMRT, although comparisons may not be possible due to advances in target localization. Daily localization of the prostate with ultrasound, CT, or electronic portal imaging has allowed treatment planners to reduce the margin around the target that must be added for organ motion and uncertainty of target location. These reduced margins also allow higher doses to be delivered with reduced dose to bladder and rectum.

Brachytherapy

Prostate brachytherapy is the method that delivers the maximum dose of radiation to the prostate and minimizes the radiation exposure of the bladder and rectum. There is an extensive literature on two different techniques. The most common method is low dose rate brachytherapy initially developed by Hilaris and colleagues at Memorial Sloan-Kettering Cancer Center.³⁸ Men initially underwent retropubic exposure of the prostate and needles were placed into the prostate through the incision. This treatment required a 4-day hospitalization, and although an attempt was made to distribute the seeds evenly through the gland, dose inhomogeneity was a frequent problem.

For these reasons, the procedure was subsequently superseded by the transperineal ultrasound-guided implant developed by Blasko and colleagues.³⁹ Computer programs have been developed to use parallel ultrasound images obtained at the time of implant to produce three-dimensional reconstructions of the prostate and rapidly produce plans that provide a homogeneous radiation distribution through the prostate and minimize radiation dose to the urethra and the periprostatic structures. Needles can be loaded to complete the implant quickly and allow the patient to be discharged to home with self-care the same day. If a preplan is used and needles are preloaded, the procedure takes between 30 and 45 minutes. If real-time planning is done in the operating room, the procedure can be completed in 45 to 90 minutes.

Two isotopes have been used for low dose rate prostate brachytherapy, iodine-125 and palladium-103. Both isotopes produce low-energy photons that travel short distances in tissue. The two processes that determine the dose are energy absorption by tissue and inverse square falloff as distance from the source increases. Because the sources are placed inside the prostate, all normal tissue is further from the seeds than the tumor, and the inverse square law stipulates that the dose falls off in proportion to the square of the distance from the source, that is, doubling the distance reduces the dose by 75%. The tissue absorption of energy by both isotopes is approximately 50% for every 2 cm of tissue. Combining these two factors means that increasing the distance from the source from 2 to 4 cm will reduce the dose by 87.5% (50% attenuation by absorption \times 75% reduction due to inverse square falloff).

One advantage of low dose rate low-energy brachytherapy is that the radiation may have a greater biologic effect on a slow-growing tumor cell that may be hypoxic than on an exponentially growing cell such as is found in the rectal mucosa. Freeman et al.⁴⁰ investigated this by exposing Chinese hamster ovary fibroblasts to radiation at various dose rates from both iodine-125 (average energy, 27 keV) and cesium-137 (average energy, 662 keV). They showed there was greater effect on slowly growing or plateau-phase cultures, similar to well to moderately differentiated prostate cancer, than there was on the exponentially growing cells, similar to rectal mucosa. This effect was also more pronounced at dose rates seen in low-dose permanent implants such as are used in prostate brachytherapy than they are in high dose rates as are used in temporary implants.

The largest reported series of men treated with brachytherapy and external radiation is the series from the Seattle group.⁴¹ They report that 10-year biochemical disease-free survival is 86% in patients with Gleason score of 6 or less and PSA less than 10.0 and 90% among men with tumors of Gleason score of 7 or more and a PSA of 10.0 to 20.0. Among men with Gleason score of 8 or more or PSA of 20.0 or more, the 10-year bNED survival was 49%. In a second report of men treated with brachytherapy alone, they report the 5-year bNED survival is 88% among men treated with brachytherapy alone and 79% among patients with intermediate-risk disease.⁴² Because of patient selection issues, it remains to be determined whether there is any benefit to the addition of external radiation to brachytherapy.

Dosoretz et al. have reported the results of a nonrandomized patient series of 130 high-risk patients with Gleason scores of 8 to 10 or PSA of 20.0 or more or clinical stage T2c or T3 treated with 45-Gy external radiation and hormones with implant (130 patients) and found that the 5-year bNED survival was 90% compared with 78% in 82 high-risk patients treated with hormones and brachytherapy and with 62% in 37 high-risk patients treated with brachytherapy alone. These results suggest that external-beam radiation and hormones may serve complementary effects in men with aggressive prostate cancer.⁴³

The effects of the treatment with brachytherapy are similar to those reported with external radiation. Both procedures cause bladder irritative symptoms with frequency, urgency, and nocturia usually lasting 8 to 16 weeks. The reported risk of rectal ulcer with tenesmus, pain, or bleeding is 2% to 4% in series reporting either interstitial or external radiation. Some series report that an additional 10% of men may have intermittent painless rectal bleeding. Perineal discomfort is common after transperineal brachytherapy but is usually controlled with nonsteroidal antiinflammatory analgesics with small doses of codeine-like medication used intermittently during the first 2 to 4 days. There is a small risk of urinary retention lasting 2 to 4 days that is caused by edema of the gland due to the multiple punctures, similar to the risk reported after prostate biopsy. The severity of the edema and the risk of retention is also affected by the skill of the brachytherapist in placing the needles, as multiple punctures to reposition the needles increase the risk of retention.

The duration of postoperative catheter drainage of the bladder can also affect the risk of retention as the catheter will stabilize the urethra during the period that the edema develops. Most institutions use 6 to 24 hours of drainage, and

we have reported that the risk is 5% after 24 hours of drainage.⁴⁴ The major putative advantage of brachytherapy is a lower risk of impotence associated with interstitial therapy. Sanchez-Ortiz et al. reported the results of a survey following brachytherapy or external-beam radiation with a strict definition of impotence, erection sufficient for intromission, and ability to achieve orgasm without mechanical or pharmacologic assistance⁴⁵; 49% of men undergoing brachytherapy were potent and an additional 26% had partial erections or were fully potent with sildenafil. Talcott et al.⁴⁶ reported that only 30% of men treated with external radiation were fully potent following external radiation. The effects of combinations of external radiation and brachytherapy have not been studied to know whether this would lead to increased effect on sexual function or rectal or bladder effects.

Selection of patients for brachytherapy is critical for a successful brachytherapy program. For mechanical reasons it is technically difficult to implant prostates larger than 55 cm³ due to interference from the ischium. Patients with larger prostates may be candidates if they undergo androgen deprivation for 3 to 6 months. We have treated men and carried out serial ultrasounds.⁴⁷ Among men in the largest quartile, that is, glands greater than 56 cm³, the median reduction in volume was 60%, which would suggest that men with glands as large as 80 cm³ may undergo the procedure. The reduction in volume appears to be related to the extent of benign prostatic hyperplasia (BPH) as the volume reduction was only 10% among men with glands smaller than 24 cm³. Men with PSA greater than 20 or Gleason score of 8 to 10 do not do well with androgen deprivation and subsequent prostate brachytherapy; this is likely related to the shorter doubling times of a poorly differentiated tumor. Also, the highly conformal nature of the dose distribution of prostate brachytherapy is a disadvantage in these patients because they are at higher risk for occult extracapsular tumor or distant metastatic disease. Other contraindications to brachytherapy include men with recurrent prostate infections, as the placement of foreign bodies within the prostate increases the risk of recurrent infection and possibly abscess, and men with moderate to severe bladder outlet obstruction do not tolerate brachytherapy well as these symptoms frequently worsen in these men. Additionally, men with prior transurethral resection of the prostate are not good candidates for the procedure if there is a substantial central defect, as this prostate tissue is necessary to hold sources and there is a greater risk of stricture or bladder neck contracture due to fibrosis from two procedures.

High dose rate brachytherapy using temporary implants has also been studied in men with locally advanced prostate cancer to increase the dose of radiation to the tumor while limiting the dose to the bladder and rectum. Guerriero et al.⁴⁸ reported a series of men treated with external radiation and radioactive gold-198 implant. In this procedure only three to four seeds were used, which made the dosimetry much more sensitive to source position. There is a theoretical advantage to the high dose rate implant as there is less attenuation of the energy by tissue so that the dose to tissues immediately adjacent to the prostate is higher, which may treat microscopic extracapsular disease more effectively. Similarly, it may deliver a higher dose to T3 tumors with a lower dose to the rectum.

Guerriero et al. delivered 46 Gy to the prostate with external radiation and carried out two implants to deliver a total

dose of approximately 80 Gy. They report a 5-year bNED survival among high-risk patients with poorly differentiated Gleason of 7 or more or PSA of 10.0 or more or locally advanced tumors (T2b or greater) as 74% without the addition of adjuvant hormonal therapy.

A similar experience has been reported by physicians at the Swedish hospital in Seattle.⁵⁰ They have treated a similar number of patients, with a large percentage falling into the high-risk population, with a median follow-up of 45 months. No patient received adjuvant hormonal therapy. They combined 50.4-Gy external radiation with four implants delivering 3.0 to 4.0 Gy each time to the prostate. They report a 5-year bNED survival of 84%.⁴⁹

To Treat the Nodes or Not to Treat the Nodes?

This is a controversial issue among radiation oncologists because the data can be interpreted to support both positions. Many institutions have routinely delivered radiation to the lymph nodes to treat high-risk patients for occult nodal involvement, whereas others have insisted that nodal involvement in patients with clinically limited disease is invariably associated with occult distant metastatic disease, arguing that the effect on survival and disease-free survival is greater than that observed in node-positive breast cancer.

Two early reports supported the application of prophylactic nodal radiation based on retrospective reviews of single-institution data.^{50,51} McGowan reported a review of 342 patients treated between 1970 and 1978 with doses of 60 Gy in 6 weeks to the prostate or a dose of 32.5 Gy to the pelvic lymph nodes with a 27.5-Gy boost dose to the prostate.⁵⁰ Treatment policy changed during this time to treat the nodes as well as the prostate instead of the prostate only. The 5-year clinical disease-free survival among 36 patients treated to the prostate only was 35% compared to 62% for 91 patients treated to the pelvis and prostate.⁵⁰

Results from Stanford supported this finding after they went through a similar evolution in treatment policy.⁵¹ The dose delivered was 70 Gy. The 10-year clinical disease-free survival was 70% for patients treated to the prostate and nodes versus 40% for patients treated to the prostate only. In the same report, Bagshaw describes the results in 58 patients undergoing node sampling and treated with prostate only radiation at Memorial Sloan-Kettering Cancer Center with iodine-125 implant only versus 86 patients treated to the prostate and pelvic nodes at Stanford. There was no significant difference in survival between the two groups.

The Radiation Therapy Oncology Group (RTOG) conducted a randomized prospective trial to determine the benefit of prophylactic lymph node radiation in patients with node-negative prostate cancer.⁵² Patients were accepted after either a negative lymph node sampling or lymphangiogram or CT scan. However, both CT scan and lymphangiogram are relatively insensitive in detecting nodal metastases because CT scans require that nodes be enlarged to at least 1.0 cm in greatest dimension before they are called radiographically positive and the lymphangiogram does not evaluate the first two echelons of lymph nodes, that is, the obturator and internal iliac lymph nodes, so they only detect the common iliac nodes if they are involved. Both studies have sensitivities that are less than 50%. In a final analysis of this trial (RTOG 77-06) in stage T1b and T2 patients, there was no difference in disease-

free survival between prostate-only radiation and pelvis-plus-prostate radiation at 12 years, although the survival was 26% in patients undergoing lymphangiographic or CT staging compared to 38% among surgically staged patients ($P = 0.003$).⁵² At the same time, RTOG 75-06 accrued patients with pathologically involved lymph nodes and randomized them to pelvis and prostate radiation versus paraaortic, pelvic, and prostate radiation. There was no difference in survival between the two groups and, more importantly, there were only 2 bNED survivors at 10 years among 90 patients.

All these studies were developed and reported before the availability of PSA studies and the development of three-dimensional conformal radiation and intensity-modulated radiation. The radiation doses were lower than are commonly used today, and target volumes were smaller than are used today. The observations from these older RTOG trials still ask the clinician to explain why it seems that if the nodes are not involved there is no need to treat the lymph nodes, and if the nodes are involved there is no benefit to treating the nodes, yet if the nodal status is not known there is a benefit to prophylactic nodal radiation. Possible explanations include the following: (1) a benefit to patients with truly limited disease that may not be detected pathologically because the extremely limited microscopic involvement of the nodes may have been missed; (2) pelvic radiation may have compensated for the difficulty in defining the prostate target volume and better treated the peripheral portions of the gland and the adjacent soft tissues; or (3) there may have been a volume effect because of the greater tissue effects due to the vascular and lymphatic effects of pelvic radiation, which may have enhanced the cytotoxic effects of the prostate radiation or may have impaired tumor progression.

A recent RTOG study (94-13) included patients with locally advanced tumor but radiographically node-negative patients in whom there is an estimated risk of occult lymph node involvement greater than 15% based on the equation $(2/3) \times \text{PSA} + [(\text{Gleason score} - 6) \times 10]$ greater than 15.⁵³ Patients in this trial were randomized to whole pelvis + prostate radiation versus prostate-only radiation and were also randomized to neoadjuvant and concurrent combined androgen blockade (2 months before and during radiation; total, 4 months) versus adjuvant combined androgen blockade (beginning after the completion of radiation). They found an improvement in 4-year biochemical disease-free survival from 47% to 54% with the addition of pelvic radiation independent of hormonal effects. These patients again did not undergo CT-based treatment planning or three-dimensional conformal radiation or intensity-modulated radiation. Because these patients were selected for the increased risk of occult nodal involvement, the treatment effect may reflect the effect of nodal radiation, or it may reflect the better coverage of periprostatic soft tissues in patients who also had a high risk of capsular transgression. It is unlikely that another randomized trial can be justified, and it remains for the individual clinician to decide on the treatment volume in this patient group. It is clear that there is a benefit to larger fields in these poor-risk patients, but the exact target is not clear.

Treatment Selection Issues

Based on the data reported by all the previously mentioned studies, the question arises as to the optimal treatment. There

is unfortunately only one small randomized trial reported that randomized men to surgery or radiation for localized prostate cancer. Paulson et al. reported the results of a small series of 97 patients randomized to radiation versus radical prostatectomy.⁵⁴ Their analysis did purport to show a higher 5-year disease-free survival in patients undergoing surgery, 86% versus 59%. However, the conclusions from this trial have been called into question by some of the coauthors.⁵⁵ Unfortunately, the group was disbanded before the completion of the study and some of the coauthors complained that they did not have the opportunity to review the data or the manuscript before publication. A number of problems in data analysis were raised in the second publication,⁵⁵ including the issue that 12% of the radiation patients and 19% of the surgery patients did not receive the assigned treatment and that they were analyzed by treatment group and not intention to treat. They also point out that 48% of the radiated patients and 66% of the surgery patients did not complete follow-up. Additionally, nearly all the recurrences were documented by bone scan, which has a high probability of false-positive studies due to the multiple causes of bone scan abnormalities. Finally, there was also no central review of studies documenting recurrent disease. It should also be noted that the dose of radiation used (66Gy) is significantly lower than is used today. The results of this study⁵⁴ and the ensuing controversy⁵⁵ have precluded any potential for completing a full randomized study of this question. A subsequent attempt by the Southwest Oncology Group in concert with all the other major oncology research groups in the United States failed because of poor accrual. Two large nonrandomized patient series have also attempted to address this question.^{56,57}

D'Amico et al. compared the results of patients at the University of Pennsylvania treated with radical prostatectomy or palladium-103 brachytherapy with patients treated with external-beam radiation to a dose of 66Gy at the Joint Center for Radiation Therapy. In low-risk patients, the 8-year biochemical disease-free survival was 88% for radical prostatectomy and 78% for radiation therapy. In intermediate-risk patients the bNED survival was 79% for surgery and 65% for radiation.⁵⁷ More recently, Kupelian et al.⁵⁶ compared the results of external-beam radiation therapy, brachytherapy, and radical retropubic prostatectomy of a single-institution retrospective study. They found that in the group of patients with stage T1–T3 disease treated with radiation alone the 7-year bNED survival was significantly better if patients were treated with a dose greater than 72Gy (81% versus 48%). These results were independent of treatment Gleason score or PSA. The treatment results with radiation to doses of 72Gy or more were comparable to the results with radical prostatectomy.

Overall, in selecting treatment for a specific cohort of patients with localized prostate cancer, it is necessary to evaluate the institutional treatment results including the risks of morbidity and the available resources including 3-D CRT and IMRT. It is also necessary to allow each patient to understand the relative risks of potential rectal complications of radiation and the risk of postsurgical incontinence as well as the effects of each treatment on potency. External-beam radiation therapy will not relieve obstructive symptoms, and brachytherapy may make obstructive symptoms worse, at least transiently, whereas surgery will relieve them. Some

patients may prefer surgery because of the reassurance that they receive from an undetectable PSA and may be less satisfied with a low, but stable, PSA as found following radiation therapy. Others may take comfort from the potential effect of salvage radiation. Younger patients have a longer anticipated survival, and radiation or brachytherapy may complicate the management of subsequent pelvic problems including diverticular disease and bladder and rectal neoplasms. This possibility must be balanced against the higher risk of surgical incontinence and impotence with increasing age, whereas a similar trend has not been demonstrated with radiation therapy.

Locally Advanced Prostate Cancer: Combined Radiation and Hormones

Early results with radiation for T3 prostate cancer showed a high risk of recurrence and metastatic disease following radiation therapy. One of the earliest efforts to improve the results in these high-risk patients was reported from M.D. Anderson in 82 patients using diethylstilbestrol (DES) with radiation in a randomized trial compared to radiation alone, recently updated by Zagars et al. with a median follow-up of 14.5 years.⁵⁸ Fifteen-year relapse-free survival was 57% for radiation + DES versus 37% for radiation alone. The overall survival was 33% for radiation alone and 25% for radiation + DES. The major reason for the difference between disease-free survival and overall survival was the excess mortality in the DES group resulting from cardiovascular events. Since this trial was completed, other studies have examined the same question but have used luteinizing hormone-releasing hormone (LHRH) agonists with or without antiandrogens. RTOG 86-10 randomized men with T3–T4 or bulky T2 prostate cancer to radiation alone or radiation with 2 months of combined androgen blockade (CAB) before radiation and 2 months during radiation versus radiation alone.⁵⁹ With 8 years follow-up, the overall and disease-specific survival are not significantly different, 47% and 55% with radiation and CAB versus 44% and 56% with radiation alone. The study did show an improved bNED survival with neoadjuvant and concurrent hormones, 63% versus 45% (P less than 0.001). Some bias may be introduced into the interpretation of these data by the inclusion of men with T2 tumors and extensive BPH and limited tumors. An important finding from this study was that the quality and duration of subsequent hormonal response among men who suffered relapses was not adversely affected by the short-course hormonal therapy.

RTOG 85-31 is a Phase III clinical trial that included men with clinical T3 prostate cancer as well as men with any T stage node-positive prostate cancer, and men undergoing radical prostatectomy for stage T1–T2 disease with pathologically documented extracapsular disease or seminal vesicle involvement.⁶⁰ These men were randomized to treatment with radiation with or without lifelong androgen deprivation. Local recurrence rates were improved with hormonal therapy, 16% versus 29% (P less than 0.001). Additionally, the 5-year clinical NED survival was improved, 60% versus 44% (P less than 0.001), as was bNED survival, 53% versus 20% (P less than 0.001), but there was no difference in 5-year absolute survival, 75% versus 71% ($P = 0.52$). Patients were stratified for Gleason score (7 or less versus 8–10) and for surgery and nodal status.

The only group showing a survival benefit thus far is men with Gleason score 8 to 10 not undergoing surgery, 66% with hormones versus 48% without hormone after 5 years ($P = 0.01$).

The first report that showed a clear survival advantage with the addition of hormonal therapy was reported by Bolla et al. for the EORTC,⁶¹ in which 415 men with high-grade T1–T2 or any grade T3 tumors were randomized to conventional dose radiation to the lymph nodes and prostate to a dose of 50 Gy, followed by a boost to the prostate to a dose of 70 Gy with or without 3 years of LHRH agonist therapy. With a 66-month median follow-up, the incidence of clinical locoregional failure was 16% in the radiation-alone group and 2% in the combined therapy group (P less than 0.0001). The risk of distant metastases was reduced from 29% to 10% (P less than 0.0001), and the 5-year clinical disease-free survival was increased from 40% to 74% by the addition of hormones. Overall 5-year survival was also increased by the addition of hormonal therapy from 60% to 78% (P less than 0.0001). Importantly, the addition of LHRH agonist therapy did not increase the risk of cardiovascular events as was observed with estrogen therapy.

The RTOG 92-02 study was a randomized trial in high-risk T2b and T3–T4 prostate cancer that randomized men to neoadjuvant and concurrent androgen deprivation therapy during external-beam radiation therapy with or without 2 years of maintenance androgen deprivation.⁶² Regional nodes were treated to 44 to 46 Gy and the prostate was treated to 65 to 70 Gy. A small number of node-positive patients were also included, and very few patients had pathologic nodal involvement. The median PSA was 20, and most patients had Gleason scores of 7 or more. With the use of 2 years of post-radiation androgen deprivation, local recurrences were reduced from 12% to 6% (P less than 0.0001); the risk of distant metastases was reduced from 17% to 11% ($P = 0.03$), and the 5-year disease-free survival was increased from 28% to 46% (P less than 0.0001). However, the overall survival was not significantly improved, being 78% for short-term androgen deprivation and 80% for the longer course of treatment.

Although the survival curves published in the RTOG 92-02 study were not analyzed, it appears that the extended disease-free survival was approximately 2 years, reflecting the longer course of treatment in this population.⁶² The disease-free survival curve does not appear to plateau through 7 years. This result would suggest that the 2 years of post-radiation androgen deprivation treatment may delay rather than prevent recurrences, and further follow-up is needed to determine whether there is a survival advantage. Indeed, the EORTC study⁶¹ has been criticized because serum testosterone levels were not followed, and some have suggested that 3 years of androgen deprivation may have induced lifelong gonadal failure, and that the survival benefit seen in this trial may reflect a prolonged effect on gonadal dysfunction. The disease-free survival appears poorer in the RTOG report,⁶² although the Gleason score of the RTOG patients was generally higher than in the EORTC study.⁶¹ There may also be a better overall survival in the RTOG population because of the generally earlier application of palliative hormonal therapy in the United States than in Europe. Patients in both studies were stratified based on Gleason score, PSA, and clinical stage.^{61,62} Future subset analyses may clarify which patients benefit from prolonged hormones.

Management of Node-Positive Prostate Cancer

When prostate cancer metastasizes to lymph nodes, the implications for therapy are not dissimilar to those in breast cancer. When men with node-positive prostate cancer are followed, the results with any monotherapy are poor. Early reports showed that the risk of recurrence is high with surgery and radiation and that the major sites of recurrence were distant.^{63–66} Patients treated with hormonal therapy alone have similarly poor results but more problems with symptomatic local progression.¹⁰ Table 48.4 has previously shown that men with localized tumors treated expectantly with palliative hormonal therapy when symptoms develop have a greater than 50% risk of symptomatic local progression. The results with local therapy are shown in Table 48.12. The dominant pattern of clinical recurrence in each of these series is distant metastasis.

There is only one randomized trial of combined modality therapy in men with node-positive nonmetastatic tumors. Messing et al. reported a randomized trial of men undergoing radical prostatectomy who were randomized to either observation or androgen ablation therapy with either orchiectomy or lifelong goserelin⁶⁷ in which 98 men were randomized and the median follow-up was more than 7 years. In this patient series, there was a high incidence of seminal vesicle involvement, 60%, and positive surgical margins, 65%. Half had Gleason score 7 tumors and 15% had Gleason score 8–10 tumors, although 80% had an undetectable PSA after surgery. The 7-year overall survival was 84% with adjuvant hormones and 57% for surgery alone ($P = 0.02$), and the prostate cancer-specific survival was 97% versus 63% (P less than 0.01). The 7-year disease-free survival was improved to 83% using immediate postsurgical hormonal therapy versus 34% with surgery alone.

There are no randomized trials in men treated with radiation for node-positive prostate cancer. Two attempts at randomized trials have failed due to poor accrual. There are two sizable series of men treated with combined hormonal and radiation therapy that have shown substantially better disease-free and overall survival compared to series of radiation alone.^{68,69} These patients are not comparable to the surgical trial⁶⁷ as there is a higher percentage of patients with T3 disease and more patients have gross nodal disease before treatment. Sands et al. reported a series of 208 men with node-positive prostate cancer treated at M.D. Anderson with hormones alone (181 patients) or hormones plus local radiation (27 patients).⁶⁸ Both groups received lifelong androgen ablation and the prostate was treated to 66 Gy. They report that

TABLE 48.12. Result with local therapy alone in node-positive prostate cancer.

Author	Reference	Follow-up	Cancer-specific survival	Clinical NED survival	bNED survival
Surgery					
Sgrignoli	63	10 years	NR	47%	12%
Myers	64	10 years	65%	0%	NR
Hanks	65	10 years	29%	7%	NR
Gervasi	66	10 years	43%	7%	NR

NR, not reported.

TABLE 48.13. Results of combined modality therapy in node-positive prostate cancer.

Author	Treatment	T3	Gleason score 8–10	No. of patients	bNED survival	Overall survival
Messing ⁶⁷	S + H	0%	30%	47	84% at 7 years	83% at 7 years
Sands ⁶⁸	RT + H	59%	15%	27	100% 4 years	100% at 4 years
Robnett ⁶⁹	RT + H	70%	51%	79	61% at 12 years	81% at 12 years

S, surgery; RT, radiation therapy; H, hormone therapy.

the 4-year bNED survival was 47% with hormones alone and the incidence of local progression was 22%. Only 10% of patients had distant metastatic disease without clinical local progression. Men treated with combined hormonal-radiation therapy were all biochemically NED at 4 years. Robnett et al.⁶⁹ recently updated the results from the University of Pennsylvania in a similar group of 79 patients treated with combined hormonal-radiation therapy. Clinically uninvolved pelvic lymph nodes were treated to 45 Gy and involved nodes were treated to 50 Gy. The prostate was treated to 66 to 72 Gy. The median follow-up was 7.2 years with more than 25% of the patients followed for more than 10 years. The 12-year actuarial clinical disease-free survival was 81% and the bNED survival was 61%. This series showed no difference between androgen ablation therapy and combined androgen blockade. They did note that all 5 patients with residual gross nodal disease at the start of radiation did recur and that more than 50% of recurrences after 5 years were prostate only without distant metastases. A comparison of the combined therapies in the three series including the randomized surgical trial and two single-institution radiation therapy series are shown in Table 48.13. The evidence from each report strongly suggests that combined therapy is superior to monotherapy as these patients are at extremely high risk for occult distant disease but hormones alone cannot reliably produce durable local control.

Management of Advanced Disease

Hormonal therapy has been the mainstay in the management of advanced disease since the observations of Huggins et al. in 1943 demonstrated the high rate of symptomatic response to orchiectomy in advanced prostate cancer.⁷⁰ The initial results were encouraging, but the advantage was partially offset by the increased risk of cardiovascular events in men treated with estrogen therapy.⁷¹ In this study of stage III and IV prostate cancer patients, they found that the prostate cancer mortality was 31% among 485 men treated with placebo, 28% among 469 men treated with orchiectomy, and 21% among 476 men treated with DES.^{70,71} Cardiovascular mortality among this group was 29% in men treated with placebo, 31% in men treated with orchiectomy, and 39% among men treated with DES.

Since 1985, the use of LHRH agonists has largely supplanted the use of DES and orchiectomy. In a large meta-analysis, Seidenfeld et al. reported that the results with LHRH agonists were comparable and equivalent to the results achieved with orchiectomy.⁷²

During this same time, the antiandrogens have also been developed, and there have been a large number of investigations comparing androgen ablation therapy with either

orchiectomy or LHRH agonist with or without antiandrogen. These results were recently reviewed using a meta-analysis.⁷³ Antiandrogens have the disadvantage of causing gynecomastia as well as a small risk of liver injury. Antiandrogens also substantially increase the cost of treatment. In a meta-analysis of androgen deprivation therapy versus combined with androgen blockade, no significant difference was found in survival between the two treatments when antiandrogens were reserved for a time when patients progressed on antiandrogen therapy.⁷³

There is a spectrum of endocrine sensitivity in patients with prostate cancer that extends from the very sensitive cells that need testosterone to survive and undergo apoptosis as a result of androgen deprivation to cells whose growth characteristics are unaffected by hormones. There also appears to be a population that needs androgen stimulation to proliferate, but not to survive. For this reason, many oncologists will continue androgen ablation therapy even when refractory tumor emerges, although there are no randomized trials to support this treatment approach. Many clinicians also add cytotoxic therapy to the androgen ablation therapy. Whether the cytostatic effects of hormones affect the sensitivity to cytotoxics is also unknown.

There are two common effects of androgen deprivation therapy that patients find disturbing, vasomotor instability (hot flashes) and osteoporosis. There are a number of anecdotal reports that some drugs may reduce or eliminate the symptoms of hot flashes. Selective serotonin reuptake inhibitor (SSRI) antidepressants have been approved for women with menopausal symptoms, but similar trials have not been carried out in men undergoing androgen deprivation, although 80% of men treated with androgen deprivation, either orchiectomy or LHRH agonist, report symptoms. Quella et al. reported the results of a survey of men and women treated with megestrol for symptoms.⁷⁴ These patients continued therapy for up to 3 years, and 88% reported a benefit with doses as low as 10 mg twice daily. Townsend et al. reviewed a single-institution experience with androgen deprivation therapy and found that the cumulative risk of bone fracture unrelated to metastasis was 9% at 6 years.⁷⁵ Smith reviewed bone mineral density data in a small group of men with M0 prostate cancer and found that the annual decrease in bone mineral density was 5%, comparable to that observed in postmenopausal women. This risk was the same with orchiectomy or LHRH agonist, although a small group of men treated with DES had only a 1% annual loss in bone mineral density.⁷⁶ Diamond et al. carried out a randomized prospective double-blind cross-over study of pamidronate infusion, 90 mg given monthly, versus placebo in men treated with combined androgen blockade and found that pamidronate produced a 2% increase in femoral neck density compared to a 2.3% loss with placebo.⁷⁷ These data

suggest that bisphosphonate therapy merits consideration in men beginning androgen ablation therapy.

The greatest question in the use of hormonal therapy is when to initiate therapy. There is only one large prospective randomized trial of immediate versus delayed therapy in men with prostate cancer not undergoing curative therapy.⁷⁸ This study accrued asymptomatic men with prostate cancer including T2–T4 tumors, N0 or N+ and M0 or M1. Patients were treated with either orchiectomy or LHRH agonists and the patients randomized to delayed treatment began hormonal therapy when the patient and physician identified a symptom likely to benefit from hormonal therapy; 938 men were registered to this trial, with 53% of the men having metastatic disease, and 19% were not evaluated for metastasis. With a median follow-up of more than 5 years, patients assigned to initial deferred treatment required treatment after a median time on study of 18 months, 10 months for M1 patients and 30 months for M0 and Mx patients. Patients treated with early hormonal therapy had fewer bone fractures, 21 versus 11; myelopathy, 23 versus 9; and ureteric obstruction, 55 versus 33. There were fewer overall deaths (328 versus 361) and deaths due to prostate cancer (203 versus 257) in the early therapy group. The group receiving early therapy also has a longer interval to the development of hormone refractory disease, 4.0 versus 6.5 years. These data suggest that presymptomatic hormonal therapy will improve the quality of life and may improve overall survival.

There is a wealth of data reporting the results of screening, staging, and treating prostate cancer, including patients with subclinical, localized, and metastatic disease. The practicing clinician needs to make decisions at several levels. It is first necessary to estimate the probability that prostate cancer is present. If cancer is present, it is then necessary to determine the extent and biologic aggressiveness of the tumor. The patient and clinician must then weigh the institutional capabilities and lifestyle preferences of the patient in making a treatment decision. Some would argue that the high incidence of subclinical or nonaggressive prostate cancer would mitigate against screening, while others argue that it is wise to know the characteristics of the tumor to determine whether treatment is desirable. Pending the results of the large VA trial of observation versus radical prostatectomy, each patient and clinician need to evaluate the issue and jointly make a decision.

Cytotoxic Chemotherapy

Recent developments in cytotoxic chemotherapy have offered prostate cancer patients another therapeutic option. In general, chemotherapy is used in the setting of the development of metastatic androgen-independent disease. Many controversies surround the utilization of chemotherapy in prostate cancer. How do we define androgen independence with respect to eligibility for clinical trials? What therapeutic endpoints are most useful in assessing effectiveness of chemotherapy? Which chemotherapy regimen is most effective? Is there a role for chemotherapy in earlier stages of the disease, including hormone-naïve disease?

Until recently, prostate cancer has been viewed as a chemotherapy-resistant neoplasm without a standard role in the management of the disease.⁷⁹ However, early chemother-

apy trials were difficult to compare and interpret because of diverse entry criteria and response assessment. To address these and other issues, the Prostate-Specific Antigen Working Group published in 1999 consensus guidelines for phase II clinical trials in androgen-independent disease.⁸⁰ These guidelines define specific patient groups as they relate to eligibility for a trial. In addition, criteria for objective assessment of response including PSA response endpoints were defined. This landmark achievement stands as an important step forward in the more recent evolution of chemotherapy in prostate cancer. In 2004, all clinical trials assessing cytotoxic chemotherapy should incorporate this important work into trial design.

Mitoxantrone is an anthracenedione with documented single-agent activity in prostate cancer.⁸¹ Tannock et al. reported a Phase III trial in which 161 patients with symptomatic (pain) androgen-independent prostate cancer were randomized to mitoxantrone plus prednisone (MP) versus prednisone (P) alone.⁸² A unique aspect of this study was that the primary endpoint was pain relief. A favorable palliative response was noted in 23 of 80 patients who received MP (29%; 95% CI, 19%–40%) as opposed to only 10 of 81 who received P alone (12%; 95% CI, 6%–22%). In addition, the duration of palliative benefit was improved in the MP group (43 weeks versus 18 weeks; *P* less than 0.001). There was no statistically significant difference in either the PSA response rate or overall survival between the two groups. A correlative study demonstrated that treatment with MP was associated with improvement in several health-related quality of life domains compared to P alone.⁸³

The Cancer and Leukemia Group B also studied the combination of mitoxantrone plus hydrocortisone (MH) versus hydrocortisone (H) alone in androgen-independent patients.⁸⁴ The primary endpoint of this trial was not pain relief but overall survival. In this trial, 242 patients were randomized to either MH or H alone. There was no difference in survival between the two groups (12.3 months versus 12.6 months). A post hoc analysis demonstrated that 42 of 112 patients (38%) treated with MH demonstrated a 50% PSA response compared to 25 of 116 patients (22%) treated with H alone (*P* = 0.008). In addition, there was a trend toward improved quality of life in the MH group. Based upon these studies, the U.S. Food and Drug Administration approved mitoxantrone in combination with a steroid as a palliative treatment for men with androgen-independent prostate cancer.

Estramustine phosphate (EMP) is a nornitrogen mustard–estrogen conjugate. Preclinical studies have demonstrated synergy of estramustine with M-phase-specific cytotoxic drugs.⁸⁵ Based upon Phase II trials combining EMP with agents such as vinblastine, Hudes et al. performed a Phase III trial of vinblastine (V) versus V plus EMP in 201 patients with androgen-independent prostate cancer. The median survival of the two groups trended toward the V/EMP arm (11.9 months versus 9.2 months; *P* = 0.08).⁸⁶ The V/EMP arm was statistically superior in terms of time to progression and 50% PSA response rate.

More recent trials have focused upon combinations of EMP with a taxane. An exhaustive review of the Phase II trials of EMP/docetaxel and EMP/paclitaxel is well beyond the scope of this review. CALGB 9780 is examined as an example of these trials. In this trial, Savarese et al. treated 47 men with androgen-independent disease with a combination of EMP,

docetaxel, and hydrocortisone.⁸⁷ In the 44 patients with an elevated pretreatment PSA, the 50% PSA response rate was 68%. In 24 patients with measurable disease, the objective response rate was 50% (95% CI, 27%–73%). The median survival demonstrated in this trial was 20 months.

It is of interest that the median survival noted in CALGB 9780 is superior to those noted in the MP trials. Obviously, patient selection and other biases could result in this difference. SWOG 9916 is a randomized trial comparing MP to EMP/docetaxel in patients with androgen-independent prostate cancer. The primary endpoint of this trial is to detect a 33% increase in median survival in the EMP/docetaxel arm. The trial has completed accrual of 770 patients and the results are eagerly awaited. A second randomized trial that deserves mention is the industry-sponsored TAX 327, a three-arm randomized trial comparing MP to docetaxel/prednisone without EMP (arms 2 and 3 represent an every-3-week docetaxel schedule and a weekly docetaxel schedule, respectively). This trial is also closed to accrual, and the results are forthcoming.

Given the recent advances in chemotherapy development for patients with metastatic androgen-independent prostate cancer, the next obvious step is to move chemotherapy to earlier stages of the disease. A number of investigator-initiated, industry-sponsored, and cooperative group trials are addressing this issue, and two are described here. In RTOG 9902, patients with poor-risk localized prostate cancer are randomized to radiation therapy plus androgen ablation (the standard arm) versus a combination of radiation therapy plus androgen ablation plus cytotoxic chemotherapy (paclitaxel, etoposide, EMP). This ongoing trial hopes to accrue 1,440 patients, with the primary endpoint being survival. ECOG 1899 addresses the role of cytotoxic chemotherapy in patients with androgen-independent prostate cancer but no metastases. In this trial, EMP/docetaxel is being compared to a standard "salvage" hormone regimen, ketoconazole plus hydrocortisone. The primary endpoint of this ongoing trial is progression-free survival. These two trials and others will further define the role of chemotherapy in the management of prostate cancer. As always, clinicians are encouraged to offer patients access to well-designed clinical trials.

Testis Cancer

Timothy Gilligan and Phillip W. Kantoff

The treatment of testicular cancer is one of the great success stories of Western medical science. More than 90% of patients are now cured, and essentially all patients, regardless of how advanced their disease is at the time of diagnosis, have a real chance of cure. In contrast, 50 years ago, metastatic testicular cancer was almost always fatal. Testicular cancer represents an example of what can be learned from a systematic and determined clinical trials effort. The current standard chemotherapeutic regimens are based on a long series of randomized controlled trials, despite the fact that this is a relatively rare disease. Because there is almost always the possibility of achieving a cure and because current standard therapies have been based on a solid scientific foundation, mistakes in the management of testicular cancer patients can be particularly costly and difficult to justify. Patients with testicular cancer should be treated by physicians familiar with the disease and with the germ cell tumor literature.¹

The vast majority of testicular cancers are germ cell tumors (GCT), and most GCTs occur in the testicles. It is worth noting that there are important biologic and therapeutic differences between GCTs in adult or adolescent males, which are discussed in this chapter, and other GCTs, which include dermoid cysts, gestational trophoblastic neoplasia, intracranial GCTs of childhood and adolescence, and neonatal yolk-sac tumors and teratomas. Ovarian GCTs have many similarities to testicular GCTs, but these are discussed in a different chapter.

Epidemiology

Testicular cancer is rare, with about 7,600 cases diagnosed and 400 deaths reported annually in the United States.² Worldwide, an estimated 49,000 cases are diagnosed and 9,000 men die of the disease annually.³ It is the most common malignancy among U.S. males 20 to 34 years of age and the second most common malignancy among white males in the United States between the ages of 15 to 19 and 35 to 39.⁴ Testicular cancers represent up to 60% of malignancies diagnosed in men aged 20 to 40 years in Western countries. The incidence of nonseminomatous GCTs peaks between the ages of 20 and 35, whereas seminomas are most common between the ages of 30 and 45. Nearly 95% of all testicular cancers are diagnosed between the ages of 15 and 54, and the median age of diagnosis is 34 years.^{2,5}

The incidence of testicular cancer has increased in the United States and worldwide, but with substantial regional

variation between the years 1950 and 2000.⁶ During that period, the U.S. incidence of testicular cancer increased 168% while mortality declined 73% and relative 5-year survival improved from 57% to 96%.² Between 1975 and 2000, the incidence increased 54%, to 5.7 cases per 100,000 males.² During the same period, mortality declined by 71%. Most of the decline in mortality occurred between 1973 and 1983, when cisplatin-based chemotherapy became widely used, but a slower downward mortality trend has continued.⁷ For unknown reasons, testicular cancer is especially rare in black men. White males in the United States have a 0.42% lifetime risk of being diagnosed with testicular cancer compared to a 0.10% risk among African-Americans.²

The major risk factors for testicular cancer are cryptorchidism, an affected first-degree relative, and a personal history of contralateral testicular cancer. Male infertility and subfertility have also been strongly associated with an increased incidence of testicular cancer.⁸⁻¹⁰ Cryptorchidism confers a relative risk of testicular cancer that has been reported to range from 2 to 18, and a meta-analysis reported a relative risk of 7.8.^{11,12} The increased risk of cancer is seen in both the nondescended testicle and, to a lesser degree, the contralateral testicle. Although different studies have reached different conclusions, it appears that orchiopexy before age 10 either reduces or eliminates the increased risk of cancer.^{11,13,14} Men with a father or son with testicular cancer have a relative risk of testicular cancer of 2.0 to 5.7,¹⁵⁻¹⁹ whereas men with a brother with testicular cancer have a relative risk of 8.3 to 13 and a lifetime risk of testicular cancer of about 2% to 3%, suggesting that maternal factors may be important. Men with testicular cancer have a 1% to 4% risk of developing a second primary GCT in the contralateral testicle.²⁰⁻²⁴ Among men with bilateral cancers, the median time interval between the diagnoses of the two tumors is about 5 years, and as many as 25% of metachronous tumors are diagnosed more than 10 years after the first cancer.^{22,24} Men with gonadal dysgenesis and testicular atrophy also manifest an increased incidence of testicular GCTs.²⁵

Basic Science

Cell of Origin

Testicular GCTs, with the exception of spermatocytic seminomas, are thought to develop from primordial germ cells or slightly later gonocytes that have transformed into the pre-malignant cells that constitute carcinoma in situ of the testis,

also referred to as intratubular germ cell neoplasia (ITGCN).²⁶ This transformation is believed to occur in utero, because an increased risk of testicular cancer has been associated with (1) severe maternal nausea, (2) neonatal jaundice, (3) parity, (4) advanced maternal age, and (5) both low and high birth weights.²⁷⁻²⁹ In addition, men with a fraternal twin with testicular cancer have a higher relative risk of being diagnosed with the disease than do men with an identical twin with testicular cancer.³⁰ These findings support the hypothesis that high estrogen levels and other factors during pregnancy stimulate the transformation of primordial germ cells into pre-malignant tissue.²⁷ Similarly, the association of testicular atrophy and abnormal sperm counts with testicular cancer, as well as the finding that the incidence of testicular cancer rises sharply shortly after puberty, suggest that increased gonadotropin levels may drive the transformation of ITGCN into GCTs. Increased follicle-stimulating hormone (FSH), estrogen, and testosterone have been documented in patients with newly diagnosed testicular cancer.

The biologic relationship between pure seminomas and nonseminomatous or mixed GCTs remains poorly defined. It is currently believed that the default pathway from ITGCN is to seminoma and that additional genetic events are needed for the development of nonseminomatous tumors. An alternative hypothesis is that seminomas and nonseminomas represent different development pathways from ITGCN.

Cytogenetics

The specific genetic events involved in the malignant transformation of germ cells remain to be defined. Most GCTs are associated with an isochromosome of the short arm of chromosome 12 (i(12p)). Germ cell tumors without an i(12p) uniformly show increased 12p sequences.^{31,32} The short arm of chromosome 12 is thought to encode about 120 genes, including *SOX5*, *JAW1*, and *K-ras*, but the identity of the critical genes on 12p has not been established. Overrepresentation of the long arm of chromosome 17 has been reported in more than 50% of testicular cancers.²⁶

Basis of Chemosensitivity

The unique sensitivity of testicular germ cell cancer to cisplatin-based chemotherapy represents one of the most striking attributes of this disease. The derivation of these tumors from germ cell precursors, which are highly prone toward apoptosis, makes this sensitivity less surprising. Several factors have been identified that likely contribute to these tumors' chemosensitivity. Wild-type p53 protein is overexpressed in most GCTs, and p53 mutations are only rarely seen.³³ Although the role of P53 in inducing apoptosis makes these findings provocative, it has not been clearly demonstrated that p53 status is central to GCT chemosensitivity. Indeed, most chemoresistant GCTs have no p53 mutations, and Burger et al. have demonstrated, in cell line studies, that functional p53 is not necessary for cisplatin-induced apoptosis.^{34,35} Similarly, the antiapoptotic protein BCL2 has been shown to be either absent from or expressed at very low levels in most GCTs, but BCL2 expression has not been consistently linked to chemotherapy resistance or other clinical outcomes. In reviewing the literature in this area, Mayer and

Bokemeyer and colleagues have proposed that GCT chemosensitivity may result from a low expression of chemotherapy export pumps, impairment of both cisplatin detoxification and DNA repair pathways, a relatively high sensitivity to DNA damage, and corresponding low threshold for activation of apoptosis, as well as an intact apoptotic cascade.^{36,37} Currently, there are not adequate data to validate this model. Zurita et al. have reported that expression of the lung resistance-related protein in testicular cancers was associated with shorter overall survival and may be associated with chemoresistance.³⁸ Although it is clear that GCTs show a greater propensity for undergoing apoptosis, both spontaneously and in response to chemotherapy, the specific apoptotic pathway(s) involved are unknown and the specific basis of chemosensitivity remains to be clearly defined.

Teratomas, in contrast to seminomas, choriocarcinomas, embryonal carcinomas, and yolk-sac tumors, are highly resistant to chemotherapy. Although the reason for this resistance is not well defined, several differences have been noted. Teratomas more often express p21 and the retinoblastoma protein, both of which mediate G₁/S cell-cycle arrest.³⁷ In addition, teratomas show a higher expression of the antiapoptotic protein Bcl-2 and lower expression of the proapoptotic Bax protein.³⁷ Collectively, these findings suggest that although the other GCT subtypes are prone toward apoptosis and have an impaired ability to arrest the cell cycle and repair chemotherapy-damaged DNA, teratomas are more resistant to apoptosis and instead respond to DNA damage by stopping the cell cycle.³⁶

Serum Tumor Markers

The serum tumor markers alpha fetoprotein (AFP), human chorionic gonadotropin (HCG), and lactate dehydrogenase (LDH) play a major role in the management of GCTs. They can help to confirm the diagnosis, estimate the prognosis, determine appropriate therapy, and monitor for progression, regression, and relapse. In cases of metastatic carcinoma of unknown primary, a highly elevated AFP or HCG may suggest a diagnosis of a poorly differentiated GCT, but elevated serum tumor markers in this setting have not been shown to predict a response to platinum-based chemotherapy, and therefore the utility of measuring the markers in such tumors remains debatable.³⁹ In men with disseminated GCTs, a very high AFP, HCG, or LDH is associated with a poorer prognosis and generally leads to more-aggressive therapy.⁴⁰ Similarly, in men with no radiologic evidence of disseminated disease, a persistent elevation of serum tumor markers is generally interpreted as evidence of occult metastases. During treatment, a decline in serum tumor markers in accordance with their predicted biologic half-lives has been associated with a more-favorable prognosis, whereas a sluggish decline suggests chemoresistance and rising markers imply refractory disease. Men whose markers fail to normalize with chemotherapy are at higher risk of relapse, and when men with nonseminomatous GCTs relapse, the most common initial manifestation is rising tumor markers.

An unresolved issue is whether sluggishly declining tumor markers during chemotherapy are an indication that the chemotherapy regimen should be changed.⁴¹ Among men

receiving second-line chemotherapy, an HCG half-life greater than 3.5 days or an AFP half-life greater than 7 days is associated with shorter event-free and overall survival.⁴² A follow-up study reported that among men receiving first-line chemotherapy, overall survival was 95% in men with a normal rate of decline of HCG and AFP compared to 72% among men with a slow rate of decline.⁴³ However, it has never been demonstrated that switching therapy based on the rate of marker decline yields improved outcomes, and this remains a question for clinical trials.

Although tumor markers help monitor the response to therapy, they must be interpreted with care.⁴⁴ Initiation of chemotherapy can result in tumor lysis that leads to a rise in markers during the first 10 days of therapy, and such a rise should not be interpreted as indicative of resistance to chemotherapy.⁴⁵ The baseline marker levels to be used for monitoring response to chemotherapy should thus be drawn at the end of the first week of treatment. Similarly, chemotherapy can result in hepatotoxicity that results in rising serum AFP levels in the absence of viable germ cell cancer.⁴⁶ HCG assays may cross-react with luteinizing hormone, and hypogonadal men with elevated gonadotropins may thus test as having a mildly elevated HCG. Administration of testosterone lowers gonadotropin secretion from the pituitary and can thus help identify false-positive results.⁴⁷ Heterophile antibodies can also result in false-positive HCG results.⁴⁸ Mild, stable elevations in markers do not always indicate the presence of residual malignancy; the entire clinical picture must be considered.^{44,45}

Alpha Fetoprotein

Serum AFP is elevated in 40% to 60% of patients with testicular nonseminomatous germ cell tumors (NSGCT). AFP is a single-chain polypeptide with a serum half-life of 5 to 7 days.⁴⁹ It is produced by the fetal yolk sac, liver, and intestines and, except during pregnancy, an AFP level above 15 ng/mL is abnormal.⁴⁵ AFP is elevated not only in NSGCTs but also in pregnancy, hepatitis, hepatocellular carcinoma, and, less often, carcinomas of the stomach,⁵⁰⁻⁵² colon and rectum,⁵³ and other gastrointestinal sites.⁵⁴ Within the context of GCTs, AFP is most strongly associated with yolk-sac tumors but can also be produced by embryonal carcinomas. Seminomas do not produce AFP. *The presence of an elevated serum AFP in a patient with a histologic diagnosis of pure seminoma is interpreted as a sign of occult nonseminomatous elements, and such patients are treated as having mixed GCTs.* Men with a clinical stage INSGCT who have a persistently elevated serum AFP following orchiectomy are at high risk of having distant metastases and are typically treated with chemotherapy. As noted previously, a rising AFP can result not only from relapsed disease but also from chemotherapy-related liver toxicity.

Human Chorionic Gonadotropin

Serum HCG is elevated in 25% to 50% of men with disseminated seminomas and in 2% to 12% of men with stage I disease. In contrast, in men with nonseminomatous testicular GCTs, HCG is elevated in 45% to 60% of metastatic cases and in 25% to 50% of stage I cases. HCG is a glycoprotein

consisting of an α -chain and a β -chain. The serum half-life of HCG is about 24 to 36 hours, and the upper limit of normal serum HCG in men ranges from 0.1 to 5 IU/L, depending on the assay. Different assays can produce widely varying results, and when false-positive results are suspected, repeating the test using a different assay may be helpful.⁵⁵⁻⁵⁷ The α -chain in HCG has a polypeptide sequence identical to the α -chain found in the other glycoprotein hormones: thyroid-stimulating hormone, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). The β -chain of each of these hormones is unique and gives the hormone its specificity. Assays for HCG typically test for both the beta-subunit (β -HCG) and for intact HCG, but cross-reactivity with other glycoprotein hormones sometimes occurs, particularly with LH.^{58,59}

In healthy individuals, HCG is produced by placental trophoblasts and pituitary gonadotrophs. Elevated HCG levels occur in pregnancy as well as in gestational trophoblastic disease, hydatidiform moles, choriocarcinoma, and other GCTs. Elevated levels of β -HCG are found in 45% to 60% of patients with biliary and pancreatic cancer and 10% to 30% of most other cancers, but more than a mild elevation of intact HCG is rare in non-germ cell tumors.^{59,60}

In the context of GCTs, elevated serum HCG is most strongly associated with choriocarcinomas, which can result in HCG levels in the hundreds of thousands or even millions (IU/L). Less-extreme elevations of serum HCG are seen in other GCTs. Many experts consider serum HCG levels higher than 200 to 300 IU/L incompatible with pure seminoma and advocate treating patients with such results as having mixed germ cell tumors, but there are few data to support these opinions.^{59,61,62} Pure seminomas have been reported in which the serum HCG was highly elevated, but it is possible such cases represent mixed GCTs misdiagnosed as pure seminomas. The International Germ Cell Cancer Collaborative Group's pooled analysis reported that, among men with disseminated seminoma receiving first-line chemotherapy, 3% of the subjects had a serum HCG above 1,000 IU/L. It does not appear that an elevated HCG in seminoma is associated with a poorer prognosis, but the data are mixed.⁶³

Lactate Dehydrogenase

Lactate dehydrogenase (LDH) is an enzyme that catalyzes the conversion between lactate and pyruvate. LDH is elevated in about 50% to 75% of patients with disseminated seminoma.⁶⁴⁻⁶⁷ An elevated LDH can be seen in many settings of cell death and rapid cellular turnover, including lymphomas, myocardial infarction, and liver disease. An elevated LDH is not specific, and LDH level is not helpful in establishing or ruling out a diagnosis of germ cell cancer. Serum LDH levels do carry prognostic information once the diagnosis has been made, particularly in seminomas, which are less likely than nonseminomas to have other elevated serum tumor markers.⁶⁶ An elevation of serum LDH at diagnosis and a sluggish decay of elevated serum LDH are each associated with a higher relapse rate in seminomas.⁶³ Assays for LDH measure enzymatic activity, and the normal range is therefore assay dependent and varies widely among different tests. Knowing the LDH level without knowing the specific assay's normal range is thus meaningless.

Pathology

Most testicular cancers are GCTs, which are divided into two broad categories, seminomas and nonseminomas, by differences in natural history and treatment. Nonseminomatous germ cell tumors (NSGCTs) include embryonal carcinomas, yolk-sac tumors, teratomas, and choriocarcinomas. Most NSGCTs are mixed tumors that are composed of two or more GCT subtypes. Mixed GCTs that include both nonseminomatous and seminomatous histology are considered NSGCTs for treatment and prognostic purposes. Testicular malignancies that are not GCTs include Leydig cell tumors, Sertoli cell tumors, gonadoblastomas, granuloma-thecal cell tumors, and carcinoma of the rete testis. Pathologic staging of the primary tumor is based on the presence or absence of (a) lymphatic or vascular invasion (henceforth referred to as lymphovascular invasion, LVI), (b) invasion beyond the tunica albuginea into the tunica vaginalis, (c) invasion of the spermatic cord, and (d) invasion of the scrotum. In seminomas, the size of the primary tumor and the presence or absence of invasion of the rete testis are also of prognostic significance.⁶⁸

Intratubular Germ Cell Neoplasia

Testicular GCTs in adults, with the exception of spermatocytic seminomas, develop from the testicular form of carcinoma in situ, also referred to as intratubular germ cell neoplasia (ITGCN). ITGCN consists of noninvasive malignant-appearing cells within the seminiferous tubules. The presence of ITGCN in an orchiectomy specimen in men with testicular cancer does not carry any prognostic implications with regard to the risk of relapse of the cancer.⁶⁹ However, in men with unilateral testicular GCTs, contralateral testicular biopsies reveal ITGCN in about 5% of cases, and half of these men develop invasive testicular cancers over the subsequent 5 years.⁷⁰ In some countries, men with testicular cancer are subjected to a biopsy of the contralateral testicle to evaluate for ITGCN.⁷¹ Men with positive biopsies are then typically treated with low-dose radiotherapy (14–20 Gy) to the testis, which kills the neoplastic cells and preserves testosterone production but sacrifices fertility.⁷² Screening biopsies for ITGCN in testis cancer patients is controversial because half the men treated are treated unnecessarily and because screening has not been shown to result in improved survival or quality of life. Testis biopsies are rare in the United States.

Seminoma

The most common type of testicular GCT, seminomas occur at an older average age than nonseminomatous tumors, with most cases diagnosed in the fourth or fifth decade of life.⁷³ Syncytiotrophoblasts, which stain positive for HCG, can be identified in up to 24% of cases of pure seminoma but are of no clear prognostic significance.⁷³ Lymphocytic infiltrates and granulomatous reactions are often seen, and seminomas appear to be associated with an increased incidence of sarcoidosis.^{74,75} Seminomas can produce moderately elevated serum levels of HCG but they do not produce AFP. Even if histopathology shows a pure seminoma, an elevated serum

AFP should be interpreted as indicating the presence of yolk-sac tumor elements, and the tumor should be treated as a mixed GCT.

Spermatocytic Seminomas

Although they share a similar name, spermatocytic seminomas are biologically distinct from classic seminomas. These are very rare tumors and occur at a mean age of 54 to 67 years.^{76,77} These tumors are almost always cured with orchiectomy alone, although many patients have received prophylactic paraaortic radiation. Metastatic disease has only been reported once.⁷⁷ Unlike other testicular GCTs, spermatocytic seminoma is not associated with a history of cryptorchidism.

Embryonal Carcinoma

Embryonal carcinomas consist of undifferentiated malignant cells resembling cells from early-stage embryos. The microscopic appearance of these tumors varies considerably, and they may grow in solid sheets or in papillary, glandular, or tubular patterns. Hemorrhagic and necrotic areas are often present. In some cases, syncytiotrophoblasts are identified. Embryonal carcinomas are aggressive tumors associated with a high rate of metastasis, often in the context of normal serum tumor markers. As discussed next, the presence and proportion of embryonal carcinoma has been associated with the likelihood of postorchiectomy relapse in clinical stage I tumors.

Choriocarcinoma

Choriocarcinomas of the testicles are rare and very aggressive tumors that typically present with very highly elevated serum HCG and disseminated disease. Common sites of metastases include the lungs and brain, but reports have also been made of metastases to the skin and eye.^{78,79} Microscopically, the tumors are composed of syncytiotrophoblasts and cytotrophoblasts, and the former stain positively for HCG. As noted previously, syncytiotrophoblasts can also be present in seminomas and embryonal carcinoma. Choriocarcinoma is distinguished by the presence of these cells together with cytotrophoblasts.⁷³ Areas of hemorrhage and necrosis are prominent. As in gestational trophoblastic disease, testicular choriocarcinoma is prone to hemorrhage, sometimes both spontaneously and immediately after chemotherapy is initiated, and such bleeding can be catastrophic.⁸⁰

Yolk-Sac Tumors

In adults, pure yolk-sac tumors (sometimes called endodermal sinus tumors) represent a very small fraction of testicular cancers but are common among mediastinal GCTs. Nonetheless, mixed GCTs of the testis often include elements of yolk-sac tumor. Yolk-sac tumors almost always produce AFP but not HCG. Among men with clinical stage

I testicular GCTs with normal serum tumor markers, finding elements of yolk-sac tumor is associated with a lower risk of relapse, but this finding may simply be a result of serum tumor markers (i.e., AFP) having a higher sensitivity for detecting micrometastatic disease in this type of GCT.⁸¹

Teratoma

Teratomas are tumors that contain well- or incompletely differentiated elements of endoderm, mesoderm, and ectoderm. Well-differentiated tumors are labeled mature teratomas whereas those that are incompletely differentiated are called immature teratomas. Mature teratomas may include elements of mature bone, cartilage, teeth, hair, and squamous epithelium, a fact that most likely explains the name teratoma, which roughly means “monster tumor” in Greek. In adults, both mature and immature testicular teratomas have the potential to metastasize, and the distinction carries no clear prognostic significance.⁸² Teratomas are generally associated with normal serum tumor markers, but they may cause mildly elevated serum AFP levels.

Diagnosis and Staging

Presentation

Testicular cancers typically present as testicular nodules or enlargement, but testicular atrophy can also be a sign of cancer. Although testicular cancers are classically described as painless masses, half of all patients complain of testicular pain or tenderness at the time of presentation. Such symptoms can lead practitioners to mistake cancers for orchitis or epididymitis and to delays in diagnosis. GCTs are also associated with gynecomastia, and men with this condition should be evaluated for testicular cancer. The most common site of metastatic disease is the retroperitoneum and men with disease in this region may present with back pain. Palpable supraclavicular adenopathy can also be a presenting sign.

Diagnostic and Staging Studies

Physical examination of a man suspected of having testicular cancer should include a careful testicular palpation for induration or nodules. Any firm or fixed areas within the tunica albuginea should be considered suspicious for cancer until proven otherwise. Examination should also include lymph node evaluation, particularly in the supraclavicular region, and the abdomen should be palpated for retroperitoneal masses.

Men with suspicious or ambiguous findings on testicular palpation should be referred for testicular ultrasound, and measurement of serum AFP, HCG, and LDH should be considered. With high-frequency (7.5-MHz) transducers, lesions as small as 1 to 2 mm can be identified with very high sensitivity and specificity.⁸³ Testicular cancers are typically heterogeneous, hypoechoic intratesticular masses, and such a finding on ultrasound should lead to an inguinal orchiectomy to make a definitive diagnosis. *Transscrotal biopsy and scrotal orchiectomy are contraindicated because of the risk*

of seeding the scrotum with tumor and complicating subsequent management. Serum tumor markers should always be measured before orchiectomy; this is particularly important with regard to AFP, because an elevated AFP precludes a diagnosis of pure seminoma regardless of the results of histopathologic evaluation. In rare cases where transscrotal ultrasound results are ambiguous, testicular magnetic resonance imaging (MRI) may be helpful.

Men who are found to have testicular cancer in their orchiectomy specimen should be staged with a computed tomography (CT) scan of the abdomen and pelvis and a plain chest radiograph. Chest CT scans in men with normal chest radiographs and normal abdominopelvic CT scans is extremely low yield. Only 4% of men with normal abdominal CT scans have thoracic disease, and a prospective study of 120 patients undergoing both plain radiographs and chest CT scans identified only a single case in which the CT identified disease that had not been detected on the radiograph.^{84,85} However, because up to 40% of men with abnormal abdominal CT scans have chest metastases, a chest CT is appropriate in this subpopulation. CT or MRI scans of the brain are not routinely indicated in testicular cancer patients who do not have neurologic symptoms but should be obtained in men with choriocarcinoma and/or highly elevated postorchiectomy serum HCG (greater than 10,000 IU/L) or AFP (greater than 1,000 ng/mL). Positron emission tomography (PET) scanning has not proven useful thus far in staging testicular cancers but may be of aid in evaluating residual masses in men with pure seminoma following radiation or chemotherapy. Because teratoma does not show increased activity on PET, this modality is of limited utility with NSGCTs.

Although many staging systems for testicular cancer have been used historically, current staging follows the American Joint Committee on Cancer (Tables 49.1, 49.2).⁸⁶ For patients with disseminated disease, low-risk, intermediate-risk, and high-risk patients can be identified using the International Germ Cell Consensus Classification (Table 49.3).⁴⁰ According to this system, the prognosis of disseminated seminomas is based solely on the presence (intermediate risk) or absence (good risk) of nonpulmonary visceral metastases. For NSGCTs, prognosis depends on the level of postorchiectomy serum tumor markers, the presence of nonpulmonary visceral metastases, and the primary site of the tumor.

Treatment of Stage I Disease

Stage I Seminoma

Stage I testicular seminoma has a 5-year cause-specific survival of more than 99%.⁶⁸ Because the risk of dying of the disease is so low, minimizing treatment-related toxicity represents a priority. Standard management historically was external-beam radiation, but, due to concern about secondary malignancies and other radiation toxicities, close surveillance has become a widely accepted alternative. More recently, near-perfect results have been achieved with single-agent carboplatin chemotherapy, which has produced the lowest relapse rate of any treatment thus far. All three approaches produce comparable overall and disease-specific survival to

TABLE 49.1. American Joint Committee on Cancer (AJCC) staging of testicular germ cell tumors.

Definition of TNM

Primary tumor (pT)

pTX	Primary tumor cannot be assessed
pTO	Primary tumor cannot be assessed (e.g., histologic scar in testis)
pTis	Intratubular germ cell neoplasia (carcinoma in situ)
pT1	Tumor limited to the testis and epididymis without vascular/lymphatic invasion; tumor may invade into the tunica albuginea but not the tunica vaginalis
pT2	Tumor limited to the testis and epididymis with vascular/lymphatic invasion, or tumor extending through the tunica albuginea with involvement of the tunica vaginalis
pT3	Tumor invades the spermatic cord with or without vascular/lymphatic invasion
pT4	Tumor invades the scrotum with or without vascular/lymphatic invasion

Regional lymph nodes (N)*Clinical*

NX	Regional lymph nodes cannot be assessed
NO	No regional lymph node metastasis
N1	Metastasis with a lymph node mass 2 cm or less in greatest dimension; or multiple lymph nodes, none more than 2 cm in greatest dimension
N2	Metastasis with a lymph node mass, more than 2 cm but not more than 5 cm in greatest dimension; or multiple lymph nodes, any one mass greater than 2 cm but not more than 5 cm in greatest dimension
N3	Metastasis with a lymph node mass more than 5 cm in greatest dimension

Pathologic (pn)

pNX	Regional lymph nodes cannot be assessed
pN0	No regional lymph node metastasis
pN1	Metastasis with a lymph node mass, 2 cm or less in greatest dimension and less than or equal to 5 nodes positive, none more than 2 cm in greatest dimension
pN2	Metastasis with a lymph node mass, more than 2 cm but not more than 5 cm in greatest dimension; or more than 5 nodes positive, none more than 5 cm; or evidence of extranodal extension of tumor
pN3	Metastasis with a lymph node mass more than 5 cm in greatest dimension

Distant metastasis (M)

MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
	M1a Nonregional nodal or pulmonary metastasis
	M1b Distant metastasis other than to nonregional lymph nodes and lungs

Serum tumor markers (S)

SX	Marker studies not available or not performed
S0	Marker study levels within normal limits
S1	LDH less than $1.5 \times N$ AND hCG (mIU/mL) less than 5000 AND AFP (ng/mL) less than 1000
S2	LDH $1.5-10 \times N$ OR HCG = 5,000-50,000 mIU/mL OR AFP = 1,000-10,000 ng/mL
S3	LDH greater than $10 \times N$ OR hCG > 50,000 mIU/mL OR AFP > 10,000 ng/mL

N, upper limit of normal for the lactate dehydrogenase (LDH) assay.

TABLE 49.3. International germ cell consensus classification for disseminated tumors.

GOOD PROGNOSIS	
Non-seminoma	Seminoma
Testis/retroperitoneal primary	Any primary site
AND	AND
No nonpulmonary visceral metastases	No nonpulmonary visceral metastases
AND	AND
All of the following:	Normal AFP, any HCG, any LDH
AFP less than 1,000 ng/mL	
HCG less than 5,000 mIU/mL	
LDH less than 1.5 × upper limit of normal (ULN)	
5-year progression-free survival = 89%	5-year progression-free survival = 82%
5-year overall survival = 92%	5-year overall survival = 86%
INTERMEDIATE PROGNOSIS	
Non-seminoma	Seminoma
Testis/retroperitoneal primary	Any primary site
AND	AND
No nonpulmonary visceral metastases	Nonpulmonary visceral metastases
AND	AND
Any of the following:	Normal AFP, any HCG, any LDH
AFP 1,000 or more and 10,000 ng/mL or less	
HCG 5,000 or more and 50,000 mIU/mL or less	
LDH 1.5 or more × ULN and 10 × ULN or less	
5-year progression-free survival = 75%	5-year progression-free survival = 67%
5-year overall survival = 80%	5-year overall survival = 72%
POOR PROGNOSIS	
Non-seminoma	Seminoma
Mediastinal primary	
AND/OR	
Nonpulmonary visceral metastases	No seminoma patients classified as poor prognosis
AND/OR	
Any of the following:	
AFP more than 10,000 ng/mL	
HCG more than 50,000 mIU/mL	
LDH more than 10 × ULN	
5-year progression-free survival = 41%	
5-year overall survival = 48%

the extent that data are available (Table 49.4). Mature randomized trials are lacking.

Overall, about 15% to 20% of men with clinical stage I testicular seminomas who receive no postorchietomy treatment will relapse within 5 years of diagnosis and a few percent more will relapse in later years.^{68,87,88} If all men are treated with radiation or chemotherapy, then roughly 80% receive unneeded treatment. Efforts have been made to find risk factors for relapse that would allow clinicians to identify low-risk patients for whom surveillance would be particularly attractive and high-risk patients for whom the side effects of active treatment would be more justifiable. The most consistently identified risk factor for relapse has been tumor size. von der Maase and colleagues reported that 4-year relapse-free survival was 94%, 82%, and 64% for men with tumor diameters less than 3 cm, 3 to 6 cm, and greater than or equal to 6 cm, respectively.⁸⁹ Other identified risk factors include invasion of the rete testis, younger age at diagnosis, and lymphovascular invasion. A pooled international analysis of 638 men with clinical stage I seminoma undergoing surveillance reported that, in multivariate analysis, only larger tumor size and rete testis invasion were associated with relapse, but this

prognostic model was unable to identify a group of patients with a risk of relapse either greater than 32% or less than 12%.⁶⁸ These risk criteria have now been prospectively validated by the Spanish Germ Cell Cancer Group, which studied risk-adapted management of stage I seminoma.⁹⁰ Among 300 patients with stage I seminoma, those with tumors 4 cm or smaller and no invasion of the rete testis underwent surveillance whereas those who had rete testis invasion and/or tumors larger than 4 cm were treated with two cycles of carboplatin. With a median follow-up of 20 months, 4 of 96 (4.2%) low-risk patients put on surveillance had relapsed whereas 5 of the 204 (2.4%) high-risk patients receiving carboplatin relapsed. Although this strategy effectively identified a very low risk group and spared up to 92 men unnecessary treatment, overtreatment was a problem: 208 men received chemotherapy while only 60 would have been expected to relapse without therapy.

SURVEILLANCE

Surveillance offers patients the obvious advantage of avoiding postorchietomy therapy unless it becomes necessary

because of relapsed disease. Given the well-documented increased late mortality associated with radiation therapy as a result of excess cardiac events and secondary cancers, as well as the possibility of long-term side effects from carboplatin chemotherapy, the opportunity to avoid treating at least 80 of 100 men is attractive. Almost all relapsing patients are salvaged, and 5-year disease-specific survival ranges from 99% to 100%.^{88,89,91,92} In an international pooled analysis of 638 patients, 5-year overall and disease-specific survival were 97.7% and 99.3%, respectively.⁶⁸ There is no evidence that surveillance compromises or improves long-term survival so long as patients comply with the surveillance schedule.

Different centers have used different surveillance schedules, and no randomized trials comparing surveillance schedules have been published. The National Cooperative Cancer Network and the Princess Margaret Hospital both have proposed evaluations every 4 months for the first 3 years, every 6 months for years 4 to 7, and every 12 months during years 8 through 10.^{68,93} At each visit serum LDH, AFP, and HCG are measured, a physical examination is performed (including a testicular examination), and an abdominopelvic CT scan is obtained. A chest radiograph is recommended at alternate visits, although the three largest published surveillance series have reported thoracic relapses in only 3 of 576 men (0.52%).^{89,91,92}

The success of surveillance results from the relatively low relapse rate and the success of salvage therapy. In large published series, 74% to 83% of relapses are limited to the retroperitoneal lymph nodes, with most of the remainder involving the pelvis.^{89,91} Most postorchietomy relapses are stage IIA or IIB and can be treated with paraaortic radiation at doses ranging from 25 to 37 Gy.⁹¹ The Princess Margaret Hospital in Toronto reported a median retroperitoneal lymph node size of 3 cm with a range of 1.5 to 9 cm, whereas the Spanish Germ Cell Cancer Cooperative Group reported a median relapsed tumor size of 3.3 cm with a range of 0 to 6 cm.^{88,91} In published surveillance series from Toronto, Denmark, and the Royal Marsden Hospital, 74% to 76% of relapsing patients have received radiation therapy, with most of the remainder receiving systemic chemotherapy as a result of bulky or disseminated disease.^{89,91,92} Combining the data from these reports, 11 of 70 (16%) patients receiving radiation therapy for relapsed disease subsequently required chemotherapy for a second relapse, and only 1 death from seminoma was reported. Of all the men entered on these surveillance protocols, 6% ultimately required chemotherapy as part of their salvage therapy, which is comparable to the proportion of men requiring salvage chemotherapy for relapse following postorchietomy radiation.

ADJUVANT CARBOPLATIN CHEMOTHERAPY

Adjuvant chemotherapy using single-agent carboplatin represents the newest postorchietomy treatment for clinical stage I seminoma and has produced the lowest relapse rates. Judging from numerous phase II trials, carboplatin appears to offer patients a way to dramatically lower their risk of relapse without exposing themselves to the long-term toxicities of radiation therapy. Most of these trials have given two doses of carboplatin 21 to 28 days apart at a dose of 400 mg/m², although the Anglian Germ Cell Cancer Group doses carboplatin at an AUC (area under the curve) of 7.⁹⁴ A phase III trial

comparing a single dose of carboplatin to radiation therapy has been completed and early results presented, but mature data have not been published.

Results from eight phase II trials of two cycles of single-agent carboplatin are available, including data from 650 men^{88,90,95-101} (see Table 49.4). Only 11 (1.7%) had relapsed and all were successfully salvaged with additional therapy. None died of seminoma or acute treatment toxicity; disease-specific survival was 100%. Looking only at studies with a mean follow-up of at least 5 years, only 3 of 272 men (1.1%) have relapsed and all have relapsed within 2 years of receiving carboplatin.^{95,96,99} Although a risk of late relapses has been posited as a theoretical concern, no late relapses have been documented thus far. The European Oncology Research and Treatment Group and Medical Research Council randomized phase III trial comparing radiation to a single dose of carboplatin dosed at an AUC of 7 reported its preliminary results in abstract form in 2004.¹⁰² With 1,447 men enrolled and a median follow-up of 3 years, relapse-free survival was 96.6% in the radiation arm and 95.4% in the carboplatin arm, and the 95% confidence intervals excluded an increased risk in the carboplatin arm of more than 4%. No disease- or treatment-related deaths were reported in the carboplatin arm and only 1 was reported in the radiation arm. Seven patients receiving radiation developed second germ cell cancers compared to only 1 patient receiving carboplatin. This trial appears to establish equivalency between a single dose of carboplatin and radiation for stage I seminoma, but mature results are needed. This is the second study, however, to suggest that a single cycle of carboplatin is inferior to two cycles.¹⁰¹

Carboplatin also looks favorable from a toxicity perspective. No cases of febrile neutropenia have been reported, and carboplatin at these doses has not been associated with secondary malignancies. Two patients in the published seminoma series developed severe thrombocytopenia and received platelet transfusions, but no bleeding complications have been reported. In a randomized phase II trial, Oliver et al. reported that chemotherapy resulted in greater myelosuppression and altered taste than radiation but that radiation resulted in greater nausea, diarrhea, and fatigue.⁹⁶ Assessing the impact of testicular cancer chemotherapy on fertility represents a challenge, because most men have abnormal sperm counts at the time of diagnosis and testicular cancer is associated with infertility both before diagnosis and following treatment with orchiectomy alone.^{9,10,103-105} After treatment, sperm counts typically improve. Reassuring data were published by Reiter et al., who found that normospermia increased from 35% following orchiectomy to 68% following chemotherapy.¹⁰⁶ Similarly, no renal or neurologic toxicity has been documented. Multiagent platinum-based chemotherapy for testicular cancer has been associated with dyslipidemia, hypertension, and an increased long-term risk of cardiovascular events in some studies, but no increase in mortality has been reported.¹⁰⁷⁻¹¹¹ Most of the patients in these studies received cisplatin, rather than carboplatin, but one study that evaluated both agents found no evidence that carboplatin was safer in the context of a multidrug regimen.¹⁰⁷ There are inadequate long-term follow-up data to assess whether two cycles of single-agent carboplatin have any impact on vascular health, but this is an issue that clearly warrants future monitoring.

RADIATION THERAPY

Previously, radiation therapy was considered the preferred therapy for stage I seminomas.¹¹² It is highly effective, producing a 5-year relapse-free survival of 95% to 97% and a disease-specific survival of 99% to 100% in almost all published series.^{63,91,113-121} Interest in developing alternative therapies stems from concern not about radiation therapy's effectiveness at disease control but rather its side effects. Because the 5-year relapse-free survival rate is about 15% to 20% with surveillance and about 5% with radiation, only 10 to 15 men for every 100 treated appear to benefit from radiation. There is no evidence of a survival benefit from radiation compared to surveillance. Given the outstanding prognosis of men who receive no postorchietomy treatment and are followed on a surveillance protocol, treatments for stage I disease with significant long-term toxicity are difficult to tolerate. Radiation therapy has been associated with a variety of secondary cancers as well as with cardiovascular disease and peptic ulcers. Largely in response to these concerns, the radiation dose and field have diminished substantially over time. However, these changes in treatment have occurred too recently for there to be follow-up data clarifying whether, and if so, to what extent, they reduce long-term toxicities.

RADIATION FIELD AND DOSE

Although the radiation field previously extended to include the mediastinum, supraclavicular region, paraaortic region, and ipsilateral hemipelvis, radiation above the diaphragm is now considered inappropriate, with the risks of additional toxicity outweighing any small benefit in disease control. Multiple retrospective studies have reported a twofold or greater excess cardiac mortality among patients receiving mediastinal radiation,¹²²⁻¹²⁴ and it does not appear that mediastinal radiation significantly improves cancer control outcomes.¹²⁵ Prophylactic mediastinal radiation is therefore currently contraindicated.

Many centers omit treatment of the pelvis, using a paraaortic field only that typically extends from the 10th vertebral body down to the L4-L5 or L5-S1 disk space.^{114,116} The lateral margins vary, sometimes extending to the renal hilum on the same side as the involved testicle and to the *processus transversus* on the contralateral side.¹¹⁶ Others treat to the *processus transversus* bilaterally. Alternatively, a lymphangiogram may be obtained to visualize the lymphatic anatomy and then the lateral margins can be tailored to these radiographic findings. The other commonly used field is the "dog-leg" or "hockey-stick" field, which uses the same superior margins as the paraaortic field but extends more inferolaterally to the ipsilateral pelvis. A randomized controlled trial conducted by the Medical Research Council assigned 478 men with clinical stage I seminoma to either paraaortic or dog-leg irradiation with a dose of 30 Gy.¹¹⁶ With a median follow-up of 4.5 years, 9 patients had relapsed in each arm, yielding a 3-year relapse-free survival of 96.0% in the paraaortic field arm and 96.6% in the dog-leg field arm. Nausea, vomiting, diarrhea, and leukopenia occurred less often in the paraaortic arm, and recovery of sperm counts was delayed in the dog-leg arm. However, 4 relapsing patients in the paraaortic arm relapsed in the pelvis whereas there were no pelvic relapses in the dog-leg arm. Use of a paraaortic field was thus

associated with equivalent efficacy and less toxicity and was therefore advanced as a new standard of care, but some still use a dog-leg field because of concern about pelvic relapses.

RADIATION DOSE

The radiation dose used to treat seminomas has declined over time. Although 30 Gy or higher was often used for clinical stage I disease in older trials, recent studies have reported equally favorable results with lower doses, and many consider 25 Gy to be the standard dose today.¹²⁶ Medical Research Council study TE18 randomized 625 patients to either 20 Gy in 10 fractions or 30 Gy in 15 fractions.^{127,128} With 37 months median follow-up, the relapse-free survival was 97% in each arm. A separate multicenter study of 431 men in the United Kingdom reported that treatment with 20 Gy resulted in a 5-year relapse-free survival rate of 96.3% and a disease-specific survival of 99.8%, figures entirely comparable to studies of higher doses.¹¹³

PATTERNS OF FAILURE

The few men who relapse following radiation therapy for stage I seminoma tend to relapse outside the field that was irradiated.^{63,91,113-118} Slightly over half relapse above the diaphragm, typically in the lungs, the mediastinum, or supraclavicular lymph nodes. Most of the remaining relapses occur in the pelvis, while about 15% are in the retroperitoneum. Paraaortic field radiation is associated with about a 2% pelvic relapse rate compared to a 0.6% rate in those treated with a dog-leg field.^{91,113-118} Late relapses are unusual, with the median time to relapse in most studies ranging from 13 to 17 months, and relapses beyond 36 months are unusual. Postirradiation surveillance should include a chest radiograph, physical examination, and serum tumor marker measurement (LDH, AFP, and HCG) every 3 months for the first year, every 4 months the second year, every 6 months the third year, and then annually for at least 3 years. A CT scan of the abdomen and pelvis is obtained annually by many but not all centers, even though only about 1% of men treated with a dog-leg field and 2% of those treated with a paraaortic field will relapse in the abdomen or pelvis. Some advocate pelvic CTs without including the abdomen for those patients who are treated using a paraaortic field and no CT scan for those treated with a dog-leg field. Randomized trials comparing different surveillance strategies have not been conducted.

SECONDARY MALIGNANCIES AND OTHER RADIATION TOXICITIES

Toxicity from radiation therapy includes acute side effects such as fatigue, nausea and vomiting, diarrhea and mild leukopenia.¹²⁹ These side effects are milder and less common with smaller fields (paraaortic rather than dog-leg)¹¹⁶ and lower doses (20 Gy versus 30 Gy).^{128,130} Late and long-term side effects include secondary non-germ cell malignancies, peptic ulcer disease, cardiovascular toxicity, and compromised fertility. Numerous papers have documented an elevated relative risk of secondary non-germ cell malignancies in men receiving radiation therapy for testicular seminoma.^{120,131-136} For instance, Travis and colleagues reported an analysis of 16 population-based tumor registries including more than 15,000 men with testicular seminomas.¹³² Men who had received

radiation therapy had a relative risk of 1.45 for developing secondary non-germ cell cancers ($P = 0.05$), with increased risks of cancers of the colon, kidneys, stomach, pancreas, and urinary bladder. Chemotherapy, by contrast, was not associated with an overall increased risk of cancer [relative risk (RR) = 0.90; P more than 0.05], although men receiving etoposide chemotherapy are known to be at a low but increased risk of developing leukemia. Similarly, a review of the M.D. Anderson Cancer Center's experience with radiation therapy for testicular seminoma reported that there were 91% more cancer deaths than expected [95% confidence interval (CI); RR, 1.30–2.71], but this increase only appeared 15 years after treatment.¹²⁰ Others have reported relative risks from 1.6 to 3.4 for second cancers.^{123,137,138} Because it takes 15 to 20 years for secondary cancers to develop, studies with short follow-up periods are uninformative, and the meaningful data on secondary malignancies are unavoidably based on older radiation therapy planning and dosing. It is unknown whether modern radiotherapy with smaller doses and treatment fields will result in significantly fewer secondary malignancies, and there is no guarantee that this will be the case.

A second major concern with radiation therapy is cardiovascular toxicity. The M.D. Anderson Cancer Center reported a 61% increase in cardiac deaths among men receiving radiation therapy, and the increased risk was seen even among patients who received no mediastinal radiation. Others have reported relative risk of cardiac deaths as high as 2.3,¹²³ and other reports have confirmed that an increased risk of cardiac events is seen among men receiving radiation therapy limited to a paraaortic field.^{107–109,123} Similar findings of excess cardiac events (but not mortality) have been reported for men receiving chemotherapy for testicular cancer but not among men being followed on a postorchietomy surveillance schedule.^{107,108}

Radiation for seminoma has also been associated with peptic ulcer disease and infertility. Reported rates of peptic ulcers have ranged from 0% to 16%.^{91,116,139–143} The MRC TE10 phase III study comparing paraaortic to dog-leg radiation fields collected toxicity data systematically and reported that, with a median follow-up of 4.5 years, 33 of 478 men (7%) were diagnosed with a peptic ulcer.¹¹⁶ Regarding fertility, a series of 451 men with GCTs who had undergone orchietomy followed by surveillance, retroperitoneal lymph node dissection, chemotherapy, or radiation reported that patients who had received radiation therapy had an odds ratio for achieving conception of 0.35 compared to men who had received chemotherapy ($P = 0.017$) despite the use of testicular shielding.¹⁴⁴ In contrast, modern studies of stage I seminoma have reported that 60% to 90% of men who try to father children following radiation therapy are successful.^{115,144}

Conclusion

Current data do not permit a definitive recommendation for the treatment of stage I seminoma.¹¹² Surveillance, carboplatin, and radiation are each associated with disease-specific survival exceeding 99%, although the long-term toxicity of radiation is concerning and the long-term toxicity of carboplatin is unknown (see Table 49.4). Men should be informed of the three treatment options and the associated side effects so that they can participate in choosing the treatment that is best for them.¹¹²

Stage I Nonseminomatous Germ Cell Tumors

Clinical stage I testicular NSGCTs have an excellent prognosis, with a 5-year survival rate of 98% to 99% with any of the following three postorchietomy therapies: close surveillance, two cycles of bleomycin, etoposide, and cisplatin (BEP) chemotherapy, or retroperitoneal lymph node dissection (RPLND) (Table 49.5). As a result of the near-perfect survival rate with any of these approaches, decisions about treatment often hinge on provider bias and patient preference as well as on the side effects of the different treatment options and the availability of the appropriate technology and surgical expertise. Patients with clinical stage I disease but persistently elevated serum tumor markers following orchietomy, however, are presumed to have disseminated disease and are generally treated with chemotherapy for advanced disease (see later section).

RISK CLASSIFICATION

Men with clinical stage I testicular NSGCTs and serum tumor markers that are either normal or that are falling at a pace consistent with the markers' predicted biologic half-life face a 25% to 30% risk of relapsing without additional treatment. With the aim of treating only those men who are most likely to relapse while sparing low-risk men unnecessary treatment, many centers have attempted to identify criteria that predict relapse. The Medical Research Council (MRC) identified and then prospectively validated four independent risk factors for relapse: vascular invasion, lymphatic invasion, the presence of embryonal carcinoma elements, and the absence of yolk-sac tumor.^{81,145} However, even among men with three or four of the risk factors, fewer than half (47%) relapsed. With regard to identifying low-risk patients, 24 of 141 (17%) men with zero or one risk factors relapsed, and these low-risk men represented 39% of the study participants; 21% of men with two risk factors relapsed, and this group represented 39% of the participants, which is similar to the average relapse rate of stage I nonseminoma patients in general. The MRC approach was thus of limited utility in identifying appropriate patients for surveillance and for treatment: more than half those identified as high risk would be treated unnecessarily whereas 4 of 10 men could not be classified as either high or low risk.

Subsequent efforts at risk classification have identified lymphovascular invasion (LVI) and embryonal carcinoma (EC) as the two elements most predictive of relapse.^{146–155} However, prospective validation of models other than that of the MRC is lacking. Taking into account the proportion of the tumor that is EC rather than simply the presence or absence of this tissue type has led to models with greater predictive power.¹⁴⁷ Moul and colleagues reported, in a sample of 149 patients with clinical stage I disease who underwent RPLND, that they could accurately identify the pathologic stage in 88% using a combination of LVI and percent EC.¹⁴⁸ They reported that occult retroperitoneal lymph node metastases can be demonstrated in 89% of clinical stage I patients whose tumor showed either more than 80% EC or the combination of LVI and more than 45% EC. Similarly, Indiana University reported that 62% of men whose tumors showed LVI and a predominance of EC were found to have metastatic disease subsequently,¹⁵³ whereas Memorial Sloan-Kettering Cancer Center reported that 73% of men with pure EC had metastases detected at RPLND.¹⁵¹ Other studies have suggested that

immunohistochemical staining with the MIB-1 antibody against the Ki-67 receptor is associated with metastatic disease, but such staining has not been incorporated into common practice.¹⁵⁶

Men with low risk of occult metastatic disease have also been identified. In the Indiana series, 84% of men with clinical stage I disease and neither LVI nor a predominance of EC remained relapse free with at least 2 years follow-up.¹⁵³ In Moul's model, men with either less than 45% EC or the combination of no LVI and less than 80% EC had only a 13% risk of having metastases detected at RPLND.¹⁴⁸ The presence of mature teratoma has also been associated with low risk of occult metastases,¹⁵⁷ but in multivariate analyses mature teratoma has generally been eclipsed by LVI and the proportion of EC. Even men with clinical stage I pure mature teratomas of the testicle have a 19% risk of occult metastatic disease to the retroperitoneal lymph nodes.¹⁵⁸

RETROPERITONEAL LYMPH NODE DISSECTION (RPLND)

Retroperitoneal lymph node dissection (RPLND) involves the removal of the lymph nodes that constitute the primary draining site of the testicles. This procedure is well tolerated and has both diagnostic and therapeutic benefits by helping to define the stage of the cancer while also reducing the subsequent relapse rate. The major benefit of RPLND is to reduce the proportion of patients who require treatment with chemotherapy. It is a major operation but is extremely well tolerated in patients who have received no prior chemotherapy.

SURGICAL TECHNIQUE

Historically, a bilateral dissection of all retroperitoneal nodal material was performed, extending from the crus of the diaphragm to the bifurcation of the common iliac arteries and

laterally to the ureters.¹⁵⁹ In addition, a complete and wide excision of the spermatic cord and surrounding lymphatic tissues was and is recommended.¹⁶⁰ The field of resection was subsequently reduced, first with the superior margin coming down to the renal vessels (infrahilar dissection) and then with the development of distinct right and left modified templates.^{161–164} Studies carefully mapping the location of microscopic lymph node metastases in testicular cancer revealed that bilateral dissections in clinical stage I disease were unnecessary, as contralateral metastases were very rare, with the exception that right-sided tumors showed the potential to spread to preaortic lymph nodes between the renal vessels and the inferior mesenteric artery (IMA).¹⁶⁵ Just as the venous drainage from the testicles is asymmetric, with the right gonadal vein moving toward midline and draining into the inferior vena cava while the left gonadal vein remains more lateral and drains into the left renal vein, so too is the lymphatic drainage. Therefore, the right-sided template extends to the left of midline above the IMA while the left sided template remains unilateral.¹⁶⁶

COMPLICATIONS

Loss of antegrade ejaculatory function is the most common long-term side effect of RPLND; this should not be confused with erectile dysfunction, which is **not** associated with RPLND. The use of the unilateral modified templates reduced the incidence of dry ejaculation from nearly 100% to less than 50%.¹⁶⁷ The next development was the introduction of nerve-sparing RPLND, which involved prospectively identifying the sympathetic fibers in the field of dissection before the dissection of the nodal tissue.¹⁶⁸ In the hands of an experienced surgeon, nerve-sparing RPLND has resulted in preservation of ejaculation in 93% to 100% of patients.^{168–170} Other complications are rare.¹⁶⁷ Wound infections in less than 5% and small bowel obstruction in less than 2% are well-established risks, whereas some centers have reported a rare incidence of a prolonged ileus, incisional hernia, and urethral strictures.¹⁷¹ RPLNDs performed to remove residual masses following chemotherapy for advanced-stage GCTs are associated with a higher rate of complications than RPLNDs performed on men with clinical stage I disease.

OUTCOMES

Among clinical stage I patients undergoing RPLND, 25% to 30% have retroperitoneal nodal metastases (pathologic stage II disease), and overall survival is 98% to 99%.^{172,173} Pathologic stage I patients with normal or normalizing serum tumor markers before RPLND have about a 10% risk of relapsing, but a recent single-institution study reported that that rate had dropped from 10% before 1999 to 3% in subsequent years.^{172–174} The risk of relapse among patients with pathologic stage N1 disease and normal pre-RPLND tumor markers has been reported at 8% to 16%.^{166,175} Patients with elevated serum tumor markers before RPLND face a high risk of relapsing following RPLND. Studies of RPLND that have not excluded patients with elevated markers have reported less-favorable relapse-free survival figures than those just cited.^{166,176} Indiana University has reported that 5 of 6 men (83%) with persistently elevated AFP relapsed following RPLND, as did 6 of 24 (25%) with a persistently elevated HCG, whereas Memorial Sloan-Kettering reported that persistently elevated markers were associated with a relative risk

for relapse of 8.0 (95% CI, 2.3–27.8).^{166,177} RPLND is therefore **not** recommended for men with persistently elevated or sluggishly declining serum tumor markers following orchiectomy: such men should receive chemotherapy for disseminated disease.

Patients with tumors with lymphovascular invasion (LVI) and/or a predominance of embryonal carcinoma (EC) have a higher risk of having occult stage II disease, as discussed previously, and RPLND is less likely to be curative without subsequent chemotherapy.^{147,151,153} In the Memorial Sloan-Kettering experience, half of all clinical stage I patients with pure EC treated with RPLND subsequently received chemotherapy. Indiana University reported that men with predominantly EC have a 32% risk of having retroperitoneal lymph node metastases and that 35% of these men will relapse without adjuvant chemotherapy.^{152,153} Of the 68% of these men with no disease found at RPLND, 20% will relapse without adjuvant chemotherapy. If LVI and a predominance of EC are both present, the risk of lymph node metastases rises to 47%, of whom 36% will relapse without chemotherapy while 29% of those without lymph node metastases relapse without chemotherapy. These figures indicate that at least a third of men with predominant EC and LVI require chemotherapy following RPLND, whereas additional men may be advised to undergo chemotherapy to lower their risk of relapse. Because of the high risk of receiving chemotherapy following RPLND, some have questioned the appropriateness of surgery for men with predominantly EC and LVI.

LAPAROSCOPY

Laparoscopic RPLND has been investigated.^{178–182} The results thus far are favorable, with a relapse rate in pathologic stage I patients of 5% to 13% reported with median follow-up times of at least 40 months and loss of antegrade ejaculation reported in 0% to 3.5%.^{178,180–183} Complications have included injury to the bowel, renal artery, and ureter, and the procedure is associated with a steep learning curve. In experienced hands, the results appear favorable but there are few centers with experience.

SURVEILLANCE

Postorchietomy surveillance for clinical stage I testicular NSGCTs and normal or normalizing serum AFP, HCG, and LDH is a well-accepted option that results in disease-specific survival ranging from 97% to 100% in published series.^{81,145,149,150,154,155,157,184,185} This approach has the benefit of sparing 71% to 74% of men any postorchietomy treatment. The disadvantage of surveillance is mainly that the 26% to 29% of men who relapse then require three to four cycles of chemotherapy, which carries a higher toxicity profile than either RPLND or the two cycles of chemotherapy offered to men as primary chemotherapy for stage I disease. Men with persistently elevated tumor markers are not appropriate candidates for surveillance but instead should be treated for presumed disseminated disease with chemotherapy (three to four cycles depending on the degree of marker elevation and the choice of regimen), unless a nonmalignant source for marker elevation can be established. Similarly, men who would be unable to comply with the schedule of clinic visits and medical tests involved in surveillance and men who live in an area where such services are unavailable should be

advised to undergo active treatment to reduce the risk of relapse.

Overall, 26% to 29% of men on surveillance schedules will relapse, but almost all can be successfully salvaged with therapy at the time of relapse, and the long-term outcome for men on surveillance is similar to that of men undergoing RPLND or primary chemotherapy, although no randomized trials have been published. Surveillance schedules vary considerably among institution. Most relapses occur within the first 6 months, 76% to 90% occur in the first year, and 87% to 100% occur within 2 years. Relapses later than 5 years are highly unusual, affecting fewer than 1% of patients (in contrast, second primary tumors involving the contralateral testis are more common, affecting about 3% of patients). The most common site of relapse is the abdomen, with 60% to 80% manifesting retroperitoneal adenopathy, while a similar proportion will have elevated tumor markers. Marker elevation is the sole indication of relapse in 7% to 30% of patients. Marker-negative relapses limited to the thorax occur in less than 10% of relapsing patients.

A typical schedule includes visits every month for year 1, every 2 months for year 2, every 3 months for year 3, every 6 months for year 4, and annually thereafter. A history and physical as well as blood tests of AFP, HCG, and LDH should be performed at each visit. Some advocate obtaining a chest radiograph at every visit or every other visit, but chest imaging leads to earlier detection of relapse in only 0% to 2.6% of men undergoing surveillance. CT scans of the abdomen or abdomen and pelvis are typically obtained every 3 months during year 1, every 4 months during years 2 and 3, every 6 months during year 4, and annually thereafter. The Medical Research Council reported a multicenter surveillance trial in which different centers used different schedules, finding no difference in disease burden at relapse among men undergoing CT scans annually compared to those undergoing scans three to five times per year.^{81,186} No consensus exists regarding how long surveillance should be continued beyond year 5, and some have advocated indefinite annual surveillance, whereas the National Cooperative Cancer Network has recommended that surveillance continue for a minimum of 7 years.¹⁸⁷

PRIMARY CHEMOTHERAPY

After cisplatin-based chemotherapy was shown to be highly effective against disseminated disease, a number of European cancer centers studied an abbreviated course of chemotherapy following orchiectomy as treatment for men with clinical stage I disease and normal serum tumor markers. This approach has resulted in the lowest relapse rate of any approach to stage I disease and is associated with similar near-perfect long-term survival rates as those seen with RPLND and surveillance. However, limited long-term follow-up data are available, and thus it is impossible to currently assess the risks of long-term chemotherapy toxicity and of late relapses resulting from undertreatment of occult disseminated disease.

At least nine studies of primary chemotherapy have been published, with most patients receiving two cycles of cisplatin and bleomycin plus either vinblastine (PVB) or etoposide (BEP)¹⁸⁸⁻¹⁹⁵ (see Table 49.5). With almost 600 cases reported, the relapse rate is 2.8% with a disease-specific survival rate of 98.8%. In studies with at least 4 years of follow-

up, 265 cases have been reported, and the relapse rate is 2.6% whereas the survival rate is 98.9%. These figures are all the more impressive in that most studies of primary chemotherapy have restricted enrollment to stage I patients at high risk of relapse.

Toxicity from two cycles of BEP is less than that seen with three to four cycles but is not negligible. Acute bleomycin pulmonary toxicity has not been reported. No treatment-related deaths have been reported, except for one patient who died of a thromboembolic stroke during chemotherapy. The Medical Research Council study has conducted the most detailed evaluation of toxicity from primary chemotherapy. They reported that pre- and postchemotherapy testing revealed that 15 of 16 tested patients suffered a decline in pulmonary diffusion capacity (average decline was 15%) and that 4 of 32 tested patients (12%) showed high-pitch hearing loss, but the clinical relevance of these changes was unclear.¹⁸⁸ They found no evidence of a negative impact on sperm count or motility.

Conclusion

As all three treatment options of RPLND, surveillance, and chemotherapy offer similar, near-perfect long-term survival, decisions about treatment are often based on provider bias, on patient preference, and on side effects and convenience. In parts of the world where regular surveillance is not feasible, chemotherapy may seem the best option as it is associated with the lowest relapse rate. The optimal strategy would be to surveil those patients who are not destined to relapse while treating patients with lymph-node-only metastases with RPLND and those with occult distant metastases with chemotherapy. However, our ability to identify these subgroups prospectively remains crude. Risk-adapted treatment strategies in which low-risk patients are assigned to surveillance have reported relapse rates of 12% to 27%.^{184,192,194} And, although most patients with LVI and tumors consisting mostly of EC have been shown to have occult metastases in retrospective series, this risk stratification approach has yet to be prospectively validated. An additional consideration concerns the presence of teratoma in the orchiectomy specimen. Patients with teratoma in the primary tumor are more likely to have teratoma in their retroperitoneal lymph nodes.¹⁹⁶ Because teratoma generally does not respond to chemotherapy, some have argued that these patients should be treated with RPLND rather than chemotherapy. By the same token, the finding that pathologic stage I patients with lymphovascular invasion and a predominance of EC have a 29% chance of relapsing following RPLND has led some to advocate chemotherapy for this high-risk population.¹⁹⁷ Given the near-perfect long-term survival seen with any of the three approaches, it is reasonable to present patients with all three options (see Table 49.5).

Treatment of Stage II Disease

Stage II Seminoma

Treatment of stage II seminomas is less controversial than treatment of stage I disease. The current standard of care is to administer external-beam radiation therapy for nonbulky

disease while treating bulky stage II disease with the same chemotherapy used for disseminated disease. Bulky disease has been defined inconsistently among studies but typically refers to tumors greater than 5 cm in transverse dimension. The rationale for this treatment strategy is that radiation is generally considered to have less acute toxicity than cisplatin-based chemotherapy and thus is preferable for early-stage disease, but postradiation relapse rates are substantially higher for bulky disease. However, there are no randomized trials comparing radiation to chemotherapy to definitively address this issue and how the acute toxicity of chemotherapy (e.g., febrile neutropenia and bleomycin lung injury) and the late risk of secondary cancers from radiation balance out with regard to long-term survival is unknown. Patients with stage IIA or IIB seminomas who have contraindications for radiation therapy should receive chemotherapy for advanced-stage disease. These patients include those with either a horseshoe or pelvic kidney or patients with disease sufficiently lateral in location to necessitate significant radiation exposure by one of the kidneys or the liver.¹⁹⁸

Smalley and Van Veldhuizen reviewed the radiation experience with stage II seminomas and reported that, among 340 men treated for nonbulky disease, 30 (9%) relapsed and 322 (95%) survived their disease.¹⁹⁹ In contrast, among 356 men treated for bulky stage II disease, 124 (35%) relapsed. The Princess Margaret Hospital has recently reported similar results, with 5-year disease-free survival rates of 92% for stage IIA and 90% for stage IIB disease following radiation.²⁰⁰ However, 9 of 16 (56%) stage IIC patients treated with radiation subsequently relapsed compared to only 1 of 23 (4.3%) IIC patients treated with chemotherapy ($P = 0.0004$).

Modern radiation therapy for stage II disease uses a dog-leg field as described for stage I seminoma. Historically, an inverted-Y field was often used such that the pelvis was treated bilaterally, but contralateral pelvic relapses are uncommon, and this is no longer considered necessary. Similarly, as discussed for stage I disease, supradiaphragmatic radiation has been abandoned by most centers. The radiation dose is similar to that used for stage I disease (25 Gy), with the enlarged lymph nodes receiving a boost to a total dose of 35 Gy. Chemotherapy for bulky disease is identical to treatment of favorable-risk disseminated disease: three cycles of bleomycin, etoposide, and cisplatin (BEP) or four cycles of etoposide and cisplatin (EP).^{66,67,201} Five-year overall and disease-free survival in stage IIC patients following chemotherapy are 85% and 78%, respectively.⁶⁷

Stage II Nonseminomas

Stage II nonseminomas with persistently elevated serum tumor markers are managed with chemotherapy for disseminated disease. If the markers normalize following orchietomy, the option of performing a retroperitoneal lymph node dissection also exists. Five-year survival is 95% to 98% with either approach in the setting of normal markers.²⁰²⁻²⁰⁴ There is no consensus regarding how best to choose between the two approaches. No randomized trials have compared chemotherapy to RPLND in this setting. One goal is to limit the toxicity of treatment by trying to avoid having to use both modalities. However, if both modalities are to be used, it appears to be safer to perform surgery first, because prechemotherapy RPLND is associated with fewer complications than postchemotherapy RPLND and because only two

cycles of chemotherapy are given in the adjuvant, post-RPLND setting compared to three to four cycles given as primary therapy.^{167,205,206} An additional concern, however, is that delaying chemotherapy to perform RPLND presents an opportunity for any occult distant metastatic disease to progress. A common practice is to perform RPLND for stage IIA patients and to give chemotherapy to patients with IIB or IIC disease based on the finding that post-RPLND relapse rates rise as disease bulk rises.^{176,204}

The following issues must be taken into account when deciding between RPLND and chemotherapy. About 12% to 24% of clinical stage II patients are found to have no nodal involvement at RPLND, and surgery spares them unneeded chemotherapy.^{203,205} In contrast, men who are found to have pathologic stage IIB or higher disease at RPLND are generally advised to subsequently undergo two cycles of chemotherapy because their risk of relapse is about 50%.¹⁷⁶ Treating such men with chemotherapy instead of RPLND is usually curative in itself, but about one-third will have less than a complete radiologic response and will require postchemotherapy RPLND for resection of residual masses.²⁰⁵ The risk of having a residual mass following chemotherapy is higher in men with teratoma in the primary tumor, and thus some have advocated primary RPLND for men with such histology.²⁰⁷ In contrast, embryonal carcinomas, particularly if lymphovascular invasion is seen in the primary tumor, are likely to spread hematogenously and have a high relapse rate following RPLND.¹⁵³ Moreover, it has been reported that embryonal carcinomas are more likely to respond completely to chemotherapy than other histologies.^{204,208} RPLND for stage II disease typically involves a bilateral dissection rather than the unilateral templates used in stage I. As a result, ejaculatory dysfunction occurs more often in this setting along with other surgical complications, but nerve-sparing surgery, where feasible, can reduce this risk.²⁰⁵

ADJUVANT CHEMOTHERAPY FOR PATHOLOGIC STAGE II DISEASE

When RPLND reveals pathologic stage II disease, adjuvant chemotherapy should be considered. Among patients with five or fewer nodes involved and none larger than 2 cm, the relapse rate of 6% to 15% is similar to the 6% to 10% rate seen among those with no involved nodes.^{166,175,209} However, relapse rates are about 50% for bulkier lymph node involvement.¹⁷⁶ Therefore, it has become standard practice to give two cycles of bleomycin, etoposide, and cisplatin (BEP) for patients with pathologic stage IIB or IIC disease. An alternative regimen is to give two cycles of etoposide and cisplatin. A randomized intergroup study, however, demonstrated that although BEP dramatically lowered the relapse rate, survival was not compromised by surveilling stage II patients after RPLND.¹⁷⁶ After undergoing RPLND, 195 men were randomized to surveillance or two cycles of BEP. Of the 98 who were surveilled, 49 relapsed but almost all were salvaged, with only 3 dying of testicular cancer. In the BEP arm, 6 relapsed (6%) and 1 man died of testis cancer, but of the 6 relapses, only 1 had in fact received adjuvant chemotherapy. Subsequently, a study of 82 men who received two cycles of BEP for pathologic stage (PS) II disease reported a single relapse,²¹⁰ while a separate report of two cycles of EP reported a similar 1.1% relapse rate.²¹¹

Treatment of Disseminated Disease

The development of effective systemic therapy for disseminated germ cell cancers represents one of the greatest success stories of cancer research, and the key step was the implementation of cisplatin in the 1970s. A major breakthrough was the 1977 study by Einhorn and Donohue in which they reported that 35 of 50 men (70%) achieved a complete remission to cisplatin, vinblastine, and bleomycin (PVB), while disease-free survival was 64%.²¹² This report was followed 10 years later by an intergroup study showing that, compared to PVB, the combination of bleomycin (30 units on days 2, 9, and 15), etoposide (100mg/m², days 1–5), and cisplatin (20mg/m², days 1–5) (BEP) resulted in lower toxicity and similar efficacy, with 80% 2-year survival. Retrospective subgroup analysis revealed that patients with bulky disease had better outcomes with BEP with regard to complete responses (77% versus 61%; *P* less than 0.05) and survival (*P* = 0.048). The toxic death rate in the study was 4.7%, half of which was due to neutropenic sepsis. Five men (2.0%) died of bleomycin-induced pulmonary fibrosis. Four cycles of BEP was thus established as the new standard of care.

It had become clear that different prognostic groups of patients could be identified who had different probabilities of being cured. After four cycles of BEP was established as the standard treatment, most subsequent trials focused either on good-prognosis or poor-prognosis patients, with an aim toward reducing the toxicity of treatment for the former while increasing the efficacy of treatment for the latter. A variety of prognostic systems were developed at different centers, most of which were focused on the location and bulk of metastatic disease, but it subsequently became clear that the serum tumor marker levels also carried important prognostic implications. In 1997, collaborative groups from 10 countries pooled their data on 5,862 patients with disseminated GCTs and developed the International Germ Cell Consensus Classification system, which categorizes patients as good risk, intermediate risk, or poor risk (see Table 49.3).⁴⁰ This multivariate analysis reported that disease bulk was not important. Rather, in seminomas the only poor prognostic factor was nonpulmonary visceral metastases, whereas in NSGCTs, risk factors included highly elevated serum tumor markers, nonpulmonary visceral metastases, and a mediastinal primary tumor.

Special Considerations Regarding Chemotherapy

Chemotherapy for disseminated testicular GCTs represents an unusually high-stakes situation for the oncologist: the disease is almost uniformly fatal without chemotherapy, but chemotherapy can cure a large majority of patients. There are few such moments in oncology where chemotherapy can grant many decades of life. Unnecessary treatment failures resulting from substandard treatment can have tragic consequences. Testicular cancer is a rare disease, and most oncologists see no more than a few cases annually. Those without substantial experience treating testicular cancer should consider consulting a cancer center with appropriate expertise because specialist centers produce superior outcomes.^{1,213}

The major chemotherapy issues are not simply which regimen to use and how many cycles to give but also how to monitor for toxicity and under what circumstances to delay treatment, reduce doses, or change the treatment plan.

Regarding dose adjustments, the practice in most modern first-line chemotherapy trials has been to treat at full dose, on schedule regardless of day 1 cell counts. Patients who are neutropenic on day 1 should have blood counts checked every 1 to 2 days and etoposide should be held on day 5 if counts have not recovered. If the prior cycle was complicated by febrile neutropenia or thrombocytopenic bleeding, then etoposide and ifosfamide doses are reduced by 25%. Cisplatin is given on schedule at full dose unless serum creatinine rises above 3mg/dL. In *good-risk patients*, several trials have adjusted doses or delayed treatment up to 7 days in patients with day 1 neutropenia or thrombocytopenia without any evidence of compromising results,^{214,215} but there are no randomized data to indicate whether such a policy has an impact on survival.

Bleomycin should be discontinued if there is evidence of pulmonary toxicity, *but if bleomycin is discontinued, additional adjustments are required*. In patients with favorable-risk disease who were scheduled to receive three cycles of BEP, discontinuing the bleomycin can be accommodated by switching to etoposide and cisplatin (EP) and giving a fourth cycle, because four cycles of EP appears to be nearly equivalent to three cycles of BEP.²¹⁶ In intermediate- and poor-risk patients scheduled to receive four cycles of BEP, ifosfamide can be substituted for bleomycin with no loss in efficacy (if ifosfamide is substituted for bleomycin, then the daily etoposide dose is reduced to 75mg/m²).^{217,218} Monitoring for bleomycin pulmonary toxicity involves a careful history and physical examination before each bleomycin administration. Symptoms and signs of pulmonary toxicity include dyspnea, a persistent nonproductive cough, inspiratory rales, and an inspiratory lag. Pulmonary toxicity is also associated with a decline in pulmonary diffusion capacity. Some centers obtain pulmonary function tests every 3 weeks during chemotherapy, particularly in patients scheduled to receive four cycles of bleomycin, although the utility of pulmonary function tests in reducing the incidence or severity of bleomycin-induced pulmonary fibrosis has never been demonstrated. A low threshold for discontinuing bleomycin if pulmonary toxicity is suspected can be justified by the availability of ifosfamide, an equally efficacious drug, albeit one associated with greater myelosuppression.

Chemotherapy for Good-Risk Disease

Strategies for reducing the toxicity of treatment for good-risk patients have included reducing the number of cycles, eliminating bleomycin, and substituting carboplatin for cisplatin (Table 49.6). Only the first goal has been unambiguously accomplished.

REDUCING THE NUMBER OF CYCLES

In 1989, the Southeastern Cancer Study Group reported a study of 184 good- to moderate-risk patients randomized to either three or four cycles of BEP.²¹⁹ No significant difference was seen between three and four cycles with regard to either complete response rate (98% versus 97%) or the relapse rate (5% in each arm). No bleomycin deaths were reported. Long-term follow-up of the 188 patients who had been treated at Indiana University reported that 7 patients (6%) had died of either germ cell cancer or treatment-related toxicities, with 4 deaths in the three-cycle arm and 3 deaths in the four-cycle arm.²²⁰ When this trial was conducted, the importance of

TABLE 49.6. Randomized controlled trials for good-risk disseminated germ cell tumors.

Regimen	N	Median follow-up (months)	Complete response	Relapses	Deaths	Conclusion
Number of cycles:						
BEP × 3 ^{219,220}	88	NR	98%	5	6	Equivalent
BEP × 4	96		97%	5	3	
BEP × 3 ²¹⁵	406	25	73%	24	12	Equivalent
BEP × 3 + EP × 1	406		75%	23	12	
BEP × 3 ²¹⁴	83	33		6	3	Standard BEP superior to modified BEP
B ₃₀ E ₃₆₀ P × 4	83			12	13	
Is bleomycin necessary?

CE ₃₆₀ B × 4	25		76%	8	4	
EP × 4 ³¹²	134	22.4	90%	4	NR	EP superior
EC × 4	131		88%	16	NR	
BEP ²²⁵	268	36	94%	15	10	BEP superior
CEB	260		87%	46	27	

NR, no response; BEP, bleomycin, etoposide, cisplatin; EP, etoposide and cisplatin; CEB, carboplatin, etoposide, and bleomycin; EC, etoposide and carboplatin B₃₀, reduced bleomycin dose of 30 units per cycle; E₃₆₀, reduced etoposide dose of 360 mg/m² per cycle.

serum tumor marker levels was not appreciated, and men with highly elevated HCG levels were included. Among men with HCG levels below 1,000 IU/L, 98% were alive with no evidence of disease with a median follow-up of 10 years, whereas 5 of 14 (36%) with HCG levels above 1,000 IU/L died disease-related deaths. Such patients are now considered intermediate risk and should receive four cycles of BEP or VIP. A larger European study randomized 812 men to either three cycles of BEP or three cycles of BEP followed by a fourth cycle of etoposide and cisplatin (EP).²¹⁵ With 2 years follow-up, 2-year progression-free survival was 90% and 89%, respectively, and a 5% difference could be excluded. These two trials established three cycles of BEP as a standard treatment option for men with good-risk disseminated germ cell cancers.

ATTEMPTING TO ELIMINATE BLEOMYCIN

Bleomycin is associated with potentially fatal pulmonary fibrosis as well as a more-common occurrence of Raynaud's phenomenon and mucositis. People who have received bleomycin also have an elevated incidence of sometimes fatal postoperative pulmonary complications. Fortunately, dropping the fourth cycle of BEP in good-risk patients has almost eliminated fatal pulmonary complications. Six trials administering three cycles of BEP to 1,142 patients reported 2 (0.18%) fatalities.^{111,214,215,219,221,222} However, nonfatal pul-

monary complications have been reported in 12% to 17% in studies that have reported detailed toxicity data.^{214,215} Numerous randomized controlled trials have studied whether eliminating bleomycin compromises efficacy. Based on the existent evidence, a number of centers have adopted four cycles of EP as an alternative to three cycles of BEP, and the two regimens are considered equivalent by many in the field. However, the equivalence of these regimens has never been established by comparative trials, and BEP is better supported by the available data.²¹⁶

Prospective randomized trials have demonstrated that three cycles of BEP produced superior overall survival than three cycles of EP (95% versus 86%; *P* = 0.01),²²² that three cycles of BEP produce a higher complete response rate than four cycles of EP (95% versus 87%; *P* = 0.0075) when using the lower European etoposide dose (360 mg/m²/cycle instead of 500 mg/m²/cycle),²²³ and that PBV results in superior disease control compared to a cisplatin and vinblastine doublet.²²⁴ A randomized trial comparing four cycles of EP to three cycles of a historical regimen referred to as VAB-6 showed no difference in efficacy, but VAB-6 has never been compared to BEP, so the relevance of this trial to current practice is ambiguous. After retrospective data suggested that three cycles of BEP may produce disease control superior to that of four cycles of EP,²²¹ a randomized trial was completed that assigned 131 men to the BEP × 3 arm and 127 to the EP × 4 arm.²¹⁶ With a median follow-up of 51 months, the 4-year

event-free survival with BEP was 89% compared to 84% with EP ($P = 0.09$). When the 6 men with nonpulmonary visceral metastases (poor-risk patients) were excluded from the analysis, this difference became significant (91% versus 84%; $P = 0.037$). Overall survival showed a nonsignificant trend in favor of BEP (96% versus 92%; $P = 0.1$). Grade 3 to 4 neutropenia was more common with EP (90%) than BEP (73%), but cutaneous toxicity and neurotoxicity were more common with BEP. This trial was unable to exclude clinically relevant inferiority concerning disease control with EP. However, because the intent-to-treat analysis did not show a statistically significant difference between the two regimens, four cycles of EP is still accepted by many as a standard treatment option for good-risk disseminated NSGCTs.

CARBOPLATIN

Cisplatin is associated with much higher rates of renal, neurologic, gastrointestinal, and vascular toxicity than is carboplatin. In addition, large volumes of intravenous fluid are given with cisplatin to avoid renal toxicity by maintaining a brisk urine output, and the infusion of fluids substantially increases the time necessary to administer treatment. Multiple attempts have been made to substitute carboplatin for cisplatin in favorable-risk disease, and these randomized controlled trials have clearly established that cisplatin is more effective and is associated with higher survival rates (see Table 49.6).²²⁵⁻²²⁷ Nonetheless, carboplatin is a highly active agent and, in patients with renal failure or extremely severe cisplatin neurotoxicity, the question of substituting carboplatin for cisplatin arises; treatment decisions in such extraordinary cases must weigh the risks and benefits associated with the available regimens.

CONCLUSION

Standard chemotherapy for good-risk disseminated testicular GCTs is three cycles of BEP or four cycles of EP, but there is evidence that the BEP regimen may be more effective.

Intermediate- and Poor-Risk Disease

Despite two decades of trials, *four cycles of BEP remains the standard of care for intermediate- and poor-risk disease*, and this regimen is associated with overall survival rates of about 80% and 60%, respectively, for these two risk groups.^{112,217} The search for a more-effective regimen continues but has thus far been unsuccessful. A randomized Eastern Cooperative Oncology Group trial compared BEP to etoposide, ifosfamide, and cisplatin (VIP) and reported no significant differences in complete response (31% versus 37%; $P = 0.26$), failure-free survival (60% versus 64%; $P = 0.29$), or overall survival (71% versus 74%; $P = 0.78$).^{217,218} Although the trends in this trial favored VIP, a multicenter European trial also reported no difference between the two regimens, with the trend favoring BEP.²¹⁵ Both studies reported greater leukopenia and thrombocytopenia in the VIP arm. BEP was therefore concluded to be the preferred regimen, except in patients with compromised pulmonary status at baseline, for whom VIP represents a good alternative.

Efforts to improve results through increased dose density or dose intensity have similarly failed. Rapid cycling of three courses of bleomycin, vincristine, and cisplatin followed by

three cycles of VIP proved no better than BEP in a randomized trial.²²⁸ Similarly, a randomized multicenter U.S. trial comparing standard BEP to BEP using double-dose cisplatin (200 mg/m² per cycle) reported the same 74% survival and almost identical disease-free survival in the two arms.²²⁹ Although numerous other regimens have been studied, using up to seven different chemotherapeutic agents and many using alternating cycles of different regimens, none has been shown to produce superior results to BEP.²³⁰⁻²³⁴

HIGH-DOSE CHEMOTHERAPY AS FIRST-LINE TREATMENT

The use of high-dose chemotherapy with stem cell support has been investigated in Europe and the United States, with promising phase II trial results but no informative phase III studies yet available. The largest series using this approach come from the German Testicular Cancer Study Group and Memorial Sloan-Kettering Cancer Center. A recent update of the German experience with dose escalation describes 182 patients with poor-prognosis disseminated germ cell cancers.²³⁵ Treatment consisted of one cycle of standard-dose VIP with subsequent stem cell collection of stem cells, followed by three to four cycles of high-dose VIP. With a median follow-up of 4 years, progression-free and disease-specific survival were 69% and 79%, respectively, at 2 years and 68% and 73% at 5 years. Severe toxicity included toxic deaths (4%), leukemia (1%), chronic renal insufficiency (3%), chronic renal failure (1%), and persistent neuropathy (5%). This regimen is being compared to four cycles of standard BEP in a randomized phase III trial by the EORTC. In the United States, a multicenter phase III trial comparing four cycles of BEP to two cycles of BEP followed by two cycles of high-dose CEC (carboplatin, etoposide, and cyclophosphamide) completed accrual in 2003, and results are expected to be presented soon.

Management of Residual Masses

Pure Seminomas

Men with stage II or III seminomas commonly have residual radiographic lesions following radiation or chemotherapy. Roughly 60% of men have residual masses after chemotherapy.^{66,236} Unlike nonseminomas, where surgical resection of any residual masses represents an important part of standard care, resecting residual seminomas following radiation or chemotherapy is often technically difficult or impossible and is associated with a higher rate of major surgical complications than RPLND in nonseminomas. Indiana University reported that 37 of 97 men (38%) undergoing postchemotherapy RPLND for residual tumors that contained seminomatous elements (including 88 with pure seminoma primary tumors) required a total of 47 additional intraoperative procedures, including 25 nephrectomies, 9 inferior vena cava resections, 5 arterial grafts, 5 bowel resections, and 3 hepatic resections or biopsies.²³⁷ In contrast, additional procedures were required in only 340 of 1,269 men (26.8%) without seminomatous elements ($P = 0.02$). Relative to nonseminomas and mixed GCTs, residual viable neoplastic disease is less likely to be present when the primary tumor was a pure seminoma. For these reasons, surgery is used more selectively in semi-

nomas,²³⁸ but it must be remembered that resection of residual disease is curative for most patients and remains an important treatment modality for patients at high risk of having residual neoplasm.^{238–240} Moreover, only 7% to 14% of poorly defined, difficult-to-resect masses harbor cancer, compared to 46% to 55% of well-defined, more easily resected masses.^{239,241} In one series of 55 men with residual masses following treatment of pure seminomas, a complete resection was possible in 78% of those whose masses were well defined on CT scan compared to only 44% of those whose masses were not well defined.²³⁹ Extensive biopsies were taken when resection was impossible. Residual seminoma or teratoma was found in 8 of 27 (30%) men with masses at least 3 cm in diameter compared to 0 of 28 with masses less than 3 cm. Three series with a total of 202 men with residual masses reported that 22 of 74 (30%) with masses that were 3 cm or larger had viable cancer, compared to 5 of 128 (4%) with smaller masses.^{238,241,242}

Treating residual postchemotherapy masses with radiation therapy has fallen out of favor based on several retrospective analyses showing that routinely irradiating residual masses had a low radiographic response rate²⁴³ and had no appreciable effect on subsequent relapse rates.²³⁶ Although there is no clear consensus on the management of these patients, low-risk patients (masses smaller than 3 cm) are generally surveilled whereas high-risk patients (masses 3 cm or greater) undergo surgical exploration with either resection of residual masses or, where resection is impossible, extensive biopsies. Patients who have unresectable pathologically confirmed residual seminoma should undergo salvage chemotherapy.

The seminoma patient with residual masses represents one of the only settings in testicular cancer care where PET scans show some promise. A multiinstitutional series of 56 scans of 51 patients reported a sensitivity of 80% and specificity of 100%.²³⁸ Among 37 scans of men with lesions less than 3 cm, increased uptake was present in 1 of the 3 men who were subsequently found to have residual cancer. In contrast, PET was 100% accurate with lesions larger than 3 cm, correctly identifying the 7 with residual disease and the 12 without. An earlier study was less promising, however, and the utility of PET scans needs to be confirmed.²⁴⁴

Nonseminomatous Germ Cell Tumors

Residual masses are detected in an estimated 20% to 25% of men following chemotherapy for metastatic NSGCTs.²⁴⁵ *The current standard of care is to resect any residual masses if the serum tumor markers have normalized and if technically feasible.* As discussed next, some centers have advocated retroperitoneal exploration and lymphadenectomy in all patients with prechemotherapy retroperitoneal adenopathy or masses, regardless of the findings on postchemotherapy radiologic imaging, but this practice is not widespread.²⁴⁵ Resections of postchemotherapy masses in GCT patients are generally complex and, given the rarity of the disease, extensive experience is limited to a small fraction of practicing surgeons. Referral to a center of excellence is strongly encouraged.

The rationale for resection of residual masses derives from the finding that roughly 35% to 45% of residual masses

contain teratoma, 10% to 20% contain residual seminoma, yolk-sac tumor, choriocarcinoma, and/or embryonal carcinoma, while the remaining 45% to 50% contain only necrotic tissue and fibrosis.^{246–248} Following salvage (as opposed to primary) chemotherapy, up to 50% of patients have viable nonteratomatous germ cell cancer.²⁴⁹ Interpreting these figures is not entirely straightforward, because the observed relapse rates in men who do not undergo postchemotherapy RPLND are lower than these numbers would predict.²⁵⁰ Although it thus appears that some residual teratomas are not destined to progress, this issue is poorly characterized and poorly understood.

Surgically removing residual teratoma is generally curative in itself, and men who have only teratoma or necrosis/fibrosis discovered at surgery share an excellent prognosis, with a roughly 90% 2-year progression-free survival.²⁵¹ Men with residual cancer, however, have a poorer prognosis and are generally advised to undergo additional chemotherapy following surgery.²⁴⁹ Resection of residual masses is thus both therapeutic and diagnostic. However, half of these masses are purely necrotic/fibrotic, and resection of fibrosis and necrosis is unlikely to confer any benefit upon the patient. Numerous attempts have thus been made to develop a model that would predict the histology of residual masses with the goal of reducing unnecessary operations.^{245–247,252,253} Indiana University reported that, based on an analysis of 295 men with disseminated NSGCTs who had undergone primary chemotherapy, 92% of men who achieved a radiologic and serologic complete remission were continuously disease free with a median follow-up of 5 years.²⁵³ However, no other group could be identified with less than a 25% risk of relapse without undergoing postchemotherapy RPLND.

A more-sophisticated model has been developed by Steyerberg and colleagues, taking into account the following variables that were associated with the absence of viable teratoma or cancer in residual masses: absence of teratoma elements in the primary tumor, normal prechemotherapy HCG, normal prechemotherapy AFP, elevated prechemotherapy LDH, smaller postchemotherapy residual disease bulk, and a large percent decline in disease bulk during chemotherapy.²⁴⁷ The model was developed using a pooled international data set of 544 patients and later validated on 172 subsequent patients. In the validation study, no tumor was found at RPLND in the 15 patients predicted to have less than a 10% chance of having residual cancer or teratoma. However, in a second validation study limited to 105 good-risk patients, only 4 patients were predicted to have less than a 30% chance of having residual viable tumor. Three of these 4 (75%) had benign histology found at RPLND. The prediction rule was accurate but affected the management of only 4% of the patients. More-recent attempts to develop a clinically useful model have similarly failed.²⁵⁴ Further complicating decision making, the Norwegian Radium Hospital has reported an analysis of 87 patients with disseminated NSGCTs undergoing RPLND for postchemotherapy masses smaller than 20 mm. Of the 87 total patients, 29 (33%) had residual tumor, including 23 (26%) with residual teratoma and 6 (7%) with residual cancer. Of the 54 with masses no larger than 10 mm, 5 (9%) had residual cancer and 11 (20%) had teratoma. Thus, 29% of patients with normal postchemotherapy CT scans had residual tumor. Nonetheless, chemotherapy trials have reported that fewer than 8% of patients with radiologic and

serologic complete responses subsequently relapse.^{208,215,253} The low relapse rate seen in men with complete responses to chemotherapy as well as the complications seen in postchemotherapy RPLNDs have led most centers to avoid RPLND unless there are residual masses greater than 10mm.²⁴⁵

MANAGING RESIDUAL MASSES IN MEN WITH PERSISTENTLY ELEVATED SERUM TUMOR MARKERS

Men with rising or persistently elevated serum tumor markers are at high risk for having progressive disseminated cancer and have typically been treated with salvage chemotherapy. However, no randomized trials exist to support this practice, and data clarifying the best management of these patients remain sparse. Published series have reported that resection of residual disease is curative for most men with a persistently elevated or rising serum AFP following chemotherapy, but relapse and mortality rates range from 70% to 100% when serum HCG remains elevated in most series.²⁵⁵⁻²⁵⁷ It has also been reported that patients with rising markers have a poorer postoperative prognosis than those with stable elevated markers.²⁵⁸ A persistently elevated AFP is thus not a contraindication to resecting residual disease, but operating in the setting of a significantly elevated HCG or rising AFP is usually futile. Any decision to operate in the setting of elevated markers should be carefully considered. As previously discussed, it is essential to exclude nonneoplastic etiologies for elevated serum tumor markers following chemotherapy.

COMPLICATIONS AND EXTENT OF RESECTION

Historically, postchemotherapy RPLND has been associated with a substantially higher complication rate than primary RPLND, but the surgical template for the postchemotherapy operation has diminished over time and the complication rate has declined.^{259,260} Nonetheless, Indiana University reported that among 150 men undergoing postchemotherapy RPLND between 2000 and 2002, 29% had intraoperative complications requiring additional procedures such as nephrectomy or inferior vena cava resection and 6.7% experienced postoperative complications such as ascites, wound infections, or prolonged ileus.²⁶⁰ Although no patients in this report suffered fatal complications, others have reported a perioperative mortality rate of nearly 1%.^{206,261} The higher complication rate following chemotherapy derives from the greater bulk of disease, the higher frequency of invasion of or adherence to vital structures, the effect of chemotherapy on the patient's overall condition, and the increased rate of postoperative pulmonary complications seen in patients with prior bleomycin exposure. However, the rate of pulmonary complications appears to have declined with the implementation of anesthesia precautions, which include limiting the partial pressure of oxygen and the volume of intravenous fluids delivered to the patient during surgery and the perioperative period. Several recent studies have reported no fatal pulmonary complications.^{206,260}

A major change in the template of postchemotherapy RPLNDs has occurred during the past two decades. Historically, an extensive bilateral dissection was performed in addition to removing any visible residual disease. More recently, favorable results have been reported following a more-limited resection in which all visible residual masses are removed and

a more-limited template dissection is performed, with nerve sparing when possible, if no residual tumor is found on frozen section.²⁶²⁻²⁶⁴ In cases where frozen section shows viable tumor, most reporting centers have performed an extensive bilateral dissection. Memorial Sloan-Kettering Cancer Center reported, in 62 patients undergoing such an approach, that 37 showed only necrosis on frozen section (and thus underwent a limited dissection), and only 1 of these 37 relapsed in the retroperitoneum. Among the total 62 patients, only 3 had teratoma or cancer outside the palpable disease and only 2 relapsed within the retroperitoneum.²⁶⁵ In patients with residual masses in the lungs, liver, or other sites, standard practice has been to resect these lesions as well, either in a single operation sequentially, if all residual disease can be resected. Whether a finding of necrosis only in the retroperitoneum justifies aborting any attempt to resect other sites of residual disease remains controversial.^{266,267} Most reports have advocated a resection of all residual masses because up to 23% of men with necrosis in the retroperitoneum have teratoma or cancer in the thorax. In cases in which a complete resection is impossible, a resection of those masses that are resectable is not generally recommended because the benefit of a partial resection has not been established.

TREATMENT OF MEN WITH VIABLE CANCER IN POSTCHEMOTHERAPY MASSES

Men with viable cancer discovered at postchemotherapy surgery have a poor prognosis compared to those with necrosis or teratoma.^{249,268-270} Hannover University reported, among 27 patients undergoing resection of residual masses, that overall survival was 87% among those found to have necrosis or residual teratoma versus 22% among those found to have viable cancer.²⁷¹ EORTC reported that 23 of 26 (88%) men with residual teratoma were alive without evidence of disease compared to 13 of 22 (59%) of those with residual cancer.²⁷⁰ Some have therefore recommended chemotherapy for these patients following surgery, and the standard practice among those giving chemotherapy has been to administer two cycles of cisplatin-based chemotherapy, typically either EP, VIP, or VeIP. An international multivariate analysis of 146 patients with viable cancer in residual masses reported a progression-free survival advantage favoring chemotherapy (69% versus 52%; *P* less than 0.001) but no overall survival difference when comparing those who received adjuvant chemotherapy to those who did not.²⁷² The three factors independently associated with overall survival were complete versus incomplete resection, less than 10% viable malignant cells, and a good-risk international germ cell consensus classification (IGCCC).

Treatment of Relapsed and Refractory Disease

Progressive disease during or following first-line chemotherapy carries a distinctly poorer prognosis than metastatic chemonaive disease. Although ifosfamide and etoposide have activity in patients with cisplatin-resistant disease, they have produced disappointing long-term survival. Subsequently, paclitaxel and gemcitabine were shown to have activity in cisplatin-resistant disease, but whether regimens incorporating these drugs can improve survival remains unproven, favorable phase II trial results notwithstanding. Great inter-

est has developed in high-dose chemotherapy as salvage treatment, but data showing a survival advantage are lacking.

Standard-Dose Salvage Chemotherapy

The most widely used salvage chemotherapy regimens for relapsed or refractory GCTs have been cisplatin, ifosfamide, and either etoposide (VIP) or vinblastine (VeIP), and these remain the standard of care. Because most patients now receive etoposide as part of their first-line chemotherapy, VeIP, which offers two new agents to men who have previously been treated with either EP or BEP, is the most commonly used salvage regimen. In patients with relapsed NSGCTs, VIP and VeIP have resulted in long-term survival of 20% to 30%.²⁷³⁻²⁷⁷ Men with relapsing seminoma fare better, with VeIP and other ifosfamide-cisplatin-based regimens producing long-term survival of 53% to 54%.^{65,278} These results led to the investigation of alternative regimens and the use of high-dose chemotherapy with stem cell rescue. Gemcitabine and paclitaxel both have activity against cisplatin-resistant GCTs, with response rates in the 11% to 30% range and reports of rare durable remissions.²⁷⁹⁻²⁸² Using these agents in multidrug regimens has produced more-favorable results. Motzer et al. reported 30 relapsing GCT patients with favorable prognostic features in whom paclitaxel, ifosfamide, and cisplatin (TIP) produced an overall and progression-free survival of 80% and 73%, respectively, at a median follow-up of 33 months.²⁸³ Because this study involved a favorable subset of relapsed patients, comparing the results to other regimens is problematic, but a multicenter U.S. randomized phase III trial comparing TIP to VeIP is under way. The combination of gemcitabine and paclitaxel has been investigated in relapsing patients with adverse prognostic features.²⁸⁴ Six of 28 (21.4%) responded, including 3 complete responses and 2 durable responses at 15 and 25 months. Oxaliplatin, alone or combined with gemcitabine, has also shown modest levels of activity in heavily pretreated patients.^{285,286}

High-Dose Salvage Chemotherapy

High-dose chemotherapy with stem cell support for patients with relapsing or refractory GCTs has been investigated since the early 1980s as salvage therapy, but early results in heavily pretreated patients were disappointing, with more than 20% of patients suffering toxic deaths and few long-term survivors. More recently, high-dose salvage chemotherapy has been used on less heavily pretreated patients and the results, as discussed next, have been more promising. Whether high-dose salvage chemotherapy results in better long-term outcomes than standard-dose chemotherapy remains unresolved. Prognostic criteria have been identified that help predict the likelihood of a successful outcome with high-dose salvage chemotherapy. Analyzing 310 patients treated at four centers between 1984 and 1993, Beyer et al. reported that five factors were associated with treatment failure: progressive disease immediately before high-dose chemotherapy, HCG level above 1,000 U/L, mediastinal primary tumor, and disease that was relatively refractory (progression within 4 weeks of treatment) or absolutely refractory (progression during treatment) to cisplatin.²⁸⁷ Using a scoring system that gave each prognostic factor one point, except for mediastinal primary or absolutely refractory disease, which each were worth two points, the study identified a good-risk category (no

points), an intermediate-risk category (one or two points), and a poor risk category (more than two points). Failure-free survival was 51%, 27%, and 5%, respectively. Indiana University, however, reported that among the 23 poor-risk patients transplanted using a tandem transplant strategy, failure-free survival was 30% (95% CI, 11%–49%) and the most important adverse prognostic factor was a mediastinal primary tumor (0% survival in the Indiana series compared to 12% survival in Beyer's study). In contrast, recent European studies using a single cycle of high-dose chemotherapy have reported no survivors among 18 poor-risk patients.²⁸⁸⁻²⁹⁰ Whether these results indicate that poor-risk patients are poor candidates for transplant or that they require at least two cycles of high-dose chemotherapy is controversial.²⁹¹

Different institutions have used different regimens and have targeted different prognostic groups, with the result that comparing results among different institutions is challenging. Recent studies, however, have reported that about 50% of relapsing or refractory patients can be successfully salvaged with high-dose chemotherapy when it is used at first or second relapse.^{290,292-294} Although many centers have evaluated multiple cycles of high-dose chemotherapy, the benefit of this approach relative to a single cycle remains untested; the high-dose results appear favorable compared to historical results with standard-dose regimens, but the patients undergoing high-dose therapy have been more carefully selected. A European trial randomized 280 men to either four cycles of standard salvage therapy (VeIP or VIP) or three cycles of standard therapy followed by one cycle of high-dose carboplatin, etoposide, and cyclophosphamide.²⁹⁵ Men who were relatively or absolutely refractory to cisplatin were excluded, but men with mediastinal primary tumors were permitted. Three-year overall survival was 53% in each arm, indicating no advantage to high-dose chemotherapy, but mature results have not been published. A retrospective matched-pair analysis has been published comparing the outcomes of men who relapsed after first-line cisplatin-based chemotherapy and received either high-dose or standard-dose salvage chemotherapy.²⁹⁶ This analysis reported a statistically significant 10% 2-year survival advantage with high-dose chemotherapy, but it is subject to all the limitations of a retrospective, nonrandomized investigation.

Men who relapse following high-dose salvage chemotherapy relapse early and have a poor prognosis. Indiana University reported 101 relapsing patients, all of whom relapsed within 17 months of high-dose therapy.²⁹⁷ After relapse, 47 underwent chemotherapy, either with ($n = 35$) or without ($n = 12$) surgery, and 7 underwent surgery alone. The response rate to chemotherapy was 18% and only 5 patients (5%) were disease free at the time of the report, all of whom had received surgery as part of their treatment. A French study of 32 relapsing patients reported similarly poor chemotherapy results: 6 patients were successfully salvaged, all of whom had had surgical resection of residual masses as part of their treatment.²⁹⁸

Conclusion

Currently, high-dose salvage chemotherapy represents a standard treatment option at most centers treating a large volume of germ cell cancers. Choosing between standard- and high-

dose chemotherapy presents a challenge in the absence of mature randomized trials. The only setting in which high-dose chemotherapy appears to be almost completely ineffective is relapsed mediastinal GCTs.

Extragenadal Germ Cell Tumors

Germ cell tumors in adolescent and adult men also occur in the retroperitoneum and mediastinum. Primary mediastinal GCTs almost always occur in the anterior mediastinum, which is a rare site of metastasis for testicular or retroperitoneal GCTs.²⁹⁹ As part of the diagnostic workup, it is standard practice to obtain a scrotal ultrasound to exclude a testicular primary. Although retroperitoneal GCTs carry the same prognosis as testicular GCTs after correcting for stage, mediastinal NSGCTs carry a worse prognosis and are considered poor-risk GCTs unless they are composed of mature teratoma.^{40,300} Mediastinal seminomas have an excellent prognosis that is no different from that of disseminated testicular seminomas. They are treated with the same systemic chemotherapy protocols as disseminated testicular seminomas and carry the same good or intermediate prognosis, depending on whether nonpulmonary visceral metastases are present. Residual masses are handled in the same fashion as in gonadal seminomas. The treatment of retroperitoneal GCTs is similar to that of testicular tumors with respect to the choice of chemotherapy and the practice of rapid diagnostic workup and treatment, including, in nonseminomatous tumors, the resection of all residual masses. Retroperitoneal seminomas are considered favorable risk unless nonpulmonary visceral metastases are present and are generally treated with chemotherapy using the same chemotherapy protocols used for disseminated testicular seminoma. Although radiation therapy may be an acceptable alternative for low-volume disease, retrospective analysis has suggested better progression-free survival with chemotherapy (87% versus 33%; $P = 0.01$).³⁰¹ Retroperitoneal NSGCTs are also staged and treated in the same fashion as testicular NSGCTs. Patients with retroperitoneal GCTs typically present either with abdominal or back pain or with symptoms of advanced disease such as weight loss, fevers, night sweats, or venous thrombosis. Most patients are found to have a significant disease burden at the time of diagnosis. Median primary tumor size is 7 cm and 8 cm for seminomas and NSGCTs, respectively. Metastases are present at diagnosis in 46% of patients with seminomas and 76% of those with NSGCTs, and most patients have elevated tumor markers.³⁰¹

Mediastinal NSGCTs differ from testicular NSGCTs in several respects. The distinction of pure teratomas from other histologies and the distinction of mature versus immature teratoma carries a prognostic significance in mediastinal tumors that does not apply to testicular cancers. Mature teratomas of the mediastinum are benign tumors that can be cured with surgical resection alone in almost all patients. In three series reporting a total of 157 patients, the only 2 deaths were due to surgical complications.^{299,302,303} Immature teratomas, in contrast, often behave more malignantly in individuals over 15 years of age (in children, teratomas of the mediastinum are benign regardless of whether there

are immature elements). Dulmet et al. reported that among 6 adult patients with immature teratoma, 4 died of the disease.³⁰² In contrast, Hiroshima et al. found that 5 of 6 men with immature teratomas survived when treated with chemotherapy followed by complete surgical resection.³⁰³

Nonseminomas of the mediastinum have a poorer prognosis than other GCTs and are considered poor risk regardless of the extent of disease. The pooled analysis by Bokemeyer et al. of 287 cases from around the world reported that 49% were alive at a median follow-up of 19 months. Standard treatment is four cycles of BEP chemotherapy followed by a resection of any residual masses. An aggressive postchemotherapy surgical approach resecting all residual disease when possible is standard, partly because relapses are extremely difficult to cure. A representative study reported that among 79 patients receiving second-line chemotherapy for recurrent disease, only 9 (8%) were alive at a median follow-up of 45 months.³⁰⁰ High-dose salvage chemotherapy has been similarly ineffective in this population. Indiana University reported that all 28 patients receiving high-dose salvage chemotherapy subsequently relapsed.²²⁰ An international pooled analysis reported that failure-free survival following high-dose salvage chemotherapy was only 12%.²⁸⁷ In contrast, 2-year progression-free and overall survival were 64% and 68%, respectively, following *first-line* treatment with high-dose chemotherapy, but whether first-line high-dose chemotherapy results in superior results compared with standard BEP has not been addressed in prospective trials.³⁰⁴

Mediastinal NSGCTs are associated with an increased risk of hematologic malignancies, particularly disorders of the megakaryocyte lineage. Analysis by Hartmann et al. of 287 patients treated in the United States and Europe reported 17 individuals (5.9%) with fatal hematologic malignancies.³⁰⁵ The median time from diagnosis of the mediastinal tumor to the diagnosis of the hematologic neoplasm was 6 months. These tumors appear to share their origin with that of the mediastinal tumor, as they often share the isochromosome 12p seen in GCTs. They are highly resistant to treatment and are almost universally fatal, with a median survival of 5 months.

Cervix, Vulva, and Vagina

Julian C. Schink

In the United States and other developed countries, remarkable progress has been made in the prevention and treatment of cancer of the female lower genital tract. Cervical cancer is still the most prevalent of the lower genital tract cancers, followed by vulvar cancer and finally vaginal cancer, which is quite rare. Unfortunately, invasive cervical carcinoma remains one of the most common causes of cancer death for women in the developing world. On a global basis, cervical cancer remains a significant health problem, with 500,000 new cases occurring each year and an annual death rate of 230,000 worldwide.¹ In the United States, approximately 13,000 new cases of cervical cancer are diagnosed each year and only 4,500 deaths due to cervical cancer. This stark contrast between the low number of cases in the United States and tragic number of cases in the developing world is primarily a reflection of the effectiveness of screening for and treating preinvasive cervical disease.

Cervical, vaginal, and vulvar cancer are usually squamous cell carcinomas arising from a preinvasive lesion. The relatively slow progression from an *in situ* lesion to invasive cancer, which may take anywhere from 5 to 20 years, offers an important opportunity for screening interventions to prevent invasive cancer from developing in these women. Cervical cytology screening lowers the mortality from cervical cancer, as evidenced by both population-based and case-controlled studies.² Women having cervical cytology screening at least every 3 years have a 10-fold decrease in their risk of cervical cancer when compared with women who have never been screened.³ The focus of this chapter is primarily on the evaluation and treatment of squamous cell carcinoma of the cervix, vagina, and vulva because the principles of treating squamous cell carcinoma in these tissues are applicable to the other histologies. Cervical cancer is clearly the most common of the lower genital tract malignancies in women, accounting for approximately 16% of all gynecologic cancers. Vulvar cancer is quite uncommon and represents only 4% of malignancies in the female genital tract and, in contrast to cervical cancer, occurs most commonly in elderly women, compared to cervical cancer where the mean age is 51 years old. Vaginal cancer is even more rare, accounting for only 1% of gynecologic malignancies. In this chapter, we concentrate first on cervical cancer, then vulvar cancer, and finish with the diagnosis and management of vaginal cancer.

Cervical Cancer

Background and Prevalence

Cervical cancer remains a common event in the developing countries, with annual incidence rates ranging from a high of 83 cases per 100,000 women per year in Brazil to as low as 3 per 100,000 in developed countries such as Israel and the United States. The highest risk areas around the world are in Central and South America, the Caribbean, and southern and eastern Africa.⁴ The marked contrast in these incidence rates has been attributed primarily to the success of screening programs in the United States and other developed countries. Other explanations for the high incidence in underdeveloped countries, which are lacking consistent evidence, include the higher rate of cigarette smoking and the more frequent early age of initiating sexual intercourse.

The prevention of cervical cancer is attributed to screening asymptomatic women on a regular basis with cervical cytology. The identification of preinvasive cervical dysplasia, which can be successfully treated with a number of modalities including cryotherapy, surgical excision, or laser ablation, has resulted in a marked decrease in the number of women developing cervical cancer. In countries where cervical cytology screening is commonly performed, such as the United States, at least half the cases of cervical cancer occur in women who have not had regular Papanicolaou (Pap) smear screening. The cases that do occur in women who have had regular Pap smear screening tend to be unusual tumors, such as adenocarcinoma arising within the glands of the cervix, or in women who have been incompletely or previously treated for preinvasive disease and then develop a lesion high in the cervical canal.

The risk factors for developing cervical cancer are tied closely to the commonly identified etiologic agent human papillomavirus (HPV).⁵ This HPV is considered to be a necessary and critical factor in the development of cervical intraepithelial neoplasia and the subsequent progression to cervical cancer. Cervical carcinoma usually arises in metaplastic squamous epithelium at the junction of the ectocervix and endocervical canal. This squamous epithelium, which has undergone metaplasia during adolescence, appears to be particularly susceptible to the tumor suppressor effects of

HPV. The preinvasive lesions of cervical dysplasia, also called cervical intraepithelial neoplasia, will progress to invasive cervical cancer in 30% to 70% of women if left untreated. Fortunately, this progression usually takes between 10 to 20 years, allowing many opportunities to prevent the development of invasive cancer. The HPV is easily transmitted by sexual intercourse, so many of the risk factors for cervical cancer relate to sexual activity. Risk factors associated with the development of cervical cancer include early age of first intercourse, lower socioeconomic status, number of sexual partners, and a smoking history.⁶ Smoking is associated with both cervical dysplasia and invasive cancer, suggesting that cigarette by-products may affect the early evolution of HPV-related lesions, possibly by increasing the rate of cell turnover or by the presence of carcinogens in cervical mucus combined with the immunosuppressive effects of HPV.⁷ In 2002, results of the first controlled trial of an HPV vaccine were published, documenting an HPV-16 vaccine's efficacy in reducing the incidence of HPV-16-related cervical dysplasia.⁸ The editorial response to this vaccine breakthrough was "The Beginning of the End for Cervical Cancer?," emphasizing the importance of preventing HPV infection and thus decreasing the incidence of both cervical dysplasia and cervical cancer.⁹

Although vaccination to prevent HPV infection worldwide carries great promise, there are several short-term barriers to the success of this strategy. First, there are numerous oncogenic strains of HPV, with HPV-16 only accounting for half the cases of cervical cancer. A multivalent vaccine is currently in clinical trials; if effective it will be a next critical step in vaccine development. Second, vaccination does not appear to reduce the incidence of cervical cancer or dysplasia in women already infected with HPV. Therefore, the benefits of an HPV vaccination program will be confined to women who are not yet infected by HPV, and will take several decades before a marked reduction in cervical cancer results. Unfortunately, despite the possible long-term benefits of an HPV vaccine, in our lifetime we will continue to see women with cervical, vaginal, and vulvar cancer.

Diagnosis

The diagnosis of cervical cancer segregates into two groups of patients. The asymptomatic patient identified on cervical cytology screening often has an early stage 1 cancer. In contrast, women who have not had regular cervical cytology screening usually present with signs and symptoms of advanced disease, including pelvic pain and vaginal bleeding.

THE ASYMPTOMATIC PATIENT

Most asymptomatic patients will be diagnosed with a Pap smear showing either malignant cells or a preinvasive lesion, possibly even atypical squamous cells of undetermined significance (ASC). The evaluation of an abnormal Pap smear includes the use of colposcopic inspection of the cervix followed by colposcopically directed biopsies. If the colposcopy, or the biopsies, suggest an invasive malignancy, then a cone biopsy will confirm both the presence of invasion, the size of the tumor, and the depth of invasion. Occasionally, a patient with a more-advanced cervical cancer remains asymptomatic and has false-negative cervical cytology. These false-negative cytology tests usually occur because the tumor

originated high in the endocervical canal or did not shed malignant cells.

SYMPTOMS OF CERVICAL CANCER

The most common symptom of cervical cancer is abnormal vaginal bleeding, often presenting as postcoital bleeding. Women with cervical cancer also frequently complain of a watery and malodorous discharge. As cervical cancer becomes more progressive, patients may note urinary frequency, bladder pressure, or back pain. In the most advanced cases, patients can present with inguinal lymph node metastasis, lower extremity edema secondary to pelvic sidewall invasion or tumor replacing the pelvic lymph nodes, or in stage IV cases vesicovaginal or rectovaginal fistula.

PHYSICAL FINDINGS OF CERVICAL CANCER

The physical examination findings of cervical cancer are an essential component to the clinical staging of this cancer. The examination focuses on defining the extent of local invasion, primarily by pelvic examination. This examination includes visual inspection of the cervix and vagina, bimanual pelvic/abdominal examination, and rectovaginal examination. Evidence of vaginal mucosal involvement, parametrial tumor invasion, uterosacral tumor invasion, rectovaginal septum involvement, and fixation of one or both of the pelvic sidewalls are important considerations. An observational study by Hoffman and colleagues demonstrated only 50% accuracy in predicting tumor diameter when pelvic exam findings were compared with pathology specimens,¹⁰ but clinicians are accurate in predicting other prognostic factors, including outer third invasion (80%) and vaginal involvement (90%). Determining the extent of local and distant metastasis is critical in selecting between surgical and radiotherapy treatment options. Because physical examination findings are not very reliable, especially for tumors larger than 4 cm, most clinicians rely on magnetic resonance imaging (MRI), computed tomography (CT), and positron emission tomography (PET) imaging, when available, to better define the extent of disease. The most common patterns of spread of cervical cancer are direct extension and lymphatic metastasis. Examination of the groin and supraclavicular nodes for evidence of extensive nodal spread is critically important. Although hematogenous metastasis is less likely, especially with early cervical cancer, chest radiography at a minimum is indicated in the initial evaluation of all patients.

HISTOLOGIC DIAGNOSIS OF CERVICAL CANCER

A clinical diagnosis or cytology diagnosis of cervical cancer must be confirmed by biopsy-proven histology. A cytologic evaluation is not definitive evidence of invasive disease in these patients and is rarely adequate evidence to proceed with treatment. A colposcopically directed biopsy for a patient with a visual lesion is generally adequate for establishing the diagnosis, and these patients can usually be spared the risks and treatment delay that may result from a surgical biopsy known as cold knife conization. The pathologic diagnosis of invasive disease is sometimes difficult in women with a small lesion and only minimal invasion. The histologic features of early invasion of squamous cancer of the cervix include differentiation of the invading squamous cells and a brisk

adjacent inflammatory response. Involvement of the endocervical glands by carcinoma in-situ is a common finding in preinvasive disease, and any question of invasion versus glandular involvement deserves thorough pathology review. For patients with a microinvasive lesion, complete excision of the lesion by cervical conization with negative margins is mandatory to determine the extent of disease and the risk of metastatic disease.

Pathology

Squamous cell carcinoma and adenocarcinoma are the most frequent histopathologic types of cervical carcinoma. Squamous cell carcinoma has been subcategorized into keratinizing, nonkeratinizing, and small cell carcinomas. Adenocarcinoma has been subcategorized to include endometrioid adenocarcinoma, endocervical adenocarcinoma, and clear cell adenocarcinoma. Other much less common histologies seen with cervical cancer include adenosquamous carcinoma, small cell carcinoma, adenoid cystic carcinoma, and undifferentiated carcinoma.

SQUAMOUS CELL CARCINOMA

The majority of squamous cell carcinomas are exophytic or ulcerative lesions that arise within the transformation zone of the cervix. These lesions are generally visible on the ectocervix and are easily biopsied. The current classification scheme for squamous cell carcinomas was developed by the World Health Organization and divides these tumors into large cell keratinizing, large cell nonkeratinizing, and small cell nonkeratinizing types. The presence of keratin pearls is required for the tumor to be classified as keratinizing.¹¹ Small cell squamous carcinomas are as common as the keratinizing large cell carcinomas and are characterized by focal squamous differentiation without keratin pearl formation. It is important to distinguish small cell squamous carcinoma from small cell undifferentiated carcinoma, which may have neuroendocrine features and a significantly more-aggressive behavior.

Verrucous carcinoma is a variant of squamous cell carcinoma that is characterized by its exophytic growth resembling a giant condyloma. Verrucous carcinomas tend to be locally aggressive and may spread to adjacent organs including the vagina and the endometrium. The malignant behavior of this tumor is unpredictable, although some have suggested that the risk of nodal metastasis is considerably lower. Nodal metastases have been reported with this tumor, as has aggressive dedifferentiation when treated with radiotherapy.

INVASIVE ADENOCARCINOMA

In the United States and other developed countries where cervical cancer screening is common, there has been a relative increase in the incidence of adenocarcinomas of the cervix. In some studies adenocarcinomas now comprise between 15% and 25% of invasive cervical carcinomas. Adenocarcinomas are most commonly mucinous adenocarcinoma arising from endocervical glands, usually developing within the endocervical canal. These tumors are likely to be endophytic and may expand the cervix before becoming clinically apparent. Although the prognosis associated with adenocarcinomas has remained controversial, most studies have

demonstrated that prognosis is similar to squamous lesions size for size and stage for stage. In one recently published Italian randomized clinical trial of radical surgery versus radiation therapy for stage 1B and 2A cervical cancer, 46 of the 343 patients had adenocarcinomas. In that study, there is a suggestion that adenocarcinomas were more radiation resistant as the overall survival for adenocarcinoma patients treated with surgery was 79% versus 59% for patients treated with radiotherapy. This difference was statistically significant for the adenocarcinoma group, but in the squamous cell carcinoma group there was no difference in survival.¹² Intestinal-type mucinous adenocarcinomas of the cervical canal have the histologic appearance of cells that would ordinarily arise as intestinal adenocarcinomas but in this case arise within the endocervical canal. Endometrioid adenocarcinoma has a histologic appearance of its endometrial counterpart. It is important to distinguish the primary location of this tumor as it may represent endocervical extension of an endometrial carcinoma.

Well-differentiated villoglandular adenocarcinomas are a variant of adenocarcinoma typically seen in young women and may be associated with oral contraceptive use. Initial reports of this tumor included no recurrences or deaths among 37 patients, suggesting that metastasis was unlikely. Unfortunately, subsequent cases of metastatic disease, especially nodal metastasis, have been reported and are typically associated with deep cervical invasion; this is an important distinction that has led to the recommendation that these patients be treated in the same fashion as any other adenocarcinoma of the cervix.¹³

Clear cell carcinoma of the cervix can be seen in patients with a history of diethylstilbesterol (DES) exposure or as an extremely rare variant of adenocarcinoma. These tumors frequently present at an advanced stage and as a high-grade lesion and have a relatively poor prognosis.¹⁴

Adenosquamous carcinoma is a cervical cancer with both squamous and glandular features. These tumors can have a wide range of presentations, including atypical squamous cell carcinoma with small areas of mucin to an endometrioid-appearing carcinoma with squamous differentiation, to a single carcinoma of endocervical type with both squamous and glandular differentiation. Some controversy is expressed within the literature as to whether the prognosis associated with this malignancy is unfavorable, and it likely depends on which of these different types of adenosquamous carcinoma is involved.¹¹

Neuroendocrine small cell undifferentiated carcinoma is a very aggressive malignancy that is characterized by the presence of neuroendocrine granules. This highly aggressive tumor has been identified as having a very poor prognosis, with a 5-year survival as low as 14%.¹⁵

Adenoid cystic carcinoma is a malignant lesion with poor prognosis that resembles its more-common counterpart within the salivary glands. It is very important to distinguish adenoid cystic carcinomas from adenoid basal carcinoma, which is typically a small lesion associated with cervical dysplasia or early invasive squamous cancer and carrying with it a very good prognosis.

Although a wide range of histologies can arise within the uterine cervix, the treatment principles for these lesions are generally quite similar. The exceptions are neuroendocrine small cell carcinomas, which have an extremely aggressive

behavior, and villoglandular and verrucous carcinomas, which are not particularly aggressive. With neuroendocrine tumors, many clinicians have advocated using lung cancer chemotherapy regimens in addition to chemoradiation; however, there are no prospective trial data for this rare histology that support or confirm the benefit of this management.

Staging and Pretreatment Evaluation

Cervical cancer is staged clinically because the majority of patients are treated with a nonsurgical therapy. The commonly accepted staging system for cervical cancer was adopted by the International Federation of Gynecology and Obstetrics (FIGO) in 1994 (Table 50.1; 2002 staging).¹⁶ The clinical staging rules are based on clinical evaluation and basic radiographic studies. The only examinations of the patient allowed for staging include palpation, inspection, colposcopy with biopsy and endocervical curettage, cervical conization, hysteroscopy, proctoscopy, intravenous pyelogram, and plain film radiographs of the chest and bones. Suspected bladder or rectal involvement must be confirmed

by biopsy, with histologic evidence of invasion into the mucosa of either the bladder or rectum required for a diagnosis of involvement of those organs. If there is any doubt between two stages, the lower stage must be chosen. Because the majority of patients with cervical cancer are treated in the underdeveloped world where CT scans and MRI are not available, the use of those studies has not been adopted for the clinical staging of cervical cancer. Patients undergoing surgical assessment or further radiographic assessment with newer imaging modalities should have these findings noted and treatment directed based on the results of these studies, even though they are not allowed to change the clinical staging for these patients. Fine-needle aspiration of scan-detected suspicious lymph nodes may be helpful in treatment planning but is not allowed as part of the staging.

Although the rules for clinical staging are very clear that only plain film radiographs and routine available examination techniques may be considered in the assignment of the clinical stage, most patients in the United States are further investigated either by surgical staging or with noninvasive diagnostic studies ranging from lymphangiography to PET scanning. The goal of more-extensive imaging evaluation is to better define the radiation treatment fields and doses. The risk of paraaortic lymph node metastasis is 16% for stage II disease and 29% for stage III cervical cancer.¹⁷ The added toxicity of including the paraaortic lymph nodes in the radiation field has motivated investigators to look for better ways to identify nodal disease.

For many years, bipedal lymphangiography was considered to be one of the more-sensitive techniques for identifying nodal metastasis in cervical cancer patients. The difficulty in reading lymphangiograms as well as the technical challenges of performing this study combined with the side effects and high false-positive rate have led to lymphangiography falling out of favor. CT and MRI remain popular tools for better defining nodal metastasis and evaluating tumor size and parametrial infiltration.

Magnetic resonance imaging may be particularly important in evaluating patients as possible candidates for surgical therapy because it is useful in identifying parametrial invasion, a relative contraindication to primary surgical therapy in cervical cancer. Pakkal and colleagues evaluated the accuracy of MRI for the assessment of parametrial and lymph node involvement in cervical cancer patients undergoing surgical therapy. They compared the surgical staging and pathology findings with the MRI results and found accuracy in detecting parametrial and lymph node involvement in patients with cervical carcinoma to be 71% and 86%, respectively. Their conclusion was that MRI helps decide operability and the type of operation and aids in the selection of patients who need to be considered for specialist referral to a gynecologic oncologist.¹⁸ A recent retrospective analysis of 106 consecutive cervical cancer patients treated in the United Kingdom showed that pretreatment tumor volume measured using MRI with both an endovaginal and an external coil provides a more-accurate prediction of prognosis and defines a population at high risk of recurrence and death. Their results suggest that a tumor volume of 13 cm³ or greater is associated with poor prognosis and is more important in determining outcome than depth of invasion or invasion beyond the cervix.¹⁹

Recent studies of strategies to detect cervical cancer metastasis have focused on ¹⁸F-fluorodeoxyglucose positron

TABLE 50.1. International Federation of Gynecology and Obstetrics (FIGO) staging of cervical cancer, 2002.

<i>Carcinoma of the cervix uteri</i>	
Stage 0	Carcinoma in situ.
Stage I	Cervical carcinoma confined to uterus (extension to corpus should be disregarded).
Stage IA	Invasive carcinoma diagnosed only by microscopy. All macroscopically visible lesions, even with superficial invasion, are IB. Stromal invasion with a maximal depth of 5.0mm measured from the base of the epithelium and a horizontal spread of 7.0mm or less. Vascular space involvement, venous or lymphatic, does not affect classification. IA1—Measured stromal invasion of 3.0mm or less in depth and 7.0mm or less in horizontal spread. IA2—Measured stromal invasion more than 3.0mm and not more than 5.0mm with a horizontal spread 7.0mm or less.
Stage IB	Clinically visible lesions confined to the cervix or microscopic lesion greater than IA2. IB1—Clinically visible lesion 4cm or less in greatest dimension. IB2—Clinically visible lesion more than 4cm in greatest dimension.
Stage II	Cervical carcinoma invades beyond the uterus, but not to the pelvic wall or to the lower third of the vagina. IIA—Tumor without parametrial invasion. IIB—Tumor with parametrial invasion.
Stage III	Tumor extends to pelvic wall and/or involves lower third of the vagina and/or hydronephrosis or nonfunctioning kidney. IIIA—Tumor involves lower third of vagina, no extension to pelvic wall. IIIB—Tumor extends to pelvic wall and/or hydronephrosis or nonfunctioning kidney.
Stage IVA	Tumor invades mucosa of the bladder or rectum and/or extends beyond true pelvis (bullous edema is not sufficient evidence to classify a tumor as T4).

emission tomography (FDG-PET scanning) and on surgical staging with or without sentinel node biopsies. These studies have shown the utility of both surgical staging and PET scanning in detecting occult nodal disease and in treatment planning. A study by Grigsby and colleagues at Washington University demonstrated excellent lymph node control in a group of 208 women with cervical cancer evaluated by both PET and CT scan. They accomplished control of PET-positive pelvic and paraaortic lymph nodes in most patients using radiation doses tailored to the size of the lymph nodes and the PET status of the nodal disease. They found no nodal failures in the 76 patients with PET-negative pelvic lymph nodes less than or equal to 1 cm when treated with a nodal radiation mean dose of 66.8 Gy. They also showed remarkably good regional control for patients with PET-positive pelvic nodes as follows: only 3 of 89 failures for nodes less than or equal to 1 cm treated with 66.8 Gy, and for nodes ranging from 3.1 to 4.0 cm treated with 74.1 Gy, there were no failures in the 5 patients. There were no failures for the 33 women with PET-positive paraaortic lymph nodes ranging up to 3 cm in diameter when treated with a mean paraaortic lymph node dose of 43.3 Gy. The most common site of failure in this study was distant metastasis, which was best predicted by PET-positive lymph nodes of any size.²⁰

Surgical staging with laparoscopic lymphadenectomy has been markedly refined over the past decade. Thorough evaluation of the pelvic and paraaortic lymph nodes can now be accomplished with minimal morbidity for these women. Although minimally invasive surgery (MIS) using laparoscopy is thorough and safe, the survival benefit of this surgical staging has not been established in a clinical trial and is unlikely to be so in the future. It is difficult to justify the need to identify occult positive lymph nodes by surgical resection considering the nodal control rates demonstrated by Grigsby using PET and CT imaging and with the improved regional control now seen with the combination of chemotherapy and radiotherapy.²⁰

The use of sentinel lymph node biopsies has been studied as a strategy to plan radiation treatment fields and minimize the complications of complete lymphadenectomy, most notably lymphedema. Although some of these trials have reported an excellent correlation between the sentinel node and subsequent lymphadenectomy results, others have failed to demonstrate the excellent results seen in breast cancer and melanoma. A prospective clinical study from France in particular raises concern about the use of sentinel lymph node biopsy as a strategy for further improving on surgical staging. In this study of 28 patients, multilevel sectioning followed by cytokeratin immunohistochemistry was used to identify micrometastasis within lymph nodes. Five of the 28 patients had metastasis; in 2 patients these metastases were in the sentinel lymph node, but in the other 3 patients the sentinel lymph node was negative and the metastases were in nonsentinel pelvic lymph nodes.²¹

Currently, in the United States most women with cervical cancer undergo thorough pretreatment staging with chest radiograph and either CT scan or MRI. PET scanning is also rapidly being integrated into the treatment planning, especially for patients being treated with chemoradiation. Pretreatment cystoscopy and proctosigmoidoscopy are generally reserved for patients with radiographic or clinical evidence of bladder or rectal invasion. Prospective randomized trials showing improved outcomes, in particular improved

survival, with either surgical or PET staging have not been published.²²

Treatment

STAGE I CERVICAL CANCER

The treatment of cervical cancer is divided into two groups of patients, those with early disease, stage I, and those with advanced disease, stage II and beyond. In early local disease, the decision is between surgical therapy and chemoradiation therapy. For cervical cancer patients, surgery and radiation therapy are equally effective in stage I disease, and the decision on which treatment modality to use is based primarily on patient preference and the respective side effects. Stage Ia cervical carcinoma represents microscopic disease and is broken down into two subgroups; stage Ia1 is microinvasive disease with stromal invasion of 3 mm or less, squamous histology, and less than or equal to 7 mm of horizontal spread of the lesion. Ostor et al. reported on more than 3,000 women who met the criteria for stage Ia1 disease and found the incidence of lymph node metastasis is about 1%.²³ The recurrence rate is about 1% and the death rate is 0.2% for stage Ia1 cervical carcinoma. The treatment options range from cervical conization, which is adequate treatment so long as all margins are free of disease, to extrafascial hysterectomy.

For patients with lymphovascular space invasion, there may be an increased risk of nodal metastasis or recurrence, but this is controversial. In DiSaia and Creasman's *Clinical Gynecologic Oncology*, it is stated: "... the role of vascular space involvement in this group of patients does not predict lymph node metastasis nor recurrence."²⁴ However, Benedette et al. showed, in these stage Ia1 patients with lymphovascular space invasion, an increased risk of recurrence in the range of 3% to 4%.^{25,26} Based on these findings, the presence of lymphovascular invasion suggests the need for more-radical treatment with particular attention paid to the regional lymph nodes.

Patients with Ia2 cervical carcinoma have a significantly greater risk of lymph node metastasis, in the range of 6%.²⁷ Stage Ia2 is characterized as having more than 3 mm but not more than 5 mm of invasion and still less than 7 mm of horizontal spread. As invasion into the cervical stromal increases, so does the risk of lymph node metastasis. This higher risk of nodal metastasis precludes conservative therapy with cervical conization or extrafascial hysterectomy. Management of these early cervical carcinomas must include evaluation or treatment of the regional lymph nodes. Surgical therapy with radical hysterectomy and pelvic lymphadenectomy results in a 95% 5-year survival.

A fertility-sparing variation avoiding radical hysterectomy is radical trachelectomy with pelvic lymphadenectomy. The published results of this procedure using a vaginal and laparoscopic approach have outcomes that are comparable to radical pelvic surgery.²⁸⁻³⁰ The best candidates for radical trachelectomy have tumor less than 2 cm, no lymphovascular space involvement, stage IA2 or IB1, and either adenocarcinoma or squamous carcinoma (Table 50.2). Pelvic radiotherapy is an acceptable approach for these stage I patients but is generally confined to those women who are not candidates for surgical therapy, because the late side effects of radiotherapy are generally more troublesome than the minimal late effects of surgery. These consequences of pelvic radio-

TABLE 50.2. Radical trachelectomy: a fertility-sparing treatment alternative for early-stage cervical cancer.

Trial	Reference	Year	No. of patients	Study design	Median follow-up	Procedures aborted	Recurrence rate	Survival
Plante	28	2004	82	Prospective serial	60 months	10	4.2%	2.8%
Covens	29	2002	93	Prospective	30 months	0	7.3%	4.2%

The patients with recurrent disease generally have tumors more than 2 cm or high-risk histology. The best candidates for radical trachelectomy have tumor less than 2 cm, no lymphovascular space involvement, stage IA2 or IB1 disease, and either adenocarcinoma or squamous carcinoma.³⁰

therapy include radiation cystitis, proctitis, and ovarian failure in premenopausal patients.

MICROINVASIVE ADENOCARCINOMA

The concept of microinvasive adenocarcinoma is controversial because of a lack of extensive data on prognosis for these patients and a lack of a clear definition of microinvasion for glandular lesions. The definition of microinvasion is challenging because these tumors tend to arise within endocervical glands, making the point of measurement difficult. It is debated whether invasion should be from the base of the surface epithelium or from the endocervical gland. The volume of involved stroma and the risk of lymphovascular space invasion by these tumors vary considerably depending on where in the endocervical canal the lesion arises. Glandular lesions also tend to be multifocal as evidenced by a study by Ostor et al. in which 27% of the 77 patients had multicentric lesions.³¹ In patients with adenocarcinoma lesions invading from 2 to 5 mm, Berek et al. identified positive lymph nodes in 2 of 18 women.³² Both Ostor and Berek report no lymph node metastasis in women with less than 2 mm of invasion.

Successful treatment of microinvasive cervical carcinoma requires a strict adherence to the staging definitions. The diagnosis of microinvasive disease is based on complete surgical resection of the lesion by cone biopsy with negative surgical margins. When these criteria are met and other factors such as lymphovascular space invasion are taken into account, we can expect a death rate of much less than 1% for stage 1a1 lesions and a death rate of approximately 2.4% for stage 1a2 lesions.

STAGE 1B

When the tumor exceeds 5 mm of invasion or 7 mm of lateral extent or is visible but confined to the uterine cervix, it is stage 1b. Tumor size is the most important prognostic factor in stage 1 lesions and therefore stage 1b has been further categorized into stage 1b1, where the tumor is less than or equal to 4 cm in size, and stage 1b2, which is greater than 4 cm. The overall survival for patients with stage 1b cervical carcinoma is comparable whether they are treated with radical hysterectomy and pelvic lymphadenectomy or primary radiotherapy. An Italian prospective randomized clinical trial in stage 1b cervical cancer compared radical hysterectomy with primary radiotherapy.¹² In this study, patients undergoing radical hysterectomy who had high-risk features identified in the pathology specimen then received adjuvant radiotherapy also. The two treatment groups had identical 5-year survival (83%), comparing the radiation group with the surgery plus tailored postoperative radiotherapy group. Severe toxicity was noted in 28% of patients in the surgery group and only in 12% of patients in the radiotherapy group. In this study, 54% of the stage 1b1 patients (those with tumors 4 cm or less) received adjuvant radiotherapy, and 84% of the stage 1b2

patients received adjuvant radiotherapy. This study clearly served to highlight the added toxicity that results from combining surgery and radiotherapy in this patient population. In the current era of treating all radiotherapy patients with concurrent chemotherapy, the rationale of including a treatment group that receives both surgery and radiation is increasingly difficult to support. A justification voiced for combining surgery and radiotherapy is the concept that large tumors may have poor oxygenation, compromising the radiation effectiveness and therefore hampering the central pelvic control. To date there are no controlled trials supporting that concern, and with the increasing effectiveness of the chemoradiation schema's central pelvic control it is unlikely to be a critical issue in stage I disease treated with chemoradiotherapy.

Although radical hysterectomy clearly has the option of preserving ovarian function and minimizing the late effects of radiation therapy, there remains a role for postoperative adjuvant therapy in radical hysterectomy patients with specific risk factors. The addition of pelvic radiotherapy with concurrent cisplatin chemotherapy significantly improves the overall survival rate when compared to radiation therapy alone for patients with metastatic disease in the form of pelvic nodal metastasis, positive margins, or extension into the parametrial tissues.³³ Radical hysterectomy patients with negative lymph nodes but with large tumors, deep cervical stromal invasion, and lymphovascular space involvement also benefit from adjuvant radiotherapy. A Gynecologic Oncology Group (GOG) study of 277 women with stage 1b1 cervical cancer and negative lymph nodes identified that those with risk factors including tumor size greater than 4 cm, stromal invasion greater than one-third of the cervical stroma, or presence of lymphovascular space involvement benefited from adjuvant pelvic radiotherapy.³⁴ In this study, the recurrence rates were 15% for those patients who received radiotherapy and 28% for those who received no further therapy. In that study, the grade 3 and 4 toxicity rates were 9.3% for the radiotherapy group and only 2.1% for the no further therapy arm, but considering the significant improvement in recurrence-free survival, those toxicities were considered acceptable (Table 50.3).

STAGE II–IVA

CHEMORADIATION

Radiotherapy to the cervix, parametria, and nodal areas at risk for metastatic disease, using external-beam irradiation combined with brachytherapy inserted directly into the cervix, provides a reasonable chance of cure even in advanced disease. The 5-year survival rates are 50% to 80% for stage IIB and 25% to 50% for stage III.³⁵ There are several different strategies for brachytherapy, ranging from high dose rate (HDR) to low dose rate techniques to interstitial therapy, all with fairly comparable outcomes. Surgery alone is not effective in controlling advanced-stage cervical cancer.

TABLE 50.3. Adjuvant radiotherapy in stage 1 cervical cancer.

Trial	Year	Stage	No. of patients	Study design	Median follow-up	Intervention	Disease-free survival	Conclusions
Sedlis (GOG 92) ³⁴	1998	IB	277	Randomized Cooperative Group Trial	5 years	No further therapy versus pelvic radiotherapy	72% versus 85%	For women with at least two risk factors: more than one-third invasion, CLS, or tumor more than 4–5 cm, the addition of pelvic radiotherapy significantly improves disease-free survival RR 0.53, $P = 0.008$
Peters ³³	2000	IA2, IB, IIA	268	Randomized Intergroup Trial	42 months	Radiotherapy alone versus radiotherapy plus chemotherapy: cisplatin 70 mg/m ² , days 1, 22 5-FU 1,000 mg/m ² /day, for 96 hours		The addition of chemotherapy to adjuvant pelvic radiotherapy significantly improves disease-free survival for women with node-positive early-stage disease $P = 0.03$

These two cooperative group trials established the benefit of adjuvant radiotherapy in high-risk early-stage cervical cancer, and that the addition of chemotherapy to adjuvant radiotherapy is beneficial.

The combination of cytotoxic chemotherapy given as a radiation-sensitizing agent has markedly improved outcomes in the last decade. Cisplatin is the most effective single agent and has been shown in cell lines to be synergistic with radiotherapy. The interaction between chemotherapy and radiation inhibits DNA repair after sublethal damage, especially increasing the sensitivity of hypoxic cells.³⁶ The early side effects of the combination of chemotherapy and radiotherapy are now well known and appear quite safe. The late chronic effects of radiotherapy on the rectum, urinary tract, and vagina may increase with combined therapy, but long-term data are still pending.

In the 1990s, several Phase II studies established the relative safety of combining chemotherapy with radiotherapy for cervical cancer. Although most of the studies were small, two larger series served to demonstrate that combining chemotherapy and radiation in women with cervical cancer was feasible.^{37,38} These prospective Phase II studies paved the way for several Phase III trials that ultimately demonstrated the significantly improved outcomes of combination chemotherapy and radiotherapy^{39–41} (Table 50.4). This table details the improved disease control and survival and compare the toxicity data from the three pivotal studies. Although the incidence of grade III and IV toxicity is quite variable, one study reported acute grade III and IV toxicity in 49% of patients. As the widespread use of chemoradiation for cervical cancer is still relatively new, the incidence of grade III and IV late toxicity is not yet well defined.

In 1999, with several large randomized trials demonstrating benefit for concomitant cytotoxic chemotherapy with radiation (chemoradiotherapy), the National Cancer Institute issued a clinical alert stating that chemoradiation should be considered for all patients with advanced cervical cancer.⁴² These compelling results prompted a recent meta-analysis from the Cochrane Review of data available from 11 trials to directly, or indirectly, estimate a hazard ratio (HR) for overall survival.⁴³ They found a highly significant overall survival benefit for chemoradiation. The HR of 0.71 across all trials [95% confidence interval (CI) = 0.63–0.81; P less than 0.0001]

represents a 29% reduction in the risk of death and an absolute improvement in survival of 12% (95% CI = 8%–16%) from 40% to 52%. For progression-free survival, the overall results also support the use of chemoradiotherapy, with a HR of 0.61 (95% CI = 0.55–0.68) and an absolute improvement in progression-free survival of 16% (95% CI = 13%–19%) from 47% to 63%. The significant toxicities (grade III and IV) for these chemoradiation trials are shown in Table 50.4. As expected, the hematologic toxicity occurred in a significantly greater proportion of patients in the chemoradiotherapy group compared to the control group (white cell count, 16% versus 8%; platelets, 1.5% versus 0.2%; hematologic, 29% versus 1.3%). Grade III or IV gastrointestinal toxicity is also more common in the combined arm (9% versus 4%). Other toxicities including neurologic, skin, and urinary are essentially comparable for the two groups. Late toxicity is only available for one of the large Phase III studies.⁴⁰ There is no evidence to date of a difference in the late side effects, but follow-up is still relatively early.

In view of the marked survival benefit of combining chemotherapy with radiation therapy and the relatively minimal impact on toxicity, chemoradiation has emerged as the treatment standard for large or advanced cervical cancer, usually beginning with stage IB2 (lesion greater than 4 cm). The combination of chemotherapy and radiation therapy appears to improve the therapeutic ratio and results in improved local control. The majority of the improvement for these patients is in local control, implying that radiation sensitization is the most important factor in improving outcomes for these patients. However, in the Phase III Gynecologic Oncology Group (GOG) trial the frequency of lung metastasis was 3% and 4% for the two cisplatin arms and 10% for the less-active hydroxyurea arm.⁴¹ These data certainly suggest that some patients may also derive improved distant control when treated with a cisplatin-based regimen.

Initial studies of chemoradiation considered drugs such as hydroxyurea and 5-fluorouracil (5-FU). In the 1980s, with chemoradiation proliferating for the treatment of head and neck malignancies, the promising combination of cisplatin

TABLE 50.4. Radiotherapy with or without chemotherapy as the primary treatment of cervical cancer.

Trial	Year	Stage	No. of patients	Study design	Median follow-up	Intervention	Progression-free survival	Toxicity	Conclusions
Keys (GOG) ³⁹	1999	IB Tumor > or = to 4 cm	369	Randomized Cooperative Group Trial	36 months	Radiotherapy alone versus radiotherapy combined with cisplatin 40 mg/m ² weekly for 6 weeks	63% vs. 79% favoring the combined therapy arm	Grade 3–4 Hematologic: 2% vs. 21% GI: 5% vs. 14%	Adding weekly cisplatin to pelvic radiotherapy significantly improves survival, while increasing transient toxicities but not long term toxicity HR 0.51 for combined therapy <i>P</i> < 0.001
Morris (RTOG) ⁴⁰	1999	IB2-IVA	403	Randomized Cooperative Group Trial	43 months	Radiotherapy alone versus radiotherapy combined with 2 cycles of 5-FU and cisplatin	40% vs. 67% favoring combined therapy	No significant difference in the late side effects	The rates of both local and distant metastasis were significantly higher for the radiotherapy-only arm <i>P</i> < 0.001
Rose (GOG) ⁴¹	1999	IIB,III, IVA	526	Randomized Cooperative Group Trial	35 months	Radiotherapy combined with either: weekly cisplatin, vs. 2 cycles of cisplatin, 5-FU and hydroxyurea vs. hydroxyurea alone	67% vs. 64% vs. 47%, respectively, at 24 months	There were no treatment related deaths; the three- drug regimen had the highest frequency of adverse events	Regimens that combine cisplatin with radiotherapy improve survival in locally advanced cervical cancer <i>P</i> < 0.001

Randomized cooperative group trials have clearly demonstrated the benefit of combining cisplatin with radiotherapy in the treatment of cervical cancer.

and 96-hour 5-FU was tested in several Phase II trials. In the GOG trial that compared cisplatin alone or in combination, the rate of progression-free survival was significantly better in the group given radiotherapy combined with cisplatin therapy (109 of 176; P less than 0.001) and for patients given radiotherapy combined with treatment with cisplatin, fluorouracil, and hydroxyurea (106 of 173; P less than 0.001) than among patients in the group given radiotherapy combined with hydroxyurea therapy (73 of 177).⁴¹ The progression-free survival and the overall survival for the group receiving cisplatin 40 mg/m² weekly 4 hours before radiotherapy were almost identical to the group receiving cisplatin 50 mg/m² days 1 and 29 combined with two 96-hour infusions of 5-FU and hydroxyurea. The frequencies of both grade 3 and grade 4 leukopenia in the group given radiotherapy combined with treatment with cisplatin, fluorouracil, and hydroxyurea were more than double the frequencies in the other two groups (P less than 0.001). Based on comparable efficacy, and less toxicity, the weekly cisplatin 40 mg/m² regimen has emerged as the preferred combination chemoradiation treatment.

NEOADJUVANT CHEMOTHERAPY

The concept of neoadjuvant chemotherapy before surgery or radiotherapy to reduce tumor burden and facilitate local treatment is popular in some parts of the world.⁴⁴⁻⁴⁶ In a randomized prospective trial of 205 women with stage IB cervical cancer with lesions more than 2 cm in diameter, patients were randomly assigned to either surgery followed by radiotherapy or neoadjuvant chemotherapy followed by surgery and adjuvant radiotherapy.⁴⁴ The neoadjuvant chemotherapy regimen for this study was three courses of cisplatin 50 mg/m², vincristine 1 mg/m², and bleomycin 25 mg/m² on days 1 to 3, at 10-day intervals. The neoadjuvant chemotherapy arm of this trial had a higher rate of negative margins (100% versus 85%) and significantly fewer pelvic failures. However, there was no significant difference in the overall survival for the study. For the women with larger lesions (stage IB2), there was an improvement in long-term survival with neoadjuvant chemotherapy of 80% versus 61%. A critique of this study is that no chemoradiation was used in the control arm, despite data showing the significant improvement that occurs when chemotherapy is added to adjuvant radiotherapy.³³ A meta-analysis of randomized controlled trials of neoadjuvant chemotherapy before radiotherapy found insufficient evidence of a survival benefit, despite showing a significant reduction in disease volume by chemotherapy.⁴⁷

RADIATION THERAPY TECHNIQUES

The two radiation therapy modalities used in treating cervical cancer are external-beam radiotherapy and brachytherapy. The brachytherapy is usually placed intracavitary, through the cervix into the uterus, using any of a variety of afterloading or high dose rate applicators. Interstitial brachytherapy is used for women with advanced disease involving the lower vagina or extensive parametrial involvement that cannot be adequately treated with an intracavitary insertion.

The American Brachytherapy Society (ABS) has recently published guidelines for the use of either high dose rate or low dose rate brachytherapy as a component of cervical cancer treatment.^{48,49} The treatment dose and technique depend on many variables including disease volume, ability to displace the bladder and rectum, and institutional prac-

tices. Low-dose brachytherapy, usually with ¹³⁷Cs, is more common; however, the number of institutions using high dose rate (HDR) applicators with ¹⁹²Ir is rapidly increasing. The radiation safety and patient convenience factors have made the HDR approach attractive. In several randomized trials of women with cervical cancer, HDR was comparable to low dose rate (LDR) brachytherapy in terms of survival and complication rates. It is now accepted by the GOG as comparable to low dose rate therapy for their clinical trials.⁵⁰⁻⁵²

Improved regional control of the paraaortic lymph nodes can be accomplished with extended-field radiation. The RTOG conducted a Phase III trial evaluating the effect of prophylactic paraaortic radiation to 45 Gy in patients with tumors greater than 4 cm but confined to IB2 and Stage II cervical cancers. In this trial of patients who were without clinical evidence of paraaortic nodal disease, there was a significantly better 5-year survival rate of 66% versus 55% favoring the paraaortic extended-field arm.⁵³ In this trial, severe gastrointestinal toxicity, especially in patients with a history of prior abdominal surgery, was more common in the extended-field group. Future clinical trials will need to address whether pretreatment evaluation using newer modalities such as PET scan can eliminate the role of empiric extended-field radiation for patients with poor prognostic factors such as tumor size greater than 4 cm or high-risk histology.

PRIMARY AND RECURRENT DISTANT METASTATIC DISEASE

For patients presenting with stage IVB disease, or recurring with distant metastatic disease, the prognosis is quite poor, with only 20% surviving for 1 year. For these women the role of chemotherapy is palliative; a complete response to chemotherapy is quite rare. The single-agent response rates to various agents typically range from 25% for cisplatin to 17% for paclitaxel. Studies of multiagent regimens have shown improved response rates but no improvement in survival. Compared with cisplatin alone, cisplatin plus ifosfamide had a significantly higher response rate (33% versus 19%) and progression-free survival (PFS) (4.6 versus 3.2 months), but no significant improvement in survival. As expected, the adverse side effects of neutropenia, nephrotoxicity, and neurotoxicity were increased in the ifosfamide-containing arm.⁵⁴ Additional evidence of the lack of benefit comes from another GOG trial that compared cisplatin 50 mg/m² every 3 weeks versus paclitaxel 135 mg/m² and cisplatin 50 mg/m². This study, GOG 169, demonstrated response rates of 19% and 36% for the single- versus two-drug regimens, respectively. In this trial again the median PFS was improved for the two-drug regimen, but there was no difference in the overall survival or quality of life between single-agent cisplatin and the two-drug regimen.⁵⁵ Recently, Long et al. reported on a GOG Phase III study comparing cisplatin alone with cisplatin and 3-day topotecan that demonstrated a significant improvement in survival for the women receiving the cisplatin and topotecan combination. This regimen of cisplatin 50 mg/m² on day 1 and topotecan 0.75 mg/m² on days 1 to 3 had a progression-free survival of 4.6 months and an overall survival of 9.4 months. The authors suggest, based on these results, which are superior to any Phase III results reported to date, that the cisplatin/topotecan doublet should be the new standard therapy⁵⁶ (Table 50.5).

TABLE 50.5. Chemotherapy for cervical cancer.

Trial	Year	Stage	No. of patients	Study design	Intervention	Response rate	Progression-free survival (PFS)	Survival	Toxicity	Conclusions
Moore (GOG) ⁵⁵	2004	IVB, recurrent or persistent	280	Randomized Cooperative Group Trial	Cisplatin with or without paclitaxel	19% for cisplatin alone, 36% for cisplatin and paclitaxel.	2.8 months vs. 4.8 months $P < 0.001$	8.8 vs. 9.7 months not significant	Grade 3 & 4 anemia, 13% vs. 28%	Adding paclitaxel to cisplatin improves the response rate and PFI but did not significantly improve survival
Omura (GOG) ⁵⁴	1997	IVB, recurrent or persistent	454	Randomized Cooperative Group Trial	Cisplatin versus cisplatin plus mitolactol versus cisplatin and ifosfamide	18% for cisplatin alone, and 31% for cisplatin and ifosfamide; mitolactol showed no benefit	3.2 months vs. 4.6 months $P = 0.003$	8.0 vs. 8.3 months Not significant	CNS toxicity was greater with addition of ifosfamide	The addition of ifosfamide improved the response rate and PFS compared with cisplatin given alone, but is more toxic and does not improve survival
Long ⁵⁶	2004	IVB, recurrent or persistent	356	Randomized Cooperative Group Trial	Cisplatin versus topotecan and cisplatin versus methotrexate, vinblastine, adriamycin, cisplatin (MVAC)	19% for cisplatin alone, and 27% with the addition of topotecan (including 10% CR)	2.9 months vs. 4.6 months $P = 0.014$	6.5 months vs. 9.4 months $P = 0.017$	MVAC arm discontinued because of excessive toxicity	The improved overall survival and best reported duration of survival make topotecan 0.75 mg/m ² days 1-3 and cisplatin 50 mg/m ² the most active regimen reported to date

The addition of a second active drug to the chemotherapy regimen for women with recurrent or metastatic cervical cancer improves PFI and response rate. Before the cisplatin and topotecan doublet, there was no improvement in overall survival with the addition of a second drug.

SALVAGE SURGICAL THERAPY

RADICAL SURGERY AND EXENTERATION

In selected patients with central pelvic recurrence after radiation therapy, it is possible to completely resect this disease with either a radical hysterectomy or a total pelvic exenteration. Total pelvic exenteration involves the surgical removal of the bladder, uterus, cervix, parametria, vagina, and rectum. In most cases, this is accompanied by reconstruction of the vagina, formation of a urinary conduit, and reanastomosis of the rectal stump. The place of pelvic exenteration as salvage therapy continues to decrease as radiotherapy treatments and chemoradiation have markedly improved the central pelvic control for women with cervical cancer. For the rare patient with an isolated distant recurrence, such as a single pulmonary lesion, consideration should be given to surgical resection or local radiotherapy, acknowledging that there are no data demonstrating a large group of such survivors.

Posttreatment Surveillance

After completing treatment, cervical cancer patients are typically evaluated every 3 to 4 months for 2 years, then every 6 months until 5 years, and annually thereafter.⁵⁷ The role of the Papanicolaou (Pap) smear as posttreatment surveillance is controversial. The National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines recommend obtaining a cytology specimen at each visit. However, in a retrospective evaluation of 1,096 Stage Ib cervical cancer patients treated at the M.D. Anderson Cancer Center between 1983 and 1993, all asymptomatic pelvic recurrences were diagnosed by pelvic examination. In this study, there were 114 symptomatic and 19 asymptomatic recurrences, and Pap smears did not detect a single asymptomatic recurrence.⁵⁸ Furthermore, there are no data to suggest that additional surveillance strategies with CT scan, MRI, or blood tests for squamous cell carcinoma antigen levels are of any survival benefit.

Vulvar Cancer

Vulvar cancer remains a relatively uncommon gynecologic malignancy, with an estimate of 4,000 new cases in the United States in 2004 and only 850 estimated deaths.⁵⁹ The 5-year survival for this cancer ranges from 98% for stage I disease to 31% for women with stage IV disease.⁶⁰ This cancer occurs primarily in elderly women with a mean age at diagnosis of 65 years old, and a significant fraction of these cases occur in women over the age of 80. Because of the socially awkward location of vulvar cancer and the associated symptoms, there is often a delay in the diagnosis of this relatively slow-growing malignancy. In addition to the patient's reluctance to complain about a vulvar lesion, a component of physician delay in the diagnosis of vulvar cancer is also common. Many of these patients report symptoms of vulvar cancer lasting for more than a year before the definitive diagnosis. Since 1960 when Dr. Stanley Wei first described the radical surgical resection of vulvar cancer, we have made remarkable progress in the treatment of this disease and in

our ability to preserve structure and function of the lower genital tract, bladder, and rectum.⁶¹

Background and Etiology

There is no clear etiology to the development of vulvar cancer. There is an association between human papillomavirus (HPV) and the development of vulvar intraepithelial neoplasia, which is a preinvasive precursor to some but not all vulvar carcinoma. In contrast to cervical cancer, only a fraction of patients with vulvar carcinoma have tumors positive for the human papillomavirus. This group of patients tends to be younger, often uses tobacco products, and is more likely to have multifocal disease. HPV-positive patients also include women who are chronically immunosuppressed, either because of steroid use for connective tissue diseases, asthma, or organ transplantation or from human immunodeficiency virus (HIV) infection. Because of this causal association with human papillomavirus, the risk factors for vulvar cancer also include sexual activity and a history of genital warts.

For elderly women, the association with human papillomavirus is usually absent. A significant fraction of these women, however, do have an associated vulvar dystrophy. The most common of the associated vulvar dystrophies is lichen sclerosis. It has estimated that as many as 50% of elderly women with vulvar cancer have associated lichen sclerosis. For women with lichen sclerosis, however, the likelihood of developing vulvar carcinoma may be as high as 21%, with overexpression of p53 identified as a potential factor in the etiology of this cancer.⁶²

Symptoms of Vulvar Cancer

The most common symptom of vulvar cancer is pruritus. Because itching and discomfort are often associated with lichen sclerosis, those symptoms are frequently dismissed by elderly women and/or their physicians. Other symptoms include vulvar bleeding, a painful mass, malodorous discharge, or enlarged inguinal lymph nodes.

Signs of Vulvar Cancer

Vulvar cancer generally presents as an ulcerated red lesion that is slightly raised and friable. Occasionally the patient has a wartlike thick plaque with what appears to be intact epithelium. These lesions, particularly ulcerated lesions, can be quite tender to palpation.

HISTOLOGIC DIAGNOSIS

Vulvar cancer is diagnosed by histologic biopsy, typically accomplished by using either a Keyes or Baker punch biopsy. Ideally, the biopsy should be obtained from the center of the lesion and should be deep enough to include the underlying tissue to establish the presence of invasion and the depth of invasion. An excisional biopsy is not warranted unless needed to distinguish between a noninvasive lesion and early invasion. If there is a suggestion of a large raised lesion being noninvasive, then wide local excision of that lesion

TABLE 50.6. Vulvar cancer: tumor size as a risk factor for lymph node metastasis.

Study	Year	No. of patients	Trial design	<2.1 cm	2.1-3.0m	3.1-4 cm	>4 cm

should be preformed to establish the presence or absence of invasion.

PATTERNS OF SPREAD

Vulvar cancer spreads primarily by direct extension to the adjacent vagina, urethra, perineum, and rectum. As the depth of invasion increases and the lateral extent of this disease increases, so does the risk of metastatic spread to the inguinal/femoral lymph nodes. Fortunately, hematogenous spread is generally a late occurrence associated with either advanced nodal involvement, or recurrent cancer. The lymphatic spread of vulvar cancer is in an orderly fashion, starting in the inguinal femoral region and then, as those lymph nodes become involved, spreading to the pelvic lymph nodes. Isolated pelvic lymph node metastasis, without inguinal femoral node involvement, is quite rare. The incidence of inguinal lymph node metastasis ranges from 10% for stage 1 disease up to 89% for patients with stage 4 disease. The most important predictors of lymph node metastasis are stage, tumor size (Table 50.6), and depth of invasion. Only 20% of patients with positive groin nodes have positive pelvic lymph nodes.

HEMATOGENOUS METASTASIS

Hematogenous metastasis of vulvar cancer is a rare late occurrence. Most patients with hematogenous spread of their disease have advanced-stage vulvar cancer and in most cases have positive pelvic lymph nodes. A small fraction of these patients with widely metastatic disease develop a paraneoplastic hypercalcemia, either as a direct consequence of their squamous cell carcinoma or secondary to their lung metastasis.

Pathology

Squamous cell carcinoma is the most common histology causing vulvar cancer. Vulvar melanomas are quite rare in comparison to squamous cell carcinoma of the vulva and account for less than 5% of vulvar cancers. Basal cell carcinomas may also occur on the vulva and represent only about 2% of vulvar cancers. Extramammary Paget's disease of the vulva is generally an adenocarcinoma in situ, but in 10% to 12% of patients there is an underlying invasive component of Paget's disease and in 4% to 8% of patients there is an underlying gastrointestinal (GI) tract adenocarcinoma.⁶³ Adenocarcinoma of the vulva may also arise within the Bartholin's gland and simulate a vulvar primary cancer. Bartholin's gland cancer is generally managed as a vulvar cancer; half the cancers arising within the Bartholin's gland are squamous malignancies and the other half are adenocarcinoma.

Verrucous carcinoma is an uncommon variant of squamous cell carcinoma of the vulva that is associated with exo-

phytic growth which may result in a very large warty tumor of the vulva. Verrucous carcinomas tend to be slow growing and locally invasive with a relatively low likelihood of lymph node metastasis.⁶⁴ Some reports have suggested that radiation therapy may induce a highly malignant transformation of verrucous carcinomas, resulting in subsequent aggressive behavior and regional or distant metastasis. Although that concept was originally reported in 1973, subsequent studies have had difficulty confirming this aggressive behavior associated with radiotherapy.⁶⁵

MELANOMA

Vulvar melanomas are a relatively rare malignancy that occurs most commonly in postmenopausal women. The areas of the vulva most commonly affected are the labia minora and the clitoris. Any pigmented lesion of the vulva must be biopsied to rule out melanoma. The other pigmented lesion of the vulva is squamous carcinoma in situ, so careful histologic evaluation of these pigmented lesions is essential in treatment planning. The staging and management of vulvar melanoma follow the treatment guidelines for melanoma rather than squamous malignancies of the vulva.

Staging

The FIGO surgical staging system was most recently revised in 2000 (Table 50.7); within the staging system, depth of invasion is used in stage 1 to distinguish between stage 1a and 1b disease.⁶⁶ Depth of invasion is defined as the measurement of tumor from the epithelial-stromal junction of the adjacent most superficial dermal papilla to the deepest point of invasion. Depth of invasion is an important prognostic factor for lymph node metastasis, noting that in many large series tumors with less than 1mm invasion have no lymph node metastasis, whereas tumors with 1 to 3mm of invasion have an approximately 8% to 10% risk of nodal metastasis and tumors that invade more than 5mm have an approximately 35% risk of nodal metastasis.

Pretreatment Evaluation

Radiographic evaluation with chest X-ray and a complete laboratory study are essential in any patient diagnosed with vulvar carcinoma. In addition to the routine cancer staging studies, colposcopy of the vulva, vagina, and cervix is essential to define the extent of preinvasive disease, especially in younger patients where associated preinvasive lesions of the vagina or cervix may be present. A CT scan of the inguinal femoral lymph nodes and pelvis can be helpful in identifying enlarged lymph nodes in the groin or pelvis. This identification is particularly important if nodal disease is suspected as the extent of inguinal femoral lymphadenectomy may be

TABLE 50.7. Staging of vulvar cancer.

Categories	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ (preinvasive carcinoma)
T1	Tumor confined to vulva or vulva and perineum, 2 cm or less in greatest dimension
T1A	Tumor confined to vulva or vulva and perineum, 2 cm or less in greatest dimension and with stromal invasion no greater than 1.0 mm*
T1B	Tumor confined to vulva or vulva and perineum, 2 cm or less in greatest dimension and with stromal invasion greater than 1.0 mm ^a
T2	Tumor confined to the vulva or vulva and perineum, more than 2 cm in greatest dimension
T3	Tumor of any size with contiguous spread to the lower urethra, and/or vagina or anus
T4	Tumor invades any of the following: upper urethra, bladder mucosa, rectal mucosa, or is fixed to the pubic bone
Regional lymph nodes (N):	
• NX—Regional lymph nodes cannot be assessed;	
• N0—No regional lymph node metastasis;	
• N1—Unilateral regional lymph node metastasis;	
• N2—bilateral regional lymph node metastases.	
Distant metastasis (M):	
• MX—Distant metastasis cannot be assessed;	
• M0—No distant metastasis;	
• M1—Distant metastasis.

*The depth of invasion is defined as the measurement of the tumor from the epithelial-stromal junction of the adjacent most superficial dermal papilla, to the deepest point of invasion.

Histopathologic types:

Squamous cell carcinoma is the most frequent form of cancer of the vulva. Malignant melanoma is the second most common tumor and should be reported separately. Other histopathologic types are adenocarcinoma underlying Paget's disease of vulva, verrucous carcinoma, Bartholin gland carcinoma, adenocarcinoma not otherwise specified (NOS), basal cell carcinoma.

- Histopathologic grades (G):
- Gx—Grade cannot be assessed;
- G1—Well-differentiated;
- G2—Moderately differentiated;
- G3—Poorly or undifferentiated.

tailored to remove only the involved nodes if it is known that radiotherapy will be administered postoperatively.

Treatment

The surgical management of vulvar carcinoma requires the experience and additional training provided by a Gynecologic Oncology Fellowship. The treatment strategy must focus on adequate radical excision of the local lesion without disrupting the physiologic function of the adjacent bladder, urethra, or rectum. This excision should be designed to consider and preserve sexual functioning if possible. Management of the regional lymph nodes is based on the concept that nodal metastasis occurs by embolization of tumor cells from the primary tumor to the regional lymph nodes. This concept has allowed for surgical management to evolve from an ultraradical massive resection of the inguinal femoral lymph nodes en bloc with the vulva to the use of separate groin incision and a vulvar incision. The ultraradical en bloc excision of groin and vulva was complicated by a 50% to 75% wound breakdown rate and fairly devastating psychosexual morbidity. The transition to less-radical surgery and individualized surgical resection has resulted in significantly less operative morbidity without compromising the cure rate. A contemporary radical vulvectomy is now a surgical procedure with a goal of resecting the tumor with a 1.0- to 2.0-cm margin and dissection down to the underlying fascia. A review by Heaps and colleagues from University of California at Los Angeles (UCLA) of 135 vulvar cancer patients with all stages of disease revealed that a 1-cm tumor-free surgical margin resulted in excellent local control.⁶⁷ Although the term radical vulvectomy implies that the entire vulva is removed, in fact most vulvar cancers can be managed with a modified procedure that spares the uninvolved vulva. Because many of the lesions only involve the posterior vulva, preservation of the anterior vulva and clitoris is often possible for these patients.

SURGICAL MANAGEMENT OF THE INGUINAL FEMORAL LYMPH NODES

The risk of lymph node metastasis ranges from 8% for lesions 2 mm thick to almost 80% for large, deeply invasive lesions. The spread to regional lymph nodes is relatively orderly, beginning with the inguinal lymph nodes before spreading to the pelvic nodes.⁶⁸ Lymph node metastases are also reasonably lateralized so that lesions more than 1 to 2 cm from the midline can be managed with unilateral lymphadenectomy. The contralateral nodes are at risk, however, if the ipsilateral groin nodes are positive, and this must be considered in planning any postoperative adjuvant therapy. Involvement of the regional lymph nodes is the most important prognostic indicator in squamous cell carcinoma of the vulva.⁶⁰

Control rates as high as 70% have been reported for patients with positive groin nodes treated by surgical resection and radiation therapy at the time of initial diagnosis. If, however, vulvar cancer recurs in a previously undissected groin, the salvage prospects are very poor.⁶⁹ Because of the poor prognosis associated with groin node recurrence, exquisite attention is paid to the thoroughness of the inguinal femoral lymphadenectomy, and an inguinal femoral lymphadenectomy is required in any patient with more than 1 mm of stromal invasion or a lesion more than 2 mm thick.

The serious toxicity associated with inguinal femoral lymphadenectomy includes lymphedema in 15% to 30% of patients and is most common in those women receiving postoperative radiotherapy or those with chronic lymphangitis. This toxicity has prompted investigators to look at modifications to complete lymphadenectomy, many of which have been proposed but not yet verified in a prospective clinical trial. Replacing lymphadenectomy by groin irradiation was studied by the GOG in a randomized trial that was closed early because of excessive number of groin recurrences in the radiotherapy arm. In this study 5 of 26 patients in the radiation-only treatment arm had recurrence in the groin. In the surgical arm of this study, 5 of 23 patients had positive groin nodes and, when they received postoperative radiotherapy, none recurred.⁷⁰ This study was later criticized because the target depth dose for the radiation was deemed to be too superficial, at 3 cm, when a quality evaluation of the patients by CT scan revealed the average depth of the groin nodes to be 6 cm.⁷¹

In a small, 48-patient, retrospective study Petereit and colleagues demonstrated adequate nodal control using groin irradiation and found less morbidity.⁷² In view of the poor GOG study outcome, however, it is unlikely that groin irradiation will ever gain a significant place in the primary management of vulvar cancer. Another proposed treatment modification was to perform only a superficial lymphadenectomy, noting that this cancer rarely bypasses the superficial nodes and that if these are positive the patient would receive adjuvant radiotherapy.⁷³ When this was studied by the GOG, however, there were 6 recurrences in 121 women with negative superficial lymph nodes and early-stage lesions.⁷⁴ This disturbingly high recurrence rate suggests that a complete superficial and deep lymphadenectomy should be performed until a proven alternative is found. The most recent proposed treatment modification is sentinel lymph node biopsy, which may allow a much more limited lymph node dissection and consequently a decrease in the associated morbidity such as lymphedema and lymphangitis. In a recent study of 52 patients undergoing primary surgery for vulvar cancer, using isosulfan blue dye a sentinel lymph node was identified in 57 of 76 groins examined (75%) and in 46 of 52 patients (88%).⁷⁵ An ongoing GOG trial using both isosulfan blue and lymphoscintigraphy is expected to define the sensitivity and utility of sentinel lymph node biopsies in the management of vulvar cancer.

Advanced Vulvar Cancer

Patients with advanced vulvar cancer comprise three groups with a wide range of prognoses. First, women with evidence of occult nodal metastasis, with one or two positive nodes at the time of radical vulvectomy and inguinal femoral lymphadenectomy, who are then treated with radiotherapy, have a 75% disease-free survival.⁶⁰ Women with locally advanced disease involving either the urethra, bladder, rectum, or bilateral enlarged lymph nodes have a 55% to 75% complete response with a combination of surgery, radiation, and in some cases chemotherapy as a radiation-sensitizing agent. Finally, for women with distant metastatic disease, whether it be primary or recurrent, the prognosis is quite poor and these patients are treated with palliative intent.

Patients with more than one microscopic positive groin node metastasis, or occult macroscopically positive nodes,

should receive radiation to the bilateral pelvis and groins. This strategy grew out of a GOG randomized trial in which patients with positive groin nodes received either ipsilateral pelvic lymph node dissection or radiotherapy to 45 to 50 Gy. In this trial, the 2-year survival for the radiation group was 68% versus 54% for the surgery group. Recurrence in the groin was rare (5%) in the radiotherapy arm, and occurred in 24% of those women treated with lymphadenectomy alone.⁷⁶

Treating women with large vulvar tumors involving critical structures such as the rectum or urethra with a combination of chemotherapy and radiotherapy can frequently avoid an ultraradical resection of the vulva in combination with the bladder or rectum. This concept was first proposed by Boronow in the early 1970s as an alternative to pelvic exenteration.⁷⁷ Boronow later described 37 of his patients, noting a 5-year survival of 75% for locally advanced disease treated with radiotherapy followed by surgery.⁷⁸ In the 1980s and 1990s, with radiation-sensitizing chemotherapy emerging for cervical cancer treatment, it was logical to add chemotherapy to the management of these women with locally advanced vulvar cancers. Several studies have considered various combinations of chemotherapy using 5-FU, cisplatin, and mitomycin C either alone or in combination, with 5-year survival as high as 54%.⁷⁹⁻⁸³ The role of surgical resection of the primary tumor site after completion of radiotherapy has been controversial. This procedure is usually complicated by slow and poor wound healing and has not been shown to improve outcomes. Our current recommendation is to reserve surgical resection for the patient with persistent disease and then to anticipate the need to reconstruct the area with a myocutaneous flap to improve to prospects for healing.

Locally Recurrent Disease

Local recurrence of vulvar cancer occurs most commonly in patients with a large primary tumor, a close margin (less than 1 cm),⁶⁷ or chronic immunosuppression. For patients with large tumors or close margins, the disease recurrence is usually adjacent to the urethra or rectum, which explains the compromised margin. These lesions are often best managed with local radiotherapy, with or without sensitizing chemotherapy. If surgical resection can be accomplished with adequate margins, then plastic reconstruction is usually required as a component of this procedure. Hoffman and colleagues from the Moffat Cancer Center reported on excellent salvage results using aggressive radiotherapy techniques including interstitial brachytherapy.⁸⁴ They report survival of 9 of 10 patients treated with locally aggressive radiotherapy, but also noted severe radiation morbidity in 6 of the 10 women.

Vaginal Cancer

Background

The rarest of the lower genital tract gynecologic malignancies is vaginal cancer; 80% are squamous cell carcinomas, and the remainder are adenocarcinoma, melanoma, and sarcoma. This malignancy mostly occurs in elderly women with a median age of 60 years.⁸⁵ Similar to vulvar carcinoma, human papillomavirus appears to be an etiologic agent in some but

TABLE 50.8. FIGO staging of vaginal cancer.

Stage	Description
0	Carcinoma in situ
I	Tumor confined to the vagina
II	Tumor invades paravaginal tissues but not to pelvic wall
III	Tumor extends to pelvic wall
IVA	Tumor invades mucosa of the bladder or rectum and/or extends beyond the true pelvis (bullous edema is not sufficient evidence to classify a tumor as T4)

not all cases of vaginal carcinoma. The presence of vaginal intraepithelial neoplasia, an HPV-related precursor lesion comparable to cervical intraepithelial neoplasia, is present in some patients with squamous cell carcinoma of the vagina. The incidence of precursor lesions and the time to progression from vaginal intraepithelial neoplasia to invasive cancer is not nearly as well defined for vaginal cancer as compared with cervical cancer.⁸⁶

Staging

Vaginal carcinoma is staged according to the criteria of FIGO shown in Table 50.8. The staging of vaginal cancer follows the clinical staging rules for cervical carcinoma. In particular, the stage is assigned on the basis of clinical examination and may include cystoscopy and proctosigmoidoscopy as well as routine laboratory studies and chest X-ray. Further radiographic or other imaging techniques such as CT scan, PET scan, and MRI, although they may be useful in treatment planning, are not allowed as a component of the staging examination.

The FIGO staging of vaginal cancer identifies any vaginal lesion that also involves the cervix as being a cervical cancer. Similarly, any vaginal lesion that also involves the vulva is defined as vulvar carcinoma. In a patient who has a prior history of cervical carcinoma and develops a lesion within the vagina less than 5 years after treatment for cervical cancer, it is considered to be a recurrence of cervical carcinoma, but after 5 years is considered to be a new vaginal carcinoma.

Signs and Symptoms

Irregular vaginal bleeding or profuse watery discharge are the most common symptoms of vaginal carcinoma. Pelvic or back pain, lower extremity swelling, urinary frequency, change in the caliber of stool, or hematochezia are all symptoms of advanced-stage disease.

Diagnosis

Occult vaginal cancer may be diagnosed by Pap smear or colposcopic examination. For patients with a grossly visible lesion, a punch biopsy using a cervical biopsy instrument or Keys punch can be used to provide adequate histologic evidence of this cancer. For patients in whom histology reveals an adenocarcinoma, consideration should be given to other primary sites of disease such as colorectal cancer, metastatic endometrial carcinoma, or a Bartholin's gland cancer. In rare

patients adenocarcinoma of the rectovaginal septum may arise in a remnant of residual endometriosis; this is particularly true in patients who may have undergone hysterectomy for endometriosis treatment and then been treated with unopposed estrogen therapy.

Patterns of Spread

Vaginal carcinoma is similar to both vulvar cancer and cervical cancer in its propensity for direct invasion into surrounding tissues and lymphatic metastasis. Although the most common site of vaginal carcinoma is the upper third of the vagina, these generally spread directly to the pelvic lymphatics in a fashion similar to cervical carcinoma. Lesions in the lower one third of the vagina may spread to either the inguinal femoral lymph nodes or the pelvic lymph nodes, so particular care must be taken to ensure that treatment consideration is given to both these sites of lymph nodes.

Treatment

Surgical therapy plays a minor role in the management of vaginal cancer because of the difficulty in obtaining adequate surgical margins. For lesions involving the posterior vagina, the presence of the rectum immediately adjacent to the posterior vaginal wall precludes obtaining an adequate margin for anything but the earliest microinvasive lesion; this is also true for anterior vaginal lesions where the immediately adjacent bladder precludes adequate tissue margin to effect cure by surgery alone. For patients with advanced local disease involving the bladder or rectum, a pelvic exenteration may be required to adequately control this disease.

RADIOTHERAPY

Because a majority of patients with vaginal carcinoma are treated with radiation therapy, it should be noted that if the lesion is in the upper two thirds of the vagina the treatment plans generally parallel those that would be used for cervical carcinoma. If the lesion involves the lower one third of the vagina, then consideration must be given to treating the inguinal femoral lymph nodes as well as the pelvic lymph nodes. For lower vaginal lesions as well as bulky vaginal lesions, the use of interstitial brachytherapy is often required to effect adequate radiation dose to the tumor.

There is no evidence confirming the beneficial affects of adding chemotherapy to the radiation treatment plan for vaginal carcinoma. Given the significant improvement in outcomes for patients with cervical carcinoma when treated with combined therapy, most academic centers now treat these patients with chemoradiation using cervical carcinoma treatment schemes.

TREATMENT-RELATED COMPLICATIONS

The immediately adjacent bladder and rectum often receive very high doses of radiation therapy as a component of treatment for vaginal carcinoma, and therefore the patients may have significant radiation cystitis or proctitis. In the worst cases, patients may develop a fistula between either the bladder or rectum, depending on the location of the lesion and the dose of radiation required to control that lesion. Vaginal function is often disrupted by these treatments, with fibrosis,

stenosis, and significantly decreased lubrication resulting from the local radiation therapy. The use of a vaginal dilator and personal lubricants may help preclude some of this loss of function.

Prognosis

The prognosis for vaginal cancer is worse than that seen with cervical or vulvar carcinoma. In a compilation of several studies, Berek et al. identified a 5-year survival of 69% for stage 1 vaginal cancer, 46% for stage 2, 30% for stage 3, and 18% for stage 4 diseases.⁸⁷ They note that most recurrences of this disease are within the pelvis, either from lack of regional control of involved lymph nodes or from inability to control the primary tumor. For those patients with an isolated central pelvic failure, consideration may be given to salvage treatment with pelvic exenteration.

Pathology

Although the majority of vaginal cancers are squamous cell carcinomas, other histologic types occur rarely.

CLEAR CELL CARCINOMA ARISING AFTER DIETHYLSTILBESTROL EXPOSURE

In 1971, Herbst et al. reported on seven women who developed clear cell adenocarcinoma of the vagina.⁸⁸ They linked this unusual preponderance of clear cell carcinoma in young women to in utero exposure to diethylstilbestrol (DES). In the late 1940s and particularly in the early 1950s, DES was prescribed to women with a history of pregnancy loss. It was believed that DES decreased the likelihood of spontaneous abortion and early pregnancy loss. A randomized clinical trial in 1954 by Dieckmann and colleagues at the University of Chicago showed that DES was not effective in preventing pregnancy loss.⁸⁹ Despite early evidence that DES was not effective, it was still commonly prescribed in many parts of the country throughout the 1950s and into the 1960s.

Women who were DES exposed have several other associated complications of that exposure, including adenosis of the upper vagina, an increased risk of cervical dysplasia, and increased risk of preterm delivery, ectopic pregnancy, and uterine malformations. Although those gynecologic consequences are relatively common after DES exposure, the risk of developing a clear cell adenocarcinoma in the exposed young women is estimated to be 1 in 1,000. The mean age of clear cell carcinoma of the vagina occurring in DES-exposed women is 19 years old. As this cohort of women has aged, the incidence of these DES-exposed clear cell carcinomas has clearly decreased. There is no evidence to date of other DES-induced malignancies in the lower genital tract, but continued surveillance is indicated to detect a second peak incidence of in utero exposure-related malignancy.

SARCOMA

Vaginal sarcomas are extremely rare and are generally managed by a combination of surgical resection followed by adjuvant chemotherapy or radiation therapy. Embryonal rhabdomyosarcoma is a pediatric variant of vaginal sarcoma that is treated by the combined modality approach involving

neoadjuvant chemotherapy followed by radiation therapy and in some cases surgery. This multimodality approach has led to significant improvements in survival during the past 20 years.

MELANOMA

Malignant melanoma involving the vagina is also exceedingly rare and in many cases has a very poor prognosis. The median age of this disease is 58 years old, with most patients presenting with a Clark's level 4 lesion at the time of detection. Because of the deep invasion at the time of diagnosis, it is quite common for patients to develop hematogenous metastasis from this disease, and the 5-year survival is only 10%. For women with melanoma involving the vagina, it is often necessary to perform anterior, posterior, or total pelvic exenteration to obtain adequate surgical margins around the melanoma.⁹⁰

Gestational Trophoblastic Neoplasia

John R. Lurain

Gestational trophoblastic neoplasia includes invasive mole, choriocarcinoma, and placental site trophoblastic tumor. The overall cure rate in the treatment of these tumors currently exceeds 90%. This success is the result of the inherent chemotherapy sensitivity of trophoblastic neoplasms, the effective use of the tumor marker human chorionic gonadotropin (hCG) for diagnosis of disease and monitoring of therapy, the referral of patients to or consultation with specialized treatment centers, the identification of prognostic factors that enhance individualization of therapy, and the development of active combinations of chemotherapy agents used in conjunction with irradiation and surgery to treat patients with the most advanced disease.¹

Diagnosis and Classification

Gestational trophoblastic neoplasia is diagnosed by rising or plateauing hCG levels following evacuation of a hydatidiform mole, a histopathologic diagnosis of invasive mole, choriocarcinoma or placental site trophoblastic tumor, or persistent elevation of hCG usually in conjunction with demonstrated metastases following any pregnancy event. Once the diagnosis of a gestational trophoblastic neoplasm has been made, it is necessary to determine the extent of disease. After a thorough history and physical examination, the following clinical studies should be obtained: chest X-ray, computed tomography (CT) scans of the chest, abdomen, and pelvis, CT or magnetic resonance imaging (MRI) of the brain, complete blood and platelet counts, serum chemistries including liver and renal function studies, and quantitative serum hCG.

After these initial studies, patients are categorized as having nonmetastatic, metastatic low-risk, or metastatic high-risk gestational trophoblastic neoplasia. Patients with metastatic tumors were originally classified as being at higher risk for treatment failure based on one or more of the following poor prognostic factors described by investigators at the National Cancer Institute (NCI): (1) more than 4 months from antecedent pregnancy to diagnosis; (2) pretreatment hCG level more than 100,000 IU/24-hour urine or more than 40,000 mIU/mL serum; (3) metastases to sites other than the lung and vagina; (4) antecedent term pregnancy; and (5) previous failed therapy.² In 1983, the World Health Organization (WHO) adopted a prognostic scoring system, initially proposed by Bagshawe and subsequently modified, based on the patient's age, parity, and type of antecedent pregnancy, the interval between antecedent pregnancy and trophoblastic

tumor event, hCG level, number and sites of metastases, largest tumor mass, and previous chemotherapy. A weighted numerical value is applied to each prognostic factor and then added together; the resultant score is used to divide patients into low-risk (less than 7) and high-risk (7 or more) groups (Table 51.1). An anatomic staging system was adopted by the International Federation of Gynecology and Obstetrics (FIGO) Cancer Committee in 1982 (Table 51.2) and changed to include the modified WHO score in 2000.³ In this system, the modified WHO score is depicted by an Arabic numeral following and separated by a colon from the stage, which is depicted by a Roman numeral.

Patients with nonmetastatic (FIGO stage I) and low-risk metastatic (FIGO stages II and III, WHO score less than 7) gestational trophoblastic neoplasia can be treated with single-agent chemotherapy resulting in a survival rate approaching 100%. Patients with high-risk metastatic disease (FIGO stage IV or WHO score 7 or higher) should be treated more aggressively with initial combination chemotherapy with or without adjuvant radiotherapy or surgery to achieve a cure rate of 80% to 90%. Patients with gestational trophoblastic neoplasia must be chosen for single-agent or multiagent chemotherapy based on careful attention to selection criteria to ensure the best outcome with the least morbidity.

Development of Chemotherapy for Gestational Trophoblastic Neoplasia

Investigators at the National Cancer Institute (NCI) in the United States first demonstrated the efficacy of chemotherapy in the treatment of metastatic gestational trophoblastic disease in the late 1950s and early 1960s. In 1948, Hertz⁴ presented data demonstrating that fetal tissues required large amounts of folic acid to support trophoblastic growth in experimental animals and that this growth could be inhibited by the folic acid antagonist methotrexate. In 1956, Li et al.⁵ first reported complete regression of metastatic gestational trophoblastic disease in women treated with methotrexate. During the decade that followed, the group at the NCI systematically studied the effects of chemotherapy on gestational trophoblastic disease.⁶⁻⁸ In patients with metastatic disease, they obtained complete sustained remissions in 47% using methotrexate alone and in 74% using methotrexate and actinomycin D (an antitumor antibiotic that intercalates DNA), sequentially. In patients with nonmetastatic disease, they achieved complete remissions in 93% using methotrex-

TABLE 51.1. Modified World Health Organization (WHO) scoring system for gestational trophoblastic neoplasia.

	SCORE			
Risk factors	0	1	2	4
Age factors	<39	>39		
Antecedent pregnancy	Hydatidiform mole	Abortion	Term	
Pregnancy event to treatment interval (months)	<4	4–6	7–12	>12
Pretreatment human chorionic gonadotropin(hCG) (mIU/mL) < 10 ³	<10 ³	10 ³ –10 ⁴	10 ⁴ –10 ⁵	>10 ⁵
Largest tumor mass, including uterus (cm)		3–4	>5	
Site of metastases		Spleen kidney	Gastrointestinal tract	Brain Liver
Number of metastases		1–4	4–8	>8
Previous failed chemotherapy			1 drug	>2 drugs

The total score for a patient is obtained by adding the individual scores for each prognostic factor: <7 = low risk; ≥7 = high risk.

ate without hysterectomy and an overall cure rate of 98%.

The NCI investigators made many important contributions to the treatment of trophoblastic disease and to cancer chemotherapy in general. First, they proved that metastatic, as well as nonmetastatic, cancer could be cured by drug therapy. Second, they established that higher-dose intermittent chemotherapy was more effective than a lower daily dose. Third, they demonstrated that chemotherapy response could be effectively monitored by accurately measuring hCG. They also recognized that the outcome of therapy depended largely on duration of disease, height of the pretreatment hCG level, presence or absence of brain or liver metastases, and expertise in the use of chemotherapy drugs. More than 95% of patients who were diagnosed early and treated vigorously were cured, whereas patients in whom there was a delay in diagnosis or inappropriate therapy resulting in more-extensive disease had only a 36% remission rate.

Chemotherapeutic agents other than methotrexate and actinomycin D were subsequently found to be effective in gestational trophoblastic disease. Sung et al.⁹ and Bagshawe¹⁰ reported on the use of 6-mercaptopurine (6-MP), an antimetabolite purine analogue. There seemed to be no advantage of 6-MP over methotrexate or actinomycin D, and toxicity was significantly greater. The alkylating agents cyclophosphamide and chlorambucil were combined with methotrexate and actinomycin D (MAC) to produce some cures in patients resistant to single-agent chemotherapy.¹¹

Sung et al.¹² reported excellent results with 5-fluorouracil (5-FU), an antimetabolite fluoropyrimidine. Yim et al.¹³ were able to demonstrate a good response to bleomycin, an antitumor antibiotic that induces single-strand breaks in DNA. They suggested that bleomycin should not replace methotrexate or actinomycin D as first-line therapy because of pulmonary and cutaneous toxicity, but should be used in

combination chemotherapy regimens for patients who become resistant to more-conventional drugs. The vinca alkaloids vincristine and vinblastine, which inhibit microtubular polymerization, thereby arresting function of the mitotic spindle, have known activity in gestational trophoblastic disease and have been used in combination therapy.^{14,15}

In the 1970s, Newlands et al.^{16–18} identified etoposide (VP16-213), an epipodophyllotoxin that binds to the microtubules and interferes with the normal functioning of the topoisomerase II enzyme, as a very active agent in the treatment of resistant gestational trophoblastic neoplasia and suggested that it be incorporated into initial chemotherapy for high-risk disease. Ifosfamide, an alkylating agent similar to cyclophosphamide, has been used successfully alone or in combination for the treatment of resistant gestational trophoblastic tumors.¹⁹ Cisplatin and carboplatin, alkylating-type drugs that form platinum adducts with DNA, have been employed in combination with other drugs, most commonly etoposide, bleomycin, and ifosfamide, for the treatment of resistant trophoblastic disease.^{14,15,20–23} Most recently, paclitaxel, an extract from the bark of the Western yew tree *Taxus brevifolia* that binds to and stabilizes the intracellular microtubules disrupting normal mitotic spindle function, has been shown to inhibit growth of choriocarcinoma in vitro,^{24,25} and a few remissions using paclitaxel in patients with resistant gestational trophoblastic neoplasia have been reported.^{26–28}

Nonmetastatic Disease

Patients with nonmetastatic gestational trophoblastic neoplasia (FIGO stage I) should be treated with single-agent methotrexate (MTX) or actinomycin D (Act D) chemotherapy. Several different outpatient chemotherapy protocols have been used, all yielding excellent and fairly comparable results (Table 51.3). Hysterectomy is used as part of primary therapy in patients who no longer wish to preserve fertility and when the diagnosis is placental site trophoblastic tumor or as secondary therapy for resistant uterine disease.

Methotrexate given IM or IV for 5 days every 2 weeks has been the traditional treatment. In 1995, we reviewed nearly 30 years of experience in treating nonmetastatic gestational trophoblastic neoplasia at the Brewer Trophoblastic Disease Center to determine effectiveness of therapy, evaluate toxicity, and assess factors associated with chemotherapy resis-

TABLE 51.2. International Federation of Gynecology and Obstetrics (FIGO) staging for gestational trophoblastic neoplasia.

Stage I	Disease confined to the uterus
Stage II	Disease extends outside the uterus but is limited to genital structures (adnexa, vagina, broad ligament)
Stage III	Disease extends to lungs with or without genital tract involvement
Stage IV	Disease involves other metastatic sites

TABLE 51.3. Chemotherapy for nonmetastatic and low-risk metastatic gestational trophoblastic neoplasia.

Drug	Dosing regimen
Methotrexate (MTX)	0.4 mg/kg/day i.v. or i.m. (max. 25 mg) for 5 days Repeat every 14 days (9-day window)
Actinomycin D	10–12 mg/kg/day i.v. for 5 days Repeat every 14 days (9-day window)
Methotrexate	1.0–1.5 mg/kg i.m. every other day for 4 doses (days 1, 3, 5, 7) Folinic acid (FA) 0.1–0.15 mg/kg i.m. every other day for 4 doses (days 2, 4, 6, 8) Repeat every 15–18 days (7- to 10-day window)
Methotrexate	100 mg/m ² i.v. push, then 200 mg/m ² in 500 mL D 5W over 12 h Folinic acid 15 mg i.m. or p.o. every 12 h for 4 doses beginning 24 h after the start of MTX Repeat every 18 days, as needed
Methotrexate ^a	30–50 mg/m ² i.m. weekly
Actinomycin D ^a	1.25 mg/m ² i.v. every 2 weeks

^a Should not be used for patients with metastatic or resistant disease.

tance using the 5-day MTX regimen.²⁹ Of 337 patients treated between 1962 and 1990, 253 were initially treated with single-agent MTX 0.4 mg/kg (maximum, 25 mg) IV daily for 5 days every other week (9-day window). Primary remission was achieved in 226 (89.3%). Of the 27 patients (10.9%) resistant to methotrexate, 22 (8.7%) were placed into remission with a second agent, Act D. Multiagent chemotherapy or surgery was required in only 5 patients (2.0%). Relapse from remission occurred in 6 patients (2.4%) from 1 to 9 months after completing initial therapy. All 253 patients were eventually placed into permanent remission. Factors found to be significantly associated with the development of MTX resistance were pretreatment hCG levels greater than 50,000 mIU/mL, nonmolar antecedent pregnancy, and clinicopathologic diagnosis of choriocarcinoma. Significant toxicity to MTX necessitating a change to another chemotherapeutic agent occurred in only 12 patients (4.7%); no life-threatening toxicity occurred. There was no alopecia related to MTX, and nausea was not a common side effect. The most common toxic reaction to MTX was oropharyngeal ulcerations (stomatitis), which were managed symptomatically with “cocktails” including antacids, sulcralfate, viscous lidocaine, and antifungals. These manifestations usually persisted for only a short time but must have been resolved before another course of chemotherapy was initiated. Other less common or minor toxic side effects were conjunctivitis, pleuritic or peritoneal pain, and skin rash. Our results of approximately 90% complete response and 100% overall survival confirmed earlier reports from our center and others that single-agent methotrexate in a 5-day outpatient course every 2 weeks is a highly effective and well-tolerated treatment for nonmetastatic gestational trophoblastic neoplasia.

In an attempt to reduce toxicity to methotrexate, Bagshawe and Wilde³⁰ introduced folinic acid rescue. Methotrexate with folinic acid (MTX-FA) has been applied to the treatment of nonmetastatic gestational trophoblastic neoplasia. This regimen uses slightly high doses of MTX, 1.0–1.5 mg/kg IM every other day for 4 doses, plus FA 0.1–0.15 mg/kg IM 24 hours after each MTX dose, repeated as needed after a minimum rest period of 7 days. Berkowitz et al.³¹ from the New England Trophoblastic Disease Center reported that MTX-FA induced primary remission in 147 (90.2%) of 163 patients with nonmetastatic disease. Complete remission was subsequently achieved in all patients, but 7.1% required multiagent chemotherapy or surgery. Bagshawe et al.,³² from Charing Cross Hospital in London, reported that they were

able to cure 99.7% of 348 low-risk patients (most with nonmetastatic disease) with the use of MTX-FA. They noted that 26% of patients had to switch treatment because of drug resistance (20%) or drug-induced toxicity (6%). Similarly, Wong et al.³³ from Hong Kong treated 68 low-risk patients with MTX-FA. Sustained remission was achieved in 76% with MTX-FA alone; 11.8% developed drug resistance requiring multiagent chemotherapy to achieve cure, and 8.8% had a treatment change because of MTX toxicity.

Rotmensch et al.³⁴ suggested that the reduced toxicity of the MTX-FA regimen compared with MTX alone was due to the every-other-day scheduling of MTX and not to FA. They measured plasma methotrexate levels in patients being treated with MTX-FA and noted that MTX levels at the time of FA administration were below levels necessitating FA rescue.

Single, weekly dose scheduling of methotrexate has been devised in an attempt to develop a more-efficient and less costly, yet safe and effective, chemotherapy for patients with nonmetastatic gestational trophoblastic neoplasia. The Gynecologic Oncology Group used single, weekly IM doses of MTX 30–50 mg/m² to treat patients with nonmetastatic postmolar disease. Homesley et al.³⁵ reported a primary remission rate of 74% in 62 patients using this regimen; 4.8% required multiagent chemotherapy, 3.2% required surgery, and 1 patient eventually died. Hoffman et al.³⁶ subsequently reported on a single-institution experience using weekly IM MTX to treat 20 similar patients. The primary remission rate was 60%; 5% required multiagent chemotherapy for cure.

High-dose methotrexate IV infusion with folinic acid rescue (HDMTX-FA) has been used to treat patients with nonmetastatic gestational trophoblastic disease. Berkowitz and colleagues^{37,38} reported on the use of a 100 mg/m² IV bolus and then a 200 mg/m² 12-hour IV infusion of MTX followed by FA 15 mg IM or PO every 12 hours for 4 doses starting 24 hours after beginning MTX. The primary control rate was only 69%, and 18.8% of patients required multiagent chemotherapy to attain remission. Elit et al.³⁹ treated 65 patients with a 1,000 mg, 6-hour MTX infusion followed by FA rescue at 24 hours, resulting in a remission rate of 86%. Wong et al.,⁴⁰ using a similar MTX infusion protocol in 51 patients, obtained a 90% remission rate.

Different MTX chemotherapy regimens for treatment of nonmetastatic disease have been compared. At the Southeastern Regional Trophoblastic Disease Center, Smith et al.⁴¹ compared 29 patients treated with MTX-FA with 39 histori-

cal controls treated with a 5-day course of MTX. A change in chemotherapy because of MTX resistance was required in 27.5% of patients receiving MTX-FA compared with 7.7% of patients receiving MTX alone. Gleeson et al.⁴² reported primary remission rates of 69% in 13 patients treated with weekly IM MTX and 75% in 12 patients treated with MTX-FA.

The lower primary remission rates achieved with the MTX-FA, weekly MTX, and MTX infusion protocols compared with 5-day MTX regimen may be attributable to shorter overall duration of chemotherapy exposure of trophoblastic cells to inhibiting levels of the drug during the S phase of the cell cycle, where MTX exerts its cytotoxic effect by interrupting thymidylc acid biosynthesis.⁴³ Methotrexate administered at set intervals over 5 days affords increased drug exposure compared to other MTX regimens. Another reason for increased failure to achieve remission with various MTX protocols is that some patients may actually have metastatic disease. Mutch et al.⁴⁴ reported that at least 40% of patients with negative chest X-rays, who presumably had nonmetastatic disease, actually had micropulmonary metastases on CT of the lungs, and that 50% of these patients developed resistance to treatment with MTX-FA. Therefore, one must take into consideration toxicity, patient convenience, and cost, as well as the chance of requiring a change in chemotherapy, including multiagent chemotherapy, to achieve cure when choosing a MTX regimen for treatment of nonmetastatic disease.

Actinomycin D 10–12 µg/kg IV daily for 5 days or as a single 1.25 mg/m² IV dose every 2 weeks is an acceptable alternative to MTX for treatment of nonmetastatic gestational trophoblastic neoplasia. Act D generally causes more nausea and alopecia than MTX and produces local tissue injury if IV extravasation occurs. Therefore, Act D is most often used as secondary therapy in the presence of MTX resistance rather than as primary therapy. However, Act D is the appropriate primary therapy for patients with hepatic or renal disease or effusions contraindicating the use of MTX.

The New England Trophoblastic Disease Center first reported on the use of the 5-day Act D regimen to treat 31 patients with nonmetastatic gestational trophoblastic neoplasia, yielding a primary remission rate of 94%.⁴⁵ Subsequently, Petrilli and Morrow⁴⁶ and Kohorn⁴⁷ reported 77% and 88% primary remission rates in 13 and 43 patients, respectively. In our series from the Brewer Center, 78% of 13 patients initially treated with Act D achieved primary remission.²⁹ Pulsed Act D (1.25 mg/m² every 2 weeks) has been used to treat nonmetastatic postmolar disease.^{48–50} Complete response rates of 75% to 100% have been reported in a small number of patients meeting these limited criteria.

Alternating 5-day regimens of MTX and Act D every other week for treatment of nonmetastatic trophoblastic neoplasia have been suggested to decrease drug resistance and cumulative toxicity. Smith⁵¹ first reported a 100% primary remission rate using this scheme. Rose and Piver⁵² and Lurain and Elfstrand²⁹ subsequently confirmed the excellent results with this treatment plan. The tendency, however, has been to use MTX as primary therapy and avoid Act D if possible because of the greater hair loss and nausea as well as local IV infiltration tissue damage associated with Act D.

In summary, single-agent chemotherapy with MTX or Act D by a variety of regimens is the appropriate treatment for

nonmetastatic gestational trophoblastic neoplasia (Table 51.4). Overall, cure is anticipated in essentially all patients with nonmetastatic disease. Approximately 85% to 90% of patients can be cured by the initial chemotherapy regimen. Most of the remaining patients will be placed into permanent remission with additional single-agent chemotherapy. Rarely do patients require multiagent chemotherapy or surgery for cure.

Low-Risk Metastatic Disease

Patients categorized into the low-risk metastatic disease group (FIGO stages II and III, WHO score less than 7) should be treated with single-agent chemotherapy using 5-day dosage schedules of MTX or Act D or the 8-day MTX-FA protocol. The weekly MTX or biweekly Act D single-dose protocols currently in use for nonmetastatic postmolar disease should not be employed for treatment of metastatic disease. If resistance to the initial drug occurs, the alternate single agent in a 5-day dosage schedule is begun. Patients who develop resistance to sequential single-agent MTX and Act D chemotherapy are then treated with combination chemotherapy, as for high-risk disease. Hysterectomy may be performed as adjuvant treatment coincident with the institution of chemotherapy to shorten the duration of therapy or to eradicate persistent, chemotherapy-resistant disease in the uterus. Several studies have demonstrated the high curability of low-risk metastatic disease using this approach.^{53–55}

DuBeshter et al.⁵³ at the New England Trophoblastic Disease Center treated 48 patients with low-risk metastatic gestational trophoblastic neoplasia with single-agent MTX with or without FA or Act D between 1965 and 1990. All patients achieved sustained remission, although 50% required a second single agent, 14% needed multiagent chemotherapy, and 12% underwent surgical resection of resistant tumor foci. Multiagent chemotherapy was more often required after the use of MTX-FA protocols (30%) than single-agent MTX or Act D (4%).

Soper et al.⁵⁴ at the Southeastern Regional Trophoblastic Disease Center retrospectively analyzed 52 patients with low-risk metastatic gestational trophoblastic disease treated with 5-day cycles of IM MTX repeated every 14 days. Primary remission was achieved in 60%. Therapy was changed because of drug-resistance in 19% and toxicity in 21%. Only 2 patients (4%) required multiagent chemotherapy, 1 of whom also underwent hysterectomy. Pretherapy hCG at

more than 10,000mIU/mL was associated with the development of drug resistance. Sustained remission was achieved in all patients.

At the Brewer Center, we treated 92 low-risk metastatic disease patients between 1962 and 1992.⁵⁵ Initial treatment consisted of 5-day cycles of IV MTX (61), Act D (4), alternating MTX/ACT D (5), and hysterectomy with single-agent chemotherapy (22). All patients were cured. Remission was achieved in 98.9% of patients with MTX and Act D used alone or sequentially with or without hysterectomy; only one patient (1.1%) needed multiagent chemotherapy. Toxicity was relatively mild and easily remedied, necessitating a change in chemotherapeutic agents in 10.7% of patients. Patients in whom initial therapy failed tended to be older and had higher pretreatment hCG levels and WHO scores than those successfully treated; however, the only statistically significant finding was that patients with large vaginal metastases were more likely to require secondary therapy.

In summary, single-agent chemotherapy with MTX or Act D, each given for 5 consecutive days every other week, is the preferred treatment for patients with low-risk metastatic gestational trophoblastic neoplasia (Table 51.5). With appropriate selection of patients as well as proper administration of treatment, cure should approach 100%, and the greater morbidity associated with the use of multiagent chemotherapy can usually be avoided. Approximately 30% to 50% of patients in this category develop resistance to the first chemotherapeutic agent and require alternate treatment. Eventually, 5% to 15% of patients treated with sequential single-agent chemotherapy will require multiagent chemotherapy with or without surgery to achieve remission.

High-Risk Metastatic Disease

Patients with high-risk metastatic gestational trophoblastic neoplasia (FIGO stage IV or WHO score 7 or more) should be treated with initial multiagent rather than single-agent

chemotherapy with or without adjuvant radiotherapy or surgery.⁵⁶ During most of the 1970s and 1980s, the primary multidrug regimen used was MAC: methotrexate, actinomycin D, and cyclophosphamide or chlorambucil. Reported cure rates ranged from 63% to 71%.⁵⁷ In the late 1970s, Bagshawe and colleagues at Charing Cross Hospital in London introduced the seven-drug CHAMOCA protocol, using cyclophosphamide, hydroxyurea, actinomycin D, methotrexate with folinic acid, vincristine and doxorubicin, for treatment of high-risk patients and reported a primary remission rate of 82%.⁵⁸ However, in a randomized clinical trial comparing MAC and CHAMOCA for primary treatment of high-risk patients, the Gynecologic Oncology Group found that the MAC regimen was more effective (cure rates, 95% versus 70%, respectively) and less toxic than the CHAMOCA regimen.⁵⁹ After the discovery in the late 1970s that etoposide (VP16-213) was a very effective chemotherapeutic agent for gestational trophoblastic neoplasia, Newlands et al.⁶⁰ formulated the EMA-CO regimen, employing etoposide, high-dose methotrexate with folinic acid, actinomycin D, cyclophosphamide, and vincristine (Table 51.6). They originally reported an 80% complete clinical response rate and 82% survival with minimal toxicity in 76 high-risk patients who had not received any prior chemotherapy. Since then, complete response rates and long-term survival rates of more than 80% have been reported by several groups, making the EMA-CO protocol, or some variation of it, the initial multiagent chemotherapy of choice for treatment of patients with high-risk metastatic gestational trophoblastic neoplasia (Table 51.7).

Bolis et al.⁶¹ reported an initial complete response rate of 94% and survival in 88% of 17 patients with high-risk disease treated primarily with EMA-CO. Only 1 patient failed to achieve an initial complete response, and 3 patients (19%) relapsed from remission. In 1992 we reported our preliminary results with EMA-CO for primary treatment of patients with high-risk metastatic gestational neoplasia at the Brewer Trophoblastic Disease Center between 1986 and 1991. Ten

of 12 patients (83%) had lasting complete clinical responses to EMA-CO.⁶² Soper and colleagues⁶³ treated 22 high-risk patients with EMA-CO. Four (67%) of six patients receiving primary therapy and 13 (81%) of 16 patients receiving secondary therapy had complete responses; 6 (35%) of 17 complete responders developed recurrences within 6 months of therapy. Overall, 68% of patients remained without evidence of disease. Quinn et al.⁶⁴ from Australia treated 35 patients with metastatic disease with EMA-CO. Most of the patients had high-risk features and all had WHO scores above 4. The survival rate was 89%. All four deaths occurred in patients who had hepatic and/or central nervous system metastases.

More recently, Bower et al.⁶⁵ updated the Charing Cross-London experience using EMA-CO to treat 272 women with high-risk disease. There were 11 (4%) early deaths, 214 (78%) complete remissions to EMA-CO, and an additional 33 (12%) complete responses to subsequent cisplatin-based chemotherapy and surgery, yielding an overall survival rate of 88%. Kim et al.⁶⁶ from Korea treated 165 high-risk patients with the EMA-CO regimen. Of 96 patients who received EMA-CO as first-line treatment, 87 (91%) had complete remissions, whereas only 51 (74%) of the 69 patients who received EMA-CO as second- or third-line therapy entered into remission. The overall survival rate was 84%. Factors that predicted poor prognosis were tumor age greater than 12 months, metastases to more than two organ systems, and previous inadequate chemotherapy or unplanned surgery. In patients with two or three of these factors, death rates were 18% and 57%, respectively. We recently updated our experience with EMA-CO for treatment of high-risk disease at the Brewer Center from 1986 to 2001.⁶⁷ Of the 45 patients treated with EMA-CO (25 as primary therapy and 20 as secondary therapy), 32 (71%) had a complete response, 9 (20%) developed resistance but were subsequently placed into remission with platinum-based chemotherapy, and 4 (9%) died of widespread metastatic disease, resulting in an overall survival rate of 91%.

Two groups have reported on the use of an EMA protocol without CO for treatment of high-risk disease, yielding similar results. Soto-Wright et al.⁶⁸ from the New England Trophoblastic Disease Center were able to achieve remissions in 5 (71%) of 7 patients treated primarily with EMA and in 21 (95%) of 22 patients treated secondarily with EMA, eventually placing all 29 patients into remission. Matsui et al.⁶⁹ from Japan reported obtaining complete remissions in 21 (78%) of 27 patients treated primarily with EMA and in 8 (67%) of 12 patients who had received chemotherapy prior to EMA. The overall survival rate was 87%. Of note, grade 4 neutropenia and thrombocytopenia occurred in 5.3% and

6.4% of treatment cycles, respectively, resulting in one chemotherapy-related death.

In almost all the reports, treatment with EMA ± CO was generally well tolerated and toxicity was mild. In our series, there were no treatment-related deaths or life-threatening toxicity.⁶⁷ Neutropenia necessitating a 1-week delay of treatment occurred in 13.5% of 257 treatment cycles. We have been using granulocyte colony-stimulating factor (G-CSF, 300 µg SC days 9–14 of each subsequent treatment cycle) if any neutropenia-associated treatment delay is encountered. Anemia requiring blood transfusions and grade 3–4 neutropenia without thrombocytopenia were associated with only 5.8% and 1.9% of treatment cycles, respectively.

Primary treatment of high-risk gestational trophoblastic disease using cisplatin/etoposide-containing combinations has also been reported. Theodore et al.⁷⁰ treated 8 patients with high-risk disease primarily with cisplatin/etoposide/actinomycin D combination chemotherapy. All eight patients had complete responses to this chemotherapy and were apparently cured. Although all patients had WHO scores above 7, several had nonmetastatic disease and none had metastases to more than one organ site, usually the lungs. Bakri and associates^{71,72} reported using a similar regimen as primary therapy for patients presenting with brain or liver metastases. Eight (67%) of 12 patients survived. Surwit and Childers⁷³ substituted etoposide (100 mg/m²) and cisplatin (80 mg/m²) (EP) for cyclophosphamide and vincristine (CO) on day 8 in the EMA-CO regimen, as suggested by Newlands et al.,⁷⁴ for primary treatment of high-risk patients. They reported remission in the four patients treated with this EMA-EP protocol. In general, primary treatment of high-risk patients using cisplatin/etoposide combinations results in significant cumulative toxicity, often before a complete response is accomplished, and may compromise the ability to deliver adequate salvage chemotherapy.

When central nervous system metastases are present, whole-brain irradiation (3,000 cGy in 200-cGy fractions) is usually given simultaneously with the initiation of chemotherapy.^{75–77} Brain irradiation has the dual purpose of being both tumoricidal and hemostatic. Yordan et al.⁷⁵ reported that death due to brain involvement occurred in 11 of 25 patients (44%) treated with chemotherapy alone but in none of 18 patients treated with brain irradiation and chemotherapy. During radiotherapy, the methotrexate infusion dose in the EMA-CO protocol is increased to 1 g/m², and 30 mg folinic acid is given every 12 hours for 3 days starting 32 hours after the infusion begins. Overall, 50% to 80% of patients with brain metastases can be cured, depending on

patient symptoms as well as number, size, and location of the brain lesions.

Evans et al.,⁷⁶ at the Southeastern Regional Trophoblastic Disease Center, treated 42 patients with brain metastases with brain irradiation and chemotherapy. Twelve of 16 patients (75%) who presented initially with evidence of brain lesions and no prior therapy were successfully treated. Five of 23 patients (22%) survived who had received prior treatment (5 of 13) or developed brain lesions while undergoing systemic chemotherapy (0 of 10). At the Brewer Trophoblastic Disease Center, 26 (4.1%) of 631 patients who underwent treatment for trophoblastic neoplasia between 1962 and 1994 had or developed evidence of brain metastases. Patients were treated with chemotherapy and whole-brain irradiation. The overall 5-year actuarial survival rate was 51%:100% (6 of 6) for patients with asymptomatic or minimally symptomatic brain disease at presentation, 39% (5 of 14) for patients with symptomatic brain metastases at presentation, and 17% (1 of 6) for patients who developed brain metastases during chemotherapy.⁷⁷

As an alternative to whole-brain irradiation, the Charing Cross Hospital group has recommended the addition of intrathecal methotrexate or surgical excision with stereotactic irradiation in selected patients. Eighty-six percent of their patients with brain lesions achieved complete remission using this approach.⁷⁸ Bakri and associates,⁷¹ at the New England Trophoblastic Disease Center, reported achieving sustained remissions in four of eight patients (50%) with brain metastases who were treated with systemic chemotherapy combined with intrathecal methotrexate without brain irradiation.

Resistant High-Risk Disease

Approximately 30% of high-risk patients have an incomplete response to first-line chemotherapy or relapse from remission and require secondary chemotherapy. Salvage chemotherapy with drug regimens employing etoposide and platinum agents, often combined with surgical resection of sites of persistent tumor (usually in the uterus or lungs), will result in cure of most of these high-risk patients with resistant disease.⁵⁶

The EMA-EP regimen, substituting etoposide and cisplatin for cyclophosphamide and vincristine in the EMA-CO protocol, seems to be the most appropriate therapy for patients who have responded to EMA-CO but have plateauing low hCG levels or who have developed reevaluation of hCG levels after having had a complete response to EMA-CO. Newlands et al.⁷⁴ reported curing 30 (88%) of 34 patients with disease refractory to EMA-CO by treating them with the EMA-EP regimen. The majority of these patients had only low-level hCG plateaus and also underwent surgical procedures; however, 9 of 11 patients treated with EMA-EP without adjuvant surgery were cured.

High-risk patients who have clearly developed resistance to methotrexate-containing treatment protocols should be treated with platinum-etoposide drug combinations. Theodore and associates⁷⁰ used a cisplatin-etoposide + actinomycin D regimen to treat 14 patients with drug-resistant trophoblastic disease. Eleven (78%) achieved remission; however, all but 2 had failed only a single- or double-agent

methotrexate or actinomycin D chemotherapy regimen. Soper et al.⁷⁹ treated 7 patients who demonstrated resistance to multiagent chemotherapy with the combination of etoposide 100 mg/m² and cisplatin 20 mg/m² each, given IV daily for 5 consecutive days every 21 days. Six patients (86%) had return of their hCGs to normal, but only 3 (43%) had sustained remissions. Hematologic and renal toxicity were significant.

The combination of cisplatin, vinblastine, and bleomycin (PVB) has been used in the past to induce remissions in some patients with resistant high-risk gestational trophoblastic neoplasia.^{14,15,20} More recently, etoposide has replaced vinblastine in this regimen.^{18,21} The BEP protocol (cisplatin 20 mg/m² IV and etoposide 100 mg/m² IV on days 1–4 repeated every 21 days, as well as bleomycin 30U IV weekly starting on day 1) is currently our first chemotherapy choice for patients with resistance to EMA-CO/EMA-EP. Ifosfamide has also been combined with etoposide and cisplatin to treat patients with refractory gestational trophoblastic disease, resulting in some cures.¹⁹ The VIP protocol that we have used is etoposide 75 mg/m² IV, ifosfamide 1.2 g/m² IV, and cisplatin 20 mg/m² IV every day for 4 days. Mesna is given as a 120 mg/m² IV bolus just before the first dose of ifosfamide, followed by a 1.2 g/m² 12-hour IV infusion daily after each ifosfamide dose.²² If significant cisplatin-induced renal or neurologic toxicity occurs, carboplatin can be substituted for cisplatin in the ICE protocol: ifosfamide 1.2 g/m² on days 1–3 with mesna as noted above, carboplatin 300 mg/m² IV on day 1, and etoposide 75 mg/m² IV on days 1–3.²³ Both regimens are repeated every 21 days. To decrease the incidence of severe neutropenia, which occurs almost universally with these protocols, and to avoid treatment delays, G-CSF is administered on days 6–14 of each treatment cycle, and a complete blood count is obtained on days 8 and 15.⁸⁰

Another approach to improving response to secondary therapy for high-risk disease is to administer chemotherapy agents with known activity at doses much higher than usual. Collins et al.⁸¹ treated a patient with refractory disease in the lung and brain after both EMA-CO and PVB chemotherapy with very high dose etoposide, 4,200 mg/m² at 60 hours IV infusion and cyclophosphamide 50 mg/kg IV daily, for 4 days without bone marrow support. Although severe mucositis and pancytopenia occurred, the hCG level returned to normal within 14 days of therapy and the patient was disease free 15 months later. We treated two patients similarly; both achieved normal hCG levels immediately after treatment, but disease recurred in both, 4 and 6 months later.⁸² Lotz et al.⁸³ treated five patients with gestational trophoblastic tumors who were refractory to standard therapy with high-dose chemotherapy, consisting of ifosfamide 1,500 mg/m² and carboplatin 200 mg/m², both given IV daily for 5 days, followed by autologous bone marrow transplantation. Only two of the patients had normalization of their hCG levels, for 68 and 2 months, respectively, and 1 patient died of therapy-related complications. Giacolone et al.⁸⁴ and van Besian et al.⁸⁵ each reported on one patient with refractory gestational trophoblastic disease who had a complete response to high-dose chemotherapy. Further data on the use of high-dose chemotherapy with autologous bone marrow transplantation or peripheral stem cell support are necessary before this form of treatment can be recommended as initial salvage therapy for patients failing EMA-CO.

Newer anticancer agents have been developed that may also have a role in the treatment of gestational trophoblastic neoplasia. Paclitaxel has been shown to inhibit growth of choriocarcinoma in tissue culture.^{24,25} Jones et al.,²⁶ Termrungruenglert et al.,²⁷ and Gershon et al.²⁸ each reported remissions using paclitaxel in patients with resistant gestational choriocarcinoma. Osborne et al.⁸⁶ recently reported achieving remission in patients with resistant high-risk disease using a doublet of paclitaxel/etoposide and paclitaxel/cisplatin alternating every 2 weeks. The topoisomerase I inhibitor camptothecins, topotecan and irinotecan, and new antimetabolites, such as gemcitabine, have been shown to have significant antitumor activity against a wide range of cancers and need to be evaluated in resistant gestational trophoblastic neoplasia.

Adjuvant surgical procedures, especially hysterectomy and thoracotomy, may be of use in removing known foci of chemotherapy-resistant disease in selected patients with persistent or recurrent high-risk gestational trophoblastic neoplasia.⁸⁷⁻⁸⁹ Chemotherapy is usually administered at the time of surgery to (1) eradicate any occult metastases that may also be present, (2) reduce the likelihood of tumor dissemination at surgery, and (3) maintain cytotoxic levels of chemotherapy in tissues and plasma in the event that viable tumor cells are disseminated at the time of surgery.

Patients with evidence of uterine disease but no or very little extrauterine disease may benefit from hysterectomy. Mutch et al.⁹⁰ reported curing 10 (71%) of 14 patients who had hysterectomy as part of their treatment for recurrent disease. Resection of pulmonary nodules in highly selected patients with drug-resistant disease (solitary pulmonary nodule, no evidence of other metastatic sites or uterine disease, hCG level less than 1,000 mIU/mL) may also be successful in inducing remission. Tomoda et al.⁹¹ were able to cure 14 (93%) of 15 patients who satisfied their criteria by resection of resistant pulmonary disease. Mutch et al.⁹⁰ reported that 4 (44%) of 9 patients who underwent thoracotomy with pulmonary wedge resection of resistant choriocarcinoma survived. Prompt hCG regression within 1 to 2 weeks of surgical resection predicts a favorable outcome.⁹⁰⁻⁹²

Surgery may also have a role in the therapy of high-risk disease as a means of controlling tumor hemorrhage, relieving bowel or urinary obstruction, treating infection, or dealing with other life-threatening complications. Selective angiographic embolization of the uterine arteries may be used to control uterine or pelvic tumor bleeding in lieu of surgical intervention.⁹³

In summary, intensive multimodality therapy with EMA-CO or some variation of it, along with adjuvant radiotherapy and surgery when indicated, has resulted in cure rates of 80% to 90% in patients with high-risk metastatic gestational trophoblastic neoplasia. Approximately 30% of high-risk patients will fail first-line therapy or relapse from remission. Most of these patients have a clinicopathologic diagnosis of choriocarcinoma, multiple metastases to sites other than the lungs and vagina, and inadequate previous chemotherapy. Salvage chemotherapy with drug regimens combining platinum agents, etoposide, and bleomycin, ifosfamide, or paclitaxel, often in conjunction with surgical resection of sites of persistent tumor, will result in cure of most of these high-risk patients. Colony-stimulating factors should be used to prevent treatment delays and dose reductions. Newer

anticancer drugs, such as paclitaxel and gemcitabine, or high-dose chemotherapy may have a role in the future management of selected patients.

Placental-Site Trophoblastic Tumor

Placental-site trophoblastic tumor (PSTT) is an uncommon variant of gestational trophoblastic neoplasia. Pathologically, it consists predominantly of intermediate trophoblasts that secrete human placental lactogen (hPL), is associated with less vascular invasion, necrosis, and hemorrhage than typical choriocarcinoma, and has a propensity for lymphatic spread. The most common presentation is irregular vaginal bleeding, often distant from a preceding nonmolar gestation. Placental-site tumors tend to remain within the uterus, disseminate late, and produce low levels of hCG relative to their tumor mass. The clinical classification schemes and scoring systems used for other gestational trophoblastic neoplasms do not apply to PSTT. These tumors are relatively resistant to chemotherapy.

Hysterectomy is the treatment of choice for PSTT. Patients with metastatic disease should be treated with EMA-EP chemotherapy. Newlands et al.⁷⁴ managed 17 patients with PSTT: 8 nonmetastatic and 9 metastatic to lungs (5), pelvis (3), and lymph nodes (1). All but 1 patient had a hysterectomy, and 14 had chemotherapy. The overall survival rate was 76%: 100% for nonmetastatic disease and 56% for metastatic disease. The most significant adverse prognostic variable was an interval of more than 2 years from antecedent pregnancy event to treatment. Cure was achieved in all 12 patients whose interval was less than 2 years compared with only 1 of 5 whose interval was more than 2 years.

Follow-Up After Treatment for Gestational Trophoblastic Neoplasia

Disease Surveillance

After completion of chemotherapy, serum quantitative hCG levels should be obtained at 1-month intervals for 12 months. The risk of recurrence is exceedingly low after 1 year. Physical examinations are performed at 6- to 12-month intervals; other examinations such as chest X-rays are rarely indicated. Contraception should be maintained during treatment, preferably with oral contraceptives, and for 1 year after completion of chemotherapy. During a subsequent pregnancy, pelvic ultrasound is recommended in the first trimester to confirm a normal gestation, because these patients are at increased risk for another gestational trophoblastic disease event. The products of conception or placentas from future pregnancies should be carefully examined histopathologically, and an hCG level should be obtained 6 weeks after any pregnancy event.

Reproductive Performance

The successful treatment of gestational trophoblastic neoplasia with chemotherapy has resulted in a large number of women whose reproductive potential has been retained despite exposure to drugs that have ovarian toxicity and

teratogenic potential. Most women resume normal ovarian function following chemotherapy and exhibit no increase in infertility. Many successful pregnancies have been reported.⁹⁴ In general, these women experience no increase in incidences of abortions, stillbirths, congenital anomalies, prematurity, or major obstetric complications. There is no evidence for reactivation of disease because of a subsequent pregnancy, although patients who have had one trophoblastic disease episode (hydatidiform mole or choriocarcinoma) are at greater risk for developing a second episode in a subsequent pregnancy, unrelated to whether they had previously received chemotherapy.

Secondary Malignancies

Because many anticancer drugs are known carcinogens, there is concern that the chemotherapy used to induce long-term remissions or cures of one cancer may induce second malignancies. Until recently, there were no reports of increased susceptibility to the development of other malignancies after successful chemotherapy for gestational trophoblastic tumors⁹⁵; this was probably due to the relatively short exposure of patients to intermittent schedules of methotrexate and actinomycin D and the infrequent use of alkylating agents. However, after the introduction of etoposide-containing drug combinations for treatment of gestational trophoblastic tumors in the 1980s, an increased risk of secondary malignancies, including acute myelogenous leukemia, colon cancer, melanoma, and breast cancer, was identified.⁹⁶

Ovarian Cancer

Yukio Sonoda and David Spriggs

Ovarian cancer consistently ranks as the most common cause of death among the gynecologic malignancies. There will be an estimated 16,090 deaths attributable to this illness in the year 2004,¹ and with 25,580 annual new cases of ovarian cancer, it ranks as the fifth most common cancer among females in the United States. The incidence rates for this particular malignancy are higher in white compared to black women.² The lifetime risk in the general population is 1.4%, with incidence increasing with age up to age 80.

The management of ovarian cancer, fallopian tube cancer, and primary peritoneal cancer are generally indistinguishable. The number of fallopian tube cancers is far too small to constitute an independent literature whereas the diagnosis of primary peritoneal cancer is often presumptive, based on the distribution of tumor deposits or prior oophorectomy. The surgical and chemotherapy management principles described here for ovarian cancer can be generally applied to fallopian tube cancers or peritoneal cancers unless otherwise specified. For purposes of conceptualization, it is useful to imagine ovarian cancer as a series of networked *disease states* or groups of patients with similar outcomes. The material is organized within this framework.

Screening and Prevention

Epidemiology of Ovarian Cancer

Multiple risk factors have been associated with an increased risk of ovarian cancer. Race and country of origin have been associated with increased risk for this disease. Industrialized countries, with the exception of Japan, have the highest rates of ovarian cancer and the nonindustrialized countries the lowest. The incidence in the United States among the white population is 14.2 per 100,000. In Japan, the incidence is 2.7 per 100,000 and in India it is 4.6 per 100,000. However, when immigrants from Japan move to the United States, after one or two generations, their risk is similar to that of a native-born American.³ Race may also play a role in the development of this disease because the risk of developing ovarian cancer is 46% greater in Caucasians compared to African-Americans.⁴

DIET

Dietary factors such as dietary fat intake, milk product consumption, and antioxidant intake all have been investigated as

potential risk factors. Although epidemiology and case-control studies have suggested increased risk associated with each of these factors, none has been confirmed in the large, prospective Nurses Health Study cohort. In that study, subjects' dietary intake was assessed using a self-administered food frequency questionnaire.⁵⁻⁷ There were 301 cases of invasive epithelial ovarian cancer confirmed among 80,258 participants. None of the dietary features studied were found to increase ovarian cancer risk. For dietary fat, those women in the highest quintile of fat intake had a relative risk of 1.03 [confidence interval (CI) 0.72, 1.45; $P = 0.97$] of developing ovarian cancer when compared to women in the lowest quintile.

Lactose and its metabolic product galactose have also been implicated in retrospective analysis.⁸ Using the Nurses' Health Study data, Fairfield et al. observed a 40% increase in risk of all types of ovarian cancer for subjects in the highest category of lactose consumption compared to those in the lowest.⁹ This increase of risk did not achieve statistical significance. In the same study, Fairfield et al. prospectively assessed the consumption of vitamins A, C, and E, and specific carotenoids as well as fruit and vegetable intake among 80,326 women in the Nurses' Health Study. A high consumption of these antioxidant vitamins or intake of fruits did not translate into a decreased risk of ovarian cancer.¹⁰ In summary, diet has not been convincingly shown to contribute to ovarian cancer incidence.

REPRODUCTIVE FACTORS

There have been multiple studies examining the effect of parity on the incidence of ovarian cancer. Whittemore et al., reporting for the Collaborative Ovarian Cancer Group, summarized the results of 12 case-controlled studies from the United States and demonstrated a significant protective effect from pregnancy.¹¹ A single term pregnancy resulted in a significant reduction in risk of ovarian cancer [odds ratio (OR), 0.47; 95% CI, 0.40-0.56]. This risk reduction continued with future pregnancies; after six term pregnancies, the OR was 0.29 (95% CI, 0.20-0.42).

Reproductive factors were prospectively studied in the Nurses Cohort study, which followed 121,700 women since 1976.¹² The authors found that each parity reduced the risk of ovarian cancer (OR, 0.84; 95% CI, 0.77-0.91 for each pregnancy). This protective effect of parity supports the "incessant ovulation" hypothesis, which is based on the premise that ovarian cancer develops from an aberrant repair process of the surface epithelium that is ruptured and repaired during

each ovulatory cycle.¹³ By reducing the number of ovulatory cycles by pregnancy, there theoretically is a reduction in the probability that a cancer would develop.

GENETIC PREDISPOSITION

This strongest risk factor for the development of ovarian cancer is genetic predisposition. Family history of ovarian cancer has long been known to be a strong risk factor for ovarian cancer. Case-controlled studies have demonstrated that relatives of patients with ovarian cancer had an increased risk themselves of developing ovarian cancer.¹⁴ The odds ratios for patients with first- or second-degree relatives with ovarian cancer were 3.6 (95% CI, 1.8–7.1) and 2.9 (95% CI, 1.6–5.3) when compared to subjects without a family history of this disease.

It has been estimated that approximately 10% of all epithelial ovarian carcinomas result from a hereditary predisposition, and two distinct syndromes have been currently identified.¹⁵ The most common is the hereditary breast-ovarian cancer syndrome, which accounts for 75% to 90% of all hereditary ovarian cancers. It is linked to mutations of the BRCA 1 and BRCA 2 genes, which were both identified in the early 1990s. These genes are inherited in an autosomal dominant manner, which leads to increased susceptibility to ovarian cancer with variable penetrance. Linkage studies have demonstrated that the lifetime risk for the development of ovarian cancer for carriers of the BRCA 1 gene is in the range of 16% to 63%.¹⁵ Similar studies have estimated the risk in BRCA 2 carriers to be 16% to 27%. These genes clearly place one at significantly higher risk than the 1.4% risk of the general population.^{16,17}

The second recognized ovarian cancer syndrome is the hereditary nonpolyposis colorectal cancer syndrome (HNPCC). Mutations in the DNA mismatch-repair (MMR) genes are responsible for this syndrome. Specifically, mutations in MLH1 and MSH2 account for 90% of subjects with HNPCC.¹⁸ In a study of 50 HNPCC families, Aarnio et al. determined the average lifetime risk of ovarian cancer in patients belonging to the HNPCC kindred is 12%.¹⁹ Although this syndrome accounts for only a small fraction of hereditary ovarian cancer, these patients clearly have a lifetime risk significantly higher than the general population and should be considered for prophylactic surgery or screening.

Risk Reduction

ORAL CONTRACEPTIVE PILLS

Oral contraceptive pills are one of the established findings to be associated with risk reduction for ovarian cancer. They have been shown to provide a protective effect for the development of ovarian cancer in many case-controlled trials. The World Health Organization (WHO) conducted a review of 368 patients with ovarian cancer compared to 2,397 matched controls.²⁰ The relative risk for women who had ever used oral contraceptives was 0.75. The risk decreased with increasing time since cessation of use and with longer duration of use.

Although the early studies that demonstrated the protective effect of oral contraceptives were based on formulations containing 50 µg or more estrogen, recent case-controlled studies have demonstrated that the lower-dose formulations also provide a similar degree of risk reduction. In a case-

controlled study, Ness et al. demonstrated that ovarian cancer risk reduction was similar when on oral contraceptives independent of low-dose and high-dose formulations.²¹ Similar findings were reported in a study from Norway and Sweden consisting of 103,551 patients. Any use of oral contraceptives was associated with a decreased relative risk of 0.6 (95% CI, 0.5–0.8), and longer duration of use appeared to have an increasing protective effect.²² The obvious benefits observed with oral contraceptive use in the general population are also evident in those patients who are members of a hereditary ovarian cancer syndrome.²³

PROPHYLACTIC SURGERY

The high mortality associated with ovarian cancer has prompted physicians to recommend that patients who are at risk for developing this deadly malignancy may opt to undergo prophylactic surgery to remove the source before it can develop. This concept of removing the ovaries to prevent a potential ovarian cancer is not new, as gynecologists have been performing this for many years at the time of surgery for benign disease. It has also been used in premenopausal patients as a hormonal adjuvant treatment for metastatic breast cancer. Patients with a germline mutation in *BRCA1/2* or the MMR genes or those with a clinical diagnosis of hereditary breast-ovarian cancer (HBOC) or HNPCC syndrome are typically candidates for this procedure. In the majority of cases, prophylactic oophorectomy can be performed by laparoscopy as an outpatient procedure with an acceptable complication rate.²⁴

Because the majority of these patients have a genetic predisposition for cancer, occasionally an unrecognized ovarian cancer is found in patients undergoing prophylactic oophorectomy. Rebbeck et al. identified 6 (2.3%) stage I ovarian cancers in 259 patients with germline *BRCA* mutations at time of prophylactic oophorectomy.²⁵ There were also 2 cases of primary peritoneal cancer diagnosed 3.8 and 8.6 years, respectively, after the procedure. This result was compared to a control group of 292 patients who did not undergo prophylactic oophorectomy. After a mean follow up of 8.8 years, 58 (19.9%) women in the control group were diagnosed with ovarian cancer; thus, there was a 96% risk reduction for coelomic epithelial cancer in those patients undergoing a prophylactic oophorectomy. The risk of breast cancer was also decreased by 53% in those patients who had a prophylactic oophorectomy. Kauff et al. reported such a finding in 98 women who underwent a prophylactic bilateral salpingo-oophorectomy.²⁴ One primary peritoneal cancer was diagnosed, whereas in the control group there were 5 ovarian or primary peritoneal cancers, resulting in a risk reduction of 85%. A reduction in the risk of breast cancer by almost 70% was also reported.

Patients at high risk for ovarian cancer are likely at increased risk for carcinoma of fallopian tube cancer.²⁶ Thus, a complete bilateral salpingo-oophorectomy is warranted, with emphasis on removing as much of the tube as is technically possible. It is likely that a small interstitial portion of the tube will remain within the cornu of the uterus. Some may recommend a hysterectomy to remove this, but fallopian tube cancers tend to arise at the fimbria or in the isthmus portion and not within the interstitial portion. There have been no reports of fallopian tube cancer arising subsequent to

a prophylactic bilateral salpingo-oophorectomy. Some may contemplate a hysterectomy at the time of prophylactic oophorectomy for the prevention of endometrial cancer; however, there are no good data to support that germline *BRCA* mutations increase the risk of endometrial cancer. In contrast, patients belonging to the hereditary nonpolyposis colorectal cancer syndrome group are at significant risk of developing ovarian and endometrial cancer. Such patients should be offered prophylactic hysterectomy and bilateral salpingo-oophorectomy.

Prophylactic surgery is not 100% effective. Patients undergoing prophylactic surgery should be made aware of the risk of primary peritoneal cancer. Previous estimates of this risk after prophylactic surgery are in the range of 0.5% to 2.0%.^{24,25,27} In a retrospective review of 22 Jewish patients with primary peritoneal cancer, Levine et al. predicted the lifetime risk for *BRCA* mutation carriers to be 1.3%.²⁶

Extensive counseling before prophylactic surgery, whether bilateral salpingo-oophorectomy with or without a hysterectomy, requires a detailed discussion of the risks and benefits with the patient. The after-effects of such surgery should be addressed before the procedure because some of these patients will experience symptoms such as vaginal dryness and pain with sex, which can significantly contribute to dissatisfaction with surgery.²⁸

Screening and Early Detection

WHO SHOULD BE SCREENED?

Although the majority of patients with ovarian cancer present with advanced disease and have a poor prognosis, those patients fortunate enough to have their cancer detected when it is still limited to the ovaries have an associated 5-year survival between 80% and 90%.²⁹ Because the majority of patients are found to have ovarian cancer at an advanced stage, an effective screening program for this disease would clearly be beneficial. Unfortunately, such a program has yet to be determined. Although the average lifetime risk of developing ovarian cancer is 1 in 70, only 1 in 2,500 women will develop the disease in any given year. This low incidence necessitates that any test used for ovarian cancer screening be both highly sensitive and highly specific. To date, however, the sensitivity and specificity of available screening technologies (i.e., transvaginal ultrasound and serum CA 125) are not adequate to be used in women at average risk.³⁰

Because of the low prevalence of disease in the general population, research in screening for this disease has begun to focus on populations at increased risk. As mentioned, epidemiologic studies have identified a number of risk factors for ovarian cancer. Although both reproductive and environmental influences may modify risk to a small degree, family history of early-onset breast cancer and ovarian cancer is clearly the most important risk factor identified to date. It is believed that approximately 10% of all ovarian cancers are the result of an inherited mutation in either the *BRCA1* or *BRCA2* genes. A much smaller proportion of inherited ovarian cancer is caused by mutations in the genes associated with the hereditary nonpolyposis colon cancer (HNPCC) syndrome. These women are at significantly higher risk and are recommended to participate in ovarian cancer screening with transvaginal ultrasound and CA 125 starting no later than the

mid-thirties. Risk-reducing salpingo-oophorectomy after child bearing has also been shown to reduce the risk of subsequent breast and gynecologic cancer in *BRCA* mutation carriers and should be discussed.²⁴

EFFICACY OF SCREENING

SERUM MARKERS

Screening modalities that have drawn the most attention over the past two decades have been serum markers and radiologic imaging. Bast et al. initially reported on the CA 125 assay in 1983.³¹ CA 125 is a high molecular weight glycoprotein that is recognized by the murine OC 125 monoclonal antibody. Since that time, CA 125 has been the most extensively studied tumor marker for ovarian cancer screening.

Several large prospective studies have investigated the use of CA 125 levels as an initial test to screen for ovarian cancer. Einhorn et al. screened 5,500 healthy Swedish women at least 40 years of age with CA 125.³² One hundred seventy-five women with elevated CA 125 levels and an age-matched control group were followed with pelvic examination and sonography every 6 months and serial CA 125 levels every 3 months. Six ovarian cancers were found in the study population, 2 stage IA, 2 stage IIB, and 2 stage IIIC. In each of these 6 cases, CA 125 either doubled or reached 95 U/ml during a median follow-up of 32 months. Three women in the control group developed an ovarian cancer. CA 125 levels greater than 35 U/mL exhibited a specificity of 98.5% in women age 50 or older.

Jacobs et al. conducted a randomized control trial on 22,000 healthy postmenopausal women who were screened with CA 125.³³ Patients with a value of 30 U/mL or greater were examined with a pelvic ultrasound (transabdominal in the first year of study, then transvaginal in the subsequent enrollees), and those with an abnormal ultrasound were surgically explored. Twenty-nine patients underwent surgical exploration that identified 6 (3 stage I) ovarian cancers during the first 3 years of screening. Ten additional women developed ovarian cancer in the 8 years following their screening. Twenty women in the no-screening group developed ovarian cancer. The positive predictive value of this screening protocol was 20.7%. There was a higher percentage of early-stage ovarian cancers in the screened group (31.3% with stage I/II disease versus 10% in the nonscreened group), but this difference was not significant ($P = 0.17$). Ovarian cancer patients in the screened group did have a longer median survival than those in the control group (72 versus 42 months; $P = 0.011$), but this may be due to a lead-time bias rather than a true benefit from screening.

ULTRASOUND

Transabdominal ultrasound has been studied as a screening modality for ovarian cancer. In a prospective study, 5,479 asymptomatic women were subjected to three annual sonographic evaluations. Patients with abnormal findings were referred for surgical evaluation. An abnormal sonogram was found in 326 patients (5.9%), and 5 patients with ovarian cancer (all stage I) were identified. More than 25% of the false-positive sonograms had no ovarian pathology at exploration, and 74.3% had benign ovarian abnormalities. This screening method resulted in 51 surgical procedures for each cancer found.³⁴

In an attempt to improve on this, transvaginal ultrasound has been studied as an alternative modality. van Nagell et al. reported on 1,300 asymptomatic postmenopausal women who were screened with transvaginal ultrasound.³⁵ Ovarian abnormalities were found in 33 women (2.5%). Of these, 27 went on to have laparotomy, and 2 were found to have stage IA ovarian cancer. The same group subsequently reported on 3,220 postmenopausal women using both transvaginal ultrasound and a specific morphologic index. Morphologic index was abnormal in 44 of the women, and 3 were found to have ovarian cancer (2 stage IA and 1 stage IIIB).

The same authors undertook a more targeted approach directing screening to patients who were classified as at risk for ovarian cancer.³⁶ The group included women older than age 50 and women older than age 25 with a family history of ovarian cancer. Annual transvaginal sonogram was performed on 14,469 women. Patients with an abnormal scan had a repeat in 4 to 6 weeks, and those with a second abnormal scan had a CA 125, tumor morphology indexing, Doppler flow, and surgical evaluation. Of 180 patients who underwent surgical evaluation, 17 ovarian cancers were detected (11 stage I, 3 stage II, and 3 stage III). Among patients with normal screening sonograms, 4 were considered to have false-negative screening tests (development of ovarian cancer or peritoneal cancer within 12 months of a normal sonogram). The sensitivity for ovarian cancer was 81%, specificity was 98.9%, and the positive predictive value was 9.4%. The sensitivity for detecting stage I ovarian cancer (excluding borderline and granulosa tumors) was 31%.

SUMMARY OF SCREENING FOR OVARIAN CANCER

Although screening for ovarian cancer using CA 125 and ultrasound can detect disease in its earliest stage (Table 52.1), the low prevalence of this disease makes the positive predictive value (PPV) too low for use in the general population. CA 125 alone lacks specificity, especially in the premenopausal population, and may lack sensitivity for early-stage disease. Ultrasound screening still is considered experimental in the general population.³⁷ Combining CA 125 and ultrasound may sacrifice sensitivity and only achieves a high PPV in the postmenopausal population.

To be effective, a screening test should result in a decrease in mortality. There has yet to be a well-designed clinical study that has been able to demonstrate this. Currently, there are three large ongoing randomized trials that, it is hoped, will provide more information on the role of CA 125 and ultrasound in the screening for ovarian cancer in the general population. The Prostate, Lung, Colon, and Ovarian trial is being conducted by the National Institutes of Health and is a randomized trial of screening versus no screening for these cancers. Approximately 74,000 women over age 60 years will be randomized to CA 125 testing, ultrasound, and physical examination or to a no-screening control group. This sample size will require 16 years of follow-up to have an 80% power to detect a 30% decrease in mortality.

Two European groups are also conducting large randomized screening trials. The St. Bartholomew's group will randomize 120,000 postmenopausal women over 50 years to annual CA 125 screening or to a no-screening control group. Women with an abnormal CA 125 will have follow-up with a sonogram, which may lead to surgical evaluation. This study is designed to have an 80% power to detect a 30% reduction in mortality. Third, the European Multicentre Study group will randomize 120,000 postmenopausal women to screening with transvaginal sonography or no screening.

These large randomized studies will provide more information on the role of CA 125 and ultrasound for the screening of ovarian cancer in the general population. Until such results are available, screening in the general population remains unproven. Participation in screening clinical trials is an option for these people. For patients belonging to a hereditary ovarian cancer syndrome group who have a higher risk of developing ovarian cancer, screening with CA 125, clinical examination, and transvaginal sonography can be recommended, and eventually these patients may consider prophylactic surgery when childbearing is completed.

Primary Surgery for Ovarian Cancer

Surgery is essential for the diagnosis and treatment of ovarian cancer. Not only does it provide a pathologic diagnosis in cases of suspected ovarian cancer, it provides an opportunity

TABLE 52.2. Comprehensive staging for ovarian cancer.

Peritoneal cytology
Intact tumor removal
Complete abdominal exploration
Removal of the remaining ovary, uterus, and tubes (may be preserved in select cases)
Infracolic omentectomy
Pelvic and paraaortic lymph node sampling
Multiple biopsies from areas at risk for spread (i.e., diaphragm, paracolic gutters, pelvis)

for the cytoreduction of advanced-stage disease or the staging of apparent early-stage disease. The International Federation of Gynecology and Obstetrics (FIGO) staging system involves a comprehensive surgical staging system based on the known patterns of spread. Essential elements of this are given in Table 52.2.

Impact of “Maximal Surgical Effort” on Outcome

The term *maximal surgical effort* was first introduced for patients with ovarian cancer in 1968 by Munnell when he reported an improved survival in patients who underwent a “definitive surgery” compared to those who had “partial removal” or “biopsy only.”³⁸ Similar reports illustrating improved survival in patients who underwent surgical cytoreduction followed.³⁹

Quantification of residual disease was first described by Griffiths in 1975,⁴⁰ who reported on 102 patients with stage II or III ovarian cancer who were treated with single-agent melphalan after primary surgical cytoreduction. The patients were stratified based on the largest diameter of residual disease after primary debulking surgery. Median survival was 39 months for patients with no gross residual disease, 29 months for those with residual tumor less than 0.5 cm, 18 months for patients with 0.6 to 1.5 cm residual tumor, and 11 months for patients with residual tumor greater than 1.5 cm. Others have demonstrated the benefit of primarily cytoreductive surgery in the management of patients with ovarian cancer in retrospective series.

There have been several studies that have demonstrated that the number of residual lesions may have an effect on outcome. Gall et al. demonstrated that, in patients with less than 3 cm of residual disease, those with 1 lesion had improved survival compared to those with more than 1 lesion.⁴¹ Hoskins et al. reported on the re-review of another stage III (optimal) Gynecologic Oncology Group study and found a significant difference in progression-free interval and survival based on the number of residual lesions.⁴² Patients had an increase in relative risk for greater than 20 residual lesions.

Although diameter of residual disease may be only one of the factors that may influence prognosis, it remains the most widely used method to quantify the effects of cytoreductive surgery. Typically, the patients are reported using the terminology of “optimal” and “suboptimal”; however, the precise cutoff and the measure of outcome may vary between studies. Typically, the reported cutoffs have been between 0.5 and 3.0 cm, and currently, the Gynecologic Oncology Group (GOG) employs a cutoff of largest residual nodule 1 cm or less

as being “optimal.” Outcome measurements that have been employed include response to chemotherapy, likelihood of achieving a negative second look, and survival, but in all parameters, a clear benefit exists to patients in whom “optimal” cytoreduction is achieved.

Recently the benefits of maximal cytoreductive surgery have been illustrated in a large meta-analysis. Bristow et al. identified 53 studies on patients who predominantly had stage III or IV epithelial ovarian cancer and who underwent initial cytoreductive surgery followed by chemotherapy that included either cisplatin or carboplatin.⁴³ Maximal cytoreduction was considered to have occurred if the residual disease measured 3 cm or less in largest diameter. Ninety-five percent of studies used either 1 or 2 cm as the cutoff for defining maximum cytoreduction. There was a statistically significant positive correlation between percent maximal cytoreduction and log median survival time. Each 10% increase in maximal cytoreduction was associated with a 5.5% increase in median survival time. When survival was compared between a cohort who had 25% or less maximal cytoreductive surgery to one with greater than 75%, there was a 50% increase in median survival time in the group with the higher percent of maximum cytoreductive surgery. The authors concluded that maximal cytoreduction was one of the most powerful determinants of cohort survival among patients with stage III and IV ovarian cancer, and consistent referral of patients with suspected advanced ovarian cancer to expert centers for primary surgery may be the best means available for improving overall survival.

Value and Extent of Retroperitoneal Lymph Node Dissection

Ovarian cancer can disseminate by several proposed methods: direct extension, exfoliation of cells into the peritoneal cavity, lymphatic spread, or hematogenous dissemination. The role of retroperitoneal lymph node dissection is another topic of debate in the surgical management of ovarian cancer. Lymphatic spread to the retroperitoneal lymph nodes is believed to follow the vascular drainage of the ovary; thus, lymphatic tissue up to the level of the left renal vein is at risk for disease spread.

The diagnostic value of retroperitoneal node dissection cannot be questioned in apparent clinical stage I disease. Because adjuvant chemotherapy is prescribed in all but the earliest cases of ovarian cancer, determining node status is imperative for the management of early-stage disease. In patients with clinically apparent early-stage disease, approximately 10% will have pathologic evidence of nodal metastasis.⁴⁴

Patients with advanced-stage (III and IV) disease require chemotherapy as part of their management, and lymph node dissection has a lesser impact on management plan. The therapeutic benefits of systemic lymph node dissection are not clear. Burghardt et al. retrospectively reviewed the 5-year actuarial survival rate for stage III ovarian cancer patients who had and had not undergone pelvic lymphadenectomy.⁴⁵ The patients who had undergone lymphadenectomy had a 5-year actuarial survival rate of 53% compared to 13% in those patients who did not. Obviously, the no-lymphadenectomy group may well have been more advanced, based on selection bias.

In a comparative study of stage IIIc–IV optimally (gross residual disease less than 2 cm) cytoreduced patients with epithelial ovarian cancer, Scarabelli et al. demonstrated that systemic pelvic and paraaortic lymphadenectomy significantly improved survival in previously untreated patients.⁴⁶ With a median follow up of 26 months (range, 9–60), the estimated 4-year survival for patients who had undergone lymphadenectomy was 22% compared to those who had not, 0% (P less than 0.001). Twenty-three of the 30 patients (76.6%) who had undergone a systematic lymphadenectomy had positive pelvic and/or paraaortic nodes. There was a significant difference in survival based on nodal status, with an estimated 2-year survival of 46% for the node-positive patients compared to 100% in the node-negative patients. As in untreated patients who were optimally reduced at primary surgery, a similar survival benefit has also been shown in untreated patients with advanced-stage ovarian cancer who underwent complete resection of disease in the peritoneal cavity and who undergo systemic pelvic and paraaortic lymphadenectomy. The use of systematic lymphadenectomy does not affect survival if patients are left with suboptimally debulked disease.⁴⁷

In an attempt to better define the impact of aortic and pelvic lymphadenectomy in patients with advanced-stage ovarian cancer, Spirtos et al. conducted a prospective study of 77 consecutive patients with advanced-stage epithelial ovarian cancer who were undergoing exploratory laparotomy.⁴⁸ Complete pelvic and paraaortic lymphadenectomy was attempted whenever maximal cytoreduction was obtained to residual tumor nodules less than 1 cm. Fifty-six of the 77 patients (73%) enrolled underwent systematic lymphadenectomy. Twenty-one patients (27%) did not undergo the procedure because it would not have impacted the cytoreductive status or because intraoperative conditions precluded it. Positive lymph nodes were found in 36 of the 56 (64%) patients who had a lymphadenectomy, and of these 23 (64%) were macroscopically positive. With a median follow-up of 30 months, 10 of 20 (50%) of patients with negative lymph nodes, 6 of 13 (46%) with microscopically positive lymph nodes, 10 of 23 (43%) with resected macroscopically positive nodes, and 2 of 21 (10%) with residual disease at least 1 cm in diameter were alive without evidence of disease. The authors concluded that lymphadenectomy offers little benefit if the nodes are macroscopically negative. However, removal of macroscopically positive nodes was advocated because survival in this group was similar to that of patients with microscopically positive nodes.

Although it appears that systematic pelvic and paraaortic lymphadenectomy may have a role in the primary surgical management of advanced ovarian cancer if patients can be maximally cytoreduced, one explanation may be that a portion of patients who have undergone maximal cytoreduction may have macroscopically enlarged nodal disease greater than 1 cm, 14.3% of patients in one prospective series.⁴⁹ The results of an internationally randomized trial to evaluate the role of systematic lymphadenectomy versus resection of any bulky nodes in optimally debulked patients may provide more information to help formulate surgical algorithms.

Role of Neoadjuvant Therapy

The traditional sequence of management for ovarian cancer is composed of initial surgery followed by chemotherapy.

This sequence seems to be the optimal approach in most women because it provides an opportunity to confirm a suspected diagnosis of ovarian cancer, remove large tumor masses that may have poor blood supply, and theoretically increase the chemosensitivity of remaining tumor nodules by causing a greater number of tumor cells to enter the dividing phase.

However, the traditional approach of surgery followed by adjuvant chemotherapy may not be the best sequence to treat all patients who present with advanced ovarian cancer. In particular, patients who are too ill to tolerate a large debulking procedure or patients with tumor that cannot be reduced to remaining disease with a greatest diameter less than 2 cm may be better served by receiving chemotherapy first. This approach has the advantage of avoiding aggressive surgery in patients with chemoresistant disease.

Neoadjuvant chemotherapy, which is given to patients with advanced ovarian cancer before cytoreductive surgery, has several theoretical advantages over primary cytoreduction: (1) improvement of performance status, especially in elderly patients and those with pleural effusions and ascites; (2) decrease in the extent and morbidity of surgery by reducing tumor volume preoperatively; and (3) increase in the percentage of patients undergoing optimal cytoreduction.

Several retrospective studies have evaluated this approach in the management of advanced ovarian cancer. Vergote et al. reported on 285 patients with advanced ovarian cancer treated between 1980 and 1997.⁵⁰ Between 1980 and 1988, all patients underwent primary debulking surgery. Between 1989 and 1997, patients were surgically evaluated to determine if they should receive chemotherapy first (43%) or cytoreductive surgery (57%). Crude 3-year survival when the neoadjuvant approach was applied in the latter part of the study was 42%, compared to 26% during the early time period when all patients underwent primary debulking surgery.

Ansquer et al. reported the French multicenter experience with neoadjuvant chemotherapy for ovarian cancer deemed unresectable by either laparoscopy (61%) or laparotomy (39%).⁵¹ Patients received a median of four cycles of chemotherapy preoperatively. Eighty percent responded to chemotherapy and underwent subsequent debulking, which was optimal in 91% of patients. The authors concluded that neoadjuvant chemotherapy in unresectable ovarian cancer led to a selection of chemosensitive patients who could subsequently undergo optimal cytoreduction in the majority of cases. In addition, aggressive cytoreduction was avoided in patients with initial chemoresistance. The absence of any prospective evaluation of the neoadjuvant approach make its routine application inappropriate at this time.

A concept that has been combined with neoadjuvant chemotherapy is interval cytoreduction. In spite of the fact that employing more-aggressive surgical procedures can increase the "optimal" debulking rate, a portion of patients will undoubtedly be left with "suboptimal" residual disease. Because these patients have a substantially worse prognosis than those who are optimally cytoreduced, some have evaluated the benefit of a brief course of chemotherapy followed by a second attempt at cytoreduction ("interval cytoreduction") before completing a prescribed chemotherapy regimen. Lawton and coworkers attempted cytoreduction of 28 patients after three cycles of platinum-based chemotherapy and were successful in debulking 25 patients to residual

disease of less than 2 cm.⁵² Ng and associates described 38 patients who underwent interval cytoreduction after two intensive courses of platinum-based chemotherapy and reported that 30 of these patients could be cytoreduced to less than 1 cm of residual disease.⁵³ Thus, it appears that interval cytoreduction can be quite successful in allowing patients a second opportunity for optimal cytoreduction. The effect of this interval cytoreduction on long-term prognosis, however, is less clear. Neijt and coauthors did not find the survival rate of a small group of patients who underwent interval cytoreduction to be as high as that of those who underwent successful cytoreduction at the initial operation.⁵⁴

Although it appears feasible to improve the percentage of patients who can be reduced to optimal disease by presurgical treatment with chemotherapy, existing data are insufficient to determine whether this approach results in improved median survival. Comparison to patients who were cytoreduced initially may bias this because of the potential "favorable biology" of those who could be cytoreduced initially. A true comparison would be with those patients who could not be cytoreduced and not undergo interval cytoreduction.

The use of interval debulking for ovarian cancer has been studied in a large prospective randomized fashion by the European Organization for the Research and Treatment of Cancer (EORTC).⁵⁵ Patients with FIGO IIb-IV ovarian cancer who had been suboptimally debulked were included in this study. Four hundred twenty-five patients were initially treated with three courses of chemotherapy consisting of cisplatin and cyclophosphamide after which they were randomized to undergo either an interval laparotomy followed by another three courses of chemotherapy or another three courses of chemotherapy alone. One hundred six women were not eligible for randomization because of progression of disease, uncompleted chemotherapy, contraindication to surgery, or other reasons. Patients undergoing interval surgery had a significantly improved 2-year overall survival and progression-free survival compared to those patients treated with chemotherapy alone: 56% versus 46% and 38% versus 26%, respectively. Median survival in the interval laparotomy group was 26 months compared to 20 months in the control group.

The Gynecologic Oncology Group (GOG) undertook a similar study to evaluate the role of interval cytoreduction on progression-free and overall survival in patients with suboptimally debulked ovarian cancer. Patients who had suboptimal disease after initial therapy were clinically reassessed. Those who were responding or those with stable disease were randomized to interval cytoreduction or no surgery. All patients received an additional three courses of chemotherapy. Median overall survival and progression-free survival were not significantly different between those who underwent interval cytoreduction and the control group: 32 months versus 33 months and 10.5 months versus 10.8 months, respectively. Based on these results, the authors concluded that interval secondary cytoreductive surgery is not beneficial in regard to overall survival and progression-free survival for patients with advanced-stage suboptimal disease who had previously undergone maximal primary cytoreductive surgery. An explanation for the conflicting results of these two large randomized trials may rest in the extent of initial suboptimal surgery in that all patients in the GOG trial were initially operated on by surgeons specifically trained in

ovarian cancer surgery whereas the surgical expertise level in the EORTC trial was not as consistent. Based on these findings, interval cytoreduction does not appear to have a role in patients who have undergone an aggressive initial attempt at cytoreduction by a gynecologic oncologist and are left with suboptimal disease. Neoadjuvant chemotherapy with interval cytoreduction may have a role in patients who, at initial diagnosis, are truly deemed unresectable via CT scan or laparoscopy or those who are initially felt to be medically unfit to undergo surgery.

Impact of Spillage in Stage IC Disease

Several controversial issues surround the surgical staging of early-stage disease. The significance of intraoperative rupture in cases with disease otherwise confined to the ovaries is a situation that has attracted much attention. Dembo et al. examined the prognostic factors in stage I epithelial ovarian cancer (EOC).⁵⁶ This study was a two-part study in which data from 252 Canadian patients were used to generate a hypothesis and the result was applied to a separate group of 267 Norwegian patients. The presence of tumor rupture was not a poor prognostic factor in the relapse-free rate. Ahmed et al. reported on a series of 194 patients with stage I epithelial ovarian cancer who were entered into a trial of observation only after surgery.⁵⁷ Patients who had rupture at time of surgery did not have a significantly worse survival. Similar conclusions were reached by Sevelde et al., who performed a case-controlled analytical study on 60 patients who had tumor confined to one or both ovaries.⁵⁸ Half the patients had their tumors removed intact and the others had intraoperative rupture. All patients underwent a staging procedure consisting of bilateral salpingo-oophorectomy, hysterectomy, omentectomy, and pelvic lymphadenectomy. All patients except 10 received whole abdominal radiation therapy. Tumors were of significantly higher grade and there were more bilateral tumors in the group who had intraoperative rupture. On multivariate analysis, tumor grade, stage, and intraoperative rupture did not have a prognostic influence on 5-year survival. The authors concluded that prognosis of patients with stage I tumors does not depend on intraoperative rupture. Other studies examining the effect of intraoperative rupture on recurrence-free survival in untreated patients have also demonstrated similar findings.⁵⁹

Intraoperative rupture has been reported to be a poor prognostic factor in other series. In a large retrospective study of 1,545 patients with FIGO stage I invasive epithelial ovarian cancers from the Netherlands, Vergote et al. correlated disease-free survival with various clinical and pathologic variables.⁶⁰ All patients underwent laparotomy, hysterectomy, bilateral salpingo-oophorectomy, and infracolic omentectomy. Peritoneal washings, diaphragmatic scrapings, and retroperitoneal lymphadenectomy were not routinely done. Tumor rupture and timing of such was recorded. On multivariate analysis, degree of differentiation (moderate and poor), preoperative and intraoperative rupture, and age at diagnosis were predictive of recurrence.

The issue of intraoperative rupture remains controversial. However, capsular rupture whether preoperative or intraoperative does result in upstaging according to FIGO criteria, and adjuvant treatment should be prescribed accordingly.

Second-Look Surgery

Second-look surgery was first introduced as a diagnostic and therapeutic intervention for patients with gastrointestinal malignancies. In the management of ovarian cancer, it can be defined as a comprehensive surgical exploration in an asymptomatic patient who has completed initial surgery and a planned program of chemotherapy. After initial surgery, patients may not have measurable disease; thus, second-look surgery was initially used as a means of determining when a patient's chemotherapy could be discontinued.⁶¹ The procedure was widely used in the 1970s and 1980s, but its enthusiasm has waned, and it remains a topic of controversy.

Second-look surgery has been evaluated in patients with early-stage disease. Reporting the Ovarian Cancer Study Group and the GOG patients, Walton et al. reported on 112 patients with FIGO stage I or II ovarian carcinomas who underwent second-look surgery after completion of adjuvant therapy.⁶² Of the 95 patients who were asymptomatic at 18 months, only 5% had positive findings, compared to the 17 patients who were symptomatic (bowel obstruction, abdominal or pelvic complaints, weight loss, or other symptoms suspicious for recurrent disease). Of these patients, 53% had disease at second-look surgery.

In a smaller series, Rubin et al. reported on 54 stage I patients who underwent second-look surgery following complete surgical staging and adjuvant chemotherapy.⁶³ They found, as did Walton et al., that only 5.5% of patients had disease. None of the patients with grade 1 tumors had disease. Tumor grade was a significant predictor of recurrence following a negative second look, with grade 1 and 2 having a 0% risk of recurrence compared to 52% in the grade 3 tumors. Substage, histologic type, and chemotherapy type or duration did not predict recurrence. Given the small positive yield of second-look surgery in early-stage patients who have been initially comprehensively staged, it is not routinely recommended.

In patients with advanced ovarian cancer, the issues of second-look surgery are not as clearly defined. Surgical evaluation remains the most accurate method to date of evaluating patients with small-volume disease. In a prospective study of patients with ovarian cancer, Meier et al. demonstrated a 50% false-negative rate when correlating CA 125 levels with surgical findings.⁶⁴ Of those patients with stage III/IV disease and found to be disease free at second-look surgery, more than half have a recurrence of their disease with continued follow-up.⁶⁵ This finding brings the utility of second look into question. Experience from a large GOG randomized trial illustrates these issues. In a comparison of progression-free survival and overall survival in patients from GOG Protocol 158, Ozols and Greer compared 393 subjects preselected to undergo second look to 399 patients who did not. Second-line chemotherapy was not standardized in the study.⁶⁶ Two hundred ninety-four (75%) of the second-look group went on to have the procedure. The adjusted relative risk was 0.88 (95% CI, 0.73, 1.06), and the difference in median progression free survival was 2.1 months for the second-look group (25.0 versus 22.9 months). There was no difference in survival between the groups, and they concluded second-look surgery combined with various second-line therapies improved progression-free survival or overall survival in primarily positive patients.

Although a true benefit to second-look surgery alone has yet to be proven, the procedure does allow an opportunity for secondary cytoreduction if feasible. Several retrospective series have shown a benefit to secondary cytoreduction at time of second look. In a retrospective review of 150 patients with ovarian cancer from the Mayo Clinic who underwent second-look surgery, Dowdy et al. demonstrated that patients with macroscopic disease of 1 cm or more and who were able to be cytoreduced to microscopic disease had a better survival compared to those subjects who had residual macroscopic disease and those with disease of 1 cm or more who were secondarily cytoreduced to microscopic disease.⁶⁷ Other studies in the literature have also demonstrated such a benefit.^{68,69}

Second-look surgery does not appear to have a role in the management of patients with early-stage ovarian cancers. Its role in patients with advanced-stage disease still is controversial, although it can be justified in the clinical trial setting when response to therapy must be accurately determined. Certain situations such as placement of an intraperitoneal catheter may justify its routine use in patients with advanced-stage disease. If gross residual disease is found, strong consideration should be given to secondary cytoreduction if microscopic residual can be obtained.

Primary Chemotherapy for Ovarian Cancer

In the clinical management of ovarian cancer, management has traditionally been divided into low-stage (FIGO stage I and stage 2) cancer and advanced disease, based on the results of surgical staging. The clinical outcome for low-stage cancers is far superior to that of more-advanced disease. The clinical trials and analyses are routinely divided into these two groups, which allows the most clear-cut evaluation of the clinical data.

Low-Stage Disease

ADJUVANT TREATMENT FOR STAGE 1 AND STAGE 2 EPITHELIAL OVARIAN CANCER

The benefit of immediate adjuvant therapy for low-stage ovarian cancer is a key question when surgical therapy alone can lead to a long-term disease-free survival in excess of 80%. In the early 1980s, the Gynecologic Oncology Group conducted a pair of randomized adjuvant therapy trials for comprehensively staged patients with stage I tumors.⁷⁰ In the first, eligible patients had FIGO stage IA or IB tumors that were of well- or moderately differentiated grade. Patients either were observed or treated with adjuvant melphalan. After a median follow-up of more than 6 years, there was no significant difference between the two groups. The 5-year disease-free survival was 91% versus 98% ($P = 0.041$) and the overall survival was 94% versus 98% ($P = 0.43$) in the observation and melphalan group, respectively. Three (38%) of 8 patients who had clear cell histology relapsed as compared to only 2 (3%) of 63 patients with other histologic types. This finding led the authors to define a low-risk group that included patients with disease confined to one or both ovaries, intact capsule, no adhesions or extracystic tumor, no ascites, negative peritoneal washings, and well- or moderately differentiated histology. A prospective, observational study of 194 patients

DFS, disease-free survival.

^aMajority of patients are stage I/II.

[‡]No difference in disease-free survival for optimally staged patients.

with stage I disease reported similar survivals from stage 1A and 1B disease.⁷¹ It appears that well-staged patients with disease limited to the ovaries and who have well-differentiated tumors have high enough survival rates that they do not derive benefit from adjuvant therapy. The recommendation for patients with stage IA or IB, grade 2 disease still remains controversial, with some recommending adjuvant therapy while others do not. The importance of comprehensive staging before withholding adjuvant therapy cannot be stressed enough, given that as many as 31% of patients will have subclinical metastasis, which should be treated.⁷⁰

In contrast to the low-risk patients, patients with grade 3 cancers, stage 1C disease or stage 2 disease, are generally considered to be at high risk, and adjuvant treatment is more likely to be beneficial. Chemotherapy use as adjuvant treatment has also been studied in prospective fashion (Table 52.3). The Italian collaborative group, Gruppo Interregionale Collaborativo in Ginecologia Oncologica (GICOOG), conducted two simultaneous randomized trials.⁷² The first trial included patients with stage IA and IB, grade 2 and 3 tumors who were randomized to adjuvant therapy with cisplatin (50 mg/m² every 28 days for six cycles) or no further treatment. The second trial randomized stage IC patients of any grade to cisplatin (50 mg/m² every 28 days for six cycles) or intraperitoneal phosphorus-32 (³²P) (15 mCi). With a median follow-up of 76 months, the 5-year disease-free survival was 83% (cisplatin) compared to 65% (no treatment) in the first trial ($P = 0.09$) and 85% (cisplatin) compared to 65% (³²P arm) in the second trial ($P = 0.008$). In both trials, the difference was primarily due to a reduction of relapses in the pelvis only. In neither of the two trials was there a significant difference in 5-year overall survival due to the initiation of platinum-based chemotherapy at time of relapse for the no-treatment group. The authors also suggested the lack of difference in overall survival may be due to the limited impact of adjuvant therapy, low doses at which the cisplatin was administered, impact of salvage therapy, or that the study was underpowered. Trope et al. reported on their randomized study of adjuvant chemotherapy in stage I high-risk ovarian cancers.⁷³ They defined high risk as FIGO grade 1 aneuploid, grade 2 or 3, or clear cell carcinomas. One hundred sixty-two patients were randomized to receive either adjuvant carboplatin [area under the curve (AUC) 7] every 28 days for six courses or no

adjuvant treatment. With a median follow-up of 46 months, estimated 5-year disease-free survivals were similar, at 70% and 71% in the treatment group and control group, respectively. Five-year disease-specific survival was 86% and 85% in the treatment and control groups, respectively. The authors believed the results were inconclusive because of the small size of the study.

More recently, the results of two large prospective randomized European trials of chemotherapy treatment have been published. These trials attempted to address the issue of adjuvant chemotherapy use in high-risk early-stage ovarian cancer. Unfortunately, the patient populations from these studies were flawed by an absence of consistent, comprehensive staging. In an EORTC trial, patients were accrued from 40 centers in nine European countries. Eligibility criteria for this trial included patients with FIGO stage IA–IB (grade 2 or 3)–IIA tumors or patients with stage I–IIA clear cell carcinomas who underwent surgical treatment that consisted of total abdominal hysterectomy and bilateral salpingo-oophorectomy in most cases, in addition to surgical staging. The surgical staging consisted of at least careful inspection of the peritoneal surfaces, with biopsy of any suspicious lesion. Surgical staging had four classifications ranging from optimal, if a comprehensive staging procedure as previously described was performed, to inadequate, if peritoneal surfaces were carefully inspected. Four hundred forty-eight patients were randomized to receive either adjuvant platinum-based chemotherapy or observation, with the endpoints being overall survival and recurrence-free survival. The overall survival was similar comparing adjuvant therapy to observation with a hazard ratio of 1.45 (CI, 0.93–2.27; $P = 0.10$). The recurrence-free survival was improved in the patients who had adjuvant therapy, with a hazard ratio of 1.59 (CI, 1.09–2.31; $P = 0.02$). Because comprehensive staging was not mandated, only approximately one-third of patients qualified as being optimally staged. When the patients were analyzed based on thoroughness of staging, the patients who were not optimally staged had improved disease-free and overall survival rates if treated with adjuvant chemotherapy; however, no difference was identified among the optimally staged patients, a much smaller group. The authors concluded that adjuvant chemotherapy was associated with improved recurrence-free survival. However, the benefits of chemotherapy appear limited

to those patients who do not undergo optimal staging and thus are at risk for having subclinical disease.

Over a similar time period, the International Collaborative Ovarian Neoplasm Collaborators group conducted their own adjuvant chemotherapy trial for early-stage ovarian cancer (ICON 1).^{74,75} The eligibility criteria were even less stringent in that entry into the trial was based on the clinician's judgment, which probably resulted in some occult advanced stage patients being included in the trial. If the clinician was uncertain if the patient required adjuvant chemotherapy, the patient was eligible for the ICON 1 trial, so long as she had all visible disease removed. Hysterectomy, bilateral salpingo-oophorectomy, and omentectomy were the minimum surgical requirements. Patients were randomized to a platinum-containing regimen or observation. With a median follow-up of 51 months, the 5-year overall survival was 79% in the adjuvant therapy group, which was significantly better than the 70% in the observation arm. The disease-free survival was also significantly better in the adjuvant treatment arm (73% versus 62%). The authors concluded that platinum-based adjuvant therapy improves survival and delays recurrence in patients with early-stage epithelial ovarian cancer.

In a preplanned combined analysis of the ACTION and ICON1 trials, the authors published the results of all 925 patients. With a median follow-up of more than 4 years, 5-year overall survival was 82% in the chemotherapy arm and 74% in the observation arm ($P = 0.008$). Five-year recurrence-free survival was also improved in the chemotherapy arm compared to the observation arm (76% versus 65%, respectively; $P = 0.001$). However, because the majority of patients in this joint study were not optimally staged, the argument still remains as to whether the presence of unappreciated residual disease could account for the apparent beneficial effect of adjuvant chemotherapy in this joint analysis. Although platinum-based adjuvant therapy appears to have a role in the incompletely staged population, its role in the comprehensively staged, early-stage patient remains unanswered by this trial.⁷⁶

The drugs to be used in this setting have never been directly tested. In advanced disease, platinum-based therapy has been shown to be superior to nonplatinum therapy and combination therapy is superior to single-agent treatment.⁷⁷ That information has been extrapolated to low-stage disease, and all recent trials employ platinum-based therapy. The American approach, dictated by the Gynecologic Oncology Group (GOG), is to employ paclitaxel and carboplatin in the chemotherapy approach, although the contribution of paclitaxel in this setting has not been established. The issue of duration of adjuvant therapy has been addressed. The GOG recently reported the results of its randomized trial of adjuvant treatment for poor prognosis, early-stage ovarian cancer. The objective of this study was to determine if adding an additional three cycles of chemotherapy would significantly lower the rate of cancer recurrence. They compared adjuvant therapy with six cycles of paclitaxel (175 mg/m² over 3 hours) and carboplatin (7.5 AUC over 30 minutes) to the standard arm of three cycles of the same.⁷⁸ All patients were required to have undergone a comprehensive staging laparotomy including retroperitoneal lymph node sampling, and of the 457 accrued patients, 107 were deemed ineligible due to incomplete surgical staging. Of the 321 eligible patients, 241

(75%) were alive without recurrence with a median follow-up of 4.5 years. The risk of recurrence was 33% lower (27% in the three-cycle arm versus 19% in the six-cycle arm); however, this number did not reach statistical significance. When the analysis was performed to include incompletely staged patients, the recurrence rate was 24% less on the six-cycle regimen, which was not statistically significant. Toxicity was significantly greater in the six-cycle arm. The authors concluded that the additional three cycles of carboplatin and paclitaxel did not significantly improve the rate of recurrence in these early-stage patients but that it did result in more toxicity.

VALUE OF RADIATION-BASED THERAPY

Two types of radiation have been studied as adjuvant therapy for early-stage disease. Both external-beam radiation and intraperitoneal radiation have been evaluated, but some of the studies have included patients with advanced-stage disease who have been optimally debulked, and this must be kept in mind when interpreting these studies.

Because ovarian cancer tends to disseminate throughout the entire peritoneal cavity, adjuvant external-beam radiation therapy should be directed to encompass both the abdomen and pelvis. There have been two prospective randomized trials comparing the role of pelvic radiation to observation. A GOG study randomized 168 stage I patients between observation, pelvic radiation, and melphalan.⁷⁹ Of the entire group, only 86 were eligible for analysis; thus, the treatment arms were not equally matched for prognostic variables. Neither pelvic radiation nor melphalan reduced the recurrence rates when compared to observation. Similar results were found by Dembo et al., who randomized 41 stage IA patients to pelvic radiation therapy or observation. There were four relapses in the radiation arm and one in the observation arm.⁸⁰ They concluded that there was no benefit in survival or prevention of relapse from pelvic radiation because the entire peritoneal cavity was at risk for failure.

The lack of effective control with pelvic radiation therapy led to studies using whole abdominal radiation (WAR). Several randomized trials comparing WAR to chemotherapy as adjuvant treatment for early-stage ovarian cancer have been reported in the literature (Table 52.4). Of these, only one demonstrated a significant benefit.

Dembo et al. reported their experience with 147 patients with stage I–III ovarian cancer. Patients were treated with either abdominopelvic radiation or pelvic radiation with or without chlorambucil.⁸⁰ The benefit was seen only in patients with less than 2 cm or no residual disease, whose 10-year survival was 64% compared to 40% in the pelvic radiation group ($P = 0.0007$). Patients with residual disease greater than 2 cm did not show any benefit. In a randomized trial of WAR (2,600–2,800 cGy) with a 2,000-cGy pelvic boost versus melphalan (12 cycles of 0.2 mg/kg/day for 5 days), Smith et al. reported a 2-year disease-free survival of 85% versus 90% in the stage I patients treated with WAR and chemotherapy, respectively.⁸¹ For stage II patients, disease-free survival was 55% and 58%, respectively. No statistical significance information was reported in the study. Klaassen et al. evaluated 257 patients with ovarian cancers ranging from stage I to III optimally debulked patients who were randomized to intraperitoneal ³²P (10–15 mCi), melphalan (8 mg/m²/day for 4

days every 4 weeks for 18 cycles), or WAR (2,250cGy over 20 fractions using moving strip technique).⁸² Comprehensive staging was not mandatory. All patients were initially treated with pelvic radiation (2,250cGy before WAR or 4,500cGy before melphalan or ³²P). With a median follow-up of 8 years, 5-year disease-free survivals were similar at 66%, 61%, and 62% for the three arms, respectively, but the authors also noted that protocol violations in the whole abdominal target volume were associated with reduced survival.

Although earlier randomized trials have compared WAR to nonplatinum-based forms of chemotherapy, the Northwest Oncologic Cooperative Group of Italy attempted to compare WAR (4,330cGy/24 fractions of pelvic radiation plus 3,020cGy to the upper abdomen) to six cycles of adjuvant cisplatin (50mg/m²) and cytosin (600mg/m²) chemotherapy in patients with stage I and II disease.⁸³ The study was closed early due to poor protocol compliance and low accrual. With a median follow-up of 60 months, 5-year survival was 71% and 53% ($P = 0.16$), and relapse-free survival was 74% and 50% ($P = 0.07$) for the chemotherapy and WAR arms, respectively. When the data were analyzed according to treatment received rather than treatment assigned, no significant difference could be detected in relapse-free survival (73% versus 60%) or overall survival (73% versus 68%) for patients receiving chemotherapy and WAR, respectively.

The role of external-beam radiation as adjuvant therapy for the treatment of early-stage ovarian cancer remains unclear. It is apparent that adjuvant radiation therapy should encompass the entire abdomen because these patients are at risk for relapse in the entire peritoneal cavity. Although the older studies have seemed to demonstrate that WAR may be as effective as chemotherapy, these results have yet to be adequately demonstrated in patients with early-stage disease who have been treated with modern chemotherapy. The evolution of modern-day chemotherapy for ovarian cancer may make further efforts to study adjuvant radiation therapy difficult.

INTRAPERITONEAL RADIOACTIVE ISOTOPES

Radioactive isotopes have been used as adjuvant therapy for the treatment of early-stage ovarian cancer. The isotope most

commonly used has been ³²P. It is an emitter of beta radiation only, which avoids the toxicity associated with gamma radiation. It has a half-life of 14.3 days and an average tissue penetration of 1.4–3.0mm. After it is instilled into the abdomen, the patient is placed in several positions to assure adequate distribution throughout the peritoneal cavity. As one might suspect, distribution of the radioactive colloid may be a potential problem. The intraperitoneal distribution can be tested before ³²P instillation with radioactive technetium sulfur colloid or after radiocolloid instillation with scintigraphic imaging of Bremsstrahlung photons.

Distribution patterns of intraperitoneal ³²P have been studied by Vergote et al.⁸⁴ They used a gamma camera to detect Bremsstrahlung photons in 297 patients. Images were obtained 2 to 24 hours and 3 to 7 days following administration of P32. They demonstrated that there was an uneven distribution in 165 patients, loculation in 2%, leakage in 3%, and uptake in the thoracic lymph nodes in 54%. There was uneven accumulation of isotope in the pelvis (60%) and right flank (33%). Forty-six percent of patients were noted to initially have even distribution but later were found to have major accumulation at 3 to 7 days. No relationship was noted between uneven distribution, loculation, or leakage of ³²P and relapse or bowel obstruction.

Several studies have compared the use of intraperitoneal ³²P as adjuvant treatment for early-stage disease (Table 52.5). As previously mentioned, the National Cancer Institute of Canada examined the use of intraperitoneal ³²P compared to whole abdominal radiation and melphalan in patients with high-risk stage I-II disease or optimally debulked stage III disease.⁸³ Comprehensive staging was not mandatory, and with a median follow-up of 8 years, 5-year survival was similar. The authors noted a high incidence of bowel complications in the ³²P and pelvic radiation arm, and this trial was closed prematurely.

The GOG studied adjuvant treatment use in 141 patients with stage I poorly differentiated or stage II tumors.⁷⁰ Patients were randomly assigned to treatment with either melphalan (0.2mg/kg/day) for 5 days every 4 to 6 weeks for 12 cycles or one dose (15mCi) of intraperitoneal ³²P at time of surgery. With a median follow-up of greater than 6 years, the disease-

free survival was 80% in both arms, and the overall survival was 81% and 78% with melphalan and ^{32}P , respectively ($P = 0.48$). Twenty-four of the patients were reclassified as borderline tumors but were evenly distributed among the two groups. Excluding these patients reduced the 5-year survival to 76%. When comparing the two treatment regimens, the GOG decide to label ^{32}P as the standard, given its lower cost, ease of administration, and lack of leukemia risk.

The GOG subsequently compared adjuvant ^{32}P to three cycles of cyclophosphamide and cisplatin in patients with stage IC and II with no macroscopic residual disease and stage IA and stage IB poorly differentiated tumors.⁷⁹ There were 205 patients randomized, and median follow-up was 6 years. The 5-year recurrence-free survival was 77% for the chemotherapy arm and 66% for the ^{32}P arm. After adjusting for stage and histologic grade, the estimated recurrence rate was 31% lower for the chemotherapy arm; however, this was not statistically significant ($P = 0.075$). Overall 5-year survival was 84% for the chemotherapy arm and 76% for the ^{32}P arm. Although there was no significant difference between the two arms, the better progression-free interval with the cyclophosphamide and cisplatin and the associated problems with ^{32}P distribution and bowel toxicities made platinum-based combinations the standard adjuvant therapy for patients with early-stage, high-risk ovarian cancer.

Vergote et al. reported their experience with 347 patients with stage I–III epithelial ovarian cancer without residual disease.⁸⁴ Comprehensive staging was not required in this series. Patients were randomized to receive intraperitoneal ^{32}P (7–10 mCi) or six cycles of cisplatin (50 mg/m²). Patients randomized to the ^{32}P arm and who were found to have intraperitoneal adhesions were treated with WAR. With a median follow-up of 62 months, the estimated 5-year rates of crude survival and disease-free survival were similar. In the ^{32}P arm, these were 83% and 81%, respectively, compared to the cisplatin arm, 81% and 75%. Bowel obstruction occurred with a significantly higher frequency in the ^{32}P or WAR groups compared to the cisplatin group. The authors recommended that cisplatin be used for adjuvant therapy in future studies.

The Italian collaborative group, Gruppo Interregionale Collaborativo in Ginecologia Oncologica (GICO), simultaneously reported on two randomized trials for adjuvant therapy for early-stage ovarian cancer.⁷² In these trials, patients underwent surgical staging without routine nodal

assessment, which was done by presurgical lymphangiogram or optional surgical biopsy. The first trial included patients with stage IA and IB, grade 2 and 3 tumors, who were randomized to adjuvant therapy with cisplatin (50 mg/m² every 28 days for six cycles) or no further treatment. The second of the trials randomized stage IC patients of any grade to cisplatin (50 mg/m² every 28 days for six cycles) or intraperitoneal ^{32}P (15 mCi). With a median follow-up of 76 months, the 5-year disease-free survival was 83% (cisplatin) versus 65% (no treatment) ($P = 0.09$) in the first trial and 85% (cisplatin) compared to 65% (^{32}P arm) ($P = 0.008$) in the second trial. In both trials the difference was primarily due to a reduction of relapses in the pelvis only. In neither of the two trials was there a significant difference in 5-year overall survival, which the authors suggested may result from the limited impact of adjuvant therapy, low doses at which the cisplatin was administered, impact of salvage therapy, or that the study was underpowered.

In summary, the literature on treatment of low-stage ovarian cancer is limited by poor staging and low frequency of relapse. Randomized data suggest that low-risk patients (stage 1A, 1B with grade 1 and grade 2 histology) have an excellent prognosis and cannot be shown to benefit from adjuvant therapy. Although the randomized trial results are discordant, meta-analysis and the largest clinical trials agree that platinum-based chemotherapy appears to decrease recurrence and increase survival in high-risk patients.⁸⁵ The duration of platinum-based therapy is still uncertain, although the benefit at least three cycles is not in dispute. The contribution of paclitaxel in this setting is unknown. Randomized trials suggest that radiation therapy is probably similar to chemotherapy in survival benefit.

Primary Chemotherapy for Advanced-Stage (IIc–IV) Disease

PLATINUM-BASED THERAPY

The evolution of chemotherapy for advanced ovarian cancer began with single alkylating agents and evolved into combination therapy by the early 1980s. Cyclophosphamide, doxorubicin, altretamine, and 5-fluorouracil were all employed with limited success. This evolution culminated with the widespread implementation of platinum complex (cisplatin)-

TABLE 52.6. Platinum-based primary therapy of advanced-stage ovarian cancer: selected studies.

based treatment by the end of that decade. That question has been definitively resolved with level 1 evidence and is not revisited here. The interested reader is referred to comprehensive meta-analyses for discussion of this point.^{77,86} However, the question of which platinum complex is best has been more recently resolved (Table 52.6). In a series of comparison, either alone or in combination with cyclophosphamide and doxorubicin, carboplatin has been consistently equivalent to cisplatin treatment.⁸⁷⁻⁸⁹ More recently, two large studies of cisplatin/paclitaxel versus carboplatin/paclitaxel have been reported.^{66,90} As was seen in cyclophosphamide combinations a decade earlier, there is not a statistically significant difference between the two paclitaxel-containing regimens. Equivalence between carboplatin and cisplatin has also been confirmed in meta-analysis.⁷⁷ Because carboplatin is generally better tolerated with substantially less toxicity, the current treatment depends on carboplatin therapy. The value of oxaliplatin in ovarian cancer treatment is uncertain. Cyclophosphamide and oxaliplatin were compared to cisplatin and cyclophosphamide in a small randomized trial with similar efficacy in previously treated patients.⁹¹

Anthracyclines have been proposed to improve outcome in ovarian cancer. Omura and colleagues compared cyclophosphamide-doxorubicin-cisplatin to cyclophosphamide and cisplatin.⁹² Although there was no statistical difference, there was a trend toward improved survival. A meta-analysis confirmed a modest advantage to doxorubicin-containing regimens.⁹³ However, following the advent of paclitaxel, doxorubicin therapy has generally fallen from favor. Two large randomized trials of paclitaxel and carboplatin plus or minus epirubicin have been reported in abstract form, and neither survival or overall survival have been improved in these studies. Toxicity was clearly increased.

PACLITAXEL-BASED THERAPY

With the initial report of the GOG 111 study by McGuire et al., chemotherapy of ovarian cancer entered the taxane era.⁹⁴ The randomized studies examining the value of paclitaxel in ovarian cancer are listed in Table 52.7. Two of these trials (GOG 111 and OV 10) are clearly positive whereas two later trials (GOG 132 and ICON 3) suggest that therapy with taxane adds little to the effect of platinum complex therapy.

^b95% confidence interval.

GOG 111 was the first trial of paclitaxel that compared paclitaxel/cisplatin to cyclophosphamide/cisplatin in patients with suboptimally debulked ovarian cancer.⁹⁴ The paclitaxel arm showed a distinct advantage for both progressive-free survival (18 versus 13 months) and overall survival (38 versus 24 months). These results were essentially duplicated by a confirmatory trial performed by the EORTC and the National Cancer Institute of Canada, which found that a paclitaxel/cisplatin arm was superior for both progression-free survival (16 versus 12 months) and overall survival (35 versus 25 months).⁹⁵ Unfortunately, the issue was reopened when a subsequent GOG study, GOG 132, found that the same experimental arm of cisplatin/paclitaxel was not significantly better than cisplatin alone at 100 mg/m². In this study, the progression-free survival for the taxane arm and the cisplatin arms were similar (14 versus 16 months) and survival was not different (26 versus 30 months). Another very large study, ICON 3, was also initiated as a confirmatory study and, similar to GOG 132, could not confirm the superiority of taxane-based therapy. In the ICON 3 study, the time to treatment failure was 17.3 months for the paclitaxel-containing arm and 16.1 for the nontaxane treatment. The survival of the paclitaxel arm was similar to that seen with the control arm of either carboplatin or cisplatin, doxorubicin, and cyclophosphamide (36.1 versus 35.4 months).⁹⁶

The explanation for the discordance remains uncertain. In a meta-analysis, Sandercock and colleagues examined the potential design differences that might lead to the disagreement.⁹⁷ They make several points of interest. The time to progression is remarkably similar for the paclitaxel/platinum arms (16–18 months) in the four studies but both GOG 11 and OV 10 have a surprisingly poor outcome for the cyclophosphamide / cisplatin control groups and a negative effect of cyclophosphamide has been postulated. Results from randomized trials that compared cyclophosphamide/doxorubicin/cisplatin, a control arm in ICON 3, to cyclophosphamide/cisplatin have been inconclusive, but meta-analysis has suggested that cyclophosphamide/cisplatin may be inferior.^{92,98,99} It is also noted that paclitaxel was not available for recurrent disease patients whereas late treatment of control arm patients in the other trials might blunt the survival differences compared to GOG 111. The issue remains unresolved. In the United States, the National Comprehensive Cancer Network (NCCN) has supported paclitaxel and platinum as the standard of therapy; this standard is generally accepted around the world, and it is unlikely that additional studies of this issue will be initiated.

DOSE AND SCHEDULE

The dose, frequency, and duration of primary chemotherapy have also been subjects of intensive investigation. Dose intensity/schedule studies for platinum complex therapy are summarized in Table 52.8. The doses of cisplatin and carboplatin have both been carefully investigated without any evidence that either agent has a significant dose response within the clinically useful range.^{100–103} The analysis by Egorin and colleagues suggested that a carboplatin dose above an AUC of 5–6 is fruitless and even a carboplatin AUC 4 maybe sufficient.^{104,105} Although a small study by Kaye et al. suggested a modest survival advantage, they also recommended a

maximum dose of 75 mg/m² for toxicity reasons.¹⁰⁶ Duration of platinum-based treatment has not been as well examined. Two small randomized trials in the prepaclitaxel era have failed to show an advantage to prolonged therapy. A study of 5 cycles versus 10 cycles of cyclophosphamide, doxorubicin, and cisplatin showed no difference.¹⁰⁷ Another study of the same three-drug regimen showed no advantage for 12 cycles of therapy compared to a more standard 6 cycles.¹⁰⁸ No randomized examination of duration of therapy for carboplatin plus paclitaxel has been performed.

The number of paclitaxel schedule/dose intensity studies is smaller but the results are similar. A two by two factorial study of infusion time and dose compared 135 mg/m² with 175 mg/m² and 3-hour infusions with 24-hour infusions.¹⁰⁹ No statistical difference was identified. A GOG study comparing 135 mg/m², 175 mg/m², and 250 mg/m² was similarly negative for survival advantage, although the 250 mg/m² dose arm had a modest increase in response rate to paclitaxel therapy.¹¹⁰ In a carboplatin combination study, Bolis and colleagues randomized 504 patients between carboplatin and paclitaxel at 175 mg/m² and carboplatin and paclitaxel at 225 mg/m².¹¹¹ Although the higher dose was more toxic, there was no improvement in survival. In a single randomized study of weekly paclitaxel, a weekly dose of 67 mg/m² was nearly identical to a 200 mg/m² dose of paclitaxel given once every 3 weeks.¹¹²

INTRAPERITONEAL THERAPY

Because ovarian cancer is primarily a disease of the peritoneal cavity, regional therapy has been an area of considerable interest. Models of intraperitoneal (IP) chemotherapy show distinct theoretical advantages, especially for small-volume disease.^{113,114} The use of intraperitoneal chemotherapy has been carefully explored in several large randomized clinical trials conducted by the GOG. Although each appears to favor the arm containing intraperitoneal therapy, quirks in trial design and treatment toxicity have prevented intraperitoneal therapy from becoming the single standard of care.^{115,116} The first randomized compared cyclophosphamide plus 100 mg/m² of cisplatin, given either by the intravenous or intraperitoneal route.¹¹⁵ The study showed a survival advantage (HR = 0.76) but was overtaken by the introduction of carboplatin and paclitaxel in the primary treatment paradigm. The next study included a preparative regimen of two cycles of carboplatin (AUC = 9) and then six cycles of cisplatin and paclitaxel.¹¹⁶ As in the first study, the survival difference was statistically significant in favor of the IP arm (HR = 0.81), even though a substantial fraction of the IP arm received little or no IP therapy because of toxicity. A third large randomized trial using IP cisplatin and IP paclitaxel has also been completed. The IP arm had a superior progressive-free survival, but overall survival analysis is not yet complete.¹¹⁷

The failure of IP therapy to assume a position of therapeutic prominence is a complicated problem. Certainly, 100 mg/m² of cisplatin is toxic, and the renal, gastrointestinal, and neurologic toxicities are all daunting. The technical aspects of IP administration are also a factor. Without experienced surgeons, nurses, and medical oncologists, the frequency of complications including catheter failure, infection, and renal damage is unacceptably high.¹¹⁸ Despite the pres-

ence of a survival advantage, it seems likely that IP cisplatin therapy never become widely accepted, and studies of IP carboplatin are being initiated.

CONSOLIDATION THERAPY

PACLITAXEL BASED THERAPY

One of the most controversial areas in ovarian cancer treatment is the use of “consolidation therapy,” defined as additional therapy for patients in clinical complete response at the end of primary treatment (Table 52.9).¹¹⁹ Intraperitoneal

therapy, immune-based treatments, and extended cytotoxic therapies have all been examined in Phase II and occasional Phase III trials. No consensus has yet emerged, and the state of the art is based on comparison to no treatment rather than direct therapeutic comparisons. The only trial to show a modest advantage was GOG 178, a randomized comparison of 12 months of paclitaxel to a shorter, 3-month paclitaxel treatment.¹²⁰ This trial showed a progression-free survival advantage that was highly significant in favor of 12 months of treatment, but the trial was closed by the data safety monitoring committee and survival data will not be available. Unfortunately, without the survival analysis, this trial has

been unable to change the standard of care, although it clearly has sparked new investigations in this area.

INTRAPERITONEAL THERAPY

As noted previously, intraperitoneal chemotherapy has never achieved common usage. Although many agents (cisplatin, floxuridine, mitoxantrone, paclitaxel, and others) have had Phase I/II testing, few Phase III data exist. Although a very

large IP experience reported by investigators at Memorial showed that patients receiving IP therapy had very long median survivals compared to historical controls, the lack of prospective randomized controls is a major limitation.¹²¹ These investigators have reported a prospective Phase II trial of IP cisplatin and etoposide.¹²¹ More than 65% of the patients remained disease free with a median follow-up of 3.5 years. These results are similar to those reported by Tourigand et al. in a similar study of negative second-look patients.¹²² A ran-

domized trial of this concept comparing intraperitoneal cisplatin with a no-treatment control arm was recently reported by the EORTC.¹²³ The study was terminated for poor accrual and only reached one-half of the planned enrollment. Although no statistical difference could be discerned, the progression-free survival (5.4 versus 3.6 years), the overall survival (9.7 versus 7.3 years), and the fraction alive at 5 years (70% versus 60.5%) all favored the IP treatment arm.

CYTOTOXIC CHEMOTHERAPY

Because many optimally debulked patients begin chemotherapy with no evidence of clinical disease, all primary therapy can be considered to be "consolidation." Extension of therapy beyond the consensus six cycles of platinum complex therapy might also be a form of consolidation, proven to be an unsuccessful strategy as already noted. More recently, extended treatment with paclitaxel was also proposed as a form of consolidation, based on the toxicity profile and possible vascular targeting of paclitaxel. In a randomized trial, 277 patients were randomized between 3 months of paclitaxel and 12 months of paclitaxel at 175/m².¹²⁴ At a planned interim analysis, the progression-free survival was found to strongly favor the 12-month arm (21 versus 28 months; *P* less than 0.0023), and the study was terminated early. No survival data are expected from this study because it was terminated early and many patients crossed over to the 12-month arm. The survival value of this intervention remains controversial, and future trials planned by the Gynecologic Oncology Group will continue both a no-treatment control arm and a paclitaxel treatment arm to confirm this finding. However, not all chemotherapy appears to have this function. In a study of noncross-resistant chemotherapy, four cycles of topotecan were tested in 273 patients in patients completing six cycles of carboplatin and paclitaxel.¹²⁵ No difference in progression-free survival was noted, and the study was not designed to analyze for survival. In summary, consolidation therapy remains an area of active investigation, and to date no intervention has shown a definitive survival advantage.

Immunotherapy

Although immunotherapy has been proposed as a logical strategy for ovarian cancer consolidation, the results so far have been disappointing. Two different monoclonal antibody agents, Oregovomab and a yttrium-labeled anti-HMG1 antibody, have failed to show significant effects in randomized trials.^{126,127} A study of alpha interferon has also been negative.¹²⁸

Chemotherapy for Recurrent Disease

In the majority of ovarian cancer patients, the cancer will recur and, with few exceptions, those patients who have recurrences die of their disease. Although surgery is sometimes employed, chemotherapy forms the bulwark of therapy for recurrent disease. Based on retrospective studies, at least two clinical subgroups have been identified. By convention, patients with progression while receiving platinum-based therapy, patients who fail to achieve a complete clinical response, and those who relapse within 6 months of the end of therapy are classified as platinum resistant. Beyond 6 months, the response to platinum retreatment appears to

increase with the duration of the so-called platinum-free interval. Although this dichotomy may be an oversimplification, it is a useful intellectual construct to understand principles of management.

Potentially Platinum-Sensitive Disease

In the group of patients whose disease recurs after at least 6 months, platinum-based chemotherapy is generally preferred over nonplatinum agent therapy (Table 52.10). This practice is based on informal comparison of response rates between platinum-based therapy and nonplatinum agents. The number of randomized trials for this question is small. Cantu and coworkers compared paclitaxel to cyclophosphamide, doxorubicin, and cisplatin.¹²⁹ Certainly, the group of patients with a platinum-free interval in excess of 12 months are almost always treated with carboplatin, building on primary treatment data comparing carboplatin and cisplatin. The other issue in ovarian cancer treatment is the utility of combination therapy compared with single-agent treatment. A summary of the largest randomized studies for platinum sensitive patients is shown in Table 52.10. From this summary, it is apparent that both time to progression and overall survival appear to favor combinations of carboplatin and a second agent. The choice of the best second agent is not known, but the overall survival data imply that crossover to other agents occurs frequently and probably blunts the effect of initial choice in this group of patients. A second consistent finding is that combination therapy certainly results in more toxicity than sequential single-agent treatment. The failure of epidoxorubicin to improve on carboplatin alone may be a reflection of the lower activity of epidoxirubicin compared to paclitaxel and gemcitabine.¹³⁰ It can be seen that nonplatinum therapy with single-agent paclitaxel, topotecan, or liposomal doxorubicin appears to be inferior to platinum-based therapy in response rate and, to a lesser extent, in overall survival.¹³¹⁻¹³³ It is also of note that retrospective analysis suggests that a patient's time to progression following second-line treatment is almost always shorter than that patient's time to progression following primary therapy. The use of single-agent topotecan or liposomal doxorubicin in the patients with a relapse within 6 to 12 months appears to have a better response rate and overall survival, compared to the resistant population, possibly based on subsequent platinum-based therapy.¹³⁴

Duration of therapy for recurrent disease is controversial. Many authorities recommend treatment to best response and then a chemotherapy holiday. It should be noted that the large randomized trials have generally encouraged treatment for up to 12 months in those patients without evidence of progression.¹³¹⁻¹³³ No comparative trials are available for duration of therapy.

Platinum-Refractory Disease

The management of platinum-refractory disease is an area with limited high-quality data. Only one combination of nonplatinum agents has been tested in randomized Phase III settings (Table 52.11).¹³⁵ No advantage was observed for a combination of anthracycline with paclitaxel to paclitaxel alone. Several of the randomized trials in platinum-resistant disease were performed during the prepaclitaxel era. From the data in hand, it can be seen that oxaliplatin, paclitaxel,

topotecan, and liposomal doxorubicin have very modest response rates and median survival of less than 1 year.^{131,133,136,137} Randomized studies of these agents against supportive care have not been performed, although the superiority of intravenous topotecan to oral topotecan for overall survival implies a modest survival advantage for intravenous

topotecan therapy.¹³⁶ A number of agents have been also examined in Phase II single-agent studies. In this setting, etoposide and gemcitabine stand out as two agents with modest activity.¹³⁸⁻¹⁴³ Gemcitabine is often favored over etoposide, based on the small incidence of acute leukemia associated with etoposide treatment. Special mention should

be made of the taxanes in this setting. Weekly paclitaxel has a response rate in excess of 20% for patients previously resistant to an every-3-week cycle, and this schedule enjoys an excellent side effect profile.^{138,144} There is also some suggestion that docetaxel is not completely cross resistant with paclitaxel in ovarian cancer treatment.¹⁴⁵⁻¹⁴⁷ The choice among these agents can be based on toxicity preferences. No data exist for a preferred sequence, and it appears that there is little cross-resistance among agents.^{132,148}

It is also of note that a "platinum-resistant" cohort will contain some patients who may respond to additional platinum-based therapy. The GINECO investigators reviewed their experience with platinum-based chemotherapy for patients classified as "platinum resistant" by the standard definition. In that presentation, there was still a modest (but statistically significant) survival advantage to platinum-based chemotherapy.¹⁴⁹ In the Memorial Sloan Kettering experience, most of the platinum responders in "platinum-resistant" cohort are patients with early relapse following platinum-based therapy.¹⁵⁰

Appropriate Follow-Up Interventions

Interval

The ideal follow-up of asymptomatic patients who have completed primary surgery and chemotherapy has yet to be determined. Typically, patients are followed at 3- to 4-month intervals for the first 2 years. Using a 15-question survey, Barnhill et al. illustrated the practice patterns for patient follow up after primary treatment of gynecologic cancers among 94 gynecologic oncologists.¹⁵¹ The majority of the physicians surveyed recommended visits every 3 months for the first year, every 3 to 4 months for the second year, every 6 months for years 3 to 5, and annually thereafter.

The National Comprehensive Cancer Network (www.NCCN.org) has published their guidelines for monitoring patients with epithelial ovarian cancer who have had a complete response. Visits are every 2 to 4 months for the first 2 years, then every 6 months for the third year, followed by annual visits. Physical examination with pelvic exam and CA 125 (if initially elevated) is performed at each visit, and a complete blood count is obtained annually. Other testing is performed only if indicated.

Olaitan et al. recently reviewed their follow up protocols for 81 patients with gynecologic cancers at a tertiary referral center.¹⁵² This regimen was similar to the one previously mentioned in that patients have visits with the specialists every 3 months for the first 2 years, every 6 months for the next 2 years, and then annually. There was a total of 14 recurrences, of which 8 (57.1%) were diagnosed at the scheduled appointments, and the remainder were diagnosed by either unscheduled visits to the general practitioner or emergency room. There were 10 cases of recurrent ovarian cancer of which 7 were diagnosed at scheduled clinic visits. Four of the 7 had symptoms of recurrence for at least 1 month before their scheduled visit, and 1 patient had symptoms for 4 months. Two recurrences were detected by CA 125 elevations, 2 patients presented to the general practitioners with several days of symptoms of recurrence, and 1 patient presented to the emergency room with a bowel obstruction. In total, 354 visits were required to diagnose 8 recurrences. The authors identified that patients with scheduled visits may

delay reporting symptoms until the visit. They suggested an open-access system according to patient need may be a more cost-effective model and are currently performing a prospective randomized trial for follow-up.¹⁵³

Appropriate Examinations

In Barnhill's survey, examination of the breasts, pelvis, lymph nodes, and abdomen were performed by the majority of physicians at each exam.¹⁵¹ Physical examination by itself is limited in its ability to detect subclinical or persistent disease, but on occasion, a pelvic mass may be detected. The other test that is routinely performed in the follow-up of patients with ovarian cancer is CA 125. According to a survey of gynecologic oncologists, the median recommended number of times the CA 125 level was checked in patients with epithelial ovarian cancer was four during the first 2 years, two over the next 3 years, and either none, one, or two times annually after the fifth year.

The accuracy of CA 125 for determining recurrence was illustrated by Niloff et al.¹⁵⁴ Serum levels of CA 125 were obtained from 55 women with epithelial ovarian cancer both before and after second-look surgery. Patients were clinically and radiologically disease free and were followed until clinical recurrence. Patients with an elevated CA 125 at time of second look had a 60% chance of recurring within 4 months compared to only a 5% chance in patients with a normal CA 125. Elevation in serial CA 125 during the monitoring period was associated with recurrence in 94% of cases with a median lead time of 3 months. The accuracy of CA 125 in determining relapse illustrates its importance for ovarian cancer follow-up. However, given that there may be a lead time before detectable recurrence, ideal treatment for an elevated CA 125 alone raises a new question that is being addressed in a multicenter Medical Research Council/European Organization for Research and Treatment of Cancer (MRC/EORTC) prospective trial. The primary endpoint for this trial is overall survival, with quality of life and health economics designated as secondary endpoints.

Surgery in Relapse

Secondary Debulking

The value of primary cytoreductive surgery is well recognized. Removal of large tumors reduces the tumor load, and thus the number of chemotherapy cycles needed to eradicate residual tumor is also reduced. This concept of reducing tumor burden has also been applied to patients who have already undergone a primary cytoreductive surgery followed by chemotherapy. The data on this remain retrospective in nature and include a mixed population of patients.

Secondary operations for ovarian cancer can be grouped into four different clinical situations:

1. Recurrent disease: those patients with at least a 6-month disease-free interval.
2. Second-look laparotomy: patients who are clinically without evidence of disease and are found to have gross disease at second-look surgery.
3. Interval debulking: patients with bulky, unresectable disease at initial surgery who undergo neoadjuvant chemotherapy.

4. Progressive disease: patients with disease progression on primary chemotherapy.

Secondary surgery for recurrent disease is addressed in this section.

Because the majority of patients with advanced-stage ovarian cancer will eventually have a recurrence of their disease in spite of a period of clinical remission, the question of whether cytoreductive surgery is of therapeutic benefit at time of relapse remains. A number of retrospective studies have addressed this question of secondary cytoreduction at time of relapse.

Berek et al. described their experience with secondary cytoreductive surgery for ovarian cancer,¹⁵⁵ which included 32 patients who underwent secondary cytoreduction at the time of second-look laparotomy, at surgery for clinically detected disease, or at the time of bowel obstruction surgery. The median interval between primary and secondary surgery was 12 months, and optimal resection (defined as residual disease less than 1.5 cm) was accomplished in 38% of patients. When patients undergoing second-look surgery were excepted, 6 (29%) underwent optimal cytoreduction and had a median survival of 18 months compared to the 15 suboptimally debulked patients who had a median survival of 5 months. Although this series contained a heterogeneous group of patients, several poor prognostic variables were identified, including greater residual disease after primary surgery, disease-free interval less than 1 year, large tumor size at recurrence, ascites, and greater residual disease after secondary surgery. Several other series have reviewed the impact of residual disease on survival, and most have shown a benefit if residual disease is of small volume.

Although the majority of studies regarding the utility of secondary cytoreduction are retrospective, a prospective study was conducted by Eisenkop et al. that evaluated the feasibility and benefit of secondary cytoreduction.¹⁵⁶ Thirty-six patients who had undergone primary cytoreduction followed by platinum-based chemotherapy and who had relapsed at least 6 months after primary therapy were enrolled for secondary cytoreduction. All patients had disease greater than 1 cm at recurrence, and complete cytoreduction was achieved in 30 (83%) of patients using an aggressive surgical approach. Morbidity occurred in 30.1% of patients, and there was 1 (2.8%) postoperative mortality. Although there was not a control group who did not undergo secondary cytoreductive surgery, median survival in the group was significantly better in the patients completely resected before salvage therapy compared to those with macroscopic residual disease (43 versus 5 months; $P = 0.03$, respectively). Based on these retrospective series, secondary cytoreduction appears to be beneficial in patients with resectable recurrent disease and a reasonable disease-free interval.

It should be kept in mind that the retrospective series published on secondary cytoreduction included heterogeneous groups of patients and surgeons, involved tumors with different biologic behavior, and had strong selection bias in the authors' criteria for surgical interventions. The GOG (Protocol 213) is currently conducting a prospective bifactorial randomized trial addressing the use of sequence-dependent chemotherapy and secondary cytoreductive surgery in platinum-sensitive, recurrent ovarian and primary peritoneal cancers. Patients will be randomized to either treatment with

topotecan or carboplatin or secondary cytoreduction followed by treatment with topotecan or carboplatin.

Value and Impact of Surgery for Obstruction

Progression of ovarian cancer results in symptoms of diffuse intraabdominal spread and can lead to progressive encasement of the bowel and its mesentery, resulting in symptoms of mechanical obstruction. This is a common finding among patients with recurrent ovarian cancer, and many will eventually succumb to this problem. In a study to determine the incidence of bowel obstruction in patients with ovarian cancer, Lund et al.¹³⁹ followed the clinical courses of 310 consecutive patients with ovarian cancer. With a median observation time of 46 months, the estimated incidence of intestinal obstruction was 26% at 5 years. The complication rate associated with surgery for obstruction was high, and only 32% of patients had a survival of greater than 60 days with palliation of symptoms. The most commonly associated variables included initial stage III or IV disease, suboptimal (larger than 2 cm tumor nodules) tumor debulking at initial surgery, and the presence of intestinal carcinomatosis at initial surgical exploration.

Initial management of patients with obstruction is typically a trial of conservative management with nasogastric drainage. However, Krebs and Goplerud reported that such an approach results in sufficient improvement for discharge in only about one-third of cases, and the majority of these patients return with a subsequent obstruction within a mean of 5.5 weeks.¹⁵⁷ In cases that do not resolve with conservative management, surgical correction may be considered. This option is associated with a high rate of morbidity and mortality, and the chances of successful palliation, risk of reobstruction, and quality of life after the surgery must be taken into consideration.

A number of retrospective studies have examined the role of surgery for obstruction in patients with ovarian cancer. Pothuri et al. reported, from Memorial Sloan-Kettering Cancer Center 64 patients who underwent 68 operations.¹⁵⁸ The obstruction was surgically corrected in 57 (84%) of the 68 procedures. Of this group, 71% were able to tolerate a regular or low-residue diet at least 60 days postoperatively, and 79% were able to receive more chemotherapy. The surgical morbidity was 22% and the perioperative mortality was 6%. Median survival was significantly longer in the patients who had successful palliation compared to those who did not, 11.6 months and 3.9 months, respectively (P less than 0.01). A number of other studies have demonstrated that surgical correction is possible; however, these studies include a patient pool that is heavily preselected. Successful palliation, defined as survival greater than 60 days from surgery, was achieved for 51% to 80% of patients; however, perioperative mortality (4%–32%) and morbidity (7%–64%) can be significant.

In an attempt to better define patients who may benefit from a surgical procedure, Krebs and Goplerud used age, nutritional status, tumor spread, ascites, previous chemotherapy, and previous radiation to formulate a prognostic index.¹⁵⁹ Using a scoring system of 0–2 for each variable, they reported that 84% of patients with a score of 6 or less survived at least 60 days postsurgery compared to 0% of patients with a score of 7 or more. It would be beneficial to identify patients who would not benefit from surgery, and other series have con-

firmed the validity of using a prognostic index.¹⁶⁰ Not all reports, however, have been able to demonstrate that such variables are predictive of successful palliation or improved survival.¹⁶¹

Supportive Care

Total Parenteral Nutrition

The role of total parenteral nutrition is a question that may arise in patients with malignant intestinal obstruction. Due to the predilection for intraabdominal spread, intestinal obstruction in patients with advanced ovarian cancer is not an uncommon situation. Many patients may present with or develop bowel obstruction related to unresectable disease. In such cases which do not appear amenable to surgical correction, supportive care should be the focus of treatment. The extent of supportive efforts can be a difficult topic to address.

Many patients or families suffering from altered gastrointestinal function from unresectable ovarian cancer may raise the possibility of using total parenteral nutrition (TPN). In spite of decreased oral intake, more than 60% of terminally ill cancer patients experience no hunger or thirst.¹⁶² Thus, the value of TPN in patients with end-stage ovarian cancer remains questionable. The potential risks associated with TPN and the training required for home administration may justify its use in patients with expected survivals of more than 3 months.¹⁶³ With the exception of certain situations, such as patients who are undergoing surgical correction for obstruction or being administered TPN in conjunction with systemic chemotherapy for newly diagnosed ovarian cancer, TPN is not routinely recommended.

A review of patients with small bowel obstruction and advanced ovarian cancer demonstrated some of the rare indications for the use of TPN in advanced ovarian cancer patients. Abu-Rustum et al. identified 21 patients (3 newly diagnosed and 18 heavily treated for persistent or recurrent disease) who received chemotherapy in an attempt to restore bowel function.¹⁶⁴ All patients had a drainage gastrostomy placed. Eleven patients also received TPN (all newly diagnosed and 8 recurrent/persistent). Two of the 3 chemotherapy-naïve patients had relief of their bowel obstruction, compared to none of the patients with recurrent or persistent disease. Median survival for patients who received TPN with chemotherapy was 89 days compared to 71 days in patients who received chemotherapy alone ($P = 0.031$). However, the authors did not believe that the additional 18 days justified the routine administration of TPN and discouraged its use.

Percutaneous Endoscopic Gastrostomy Tube Drainage

Patients with malignant obstruction who either choose not to undergo a surgical procedure or who are poor candidates for surgical correction can be managed with percutaneous endoscopic gastrostomy (PEG) drainage of the stomach and small bowel. PEG has many advantages over a nasogastric tube, including patient comfort, lack of damage to the gastric mucosa, more efficient drainage due to a wide tube, and providing the satisfaction of oral liquids in spite of obstruction. PEG can be placed without necessitating a surgical procedure

that may be associated with increased morbidity. Retrospective studies have demonstrated that PEG tubes can be placed in the majority of patients with success rates of 89% to 100%.^{165,166}

Complications rates are typically low, with the major risks being leakage of gastric contents, intestinal perforation, and peritonitis. After successful placement of the PEG tube, patients can resume a liquid or soft diet in 84% to 100% of cases.^{165,166} Because improvement in comfort of the terminally ill cancer patient should be the major goal, PEG drainage should be considered in patients with malignant bowel obstruction.

Uterine Malignancies

Gini F. Fleming, Anthony C. Montag,
Arno J. Mundt, and S.D. Yamada

Etiology, Epidemiology, and Risk Factors

The American Cancer Society estimates that, in 2004, endometrial cancer will be the most common gynecologic malignancy in North America, accounting for 40,320 new cases and 7,090 deaths. Endometrial cancer is primarily a disease of postmenopausal women, with the incidence peaking between the ages of 55 and 65 years. Among Caucasian women, the incidence of uterine cancer is about twice that of African-American women; however, African-American women are less likely to survive this disease. Between 1992 and 1999, the 5-year survival for Caucasian women was 86% as compared to 60% for African-American women.¹ This disparity in survival has persisted over the past 25 years and may reflect the preponderance of tumors in African-Americans with unfavorable histology, higher grade and, possibly, more-advanced stage at diagnosis.

It is believed that there are two types of endometrial cancer: estrogen related and non-estrogen related. More than 80% of early-stage endometrial cancers are endometrioid and, most likely, estrogen related.² The majority of these cases develop from preexisting endometrial hyperplasia and reflect the effect of endogenous or exogenous estrogen stimulation. The risk and rate of progression to cancer are not well defined, although it has been estimated that endometrial hyperplasia with nuclear atypia has a 25% risk of progression to endometrial carcinoma, in contrast to hyperplasia without cytologic atypia, which has an exceedingly low rate of progression.³

Numerous factors, many related to estrogen stimulation, have been associated with the development of endometrial hyperplasia and, subsequently, endometrial cancer. Estrogen without concurrent progestin use increases the risk of endometrial carcinoma by four- to eightfold. This risk increases with both duration and amount of estrogen exposure.⁴ In the PEPI trial (Postmenopausal Estrogen and Progestin Intervention Trial), 75 of 119 (62%) women who used unopposed estrogen 0.625 mg/day (conjugated equine estrogen) over the course of 3 years developed endometrial hyperplasia. Atypical endometrial hyperplasia occurred in a statistically higher percentage of women taking unopposed estrogen as opposed to placebo: 11.8% versus 0% (P less than 0.001).⁵ Progestins used in conjunction with estrogen reduce the risk of endometrial cancer and should be prescribed to all women with an intact uterus receiving hormone replacement

therapy. In the HOPE trial (Women's Health, Osteoporosis, Estrogen, Progestin Trial), doses of 0.625 mg conjugated equine estrogen (CEE) or 0.45 mg CEE with medroxyprogesterone 2.5 mg daily did not produce any cases of hyperplasia.⁶

As a result of prolonged exposure of the endometrium to estrogen stimulation, obesity, nulliparity, and late menopause increase the risk of endometrial cancer development, as do feminizing ovarian tumors (granulosa cell tumors) and polycystic ovarian syndrome. Diabetes and hypertension are also associated with increased risk of disease development but may be surrogates for other risk factors such as obesity.

Tamoxifen use in women with breast cancer also increases the relative risk of endometrial cancer six- to sevenfold, with the risk being most pronounced after 2 years of use.⁷ Tamoxifen inhibits the action of estradiol by competitively binding to the estrogen receptor, but it inherently also has a weak estrogenic effect. In the NSABP B-14 study, the use of tamoxifen was associated with a rate of 1.6 cases of endometrial cancer in 1,000 women as compared to 0.2 cases per 1,000 women in the placebo group. The relative risk for the development of endometrial cancer increases with prolonged use: the relative risk is 2.0 [95% confidence interval (CI) 1.2–3.2] with 2 to 5 years of use and 6.9 (95% CI, 2.4–19.4) for 5 years or more of use as compared to nonusers. Although the vast majority of uterine cancers found in association with tamoxifen use are low-grade endometrial carcinomas, the long-term use of tamoxifen has been associated with the development of poor prognostic subtypes such as carcinosarcomas.⁸

Although the majority of uterine cancer cases develop in an environment of estrogen stimulation, some cases develop in the absence of hyperplasia or significant risk factors such as obesity. These endometrial cancers are often found to be of higher grade and may contain poorer prognostic histologic subtypes than their estrogen-related counterparts.

Endometrial cancer is infrequently associated with a genetic component; however, members of families with the Lynch II syndrome or hereditary nonpolyposis cancer syndromes, where there are mutations in the DNA mismatch repair genes *hMSH2* and *hMLH1*, have a lifetime risk of 25% to 50%⁹ of developing endometrial cancer in addition to colon, breast, and ovarian cancer. Finally, pelvic radiation has also been associated with the development of certain poor prognostic cancers such as sarcomas.

Diagnosis and Screening

The diagnosis of uterine cancer is most frequently established through an office endometrial biopsy, usually instituted as a result of postmenopausal vaginal bleeding. In the absence of bleeding, endometrial cancer occasionally presents with abdominal pain as a result of an obstructed, blood-filled uterus, or, rarely, with abnormal endometrial cells on routine Pap smear screening. When atypical endometrial cells are seen on a Pap smear, the risk that an endometrial adenocarcinoma will be found is approximately 20%. This risk increases to approximately 41% in women who are at least 60 years old. Grossly normal endometrial cells in a Pap smear of a postmenopausal woman should also raise suspicion for malignancy. Approximately 10% of postmenopausal women less than 60 years old and up to 20% of those who are older with endometrial cells on Pap smear have an underlying adenocarcinoma, the majority of which are grade 1 or 2 endometrioid adenocarcinomas.¹⁰

An office endometrial biopsy will diagnose endometrial cancer with certainty in nearly 95% of cases. With small tissue samples it is sometimes difficult to distinguish complex hyperplasia from adenocarcinoma. In this case, a dilatation and curettage (D&C) may be necessary. In fact, in women with complex hyperplasia with atypia found on biopsy, up to 43% of patients in a prospective Gynecologic Oncology Group study correlating findings on biopsy with final hysterectomy diagnosis were found to have endometrial carcinoma.¹¹

Once a uterine cancer is found, a careful pelvic examination is performed to determine if there is clinically apparent extension of the tumor beyond the confines of the uterus. In more than 75% of patients there will be no clinical evidence of extrauterine disease, and preoperative studies would then include a chest X-ray and routine blood tests. In patients with evidence of extrauterine spread or in patients with known aggressive histologic subtypes of tumor (see following), a computed tomography (CT) scan or magnetic resonance imaging (MRI) may delineate other areas of disease extension.

For the general population, there is no benefit to routine screening (transvaginal ultrasound and/or endometrial sampling) for endometrial cancer in asymptomatic women, even those on hormone replacement therapy.¹² Screening for women who have an increased risk for the development of endometrial cancer, such as patients on tamoxifen, has been studied extensively using a variety of techniques including transvaginal ultrasound (TVUS), sonohysterography, and hysteroscopy. The results of key prospective studies including studies of breast cancer patients on tamoxifen and controls not on tamoxifen are shown in Table 53.1. The majority of patients with abnormalities on ultrasound have benign disease in the form of atrophy, polyps, or simple hyperplasia. Tamoxifen has also been shown to cause stromal condensation that may be misinterpreted as a thickened endometrial lining on ultrasound. It is not cost-effective to screen asymptomatic breast cancer patients on tamoxifen. Most patients with significant abnormalities will manifest their disease with signs of vaginal bleeding. Only patients who experience vaginal bleeding on tamoxifen, therefore, should be further evaluated by endometrial tissue sampling. Screening even in patients with higher risk of development of endometrial cancer, such as members of hereditary nonpolyposis colon cancer syndrome (HNPCC) families, has been shown to be of

limited value. Forty-one women in an HNPCC cohort, the majority of whom were postmenopausal, underwent annual TVUS exams with a median follow-up of 5 years. A total of 179 TVUSs led to 17 endometrial biopsies in which 3 patients with complex hyperplasia and 1 patient with endometrial cancers were identified.¹³

Pathology of Neoplasia of the Uterine Corpus: Carcinomas

Uterine lesions can be broadly divided into lesions that take their origin from the epithelium, from the stroma (whether endometrial stroma or myometrial smooth muscle), or mixed tumors containing both epithelial and stromal elements. Mixed tumors may contain a benign epithelial and malignant stromal component (adenosarcoma), the converse (carcinosarcoma), or two malignant components (carcinosarcoma).

Endometrioid Adenocarcinoma

Most endometrial carcinomas are adenocarcinomas, displaying glandular differentiation mimicking one of the Mullerian-derived epithelia: endometrial, tubal, or cervical (Figure 53.1). Endometrioid carcinoma is the most common histology, comprising approximately 60% of endometrial carcinomas. Endometrioid tumors mimic normal endometrial glands to varying degrees; well-differentiated tumors form glands with several layers of cells that retain some of the normal polarity of proliferative endometrium. More poorly differentiated tumors lose the tendency to form glands, taking on a more-solid architecture, with loss of nuclear polarity and increasing cytologic atypia. The endometrioid histology and its subtypes are estrogen related, frequently accompanied by adenomatous hyperplasia, express estrogen and progesterone receptors, and tend to present at a lower stage and grade. Grading is according to the International Federation of Gynecology and Obstetrics (FIGO) system, based on the amount of solid growth pattern (excluding squamous areas): grade I is 5% or less solid, grade II is 6% to 50% solid, and grade III is more than 50% solid. If significant nuclear atypia is present, the grade should be increased by one degree. Diffuse nuclear atypia may indicate serous or clear cell histology.

Serous and Clear Cell Adenocarcinoma

In the early 1980s Bokhman¹⁴ proposed two clinically and histologically distinct forms of endometrial carcinoma: type I or endometrioid and its variants, and type II, including serous and clear cell histologies. The latter frequently arise in a background of relative atrophy, are not associated with estrogen-related risk factors, occur in an older population, and are clinically more aggressive lesions. Hendrickson et al.¹⁵ presented similar clinicopathologic support for two forms of endometrial carcinoma in their description of papillary serous carcinoma of the endometrium and its delineation from the villoglandular variant of endometrioid carcinoma. Patients with papillary serous carcinoma were on average 5 years older, had more-advanced tumors, more-frequent lymphatic involvement, and a tendency to recur in the upper abdomen. Serous tumors of the endometrium are considered to be high-grade lesions by definition and are not further graded by histology.

TABLE 53.1. Prospective studies of screening for endometrial cancer in women on tamoxifen.

Study	Reference	Year	No. of patients	Tamoxifen dose	Screening method	Classification	Screening interval	Duration of tamoxifen use (median)	Primary uterine cancers detected	Cases detected with abnormal vaginal bleeding	Positive predictive value for uterine abnormality
Fung	160	2003	304 (T)	20 mg/day	TVUS with CFDI, EMB	Normal <10 mm Abnormal ≥10 mm Bleeding	6–12 months	48 months	6	6	43.3%
Gerber	161	2000	247 (T) 98 (C)	20–30 mg/day	TVUS	Abnormal ≥10 mm	6 months	2–5 years	3	2	
Yosse	162	2002	317 (T) 823 (C)	Not noted	TVUS, EMB	Abnormal ≥8 mm	12 months	Not noted	5 (72 of 133 abnormal TVUS underwent EMB)	2	64%
Fong	163	2001	138 (T)	20 mg/day	TVUS (138), hysterosonography (133), hysteroscopy (117)	All	N/A		0	0	
Strauss	164	2000	70 (T)	20 mg/day	TVUS	Abnormal ≥10 mm or bleeding			0	0	
Barakat	165	2000	159 (T)	20 mg/day	EMB on entry	All	6 months	36 months	0	0	
Scoud	166	1999	80 (T)	Not noted	TVUS, EMB	Baseline biopsy, TVUS, EMB q 6 months	6 months	30 months	1	1	
Love	167	1999	357 (T) 130 (C)	20 mg/day	TVUS, hysteroscopy if abnormal	Abnormal ≥5 mm (postmenopausal)	Not stated	62 months	0 145/357 required hysteroscopy: 46% false positive, atrophy	0	
Timmerman	168	1998	53 (T)	20 or 40 mg/day	TVUS, hysteroscopy	Abnormal >4 mm			1 metastatic breast cancer	0	
Cecchini	169	1996	737 (T)	20 mg/day	TVUS, EMB	Abnormal >6 mm	12 months	50 months	1 (but 209 abnormal US, 108 with EMB)	0	

T, tamoxifen; C, control; TVUS, transvaginal ultrasound; EMB, endometrial biopsy; CFDI, color flow Doppler.

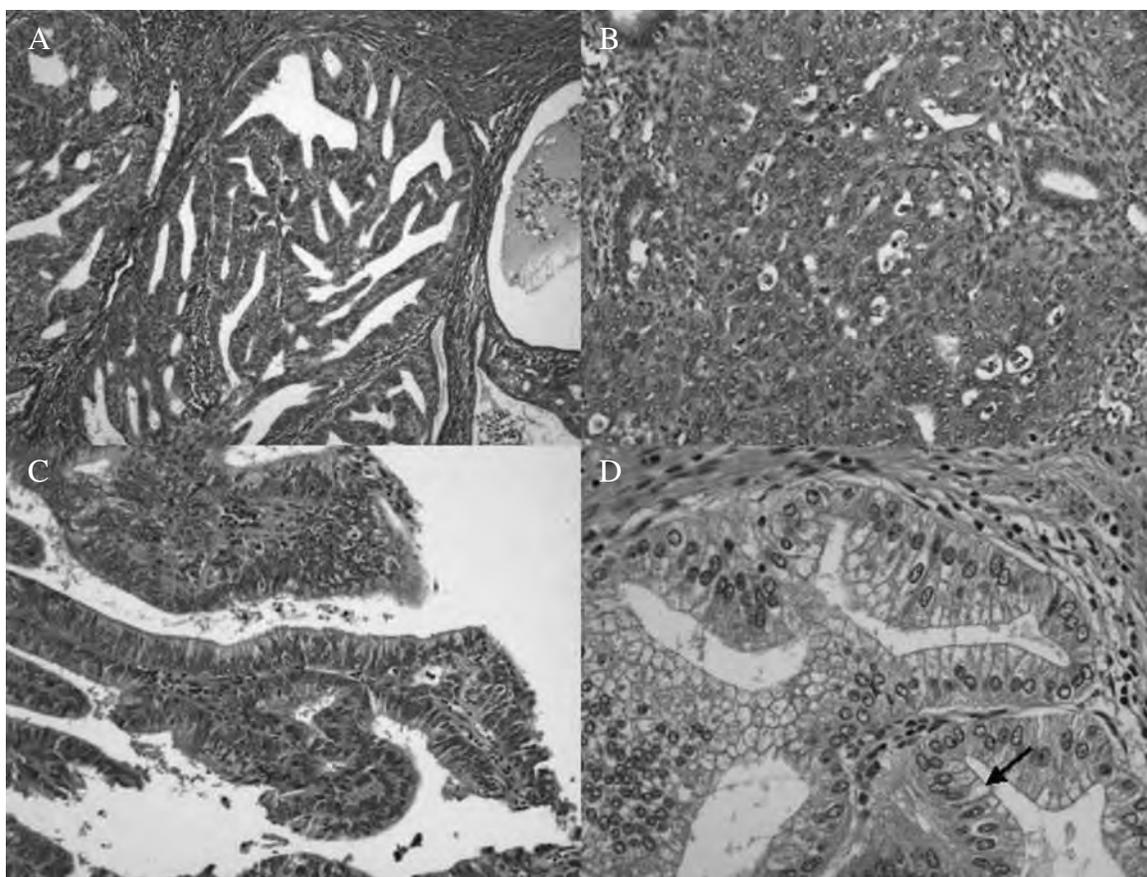

FIGURE 53.1. Endometrioid adenocarcinoma and its variants. (A) Grade I endometrioid carcinoma with cribriform architecture. (B) Grade III endometrioid carcinoma with predominantly solid architecture. (C) Villoglandular variant with long slender villous projections but with bland cytology. (D) Secretory variant with supranuclear vacuoles (*arrow*).

Clear cell carcinoma is characterized by an architecture that ranges from papillary to tubulocystic or solid and a cytologic appearance that includes clear cells, eosinophilic cells, and hobnail cells. In contrast to vaginal and cervical clear cell tumors, endometrial clear cell carcinoma has no association with maternal diethylstilbestrol (DES) exposure. Clear cell carcinoma is regarded as a high-grade histology and is not further graded.

Carcinosarcoma

Carcinosarcoma, or malignant mixed Mullerian tumor, usually occurs in older, postmenopausal women and frequently presents as a polypoid uterine mass (Figure 53.2). Histologically carcinosarcomas have both epithelial and mesenchymal differentiation, frequently including elements of endometrial stromal sarcoma and leiomyosarcoma, but also heterologous elements not native to the endometrium such as cartilaginous and rhabdomyoblastic differentiation as well. In the past, heterologous elements were believed to correlate with poor prognosis; however, recent studies have shown the mesenchymal component to have no prognostic significance. Clinically, nearly all metastatic foci are either carcinoma or contain both carcinoma and sarcoma, suggesting that the lesion is more likely a metaplastic carcinoma than a collision tumor with separate epithelial and mes-

enchymal elements. By analysis of X chromosome inactivation and mutations of p53 and *K-ras*, more than 85% of cases have identical findings in the epithelial and mesenchymal components.¹⁶ Similarly, analysis of microsatellite markers supports a monoclonal origin as an epithelial tumor with genetic progression to mesenchymal differentiation.¹⁷

Precursor Lesions

Endometrioid carcinoma and its variants are associated with endometrial hyperplasia and increased estrogenic effect. Patients with complex atypical hyperplasia have a significant risk of developing endometrial adenocarcinoma, 29%, as opposed to 1% for simple hyperplasia and 3% for complex hyperplasia without atypia.³

The precursor lesion of serous carcinoma of the endometrium has been called serous endometrial intraepithelial carcinoma, endometrial carcinoma in situ, or surface serous carcinoma,¹⁸ and has been found in up to 89% of hysterectomy specimens with serous carcinoma (Figure 53.3). The lesion frequently arises in atrophic endometrium, replacing the surface endometrium with highly atypical cells resembling invasive serous carcinoma, displaying increased nuclear/cytoplasmic ratio, irregular nuclear membranes, abnormal chromatin texture, and atypical mitotic figures.

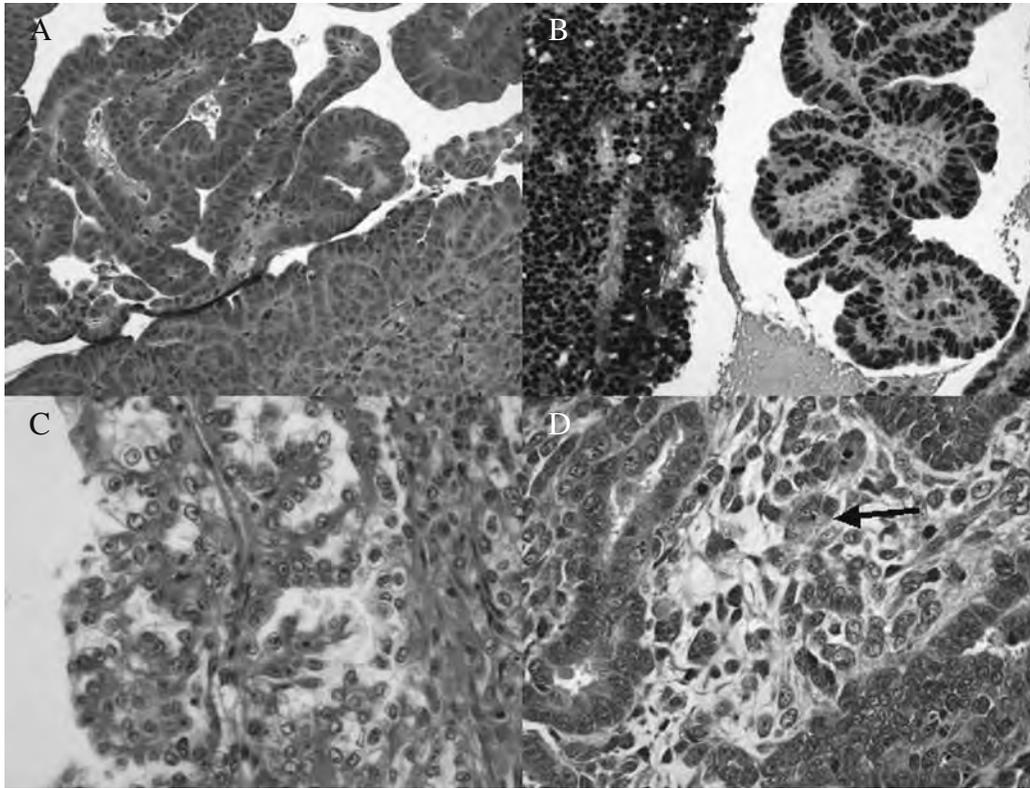

FIGURE 53.2. Type II endometrial carcinoma and carcinosarcoma. (A) Papillary serous carcinoma with fine papillae and marked cytologic atypia. (B) Immunohistochemical stain for p53 protein in papillary serous carcinoma showing uniform nuclear staining in tumor

cells. (C) Clear cell carcinoma with nuclear atypia and clear cytoplasm. (D) Carcinosarcoma (malignant mixed Mullerian tumor) with malignant epithelial and stromal (*arrow*) components.

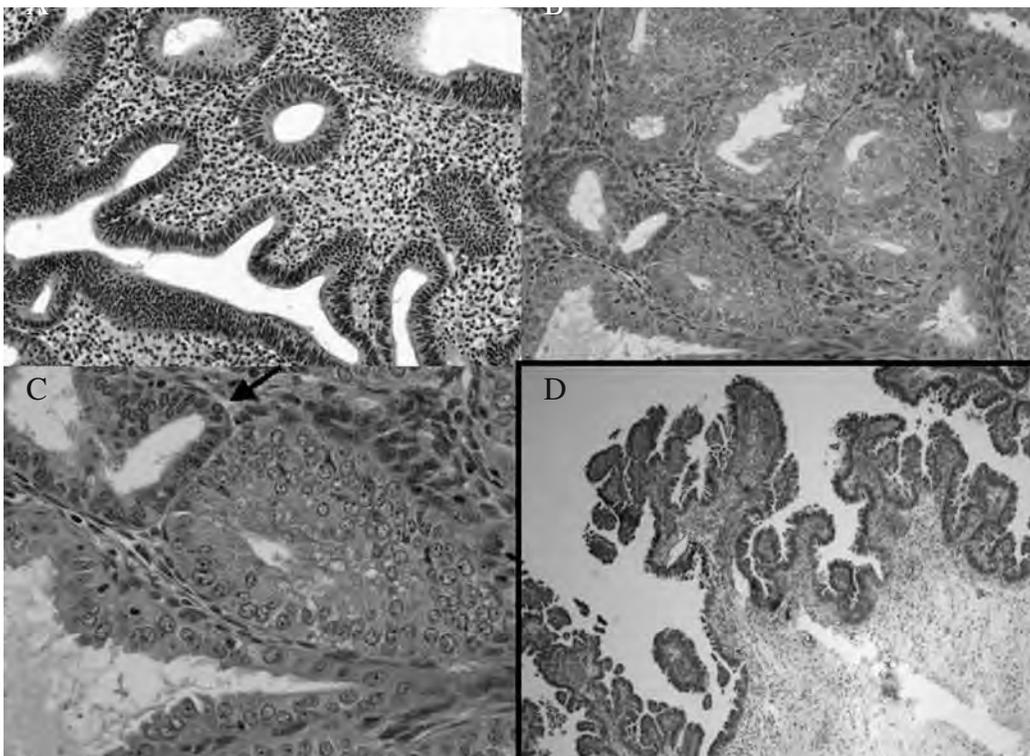

FIGURE 53.3. Precursor lesions of endometrial carcinoma. (A) Simple hyperplasia with architectural budding and branching but minimal increase in the ratio of glands to stroma. (B) Complex atypical hyperplasia with architectural crowding and increased gland to stroma ratio. (C) Complex atypical hyperplasia. Note the loss of

nuclear polarity as compared to simple hyperplasia, nuclear enlargement, and abnormal chromatin texture as compared to adjacent normal gland (*arrow*). (D) Endometrial intraepithelial neoplasia (serous carcinoma in situ) arising on the surface of an atrophic endometrial polyp.

Molecular Pathogenesis

Recent molecular studies have confirmed the concept of two pathways of carcinogenesis in endometrial carcinoma. The details of the two pathways involve numerous classes of receptors, cell-cycle regulators, and genes involved in DNA maintenance.

In endometrioid, or type I, carcinoma, the earliest molecular finding appears to be inactivation of DNA mismatch-repair genes (MMR), leading to an accumulation of other mutations that result in cellular dysregulation. Germ-line mutations in the MMR genes MLH-1 and MSH-2 are responsible for the hereditary nonpolyposis colon cancer syndrome (HNPCC), and endometrial carcinoma is the second most common malignancy found in that disorder.¹⁹ Sporadic endometrial carcinomas of endometrioid histology, in contrast, more frequently have methylation of the promoter region of an MMR gene. Goodfellow et al. recently reported the analysis of 127 cases of endometrial carcinomas for abnormalities in DNA mismatch-repair genes²⁰: 115 of 127 cases had an abnormality in mismatch-repair genes involving either promoter methylation or somatic or germline mutation.

Microsatellite instability (MSI), the tendency of short repetitive segments of DNA to mutate, is a measure of an overall increased tendency of the cell to mutation. MSI is correlated with abnormalities of DNA mismatch-repair genes and is seen in endometrioid carcinoma and its precursors. Cohn et al.²¹ found MI in 51 of 210 cases of endometrioid carcinoma, and of 21 of those cases with accompanying hyperplasia, 20 had MSI in the hyperplastic foci. Conversely, absence of MSI is highly correlated with normal expression of DNA mismatch-repair genes. MSI is almost never seen in serous carcinomas or their in situ precursor endometrial intraepithelial carcinoma (EIC). Tashiro et al. found that none of 34 cases of serous carcinoma had MSI.²²

The key gatekeeper in endometrioid carcinoma appears to be lipid phosphatase and tensin homologue deleted on chromosome 10 (PTEN), an inositol phospholipid phosphatase that acts as a tumor suppressor by negatively regulating the Akt (phosphatidylinositol protein kinase B) pathway, promoting apoptosis.²³ Human germ-line PTEN mutations are found in Cowden's syndrome, an autosomal dominant multiple hamartoma syndrome that carries an increased risk of carcinoma of the breast, thyroid, and endometrium. Deletion of 10q23, the region that includes the PTEN gene, is seen in sporadic melanomas and glioblastoma, whereas sporadic endometrioid carcinomas may have either deletion or mutation of the PTEN gene.²⁴ Loss of the expression of PTEN protein by immunohistochemistry (IHC) or evidence of mutation or deletion by molecular analysis is seen in the majority of endometrioid carcinomas in most studies, while serous carcinomas rarely display an abnormality of PTEN. The combination of estrogen-driven proliferation, abnormal DNA repair mechanisms, and decreased apoptosis and cell-cycle dysregulation caused by loss of PTEN function sets the stage for uncontrolled growth and the acquisition of additional mutations.

K-ras mutations are seen in 10% to 35% of endometrioid carcinomas, but rarely in serous carcinoma.^{21,25} Only a few cases of clear cell carcinoma have been examined for *K-ras* mutations, but mutations were present in two of three cases examined.²⁶

Abnormalities of p53 expression appear to play little role in the evolution of endometrioid carcinoma, whereas the

majority of serous and clear cell lesions have abnormalities in p53 expression. p53 abnormalities were found in none of 117 cases of endometrial hyperplasia by molecular methods.²⁷ Indeed, in cases of mixed serous and endometrioid histology, it appears that an area of the endometrioid carcinoma develops a mutation of p53, resulting in a serous component with a different phenotype. Serous carcinomas rarely have microsatellite instability, loss of PTEN expression, or *K-ras* mutations. As in invasive serous carcinoma, serous intraepithelial carcinoma is associated with p53 mutation, indicating that this is an early change in the carcinogenesis of serous tumors.²⁸

Clear cell carcinoma has a rate of p53 mutation midway between that seen in clear cell and endometrioid carcinoma.²⁹ Cases with intermixture of serous elements have a higher rate of p53 mutation and frequently have coexisting serous intraepithelial carcinoma. Cases associated with endometrioid histology tend not to have abnormalities of p53, suggesting that there may be two pathways for the development of the clear cell histology.

Abnormalities in the adenomatous polyposis coli (APC)-beta catenin pathway are also found in type I endometrial carcinoma. In normal epithelial cells, the APC gene product binds to beta catenin, targeting the latter's degradation. Although mutations in the APC gene have not been reported in endometrial carcinoma, 47% of type I endometrial carcinomas have hypermethylation of the APC gene promoter, indicating a loss of APC function.³⁰ Nuclear beta-catenin accumulation has been documented in several studies ranging from 10% to 55%³¹ and is almost exclusively limited to type I histology, having been reported in only 1 of 85 serous carcinomas examined.³⁰ When compared to other type I endometrial carcinomas, nuclear beta-catenin accumulation is associated with grade I histology, premenopausal status, and expression of estrogen and progesterone receptors.³²

Stage and Prognosis

The International Federation of Gynecology and Obstetrics (FIGO) introduced a surgical staging classification system for endometrial carcinoma in 1988 (Table 53.2) because clinical

TABLE 53.2. International Federation of Gynecology and Obstetrics (FIGO) staging for carcinoma of the corpus uteri.

Stage	Description
IA Grades 1, 2, 3	Tumor confined to the endometrium
IB Grades 1, 2, 3	Invasion to less than one-half of myometrium
IC Grades 1, 2, 3	Invasion to more than one-half of myometrium
IIA Grades 1, 2, 3	Endocervical glandular involvement
IIB Grades 1, 2, 3	Cervical stromal involvement
IIIA Grades 1, 2, 3	Tumor invades the serosa and/or adnexae, and/or positive peritoneal cytology
IIIB Grades 1, 2, 3	Vaginal metastases
IIIC Grades 1, 2, 3	Metastases to pelvic and/or paraaortic lymph nodes
IVA Grades 1, 2, 3	Tumor invasion of bladder or bowel mucosa
IVB	Distant metastases including intraabdominal involvement or inguinal lymph node involvement

TABLE 53.3. Clinical staging for carcinoma of the corpus uteri.

Stage	Description
I	Confined to the corpus
IA	Uterine cavity 8 cm or less
IB	Uterine cavity more than 8 cm
II	Involvement of corpus and cervix
III	Extension outside the uterus but not outside the true pelvis May not involve mucosa of the bladder or rectum
IV	Extension beyond the true pelvis or involves mucosa of the bladder or rectum
IVA	Spread to adjacent organs: bladder, rectum, sigmoid, small bowel
IVB	Spread to distant organs

assessment was found to be inaccurate in approximately 40% of cases.³³ At this time, clinical staging (Table 53.3) is relevant only for patients treated with primary radiation therapy. Although there is no specific staging system for uterine sarcomas, some clinicians utilize the surgical staging system for endometrial corpus cancers to classify sarcomas. Surgical staging encompasses a total abdominal hysterectomy with bilateral salpingo-oophorectomy, peritoneal washings for cytology, and, if deemed necessary, pelvic and paraaortic lymph node assessment. Suspicious lymph nodes should be resected or biopsied if unresectable. Relative depth of myometrial invasion (none, inner half, outer half) and the presence or absence of cervical involvement can be determined by gross examination or, if necessary, a frozen section, to determine pathologic factors for which lymphadenectomy would be warranted. For patients with known uterine papillary serous carcinoma, clear cell carcinoma, or carcinosarcoma, where there is risk of omental involvement, some surgeons incorporate an omentectomy into the staging procedure. A lymph node assessment should be performed in these patients with poor prognostic histologic subtypes.

Tumor stage is a well-recognized prognostic factor for uterine cancer. Overall, 5-year survival for endometrial cancers between 1992 and 1999 was 84.4%, which is primarily due to the early stage of presentation in the majority of cases. For patients who are staged, the 5-year survivals are stage I and II, 96.2%, stage III, 64.7%, and stage IV, 26%.¹ In contrast, the prognosis for uterine sarcomas is significantly poorer, with only 20% to 35% of patients surviving 5 years.³⁴ Clinical factors including patient age, race, and medical comorbidities also significantly impact on outcome. Although incorporated into the surgical staging system, individual pathologic risk factors also act as prognostic factors. These are grouped into uterine and extrauterine factors. Uterine factors include histologic cell type, tumor grade, depth of myometrial invasion, tumor size, capillary or lymphatic vessel involvement, and extension to the cervix. Extrauterine factors include adnexal metastasis, intraperitoneal involvement, lymph node involvement, and positive peritoneal cytology. Risk of extrauterine disease is most strongly related to depth of uterine invasion, followed by tumor grade (Table 53.4).³⁵ The risk of pelvic lymph node involvement is less than 1% for patients whose tumor is confined to the endometrium. In contrast, if the outer half of the myometrium is involved, the risk of pelvic lymph node involvement increases to about 10% and 20% for

grade 1 and grade 2 tumors, respectively, and 34% for grade 3 tumors. Corresponding percentages for paraaortic lymph node involvement in deeply invasive cancers are 6% and 14% for grade 1 and 2 tumors, respectively, and 23% for grade 3 tumors.³³ In patients with a combination of deep myometrial invasion and grade 3 tumor, 30% of patients in a cohort followed prospectively by PORTEC (Post-Operative Radiation Therapy in Endometrial Carcinoma) trialists experienced distant metastases despite the use of adjuvant radiation therapy.³⁶ Positive peritoneal cytology has also been identified as a factor that can influence prognosis in early-stage endometrial cancer patients; however, its role as an independent prognostic factor remains controversial because cytologic findings frequently correlate with increasing tumor grade and depth of invasion.³⁷

As mentioned earlier, histologic cell types such as the papillary serous carcinomas and clear cell carcinomas carry a poorer prognosis than the endometrioid cancers. Much of this difference in outcome is due to the presence of occult disseminated disease.³⁸ Sarcomas and carcinosarcomas are also particularly aggressive, with more than 50% of apparent stage I carcinosarcomas showing evidence of extrauterine spread when surgically staged.³⁹

Therapeutic Modalities

Surgery

Surgery for uterine cancers including the endometrial cancers, papillary serous cancers, and carcinosarcomas consists of a total abdominal hysterectomy, bilateral salpingo-oophorectomy, pelvic and paraaortic lymph node assessment, and cytologic washings. Surgery provides both prognostic information in the form of staging and, in stage IV disease, may be of therapeutic value. Improved survival has been demonstrated in those patients who were optimally surgically cytoreduced to less than 1 cm of disease.⁴⁰ In patients with stage IVB endometrioid, serous, and mixed cell types who were optimally debulked, survival was 34.3 months in comparison to 11 months ($P = 0.0001$) in suboptimally debulked patients.

Radical hysterectomy, an extended hysterectomy in which additional parametrial tissue is removed with the surgical specimen, has been used for patients with known cervical involvement and has been associated with an

TABLE 53.4. Frequency of nodal metastasis with individual risk factors.

Risk factor	No. of patients (Creasman)	Pelvic number (%) (Creasman)	Aortic number (%) (Creasman)	No. of patients (Grigsby)	Five-year DFS (%) (Grigsby)
Histology					
Adenocarcinoma	459	40 (9%)	21 (5%)	768	88.6%
Others	99	2 (9%)	4 (18%)	71	80.5%–88.9%
Grade					
1 Well	180	5 (3%)	3 (2%)	340	94.7%
2 Moderate	288	25 (9%)	14 (5%)	255	88.4%
3 Poor	153	28 (18%)	17 (11%)	161	73.2%
Myometrial invasion					
Endometrial only	87	1 (1%)	1 (1%)	199	93.4%
Superficial	279	15 (5%)	8 (3%)	250	89.6%
Middle	116	7 (6%)	1 (1%)	112	89.8%
Deep	139	25 (25%)	24 (17%)	88	67.8%
Peritoneal cytology					
Negative	537	38 (7%)	20 (4%)	240	91.5%
Positive	75	19 (25%)	14 (19%)	21	56.1%
Tumor location					
Fundus	524	42 (8%)	20 (4%)	447	88.8%
Isthmus-cervix	97	16 (16%)	14 (14%)	23	73.1%
Adnexal involvement					
Negative	587	47 (8%)	27 (5%)		
Positive	34	11 (32%)	7 (20%)		
Capillary space involvement					
Negative	528	37 (7%)	19 (9%)	549	88.9%
Positive	93	21 (27%)	15 (19%)	65	75.0%

improvement in survival.⁴¹ However, whether more-extensive surgery is of benefit in stage II disease remains controversial.

Debate also exists as to which patients with disease presumptively confined to the uterus should undergo lymph node assessment and how extensive a lymph node assessment is required as a component of the surgical staging. Proponents of lymph node sampling or lymphadenectomy in *all* patients with endometrial cancer note that relying on a staging algorithm based on intraoperative identification of high-risk factors (grade 3, papillary serous, clear cell, deep myometrial invasion, or cervical involvement) will miss 5% to 7% of patients with these risk factors.⁴² In addition, reliance on palpably enlarged nodes during surgery has been shown to identify positive nodes less than 10% of the time in prospective studies.³³ The question of whether there is a therapeutic value to the removal of lymph nodes in endometrial cancer is also a matter of controversy. An analysis of the SEER (Surveillance, Epidemiology, and End Results) data to determine whether pelvic lymph node sampling impacted on survival did not show a correlation with survival. Information on use of adjuvant therapy was not available for this analysis.⁴³ No randomized studies have been performed to elicit the specific value of a lymphadenectomy in the removal of microscopic or macroscopic nodal metastases. Overall survival appears to be better, however, for patients with positive nodes if they undergo a paraaortic lymphadenectomy than if they do not (77% versus 42%; $P = 0.05$).⁴⁴

Radiation Therapy

Radiation therapy (RT) has long occupied a role in the management of patients with endometrial carcinoma. For much of the past century, RT was commonplace in the treatment of these patients, particularly preoperative RT. By the 1980s, however, the use of preoperative RT declined, replaced by primary surgical approaches. Currently, RT is delivered almost exclusively following surgery in women with adverse pathologic features.

Today, the most common external-beam RT approach in endometrial cancer is pelvic RT, delivered at most centers with a four-field approach to a total dose of 45–50.4 Gy. Select patients receive extended-field or whole abdominal RT, delivered with opposed anteroposterior fields. Prescribed doses are 45 to 50 Gy (extended field) and 25 to 30 Gy (whole abdominal). In the latter case, the pelvis is boosted to 45–50 Gy.

The most common brachytherapy approach is intracavitary vaginal brachytherapy, delivered with either low dose rate (LDR) or high dose rate (HDR) techniques. With LDR, 60–70 Gy is prescribed to the vaginal surface (25–35 Gy if combined with pelvic RT). Various HDR schedules are recommended, including 7 Gy \times 3, 5.5 Gy \times 4, and 4.7 Gy \times 5 (at 0.5-cm depth) and 10.5 Gy \times 3, 8.8 Gy \times 4, and 7.5 Gy \times 5 (at the vaginal surface). When combined with pelvic RT, 5.5 Gy \times 2 or 4 Gy \times 3 (at 0.5 cm) or 8 Gy \times 2 or 6 Gy \times 3 (at the surface) is used.⁴⁵

Recently, intensity-modulated radiation therapy (IMRT) has received increasing attention in gynecologic tumors. Unlike conventional techniques, IMRT conforms the prescription dose to the shape of the target in three dimensions, thereby sparing nearby normal tissues. Multiple investigators have compared IMRT and conventional planning, noting significant reductions in the volume of all normal tissues irradiated (small bowel, bladder, rectum, and bone marrow) with IMRT. In a series of reports, investigators at the University of Chicago have reported fewer acute and chronic sequelae in gynecology patients treated with IMRT compared to conventional pelvic RT.²⁵ Recently, these investigators reported no pelvic failures in a cohort of 31 stage I–IV endometrial cancer patients treated with IMRT at a median follow-up of 24 months.⁴⁶

Therapy for Stage I/II Disease

Therapy for stage I/II disease usually consists of surgery with or without RT. Patients with surgically staged IA and IB grade 1 cancers with low-volume tumor (less than 2 cm) can be successfully managed with observation, as the cancer-related and recurrence-free survivals are 97% and 96%, respectively.⁴⁷ Surgically staged patients who have stage IB grade 2 disease with low-volume tumor (less than 2 cm) can also be successfully observed without adjuvant RT, although some investigators would administer vaginal brachytherapy.

Radiotherapy

PREOPERATIVE RADIOTHERAPY

Radiotherapy was commonplace for many years in the treatment of early-stage endometrial cancer. However, its benefit in clinical stage I disease is unclear and today it is performed at only a few centers. A stronger rationale exists for its use in clinical stage II disease, particularly in patients with gross cervical involvement.

ADJUVANT RADIOTHERAPY

The role of adjuvant RT in early-stage endometrial cancer is controversial (Table 53.5). At some centers, nearly all patients

receive postoperative RT, even those with minimally invasive, low-grade tumors. At others, it is rarely administered, even in women with deeply invasive, high-grade disease. Even when it is used, controversy exists over *how* it should be performed.

The decision to administer adjuvant RT in early-stage patients is typically based on pathologic features in the hysterectomy specimen including depth of myometrial invasion, grade, and cervical involvement. Other factors cited include tumor size, lymphovascular invasion, and lower uterine segment involvement. However, the significance of lower uterine segment involvement in the absence of other high-risk factors remains unclear.⁴⁸

To date, three prospective randomized trials have been published evaluating postoperative RT in early-stage disease (Table 53.6). The first was performed in Norway and published in 1980.⁴⁹ All patients had clinical stage I disease and underwent primary surgery without lymph node sampling. Excluding those found to have extrauterine disease, 540 women were treated with vaginal brachytherapy and then randomized to observation versus pelvic RT. Overall, no difference was seen in the 5-year survival between the two groups (91% observation, 89% pelvic RT). However, pelvic RT was associated with a significantly lower incidence of vagina/pelvic recurrences in women with deep myometrial invasion (14.7% observation, 6.6% pelvic RT) and high-grade disease (14.1% observation, 3.2% pelvic RT). Chronic toxicities were seen in 1.2% and 0.8%, respectively, of patients treated with and without pelvic RT.

Gynecologic Oncology Group trial 99 (GOG 99) was initially presented in 1998 and ultimately published in 2004.⁵⁰ Four hundred forty-eight stage IB, IC, and occult II patients were enrolled. Patients underwent primary surgery with pelvic and paraaortic lymph node sampling and were randomized to pelvic RT or no further therapy. Overall, irradiated patients had a superior 2-year recurrence-free survival (97% versus 88%; $P = 0.007$) compared to surgery-alone patients. Two-year rates of isolated vaginal failure in the surgery-alone and irradiated patients were 7.4% and 1.6%, respectively. The benefit of RT was most evident in the subset of 132 patients with “high” intermediate risk features (94% versus 74%), defined as (1) grade 2–3 with lymphovascular

invasion and more than 1–3 myometrial invasion, (2) at least 50 years of age with any two of the above factors, or (3) at least 70 years of age with any one of the above factors. Overall, irradiated patients had a better 4-year overall survival (92% versus 86%); however, this difference failed to reach significance ($P = 0.56$). Significantly higher rates of hematologic, gastrointestinal, genitourinary, and cutaneous toxicities were seen in the irradiated group; however, acute and chronic toxicities were combined in the analysis.

Creutzberg and coworkers reported the results of the PORTEC trial.⁵¹ All patients underwent primary surgery without nodal sampling. Eligible women had grade 1 tumors with more than 50% myometrial invasion, grade 2 tumors, or grade 3 tumors with less than 50% invasion. Seven hundred fifteen women were randomized to receive either pelvic RT or no further therapy. At a median follow-up of 52 months, irradiated patients had a superior 5-year pelvic control (96% versus 86%; P less than 0.001). However, no difference was noted in overall survival (81% RT group, 85% control group). As in the GOG trial, treatment sequelae were more common in irradiated patients (25% versus 6%; P less than 0.001).

Although these trials consistently demonstrate that RT reduces the risk of pelvic failure in patients with adverse pathologic features, it is unclear whether survival is improved. This is far from being an academic issue, for the lack of a survival benefit has led some to withhold RT. However, none of these trials is well suited to answer this question. First, their follow-up is limited. Longer observational times are needed to assess outcomes of patients who relapse following surgery. Second, only two include a no-RT control arm, for all women in the Norwegian trial received brachytherapy. Finally, the GOG included many low-risk patients (58% IB, 82% grades 1–2), whereas PORTEC excluded high-risk women (stage IC grade 3, stage II). The former thus included women the least likely to benefit whereas the latter excluded those the most likely to benefit. Although the GOG analyzed “high”-risk patients separately, the small number of such patients significantly limited the power of the analysis.

The optimal approach in early-stage patients who do receive postoperative RT is unclear. It is noteworthy that

most pelvic recurrences in the GOG surgery-alone arm were in the vagina.⁵⁰ Such a failure pattern suggests that, at least in surgically staged patients, vaginal brachytherapy may be as efficacious as pelvic RT. The more-favorable toxicity profile of vaginal brachytherapy is certainly appealing. The ongoing PORTEC-2 study randomizes between external-beam radiotherapy and vaginal brachytherapy.

The decision whether to irradiate an individual patient rests on a careful assessment of the benefits and risk of treating (and of not treating). The likelihood of cure and toxicity following adjuvant RT needs to be weighed against the likelihood of salvage and toxicity if treatment is withheld. If administered, the approach that maximizes tumor control while minimizing toxicity should be selected. The least aggressive approach should always be used if outcome is not compromised, for example, vaginal brachytherapy instead of pelvic RT in surgically staged patients.

It is difficult to give clear guidelines regarding the use of adjuvant RT in early-stage endometrial cancer, given the lack of consensus between investigators. In general, most investigators do not administer adjuvant RT in women with stage IA grade 1–2 or stage IB grade 1 disease. Stage IA grade 3 patients usually receive either vaginal brachytherapy or pelvic RT.

Patients with stage IB grade 2 tumors undergo pelvic RT or vaginal brachytherapy. Given the excellent pelvic control and low toxicity associated with brachytherapy alone, it is the preferred approach, particularly in surgically staged patients. Women with stage IB grade 3 tumors typically undergo both pelvic RT and brachytherapy. However, pelvic RT alone is associated with excellent control rates and less toxicity.⁵² In surgically staged patients, brachytherapy alone appears to result in equally favorable outcomes with low rates of toxicity.⁵³

At most centers, patients with stage IC tumors receive pelvic RT. At others, they undergo both pelvic RT and vaginal brachytherapy. However, this practice should be discouraged. In a review of 541 stage I patients with deep myometrial invasion from 12 published studies, Weiss et al. noted vaginal recurrences in 1.04% of patients undergoing pelvic RT alone versus 0.97% of patients receiving pelvic RT and vaginal brachytherapy.⁵⁴ Moreover, toxicity is more common with

the combined approach.⁵² In surgically staged patients, brachytherapy alone results in an excellent pelvic control rate with a low risk of sequelae.⁵³ Interest has emerged recently in whether surgically staged patients with stage IC disease can be observed without adjuvant radiation. One study comparing two cohorts of patients with stage IC (all grades) disease with and without RT demonstrated a 6% chance of recurrence in the RT cohort and 12% in the observation cohort but with similar 5-year overall survivals in both groups (92% versus 90%, respectively; $P = 0.717$). Five-year disease-free survival was improved only in the grade 1 tumor group receiving RT (100% versus 80%; $P = 0.036$). However, studies such as these have been retrospective in nature with observation groups chosen by physician preference.⁵⁵

Patients with stage II disease typically receive both pelvic RT and brachytherapy. However, stage IIA tumors can be treated with pelvic RT alone or, if surgically staged, vaginal brachytherapy.⁵⁶ Patients with stage IIB disease should receive both pelvic RT and vaginal brachytherapy.

DEFINITIVE RADIOTHERAPY

Although most endometrial cancer patients are treated with surgery, a subset of patients with multiple medical comorbidities and/or advanced age are considered medically inoperable. Such patients are often treated with RT, with curative intent. In addition, patients with locally advanced disease may undergo RT alone.

The most favorable outcomes following RT alone are seen in clinical stage I patients, with 5-year survival rates ranging from 48% to 66%.^{57,58} After correcting for intercurrent deaths, 5-year *cause-specific* survivals in these women range from 72% to 87%, with survivals in many series exceeding 80%. Less-favorable outcomes have been reported in clinical stage II and III patients.⁵⁷ Pelvic/uterine control rates are high in most patients treated with definitive RT, particularly in those with stage I disease (more than 80%).⁵⁹

Systemic Therapy

There are currently no data supporting the addition of systemic therapy to adjuvant RT in early-stage endometrial cancer. Older randomized trials of adjuvant progestins showed no benefit.⁶⁰ The highest risk group are those with high-grade, deep myometrial invasion and no lymph node

sampling. A recent registration trial from the PORTEC group followed 99 women with stage IC grade 3 tumors who did not undergo pelvic/paraortic node dissection. All received postoperative pelvic radiotherapy. There were 13 vaginal/pelvic relapses and 31 distant relapses, with 30 deaths due to endometrial cancer.³⁶ The Radiation Therapy Oncology Group (RTOG) recently completed a Phase II trial evaluating chemoradiotherapy in high-risk patients (grade 2–3 tumors with more than 50% invasion, cervical stromal invasion, or pelvic-only extrauterine disease).⁶¹ All patients received pelvic RT with cisplatin (50 mg/m², days 1 and 28), vaginal brachytherapy, and then four cycles of cisplatin (50 mg/m²) and paclitaxel (175 mg/m²). Although the regimen was thought to be feasible, severe (grade 3–4) acute and chronic toxicities were noted in 29% and 18% of patients, respectively. At 24 months, the pelvic recurrence, distant recurrence, disease-free survival, and overall survival of the entire group were 2%, 17%, 83%, and 90%, respectively. A recent randomized trial launched by the RTOG using this cisplatin/paclitaxel chemotherapy in stage I/II disease failed to accrue. Patients with high-risk tumors who have lymph node staging performed, and are known to be node negative, have a lower risk of recurrence than those in whom lymph node assessment is not performed, and it is not likely that adequately powered randomized trials in this subgroup will be feasible. Patients with stage I/II serous/clear cell tumors do merit consideration for adjuvant chemotherapy, as discussed next. In the future, molecular markers may aid in the selection of patients for adjuvant chemotherapy trials.

Therapy for Stage III and “Optimally Debulked” Stage IV Disease

Radiation Therapy

Adjuvant RT has been used in the postoperative treatment of stage III–IV endometrial cancer patients for many years. Patients with disease limited to the pelvis received pelvic RT with and without vaginal brachytherapy, analogous to stage I–II disease. Those with more-extensive disease were treated with more comprehensive fields, such as extended-field and whole abdominal RT.

Table 53.7 summarizes representative recent adjuvant RT series in stage III–IV disease.^{62–68} Unsurprisingly, outcomes

vary widely, with the best results seen in stage IIIA disease, particularly in patients with isolated adnexal or peritoneal fluid involvement. In contrast, less-favorable outcomes are seen in stage III–IV patients with involvement of multiple extrauterine sites and residual upper abdominal disease.

Considerable interest formerly existed for intraperitoneal ^{32}P in patients with isolated involvement of the peritoneal cytology. Today, interest has waned in light of reports questioning the prognostic significance of positive cytology in the absence of other adverse features.⁶⁹ Moreover, significant gastrointestinal toxicities may occur in patients receiving both ^{32}P and external-beam RT.

In the past, stage IIIA patients with isolated adnexal involvement received aggressive therapy, including whole abdominal RT. However, pelvic RT is most likely sufficient. Similarly, recent data have called into questions the role of whole abdominal RT in stage IIIA patients with isolated serosal involvement.⁶⁷ Stage IIIB disease is rare. These patients are usually clinically staged and undergo preoperative (or definitive) irradiation. Limited data are available to guide therapeutic decisions.⁶⁵

Adjuvant irradiation in stage IIIC disease has received considerable attention. Numerous authors have reported long-term cures in women with positive paraaortic nodes following extended-field RT, with 5-year survivals ranging from 36% to 84%.^{62,68} Patients with pelvic nodal involvement alone represent a favorable group. Nelson and coworkers treated 17 stage IIIC patients with positive pelvic (and negative paraortic) nodes with pelvic ($n = 13$) or whole abdominal ($n = 4$) RT. The 5-year disease-free and overall survivals of the entire group were 81% and 72%, respectively.⁶⁴

Patients with involvement of multiple extrauterine sites pose a therapeutic challenge. In a review of stage III patients, Greven et al. noted abdominal failures in 10% and 25% of women with involvement of one versus three or more extrauterine sites ($P = 0.03$), providing a rationale for whole abdominal RT in the latter group.⁷⁰ Promising results have been reported using whole abdominal RT in these as well as in stage IV patients. A GOG phase II trial (GOG 94) of whole abdominal RT included 77 optimally debulked stage III–IV patients. The 3-year progression-free and overall survival of this group was 35% and 31%, respectively.⁷¹

No prospective Phase III trial has been performed comparing surgery versus surgery plus postoperative RT in any subgroup of stage III–IV disease. Thus, the benefit of *any* form of adjuvant RT in these patients remains unclear. Today, interest is shifting increasingly away from postoperative RT toward systemic chemotherapy. Recently, the GOG completed a randomized trial (GOG 122) comparing adjuvant whole abdominal RT versus chemotherapy (doxorubicin/cisplatin) in optimally (less than 2 cm residual disease) debulked stage III/IV patients. This trial has not yet been published in full; at a median follow-up of 52 months, chemotherapy patients had a superior 2-year disease-free (59% versus 46%) and overall (70% versus 59%) survival. Recurrences were frequent, predominantly in the pelvis and abdomen, in both groups.⁷² A concern was the high rate of vaginal cuff recurrences in the RT group because vaginal brachytherapy was not routinely delivered.

Little interest today remains for whole abdominal RT *alone* except at select centers.⁶⁶ However, whole abdominal RT is currently being evaluated combined with either con-

comitant (GOG 9907) or sequential (GOG 9908) chemotherapy. An earlier phase I trial (GOG 9001) demonstrated the feasibility of concomitant chemoradiotherapy in this setting.⁷³ Given the heterogeneity of stage III–IV disease, it is unlikely that a single approach is appropriate in all patients. Unfortunately, the limited numbers of locally advanced patients preclude the ability to define the optimal approach in every subgroup.

Systemic Therapy

As discussed above, the only randomized trial evaluating chemotherapy in stage III disease is GOG 122, which compared whole abdominal radiotherapy to cisplatin/doxorubicin chemotherapy. About 73% of the patients had stage III disease. Survival benefit with chemotherapy was seen for both the stage III patients [hazard ratio (HR) 0.67, 0.47–0.95] and the stage IV patients (HR 0.64, 0.42–0.99). A small number (about 15%) of these “optimally debulked” stage IV patients appear to be disease free at 5 years. Fifty percent to 60% of stage III patients were disease free at 5 years.⁷²

Although select stage III patients may benefit from RT alone, current interest focuses on combined chemoradiotherapy approaches. The addition of radiotherapy to chemotherapy is supported by the high rate of locoregional failure both in GOG 122 and in retrospective series of patients treated with chemotherapy alone.⁷⁴ A subsequent GOG stage III trial, GOG 184, prescribed “involved field” (pelvic \pm para-aortic \pm intravaginal) radiotherapy to all patients; this was followed by either cisplatin/doxorubicin or paclitaxel/doxorubicin/cisplatin chemotherapy. Results of this trial are not yet available. Growth factor (granulocyte colony-stimulating factor, G-CSF) is required for most patients when pelvic radiotherapy precedes chemotherapy to maintain reasonable dose intensity.

Cisplatin/doxorubicin is the only chemotherapy combination for which any positive randomized trial data exist for use in the adjuvant setting. However, based on preliminary results in metastatic disease and ongoing adjuvant clinical trials, other regimens, such as paclitaxel/doxorubicin/cisplatin or carboplatin/paclitaxel, may be used in the future.⁷⁵

Advanced/Recurrent Disease

With the exception of isolated vaginal recurrences or the occasional solitary, resectable pulmonary nodule, therapy for metastatic or recurrent endometrial carcinoma remains palliative.

Salvage Surgery

After radiation therapy, patients with localized central recurrences have been treated surgically with a complete pelvic exenteration for curative intent. Although the complication rate is high, 5-year disease-free survival in this small group of patients was 45%.⁷⁶

Salvage Radiotherapy

Approximately 50% of endometrial cancer patients who relapse following surgery fail in the pelvis, of whom 50%

recur in the vaginal vault. Patients with recurrent disease limited to the pelvis often undergo salvage, particularly those with isolated vaginal recurrences.

Numerous investigators have reported the outcome of patients with recurrent endometrial cancer following salvage RT.^{77–79} Survival rates vary considerably between the published reports, ranging from 18% to 71%. Patients with isolated vaginal recurrences represent a favorable group. Pai and coworkers evaluated the outcome of 20 patients with isolated vaginal involvement treated with salvage RT. The 10-year actuarial local control and cause-specific survival of the entire group were 74% and 71%, respectively.⁷⁹ In contrast, others have reported poor survivals (24%–33%) in patients with isolated vaginal recurrences.⁷⁷ Additional favorable prognostic factors include long disease-free intervals, low-grade disease, adenocarcinoma histology, and no prior RT.

Local control is achieved in 35% to 92% of patients treated with salvage RT, with most series reporting control rates between 40% and 70%.⁷⁸ A major determinant of local control is tumor size. Wylie and coworkers reported 5-year local control rates of 80% and 54% in tumors of 2 cm or less and more than 2 cm, respectively ($P = 0.02$).⁸⁰ Others have reported similar results.

Hormonal Therapy

Endometrial cancers frequently express both estrogen (ER) and progesterone (PR) receptors, and high levels of PR expression have been shown to correlate inversely with stage and grade, as well as being an independently favorable prognostic indicator in some series of early-stage disease.⁸¹ About 20% of unselected patients with metastatic endometrial carcinoma will respond to therapy with progestins. Other hormonal agents may also have some activity.

Factors that have been found to predict for response to progestins and, to a limited extent, to other hormonal therapies include well-differentiated tumors, a long interval between diagnosis and tumor recurrence, and high levels of estrogen receptors (ER) and progesterone receptors (PR).⁸² However, these criteria are imperfect; for example, high-grade tumors sometimes respond to hormonal therapy. Attempts have been made to standardize definitions of ER and PR positivity so that endometrial cancer patients could be selected for hormonal therapy in a manner similar to breast cancer patients, but this has not occurred. Concern exists over the fact that some patients defined as “receptor negative” by various cutoff criteria nonetheless respond to hormones, that there can be heterogeneity between the hormone receptor status of the primary tumor and the metastatic sites, and that various metastatic sites can be discordant.^{83,84} Moreover, PR-specific antibodies may fail to detect PRB in formalin-fixed, wax-embedded tissue despite their ability to do so by immunoblot analysis,⁸⁵ and PRB may be important in response to hormonal therapy.⁸⁶

Cytotoxic Chemotherapy

Taxanes, anthracyclines, and platinum agents have shown the most activity as single agents to date. It should be kept in mind that dose intensity in some single-agent trials is limited by the older age and prior pelvic radiotherapy of many patients. For example, the Eastern Cooperative Oncology Group (ECOG) trial of topotecan in chemotherapy-naïve

women with metastatic/recurrent disease found 0.8 mg/m²/day × 5 (versus the FDA-approved dose of 1.5 mg/m²/day × 5 for second-line therapy for ovarian cancer) to be the tolerable dose in women with prior pelvic radiotherapy for endometrial cancer.⁸⁷

Table 53.8 shows randomized trials of combination therapy. In general, combinations have been shown to produce higher response rates than single-agent therapy and have therefore become standard for healthy patients. Most recently, the three-drug combination of paclitaxel, doxorubicin, and cisplatin showed a survival advantage over the two-drug combination of doxorubicin and cisplatin, but it produced more neurotoxicity⁸⁸ and required growth factor support. As treatment in the setting of metastatic disease is generally palliative, decisions about choice of regimen should be based on individual needs and wishes of the patient. The median survival from time of entry onto a chemotherapy protocol for measurable recurrent disease is about a year.

Unfavorable Histology

Papillary Serous/Clear Cell

Because of the rarity of these subtypes, many publications represent small retrospective single-institution series that include patients diagnosed over several decades with a conglomerate of stages and treatments. Often uterine papillary serous carcinomas (UPSC) and clear cell carcinomas (CCC) are analyzed together.

SURGERY

Because of the propensity for lymphatic and hematogenous spread, patients with papillary serous and clear cell carcinomas should be surgically staged. This procedure should include a total abdominal hysterectomy, bilateral salpingo-oophorectomy, cytologic washings, pelvic and paraaortic lymph node assessment, and an omentectomy, as 37% to 50% of patients believed to have cancer confined to the uterus will have extrauterine involvement found upon surgical staging.^{89,90} Twenty-six of 34 (76%) patients from selected retrospective studies who were surgically staged and shown to have disease confined to the endometrium (stage IA) were observed without adjuvant radiation or chemotherapy. Five of these 26 patients (19%) developed a recurrence in either the pelvis or abdomen. The majority, however, remain disease free.^{89–92} Other retrospective studies of presumptive stage IA patients have shown higher recurrence rates (30%) but are difficult to interpret given the lack of surgical staging.⁹³

RADIOTHERAPY

The role of RT in patients with unfavorable histologies (papillary serous, clear cell) is controversial. Because papillary serous tumors have a propensity to relapse in the upper abdomen, attention has focused primarily on whole abdominal RT. In a study of 26 patients (80% papillary serous) treated with abdominopelvic radiotherapy, Smith et al. noted a 3-year disease-free and overall survival of 87% and 87% in stage I–II and 32% and 61% in stage III–IV patients, respectively.⁶⁶ A Phase II study of whole abdominal RT conducted by the GOG (GOG 94) enrolled 88 papillary serous/clear cell patients, 49

of whom were pathologic stage I/II. The 5-year disease-free survival of stage I–II papillary serous ($n = 31$) and clear cell ($n = 18$) patients were 35% and 61%, respectively.⁷¹ Some others have also reported less-favorable results with whole abdominal RT.⁷¹

No prospective Phase III trial evaluating whole abdominal RT in papillary serous tumors has been conducted. Its benefit thus remains unclear, particularly in pathologic stage I–II patients. In a review of 193 stage I–II patients from nine studies, Mehta et al. noted abdominal failures in 6 of 68 patients (9%) treated with versus 10 of 125 patients (8%) treated without whole abdominal RT. A benefit in pelvic control was seen, however, with the use of pelvic and/or

vaginal irradiation (11% irradiated, 73% nonirradiated patients).⁹⁴ Given the high risk of distant failure, a reasonable approach may be chemotherapy combined with pelvic and/or vaginal RT.⁹⁵

Fewer data are available evaluating the role of RT in clear cell carcinoma. These tumors are often grouped with papillary serous tumors and treated with whole abdominal RT, even when confined to the uterus.⁶⁶ However, it remains unclear whether whole abdominal RT is beneficial. Murphy and colleagues reviewed the outcome of 38 clear cell patients treated with primary surgery.⁹⁶ Pelvic recurrence was seen in 0 of 22 patients treated with versus 8 of 16 (50%) without adjuvant RT (P less than 0.0001). Although no patient

received whole abdominal RT, only 1 (2%) failed in the upper abdomen.

SYSTEMIC THERAPY: RECURRENT/METASTATIC DISEASE

The worse prognosis associated with USPC and CCC appears to be related to the very high rates of advanced stage at presentation. Once a tumor has spread outside the uterus, there is no evidence that the chemotherapeutic treatment for women with UPSC or CCC should be different from that for women with high-grade endometrioid carcinomas, despite the different molecular pathways involved. UPSC and CCC do not usually express hormone receptors⁹⁷ and should not generally be treated with hormonal therapies such as progestins. Response rates and overall survival for UPSC did not differ from that for all other histologies in two large randomized trials of patients with advanced or recurrent endometrial cancer using cisplatin, paclitaxel, and doxorubicin (GOG 163 and GOG 177).

Clear cell carcinoma is less common than UPSC, and it is difficult to arrive at meaningful conclusions about how well it responds to chemotherapy. Abeler et al. reported that four of six patients treated with platinum-containing chemotherapy showed a response.⁹⁸ Three of 10 and 3 of 8 patients with clear cell carcinoma treated on GOG 163 and GOG 177, respectively, had a major response.

ADJUVANT SYSTEMIC THERAPY

Twenty-one percent of patients on GOG 122 had UPSC and 4% had CCC.⁷² As discussed earlier, this trial demonstrated an overall superiority for chemotherapy; this was true regardless of histology, and chemotherapy therefore appears to be appropriate therapy for women with stage III and debulked stage IV endometrial cancer of all histologic subtypes, UPSC and CCC included.

The particular dilemmas in the systemic treatment of CCC and UPSC arise in the stage I and II patients. First, was the patient adequately staged? What criteria should be used to determine if the patient had an adequate surgical procedure to exclude more-advanced disease? Second, what is the prognosis of a true extensively surgically staged stage I UPSC or CCC patient? Given the rarity of these histologic subtypes, adequately powered randomized trials testing adjuvant treatment strategies are not feasible. Decisions about adjuvant chemotherapy must be made on a best estimate of risk of recurrence in the absence of systemic treatment and the assumption that if chemotherapy can reduce the risk of recurrence in stage III disease, it can also do so in high-risk stage I/II disease.

GOG 94 prospectively treated patients with clinical stage I/II UPSC/CCC with whole abdominal radiotherapy.⁹⁹ A preliminary report noted only a 35% 5-year progression-free survival (PFS) for stage I/II UPSC patients ($n = 31$) and a 61% PFS for stage I/II CCC patients ($n = 18$). On the other hand, as already discussed, a number of small single-institutional series using very extensive surgical staging have reported 85% to 100% 5-year survivals using no adjuvant therapy for patients with stage Ia disease.^{91,100,101}

Patients with UPSC who have disease limited to a polyp or the endometrium and who have no further disease found in the hysterectomy specimen or by surgical staging probably have excellent survival and would not benefit from chemotherapy. This is a fairly rare situation. Those who have

stage Ia disease based on extensive surgical staging, with a reasonable number of nodes dissected, the omentum and peritoneum sampled, and washings taken, probably also have survivals of 80% or more and will have limited benefit from adjuvant chemotherapy. Most series suggest that the remainder of stage I patients have a risk of recurrence of at least 20%, and they may benefit from chemotherapy.

UPSC and CCC have been suggested to have a higher frequency of HER2 amplification than endometrioid endometrial cancers.¹⁰² The GOG reported results of HER2/neu evaluation on patients from GOG 177. A 3+ level of immunohistochemical staining was detected in 46 of 236 (20%) of cases overall; 10 of 38 USPC (26%), and 36/198 for all others (18%).¹⁰³ One complete response to trastuzumab was reported in a 2003 ASCO abstract.¹⁰⁴ However, a GOG trial of single-agent trastuzumab in patients with endometrial cancers staining 2+ or 3+ by immunohistochemical analysis noted no responses in the first stage of accrual.¹⁰⁵ That trial was amended to include only patients with HER2/neu gene amplification [i.e., fluorescence in situ hybridization (FISH) positive] patients of any histologic subtype, and accrual is ongoing.

Carcinosarcomas

Carcinosarcomas, similar to uterine papillary serous carcinomas, have a high rate (75%) of unsuspected metastatic disease.¹⁰⁶ These patients should be surgically staged, if possible, for counseling with regard to prognosis and for recommendations with regard to adjuvant therapy. Survival is directly related to stage of disease. In patients with disease truly confined to the uterus based upon staging, 5-year survival is as high as 74%, in contrast to patients who have known extrauterine disease where survival is only 24% ($P = 0.0013$).¹⁰⁷ However, even in patients left with no gross residual disease, 44% of patients have been shown to develop recurrent disease.¹⁰⁸

RADIOTHERAPY

Controversy exists regarding the role of RT in carcinosarcoma. Unfortunately, the available outcome data are difficult to interpret because many older reports fail to distinguish between carcinosarcomas and other uterine sarcomas (leiomyosarcoma, endometrial stromal sarcoma) in their analyses. Of note, most,¹⁰⁹ but not all, studies that group the various sarcoma histologies together report improved pelvic control with adjuvant RT. Moreover, most¹⁰⁹⁻¹¹¹ but not all¹¹² note improved survival as well.

Hornback and coworkers evaluated the impact of pelvic RT in uterine sarcoma patients enrolled on GOG-20 (a randomized trial of adjuvant doxorubicin). In this study, pelvic RT was optional. Of 109 stage I-II patients (87% carcinosarcoma), the pelvis was the first site of failure in 10% and 23% of irradiated and nonirradiated patients, respectively.¹¹³ In a separate GOG study, irradiated clinical stage I-II patients had a lower rate of first relapse in the pelvis (17%) than nonirradiated patients (24%).¹¹⁴ Most studies focusing *solely* on carcinosarcoma have reported better pelvic control rates in irradiated patients, particularly in stage I-II disease.¹¹⁵⁻¹¹⁷ Impact on survival has been mixed, with a benefit seen in some but not all reports.

Based on studies that noted a predominance of failures in the upper abdomen,¹¹⁸ increasing attention has been focused on the use of whole abdominal RT in carcinosarcomas. Currently, the GOG is conducting a randomized trial (GOG 150) of adjuvant whole abdominal RT versus chemotherapy in optimally debulked stage I-IV carcinosarcoma patients. The results of this trial may help define the optimal approach to these patients.

ADJUVANT SYSTEMIC THERAPY

The effects of adjuvant chemotherapy have not been well studied. The only randomized trial performed (GOG 20) tested single-agent doxorubicin versus no chemotherapy after surgery, and demonstrated no difference between the arms in recurrence rate, progression-free survival, or overall survival.¹¹⁹ This trial included stage I/II uterine carcinosarcomas, leiomyosarcomas, and sarcomas of other histologies, and the numbers in each histologic subset were too small for definitive analysis. Moreover, as discussed, use of pelvic irradiation was at the discretion of the investigator. Forty-five percent of the patients with carcinosarcoma treated on GOG 20 recurred. The current GOG adjuvant trial (GOG 150) randomizes women with optimally debulked stages I-IV carcinosarcoma to whole abdominal radiotherapy versus combination ifosfamide/cisplatin chemotherapy.

SYSTEMIC THERAPY IN ADVANCED/RECURRENT DISEASE

In advanced or recurrent disease, the number of agents studied is limited, and older trials tended to study carcinosarcomas along with leiomyosarcomas and other sarcomas. Paclitaxel, ifosfamide, and cisplatin clearly produce response rates above 10%, with the highest response rates documented for ifosfamide, although these have also been the most dose-intense and toxic regimens. No randomized trials (Table 53.9) have proven any survival benefit for chemotherapy with

advanced/recurrent disease, and median survival for this group of patients remains less than 1 year.

Uterine Mesenchymal Tumors (Sarcomas)

Uterine sarcomas, in general, are rare. However, leiomyosarcomas are responsible for a disproportionate number of deaths from uterine malignancy (40%–50% of stage I–II cancers will recur). As is the case for other soft tissue sarcomas, grade is prognostically very important.^{120–122} The overall incidence of uterine malignancies including endometrial carcinomas is lower in black patients (15.31 per 100,000 woman-years; 95% CI, 14.61–16.04) than in white non-Hispanic patients (23.43 per 100,000 woman-years; 95% CI, 23.06–23.81). However, based on SEER (Surveillance, Epidemiology, and End Results) data from 1992–1998, blacks had significantly higher incidence rates of the poorer prognostic histologic types such as carcinosarcoma and sarcoma as compared to white non-Hispanics. The comparison rate ratios for blacks were 2.33 (95% CI, 1.99–2.72) for carcinosarcomas and 1.56 (95% CI, 1.31–1.86) for sarcomas. Mortality attributable to these rare aggressive tumor types accounted for 53% of mortality among black patients as compared to 36% among white patients.¹²³ Although there is no specific staging system for uterine sarcomas, some clinicians utilize the surgical staging system for endometrial corpus cancers to classify sarcomas.

Pathology

Uterine mesenchymal neoplasms can be broadly classified into those associated with endometrial stroma and those arising from the smooth muscle of the myometrium.

ENDOMETRIAL STROMAL TUMORS

Endometrial stromal tumors are characterized by an appearance similar to the stroma of proliferative endometrium, being

TABLE 53.9. Randomized chemotherapy trials in advanced uterine carcinosarcoma.

composed of short blue spindle cells and small arterioles. Based on the pattern of growth, they are separated into benign stromal nodules, low-grade endometrial stromal sarcoma, and undifferentiated endometrial sarcoma. The latter was formerly classified as high-grade endometrial stromal sarcoma, but as it is histologically, immunophenotypically, and cytogenetically distinct and has a dismal prognosis by comparison, it is best considered as a different entity rather than a less-differentiated example of stromal sarcoma.¹²⁴

Endometrial stromal nodules are uncommon lesions, usually presenting as an intramural or polypoid well-circumscribed round or oval lesion less than 5 cm in diameter. They are most often discovered as incidental findings on hysterectomy. Microscopically they have an expansile, noninfiltrative growth pattern and are composed of bland stromal cells with variable mitotic activity. Stromal nodules are benign, and tend not to recur even if treated with simple excision.¹²⁵

Low-grade endometrial stromal sarcoma may appear circumscribed or infiltrative on gross examination, but classically presents with a worm-ridden appearance to the myometrium. Areas of cystic degeneration and necrosis may be present. Microscopically, most cases have broad tongues of infiltrating tumor pecculating through the myometrium and involving lymphatic spaces. Cells are uniform, nuclear atypia is minimal, and mitotic activity is usually low, although the latter is no longer a diagnostic criterion.¹²⁶ Stromal sarcoma typically expresses estrogen and progesterone receptors, CD10, and smooth muscle actin, but lacks expression of desmin.^{127,128} Most endometrial stromal sarcomas have a (7:17) translocation involving JAZF1 and JAZ1.¹²⁹ Survival data from many studies are biased by the inclusion of cases of undifferentiated endometrial sarcoma; however, nearly half of stromal sarcoma patients will experience recurrence, often more than 5 years from initial diagnosis. Hormonal therapy has been effective in treating metastatic disease.¹³⁰

Undifferentiated endometrial sarcoma, formerly known as high-grade endometrial stromal sarcoma, occurs in an older population than low-grade endometrial stromal sarcoma and has a dismal prognosis: most patients present with advanced stage and the median survival is less than 2 years. The tumor is composed of spindle or polygonal pleomorphic mesenchymal cells that bear little resemblance to endometrial stromal cells. Mitotic activity is typically brisk and necrosis is often present. Undifferentiated endometrial sarcoma rarely expresses estrogen or progesterone receptors, lack CD10 expression, and has a complex karyotype.¹³¹ Because of the marked difference in behavior, histology, and immunoprofile, it is recommended that the term high-grade endometrial stromal sarcoma be replaced by undifferentiated endometrial sarcoma.¹³²

SMOOTH MUSCLE TUMORS

Leiomyomas are the most common uterine neoplasm, present in as many as 25% of women over 30. Grossly they are usually well circumscribed, white, and firm to rubbery, although when degenerative changes are present they may range from deep red to yellow and have a soft consistency. Microscopically, they are composed of fascicles of smooth muscle cells with bland cytology. Mitotic activity is usually low, although in reproductive years an otherwise typical leiomyoma may have up to 20 mitoses per 10 high-power fields (mitotically active

leiomyoma) and still be benign. Although areas of hyalinization, red or carneous degeneration, or even necrosis may be present, they are different from the geographic coagulative tumor necrosis associated with leiomyosarcoma. Variants of leiomyoma include symplastic leiomyoma, with markedly atypical bizarre cells; epithelioid leiomyoma, with polygonal cells rather than spindle cells; and cellular leiomyoma, composed of cells with scant cytoplasm. Leiomyomas that have undergone treatment with gonadotropin-releasing hormone analogues may display coagulative necrosis or apoptosis.¹³³

Leiomyosarcoma is the most common uterine sarcoma, with an incidence of approximately 1 per 10⁵ population. Grossly the tumors are more likely to be poorly circumscribed, soft, fleshy, and necrotic or hemorrhagic. Microscopically, compared to leiomyomas, they are more cellular, more mitotically active, and frequently have coagulative necrosis. The histologic spectrum ranges from lesions that have recognizable smooth muscle differentiation to high-grade tumors that bear little resemblance to their cell of origin. The separation of low-grade leiomyosarcoma from leiomyoma is problematic. Taylor and Norris in 1966,¹³⁴ reporting on 63 highly cellular smooth muscle tumors, found that cases with fewer than 10 mitoses per 10 high-power fields (hpf) did not metastasize. They also noted that 74% of sarcomas had necrosis, as compared to 12% of leiomyomas. Kempson and Bari¹³⁵ studied 29 cases of problematic smooth muscle tumors and found that 6 of 7 cases with 5 to 9 mitoses/hpf recurred when associated with atypia. The malignant criteria of greater than 10 mitoses/10 hpf without atypia and greater than 5 mitoses/hpf with atypia were used for decades based on these studies. In 1988 Perrone and Dehner¹³⁶ found that mitotic index did not predict poor prognosis in cases that otherwise lacked atypia. They also noted that infiltrative margins and coagulative necrosis were seen in tumors with malignant behavior. Bell et al.¹³⁷ reported their experience with 213 "problematic" smooth muscle tumors in 1994, finding in a multivariate analysis that coagulative tumor necrosis, atypia, and mitotic activity were the important predictors of malignant behavior. When some but not all of these criteria are present, the diagnosis of atypical leiomyoma is made, which carries a small risk of malignant behavior. This expansion of malignant criteria to include coagulative necrosis is especially important in two circumstances: women with mitotically active smooth muscle tumors that lack atypia and necrosis, and tumors with necrosis and atypia that lack significant mitotic activity. The former, mitotically active leiomyomas, occur in women in the reproductive years, particularly under the influence of progesterone, and are benign even if mitotic activity is greater than 10 mitoses/10 hpf. The latter are sarcomas or atypical leiomyomas with some risk of recurrence, even if the mitotic index is low.

Although a clear sequence of neoplastic progression from precursor lesion to fully malignant tumor is seen in other organs, such as colonic adenocarcinoma, there are only anecdotal examples of leiomyosarcoma developing from preexisting leiomyomas. Indeed, the presence of multiple leiomyomas does not increase the risk of sarcoma, and the tumors have different cytogenetic and molecular characteristics.¹³⁸

Surgery

The standard surgical procedure for patients with sarcomas of the uterus is a total abdominal hysterectomy and bilateral

salpingo-oophorectomy. Often, the diagnosis will be made incidentally in a patient believed to have a benign leiomyoma. The incidence of ovarian metastasis is relatively low (5%), even in patients with high-grade sarcomas. In patients with low-grade sarcomas, there were no patients with ovarian metastases in a cohort of 108 patients. The role of lymphadenectomy and surgical staging is not of proven benefit in leiomyosarcomas of the uterus. The only patients ($n = 3$ of 37) with positive nodes (8%) in one study from Memorial Sloan Kettering had grossly enlarged lymph nodes. No patients with disease confined to the uterus or cervix had positive nodes.¹³⁹ Therefore, there is no documented benefit to taking a patient back to surgery for extended surgical staging. A young patient who underwent a myomectomy only, however, may benefit from undergoing a completion hysterectomy if high-grade leiomyosarcoma was found as there may be residual sarcoma remaining in the uterus.¹⁴⁰

Radiation Therapy

Limited data are available regarding the role of RT in uterine leiomyosarcomas and endometrial stromal sarcomas. Although some investigators have reported a benefit to adjuvant RT in endometrial stromal sarcoma,¹¹⁸ others have not.¹⁴¹ Weitman et al. evaluated 15 endometrial stromal sarcoma patients (80% stage I–II) treated with surgery and adjuvant RT. The 5-year pelvic control and overall survivals were 93% and 79%, respectively.¹⁴² Results have been mixed in leiomyosarcomas, with a benefit seen in terms of pelvic control^{143,144} and survival¹⁴⁴ in some reports. Others have noted no benefit to adjuvant irradiation.¹²¹

Systemic Therapy

UTERINE LEIOMYOSARCOMAS: ADJUVANT THERAPY

Neither adjuvant chemotherapy nor adjuvant radiotherapy has been proven to produce a survival benefit, but adequately powered randomized trials do not exist. Results for those patients with leiomyosarcoma entered on the one published randomized trial (doxorubicin versus no chemotherapy) suggest a possible modest benefit from adjuvant doxorubicin.¹¹⁹

UTERINE LEIOMYOSARCOMAS: ADVANCED/RECURRENT DISEASE

As is the case for other leiomyosarcomas, ifosfamide and doxorubicin have single-agent activity in metastatic disease. The combination of these two agents has been reported to produce a response rate of 29%¹⁴⁵ but is toxic, and the median survival of 9.5 months observed is similar to that seen in a variety of single-agent studies. Cisplatin, which has reproducible activity in uterine carcinosarcomas, is not effective in the treatment of leiomyosarcomas. Interestingly, the GOG has recently reported a response rate of 19% to single-agent gemcitabine,¹⁴⁶ which has not demonstrated activity against advanced sarcomas or leiomyosarcomas in general.¹⁴⁷ A study by Hensley et al.¹⁴⁸ used the combination of docetaxel and gemcitabine and reported an overall response rate of 53% with a median overall survival of 17.9 months in a group of patients with leiomyosarcoma (85% had uterine leiomyosar-

coma, and half had prior chemotherapy). A confirmatory trial is underway in the GOG.

LOW GRADE ENDOMETRIAL STROMAL SARCOMA (ESS): SYSTEMIC THERAPY

Although low-grade ESS (previously known as endolymphatic stromal myositis) has a relatively good prognosis, it may recur late. It has been reported that 30% to 50% of tumors localized to the uterus at the time of diagnosis eventually recur.¹⁴⁹ Aubry et al. described 16 patients with lung metastases from metastatic low-grade ESS. In that series, the diagnosis of ESS had been made an average of 9.8 years previously.¹⁵⁰ Low-grade ESS frequently expresses ER and PR. It has been suggested that the ovaries should be removed in premenopausal women with low-grade ESS and/or that adjuvant progestins should be given,¹⁴⁹ but data to support these recommendations are insufficient.

There are, however, multiple case reports documenting responses of low-grade ESS to various hormonal manipulations, including aromatase inhibitors such as aminoglutethimide¹³⁰ and letrozole,¹⁵¹ progestins such as megestrol acetate,^{152,153} and, preoperatively, to gonadotropin-releasing hormone (GnRH) agonists such as leuprolide.¹⁵⁴ Because the tumor is indolent, resection of metastases is also an option. Among the 16 patients with lung metastases described by Aubry et al.,¹⁵⁰ 14 were alive and 7 were without evidence of disease at a median follow-up of 4.1 years after diagnosis of lung metastases. The interventions used consisted primarily of resection of lung nodules and hormonal therapy.

UNDIFFERENTIATED ENDOMETRIAL SARCOMA

Undifferentiated endometrial sarcoma (high grade) is less common than uterine leiomyosarcoma but has a similar prognosis.^{122,155,156} In recurrent undifferentiated endometrial sarcoma, chemotherapy is generally tried. A prospective trial of ifosfamide in 22 patients with recurrent or disease yielded a response rate of 32%.¹⁵⁷ Multiple case reports have documented responses to doxorubicin,¹⁵⁸ and a complete response to paclitaxel and carboplatin has also been reported.¹⁵⁹

Evidence-Based Management of Breast Cancer

Lisa A. Newman and Daniel F. Hayes

The magnitude of the worldwide breast cancer burden is substantial and is increasing. Known to be a disease of greatest prevalence in heavily industrialized nations, its incidence and mortality rates are rising internationally as the populations of relatively less developed countries adopt the lifestyle and commercialism that characterize Western communities. Breast cancer has therefore been the subject of numerous clinical trials designed to improve our ability to screen for, to treat, and even to prevent the disease. This chapter reviews the highest levels of evidence that have been published for the major categories of interest in the contemporary management of breast cancer:

1. Screening/early detection
2. Primary surgery
3. Medical/systemic therapy
4. Radiation issues
5. Primary medical management (neoadjuvant chemotherapy)
6. Management of ductal carcinoma in situ (DCIS)
7. Risk reduction/prevention
8. Evaluation and treatment of metastatic disease

Breast Cancer Screening

The most commonly-accepted age-specific breast cancer screening recommendations regarding breast self-examination (BSE), clinical breast examination (CBE), and mammography are as follows:

20–40 years old: monthly BSE (optional); CBE every 1–3 years
40 years old and older: monthly BSE (optional); CBE annually; mammogram annually

BSE is generally perceived as a cost-efficient means of promoting breast health awareness, but data to document its efficacy in reducing breast cancer mortality are lacking.^{1–3} Some clinicians have even criticized this approach because of concerns that it creates excessive cancerphobia in some women, and one meta-analysis revealed that it tended to result in an excess of unnecessary biopsies for benign fibrocystic changes.² On the other hand, it may represent the only viable alternative for women who do not meet screening eligibility requirements or for whom mammography services are

simply unavailable.^{4,5} Furthermore, Shen and Zelen⁶ analyzed data from selected mammography screening trials and found the sensitivity of BSE (39%–59%) to be appreciable.

Utilization of annual mammographic screening in women beginning at age 40 is promoted by the majority of medical societies and advocacy organizations, such as the American Cancer Society, the American College of Surgeons, the American Society of Clinical Oncology, and the Susan G. Komen Breast Cancer Foundation. One issue that has generated substantial controversy involves the role of screening mammography in women 40 to 49 years old. In contrast to the annual mammography recommendation espoused by the majority of societies, the American Academy of Family Physicians and the American College of Preventive Medicine recommend that annual surveillance mammography should not begin until age 50. The U.S. Preventive Services Task Force⁷ has compiled a comprehensive evidence-based analysis of published screening trials and concluded that mammographic surveillance (with or without clinical breast examination) is appropriate at 1- to 2-year intervals for women beginning at age 40, and they also reported that data are inadequate to fully assess the value of BSE.

The history of breast imaging dates back to the early 1900s, and it has evolved into the sophisticated technology of contemporary mammographic screening. Between 1963 and 1990, eight different prospective randomized studies were conducted worldwide in an attempt to define the optimal standards for breast cancer surveillance with screening mammography. Breast cancer mortality was the endpoint for all these studies, and participants were randomized to receive either periodic mammographic imaging or “routine” health care. The design of the various studies is shown in Table 54.1,^{7–14} demonstrating notable differences between them regarding patient populations, screening intervals, and type of mammogram offered. Most of the studies were designed to be population based, and the women in the study arm were “invited” to undergo mammography, but the only trials with 100% uptake on initial screen were the two national programs coordinated in Canada. Uptake in the other six trials averaged approximately 80%. Furthermore, compliance with return for the second screen in the mammography arms ranged from only 54% to 90%, and many studies had significant contamination (13%–25%) of the control arms by patients who received mammography despite their random-

ization assignment. The “intent-to-treat” statistical design of these studies mandated that all participants were analyzed according to their randomization assignment, regardless of whether the assignment was fulfilled. Nonetheless, a 21% to 26% lower breast cancer mortality rate was seen among the women randomized to receive screening mammography in these studies (Table 54.2). It is likely that the survival benefit associated with mammography is underestimated by these studies as a consequence of the suboptimal compliance and contamination issues.

Subset analysis based on age from these trials has revealed that most of the mammography-associated reduction in breast cancer mortality was seen among patients age 50 and older, where the magnitude of protection was 23%. To some extent this is an expected finding: breast cancer incidence is substantially lower for women aged 40 to 49 years, and the relatively greater breast density of younger women can complicate the interpretation of mammographic images. The

Canadian National Breast Screening Study (CNBSS) represented an attempt to specifically address the question of mammography efficacy in younger women. In this study, 50,000 Canadian women aged 40 to 49 years were randomized to annual mammography versus routine health care and, with an average follow-up of 13 years, breast cancer mortality was unaffected by screening (rate ratio, 1.06; 95% confidence interval, 0.80–1.40).¹³ A parallel study conducted in Canadian women aged 50 to 59 years yielded similar 13-year results (rate ratio, 1.02; 95% confidence interval, 0.78–1.33).¹⁴ However, the validity of these results has been questioned because of criticisms regarding trial conduct. A fourfold excess of advanced disease was seen in the screened cohort, leading to allegations of bias in the CNBSS patient selection and randomization process.^{15,16}

Additional screening-related controversy has been generated by investigators Gotzsche and Olsen, from the Cochrane Collaboration. Their interpretations that the methods

^aAdjusted for socioeconomic factors.

employed in the various mammography trials were substantially flawed led them to conclude that mammographic surveillance yields no longevity benefit.^{17,18} A counterargument, however, is that any retrospective critical review of the mammography trials is irrelevant to contemporary screening practices. Current mammography techniques and equipment are substantially more advanced in comparison to the methods of the screening trials. In fact, screening was not implemented on an annual basis in many of these trials, nor did it uniformly involve two-view imaging.

In the United States, the practices and performance of mammography centers are now regulated by the federally mandated Mammography Quality Standards Act, implemented in 1992 and reauthorized by Congress in 1998. This program has established benchmarks regarding the necessary equipment utilized in imaging centers as well as for minimum mammogram volume requirements for individual radiologists to maintain adequate expertise in evaluating these studies. Furthermore, in an era of chemoprevention availability, mammography represents the primary means of identifying high-risk women harboring lesions that contain atypical hyperplasia. Although it would likely be impossible to replicate a Phase 3 mammography screening trial today, it appears logical to assume that widespread mammographic surveillance over the past 10 to 20 years is largely responsible for the recent declines in breast cancer mortality that have been observed in the United States as well as abroad in the United Kingdom¹⁹ and in Sweden.^{20,21}

When an abnormal breast lesion is detected on routine, surveillance mammography, comprehensive imaging maneuvers should be promptly pursued, including comparisons with prior studies whenever possible. Diagnostic mammographic views (compression, magnification, etc.) should be obtained, and ultrasound imaging should be obtained for evaluation of densities as necessary. The abnormality should be characterized as per the American College of Radiology standardized Breast Imaging Reporting and Data Systems (BIRADS)²²:

- 0: Additional imaging required.
 - 1: Negative; no architectural disturbances identified.
 - 2: Benign finding; negative mammogram, but some benign-appearing lesion identified.
 - 3: Probably benign finding; short-interval follow-up suggested; some lesion identified that has a high probability of being benign, but establishing its stability is preferred.
 - 4: Suspicious abnormality; biopsy should be considered; lesion detected that is not necessarily typical of cancer, but risk of malignancy is sufficiently high that a biopsy is warranted. The radiologist may comment specifically on the likelihood of cancer based on the type of lesion detected (calcifications, mass, etc).
 - 5: Highly suggestive of malignancy; appropriate action should be taken; these lesions have a high probability of being cancer, and histopathologic confirmation should be sought accordingly.

The limitations of conventional screening mammography are well known. A subset of palpable breast tumors will be mammographically occult, and the overall false-negative rate of mammography averages 10% to 15%. Imaging of the dense breast can be particularly challenging, leading to difficulties in evaluating the fibrocystic changes seen in young women, and in women with a history of prolonged hormone replace-

ment therapy. These issues may result in a patient "call-back" for additional diagnostic views to assess overlapping densities. This step in turn is the source of significant anxiety among patients, especially in those cases where a biopsy is ultimately necessary to definitively establish the benign versus malignant nature of a mammographically indeterminate lesion. Also, the burden of storing millions of screening mammograms has become an increasingly formidable task over time. The ability to compare a current mammogram with prior images is essential for optimal, accurate interpretations, but maintaining and archiving the growing volume of these studies is a difficult task.

In response to these acknowledged limitations, several alternative imaging modalities are being explored for their potential value in breast cancer screenings. Digital mammography is an advanced form of screening that offers electronic archiving of breast studies, with improved contrast resolution over a larger dynamic range. These advantages may obviate the need for many "call-backs" and eliminate the film storage problem. Furthermore, electronic studies can be transmitted to radiologists at any distance from the patient, thus facilitating second-opinion interpretations via tele-mammography, and they offer the potential value of computer-aided interpretations.

The major hindrances preventing widespread conversion to digital mammography programs include the considerable expenses of purchasing the advanced equipment and training staff in its use as well as maintenance. Another complexity is the difficulty inherent in comparing serial mammograms performed during the transition period and accurately distinguishing true interval changes from simple differences in tissue imaging related to technique. Prospective trials evaluating these two forms of mammography are currently under way.

Alternative methods for breast cancer screening, such as whole-breast ultrasound, magnetic resonance imaging (MRI), and positron emission tomography (PET) scanning, are also being actively investigated. Ultrasound evaluation of the breast was initially utilized to distinguish cystic versus solid lesions detected on either mammogram or physical examination. It has evolved into a highly specialized imaging modality that is useful in targeted breast studies to characterize the nature of solid mass lesions and frequently guides percutaneous needle biopsies (discussed further below). It is also possible that ultrasound may expand into the screening area. Unfortunately, whole-breast ultrasound is fairly labor intensive and is always operator dependent. Nonetheless, promising data have emerged indicating that screening with whole-breast ultrasound may be useful, particularly for women with mammographically dense tissue. Kolb et al.²³ reported a 97% sensitivity rate for the combination of whole-breast ultrasound and mammography in screening 4,897 BI-RADS category II-IV cases compared to 74% for the combination of mammography and physical examination. Kaplan et al.²⁴ reported a 0.3% cancer detection rate among women previously found to have a normal mammogram and clinical breast exam.

Breast imaging with magnetic resonance imaging (MRI) is of well-documented benefit in the evaluation of occult breast cancer in patients presenting with palpable axillary nodal metastases, where it reliably identifies those patients who may be safely treated with breast conservation (i.e., axillary

surgery and breast irradiation).²⁵ It is also useful in detecting leakage from silicone implant rupture. In screening the otherwise normal and clinically negative breast of a normal-risk adult female, the indications for MRI are less clear. A recently completed prospective observational clinical trial conducted in women with hereditary susceptibility for breast cancer (as determined by either BRCA sequencing or Claus model calculations) demonstrated promising results regarding the efficacy of breast MRI in screening high-risk patients.²⁶ This study followed 1,909 high-risk women for a median of 2.9 years, with independently read annual mammography and breast MRI. Mammography was inferior to MRI in overall sensitivity (33% versus 80%), and MRI detected cancers at earlier stages, but mammography was slightly more specific (95% versus 90%). A total of 45 evaluable cancers were identified in this cohort; 32 were visible on MRI (including 22 that were mammographically occult) and 18 were visible on mammography (including 8 that were occult on MRI). One cancer was detected by clinical exam only, and four interval cancers developed. As noted by Liberman,²⁷ these results must be interpreted with caution, because the participating centers all had substantial expertise in MR imaging.

The potential advantages and limitations of breast MRI are summarized by Morris.²⁸ MRI can detect invasive breast cancer with a sensitivity rate approaching 100% and a negative study can therefore confidently clear the breast. Falsely negative MRIs can occur in the presence of ductal carcinoma in situ, and this modality may therefore be somewhat less reliable in evaluating microcalcifications. Invasive lobular cancer may also be missed, although MRI has been reported to be more sensitive in detecting this histopathology than other imaging modalities. Any hypervascular lesion may show enhancement on breast MRI, and even benign fibroadenomas may therefore occasionally result in a falsely positive study. These patterns contribute to the unreliable MRI specificities, ranging from 37% to 97%.²⁹ Nonetheless, these limitations may be acceptable in the effort to aggressively screen women at risk for the early-onset disease associated with mutations in the BRCA-1 and -2 breast cancer susceptibility genes.^{26,30,31}

Use of breast MRI has also been suggested as a means of screening newly diagnosed breast cancer patients for the presence of multicentric disease, thereby refining the identification of candidates for breast-conserving therapy, especially in women with mammographically dense breasts.^{32,33} However, the sensitivity of breast MRI may actually be so high that occult foci of disease would be detected that might otherwise have been eradicated by breast radiotherapy. Whether a breast cancer diagnosis has been established or not, a final limitation of breast MRI is that few institutions have the capability to directly biopsy MRI-detected lesions.

Primary Surgical Management of Breast Cancer

Breast Conservation Therapy

The dawn of the 20th century marked a critical landmark in the management of breast cancer. Before this time the disease was widely considered untreatable and therefore universally fatal. It was not until Sir William Stuart Halsted popularized

the radical mastectomy as surgical management for breast cancer that some degree of locoregional control of disease was achieved, and in a few cases long-term disease-free survival was observed. Early reports of this surgical approach appeared in the medical literature in the 1890s³⁴; over the next three-quarters of a century, the radical mastectomy was established as the standard of care and sole treatment option for all stages of operable breast cancer.

In 1974, the National Surgical Adjuvant Breast Project (NSABP) published the initial outcome findings from their B-04 trial evaluating the safety of departing from the radical mastectomy as definitive treatment for breast cancer.³⁵ This study was designed to prove that variations in the locoregional management of breast cancer would not affect survival, thereby demonstrating that the major risk from this disease is related to the presence of micrometastases as opposed to whether the disease can be completely extirpated surgically. The B-04 study actually consisted of two clinical trials conducted in parallel. One trial involved randomization of 1,079 patients with clinically node-negative, operable breast cancer to one of three treatment arms: (i) radical mastectomy; (ii) total mastectomy followed by axillary nodal irradiation; and (iii) total mastectomy alone. The companion trial randomized 586 women with resectable, but clinically node-positive, disease to either radical mastectomy or total mastectomy and locoregional irradiation. Twenty-five-year follow-up from this study has recently been reported,³⁶ with survival equivalence continuing to be seen for the three arms of the clinically node-negative patients (25%, 19%, and 26%, respectively), and the two arms of the node-positive patients (14% for both arms).³⁶

Once the concept was established that breast cancer outcome is primarily determined by early detection and the related risk of micrometastatic disease, it was a natural progression to explore treatment options involving breast preservation within the context of clinical trials. Six such studies (and one combined analysis of two trials) and one meta-analysis³⁷ have now reported long-term outcome revealing survival equivalence for stage-matched breast cancer patients randomized to mastectomy versus breast conservation (Table 54.3). The addition of breast irradiation to lumpectomy results in a statistically significant decrease in risk of local recurrence, as demonstrated by the NSABP B-06 trial,³⁸ where 1,851 stage I/II breast cancer patients were randomized to either radical mastectomy, lumpectomy and axillary lymph node dissection (ALND), or lumpectomy, ALND, and breast irradiation. Twenty-year follow-up confirms that mastectomy does not confer any survival advantage over breast preservation; however, breast irradiation lowers the risk of in-breast tumor recurrence from 39.2% to 14.3%.³⁸ As demonstrated by the Guy's Hospital experience, however, locoregional control should be optimized with delivery of appropriate radiotherapy doses. The potential contribution of locoregional irradiation to breast cancer outcome is discussed further next.

Management of the Axilla

The NSABP B-04 trials have also provided the basis for ongoing controversy regarding elective management of the axilla in newly diagnosed breast cancer patients. The B-04 trial that randomized patients with palpable, suspicious axillary disease to either radical mastectomy or total mastectomy

OS, overall survival; BCT, breast conservation therapy; Lump, lumpectomy; XRT, irradiation; NSABP, National Surgical Adjuvant Breast Project; EORTC, European Organization for the Research and Treatment of Cancer; DBCCG, Danish Breast Cancer Cooperative Group; NCI, National Cancer Institute; LR, local recurrence; IBTR, in-breast tumor recurrence; Gy, gray.

^aThere were no isolated chest wall events/recurrences in the mastectomy arm, but 8 patients experienced a local failure with a regional and/or distant event; and 3 patients experienced a regional-only recurrence. In the BCT arm, 27 patients (22%) experienced an isolated local recurrence; there were 4 local with regional and/or distant failure; and there were no isolated regional recurrences.

^bThe initial Guy's Hospital trial randomized women with operable breast cancers and clinically node-negative as well as node-positive disease; patients randomized to lumpectomy arm had no surgical treatment to the axilla. After 1971 patients with clinically node-positive disease were excluded because of the high regional and distant failure rates. Regional XRT fields included supraclavicular, internal mammary, and axillary nodes; radical mastectomy arm also received 25–27 Gy regional XRT.

^cSurvival rates reported for the combined Guy's Hospital trial are 25-year rates of breast cancer-specific survival.

and locoregional breast irradiation (XRT) did demonstrate the superiority of surgery for durable control of bulky, symptomatic nodal disease. The regional failure rate of the patients randomized to radiation was 11%, compared to 8% for the patients randomized to ALND via the radical mastectomy procedure. The inaccuracy of clinical assessment for the axillary status was also apparent in this trial; of the nearly 300 patients whose axillae were assessed as being positive, 25% were found to be pathologically node negative by results of the radical mastectomy ALND.

On the other hand, numerous questions have arisen regarding management of the clinically axillary node-negative patients, and the long-term study results have been the subject of several different interpretations. It is assumed that nearly 40% of those in the two study arms randomized to nonsurgical management of the axilla (total mastectomy alone or total mastectomy plus axillary irradiation) had nonpalpable axillary metastases, because all three study arms were clinically matched and 39% of the radical mastectomy patients were found to be node positive. Nonetheless, clinically evident axillary relapse requiring delayed ALND developed in only 19% of the total mastectomy-only patients, suggesting that approximately half of untreated, occult axillary metastases will remain indolent. Only 4% of the total mastectomy plus axillary XRT arm required a delayed, therapeutic ALND (equivalent to the proportion of regional failures occurring in the radical mastectomy arm), and this finding suggests that axillary irradiation is an acceptable alternative for regional control of nonpalpable disease.

On critical reappraisal of the B-04 trial results, several concerns emerge. Pathology review of the mastectomy specimens revealed that nearly one-quarter of the total mastectomy cases actually included the incidental resection of some axillary lymph nodes, and the risk of axillary failure was inversely proportional to the number of lymph nodes retrieved. Also, this trial was not powered to address the outcome benefits of ALND, and because 22% of the long-term survivors from this study were patients found to be node positive based on pathology from the radical mastectomy procedure, the possibility of a survival contribution from the ALND cannot be definitively ruled out.

During the 1980s and 1990s, debate regarding a survival benefit from the ALND became irrelevant because of the identification of effective systemic therapy for breast cancer in the form of both endocrine and chemotherapeutic agents. Pathologic confirmation of the axillary nodal status then became a critical component of surgical breast cancer management as a means of determining which patients would be most likely to benefit from systemic treatment. Unfortunately, this is at the expense of committing breast cancer patients to the lifelong risk of lymphedema, reported to occur in 10% to 49% of ALND cases.³⁹⁻⁴² Features that increase the risk of lymphedema following ALND include obesity, regional irradiation, and a level III/apical axillary dissection.

Development of lymphatic mapping and the sentinel lymph node biopsy technology for breast cancer patients in the mid-1990s revolutionized the surgical care of breast cancer patients. This therapy, initially described by Krag et al. in 1993 with single-agent radioisotope and by Giuliano et al. in 1994 using single-agent blue dye, launched an era of minimally invasive surgery for the identification of node-negative patients who could be spared the morbidity of a

standard level I/II ALND. The procedure involves injection of the mapping agent into the breast to replicate the pathway that cancer cells would traverse through the intramammary lymphatics en route to the primary nodal basin (which is the ipsilateral axilla for more than 90% of cases). The sentinel nodes represent the initial nodes likely to have been seeded by metastases, and they are distinguished by visual inspection to identify the blue-stained node(s), and/or detection of the radioactive nodes with an intraoperative gamma detector probe. Documentation of the accuracy of the sentinel lymph node biopsy was obtained by performing a concomitant level I/II ALND. This strategy permits calculation of the identification rate (number of cases where the sentinel node is found versus the number of cases where the procedure is attempted) and the false-negative rate (number of cases where the sentinel lymph node is negative but metastases are detected in nonsentinel nodes versus the total number of cases where any axillary metastases are detected).

Two meta-analyses have been conducted with reported pooled accuracy rates for the lymphatic mapping technology. General findings have included improved identification rates when dual- versus single-agent mapping is performed, and both the false negativity and identification rates are optimized when the learning curve has been passed. The 1999 meta-analysis⁴³ involved eleven studies involving 912 patients; the overall identification rate was 97% and the false negative rate was 5%. Another meta-analysis was presented at the 2002 American Society of Clinical Oncology meeting,⁴⁴ and this more recent study reported the pooled results of 69 published studies in the worldwide literature (37% from institutions within the United States), with data contributed by lymphatic mapping and completion ALND procedures performed on 10,454 breast cancer patients. The overall identification rate was 74%, but nearly half of the studies reported identification rates of 90% or greater. The pooled analysis revealed a false-negative rate of 8.4% (range, 0%–29%) but studies that performed more than 100 cases had a lower false-negative rate of 6.7%. An additional finding from the early studies of lymphatic mapping performed in conjunction with the ALND is that metastases will be limited to the sentinel node(s) in from one-third to two-thirds of cases, and this supports the biologic validity of the mapping concept.

The future results from two multicenter, prospective clinical trials coordinated by the NSABP and the American College of Surgeons Oncology Group (ACOSOG) will provide the most definitive long-term data on locoregional control of disease achieved after a sentinel lymph node biopsy performed for early-stage breast cancer.⁴⁵ The NSABP trial randomized clinically node-negative patients to undergo sentinel lymph node biopsy with completion ALND versus sentinel lymph node biopsy with ALND only if the sentinel node was positive for metastasis. The ACOSOG trial is prospectively following more than 5,000 breast cancer patients after sentinel node biopsy for breast cancer, and patients with a positive sentinel node are eligible for the companion trial that randomizes these node-positive cases to either completion ALND or axillary observation. The primary aim of the NSABP trial is therefore to compare the impact of sentinel node biopsy alone versus ALND on recurrence-free survival in women who are node negative. The primary aim of the ACOSOG randomized trial is to determine the impact of a standard ALND on survival in patients with node-positive

breast cancer. Both cooperative groups will be evaluating the prognostic value of micrometastases identified in sentinel nodes via immunohistochemical staining for cytokeratin. There is extensive variability in the techniques utilized to perform the lymphatic mapping⁴⁶ in terms of injection site for the labeling agent (peritumoral versus overlying skin versus subareolar) and timing of the radioisotope label (same-day versus 1 day preoperatively). Thus far, excellent results have been observed with all the various strategies, and the randomized trials will include outcome data on the complete spectrum of mapping techniques.

Adjuvant Systemic Therapy for Breast Cancer

The benefits of adjuvant systemic therapy for breast cancer in eliminating micrometastases and thereby reducing risk of distant relapse have been recognized for several decades. Although breast cancer staging based on tumor size and nodal status carries strong prognostic value, 15% to 20% of patients diagnosed with stage I disease ultimately experience treatment failure, despite having been diagnosed with small, node-negative lesions. The necessity to address systemic manifestations of breast cancer before they are clinically apparent therefore became quite clear to the oncology community during the latter half of the 20th century. Success in achieving this goal, however, was dependent on identifying medical therapies that were cytotoxic and/or cytostatic against occult breast cancer metastases in distant organs.

The hormonally active, nonsteroidal estrogen receptor modulator tamoxifen became recognized as a valuable strategy in the endocrine regulation of this hormonally driven

disease during the 1970s.⁴⁷ The ability to reliably assess for the presence of estrogen and progesterone receptors via widely reproducible immunohistochemical assays confirmed the validity of this approach, particularly for tumors selected on the basis of hormone receptor expression. Investigations of chemotherapeutic agents with activity against breast tumor biology strengthened these adjuvant therapy efforts and offered promise to women with hormone receptor-negative disease. In an effort to add clarity and balance to the discussion of benefit conferred by hormonal therapy and/or chemotherapy to breast cancer outcome, the Early Breast Cancer Trialists Collaborative Group (EBCTCG) was established. These distinguished international experts have convened periodically to review and statistically analyze the pooled results of various approaches for the adjuvant systemic therapy of breast cancer. Findings from these meta-analyses (commonly called the Overview Analyses), involving phase III trials of tamoxifen, chemotherapy, ovarian ablation, and radiation as adjuvant therapy, are summarized in Table 54.4.

The Overview Analyses have essentially documented a proportional odds reduction in the risk of breast cancer relapse in conjunction with the delivery of adjuvant systemic therapy. The magnitude of absolute benefit is therefore dependent on the baseline risk of relapse, defined by the stage of disease at diagnosis. Although the heterogeneity of individual breast tumor biology allows for the potential existence of life-threatening distant micrometastases associated with even the earliest stage lesions, the potential life-threatening adverse events associated with any adjuvant systemic therapy mandates that patients cautiously appraise the risks and benefits of these treatments. Guidelines promoted by the National Cancer Institute^{48,49} include recommendations that

TABLE 54.4. Summary of worldwide overview analyses.

Treatment analyzed	No. of trials analyzed	No. of women analyzed	Proportional reduction			Comments
			Relapse	Mortality	Contralateral breast cancer	
Tamoxifen for early-stage breast cancer ^{190,191}	55	37,000	1 year: 21% 2 years: 29% 5 years: 47%	1 year: 12% 2 years: 17% 5 years: 26%	1 year: 13% 2 years: 26% 5 years: 47%	Risk of endometrial cancer doubled in trials of 1 or 2 years and quadrupled in trials of 5 years. Approximately 8,000 women had tumors with low/zero ER content; these patients had negligible benefit from tamoxifen for relapse and mortality. They are excluded from relapse and mortality data, but are included in contralateral risk data.
Multi-agent CTX for early breast cancer ^{192,193}	47	18,000 ^a	<50 years old: 35%	<50 years old: 27%	NR	No significant survival advantage for more than approximately 3 months of polychemotherapy. Anthracycline-containing regimens better than CMF alone.
			50–69 years old: 20%	50–69 years old: 11%	NR	
Ovarian ablation for early breast cancer ^{59,60}	12	2,102	18.5%	6.3%	NS	Benefit of ovarian ablation strongest in women not receiving CTX.
Radiotherapy for early breast cancer ^{69,94}	40	20,000	32.4% ^b	NS	NS	XRT reduced the annual breast cancer mortality rates by 13.2%, but increased the annual mortality rates from other causes (primarily vascular) by 21.2%. XRT reduced the annual breast cancer

CTX, chemotherapy; NR, not reported; NS, not significantly different.

^aIncluding 6,000 women in 11 trials of longer versus shorter CTX, and 6,000 women in 11 trials of doxorubicin-containing CTX versus CMF (cyclophosphamide/methotrexate/fluorouracil).

^bLocal recurrence.

adjuvant systemic therapy be considered for all invasive breast cancers measuring at least 1 cm in size, and/or tumors of any size when associated with nodal metastases. In practice, endocrine therapy with tamoxifen tends to be the first-line approach for hormone receptor-positive disease, and polychemotherapy is delivered for hormone receptor-negative disease and/or patients with node-positive breast cancer.

Endocrine Therapy for Breast Cancer

Tamoxifen was originally developed as an antifertility medication, and alternative uses in the oncology field were sought because of its dismal failure in this area because of tamoxifen's ovulatory effects. As a very effective antagonist of estrogen receptors on mammary tissue, however, it has remained extremely powerful as first-line adjuvant systemic therapy in breast cancer management. Tamoxifen's selective estrogen receptor activity also yields estrogen agonist activity on the uterus, cardiovascular, cerebrovascular, and osseous tissues; this results in the mixed benefits and risks of uterine cancer, lowered cholesterol levels, vasomotor symptoms, and protection against osteoporosis. Tamoxifen was also found to decrease the incidence of contralateral new primary tumors, motivating extension of its applications to the chemoprevention arena.

Several other endocrine therapies have been studied recently as alternatives to tamoxifen (Table 54.5), with the hope that side effects can be minimized and protection from relapse prolonged.⁵⁰ All have proven efficacy in the setting of metastatic disease and are now used in the adjuvant setting as well. One category of endocrine agents includes other selective estrogen receptor modulators and another category includes the aromatase inhibitors (AIs). The AIs exert anticancer activity via inhibition of the nonovarian hormone production that occurs in postmenopausal women and is mediated through peripheral conversion of adrenal substances.

The ATAC Trial⁵¹ was an international study that randomized 9,366 postmenopausal women to receive 5 years of the AI anastrozole, versus tamoxifen, versus a combination of these two therapies. At 33 months follow-up, the anastrozole-alone arm fared significantly better with regard to risk of relapse and new breast events; unfortunately, this improved outcome came at the expense of higher rates of osteoporotic complications.

The NSABP B-14 trial⁵² randomized early-stage breast cancer patients to receive 5 versus 10 years of tamoxifen postoperatively, and found that extended therapy resulted in higher rates of adverse events that were not outweighed by added protection. Unfortunately, substantial numbers of estrogen receptor-positive breast cancer patients continue to relapse after 5 years of tamoxifen, and this pattern motivated implementation of the MA-17 trial,^{53,54} where 5,187 postmenopausal breast cancer patients who had already completed 5 years of adjuvant tamoxifen therapy were randomized to receive 5 years of the AI letrozole versus placebo. This trial has revealed improved disease-free outcome in favor of prolonged endocrine therapy with letrozole.

Another recent trial, the Intergroup Exemestane Study,⁵⁵ randomized nearly 5,000 postmenopausal breast cancer patients to receive the AI exemestane for 2 to 3 years following tamoxifen, to a total adjuvant therapy course of 5 years, versus receiving tamoxifen for the entire 5-year course. At 31 months follow-up, the patients receiving exemestane had fewer relapses, suggesting superiority of AI therapy.

The selective estrogen receptor modulator (SERM) fulvestrant is a tamoxifen alternative that has no estrogen receptor agonist effects. Preliminary studies of application after tamoxifen failure in the setting of metastatic disease have been promising because fulvestrant does not appear to be cross-resistant with tamoxifen.⁵⁶ Evaluations of this therapy in the adjuvant setting are therefore likely to be forthcoming.

Removal or suppression of functional, estrogen-producing ovaries to control the progression of hormonally responsive

TABLE 54.5. Table of selected Phase III trials evaluating adjuvant endocrine therapy.

Trial	Accrual years	Median follow-up (months)	No. of patients	Randomization arms	Outcome		
					DFS	OS	Contralateral cancer
NSABP B-14 ^{52a}	1982–1988	81	1,172	Adjuvant tamoxifen 5 years	82%	94%	2.9%
				Adjuvant tamoxifen 10 years	78%	91%	3.5%
ATAC ^{51,195b}	1996–1000	33	9,366	Anastrozole	89%	NR	0.4%
				Tamoxifen	87%	NR	1.1%
				Anastrozole + tamoxifen	87%	NR	0.9%
NCIC MA17 ^{53,54c}	1998–2002	30	5,187	Tamoxifen × 5 years alone	90%	NR	1%
				Tamoxifen × 5 years followed by letrozole × 5 years	95%	NR	0.5%
Intergroup Exemestane Study ^{55d}	1998–2003	31	4,742	Tamoxifen × 5 years alone	87%	NR	0.8%
				Tamoxifen × 2–3 years followed by exemestane to the completion of 5 years adjuvant therapy	92%	NR	0.4%

^aImproved survival in tamoxifen 5 years arm was statistically significant; difference in rate of contralateral cancer was not significant; there were more endometrial cancers in the tamoxifen 10 years arm (12, 2.1% versus 6, 1.1%; RR 2, 95% CI 0.7–6.6).

^bSignificantly fewer endometrial cancers, cardiovascular events, and thromboembolic complications in anastrozole arm; fewer osteoporotic complications in tamoxifen arm; 47-month median follow-up report demonstrated a statistically-significant 18% reduction in risk of relapse for estrogen receptor-positive patients receiving anastrozole, and a 44% reduction in risk of contralateral new cancers.

^cDifference in disease-free outcome statistically significant in favor of letrozole following tamoxifen arm.

^dDifferences in disease-free outcome and contralateral new primary cancers statistically significant in favor of exemestane arm; Kaplan–Meier estimates for overall survival not reported, but the 93 all-cause deaths in the exemestane group was not statistically different from the 106 all-cause deaths in the tamoxifen-only arm.

breast cancer has a long history associated with several lines of evidence suggesting that this should be a successful therapeutic strategy. Unfortunately, the Phase III studies addressing this issue have usually been flawed by limited data on the estrogen expression levels of the participating patients, or by the fact that they were actually designed to answer a different question and have been interpreted retrospectively to evaluate the role of ovarian ablation and/or ovarian suppression. The benefits of this strategy must be balanced against the morbid osteoporotic and cardiovascular arteriosclerotic sequelae of premature menopause.

Bilateral oophorectomy represents one of the oldest forms of systemic therapy for breast cancer, dating back to reports by Beatson⁵⁷ and Lett⁵⁸ from approximately 100 years ago. Although surgical removal of the ovaries remains a viable and certainly effective means of eliminating ovarian estrogen, the past several decades have seen the implementation of pelvic irradiation to obliterate the ovaries, as well as the development of medical therapy to suppress function. The overview analysis^{59,60} reported an 18.5% reduction in the odds of disease relapse and a 6.3% reduction in the odds of death associated with either surgical or radiotherapeutic ablation of the ovaries. These benefits are comparable in magnitude to those achieved with adjuvant chemotherapy.

Surgical oophorectomy can be performed with relatively low morbidity as a laparoscopic procedure, although it requires general anesthesia. It also provides immediate, complete, and irreversible elimination of ovarian function. Another advantage of oophorectomy is that it can be offered in medically underserved parts of the world as straightforward and fairly cost-efficient endocrine management of breast cancer.

Pelvic irradiation also results in an irreversible blockade of ovarian function, but the extent of gonadal tissue effected and the interval to achieve this ablation can be variable. Furthermore, long-term effects on the pelvic contents may include adhesions, radiation enteritis, and/or colorectal stricture.

Medical therapies for ovarian suppression include chemotherapy-induced amenorrhea and luteinizing hormone-releasing hormone (LHRH) agonists. Chemotherapy will cause ovarian failure in 30% to 80% of cases,^{61,62} with likelihood and duration of amenorrhea varying by age of patient (older premenopausal patients at increased risk compared to younger patients), type of chemotherapy [cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) causing more amenorrhea than adjuvant chemotherapy (AC), and the addition of a taxane further increasing rates], and number of chemotherapy cycles. Some studies have reported that patients experiencing amenorrhea from chemotherapy have an improved outcome related to this diminished circulating estrogen.⁶³⁻⁶⁵ Although these effects are provocative in supporting a role for ovarian suppression to manage premenopausal breast cancer, chemotherapy-induced amenorrhea is an unreliable strategy because of its unpredictability and uncertain duration.

Use of LHRH agonists to disrupt the physiologic hypothalamic-pituitary-gonadal axis is becoming increasingly accepted as a reasonable alternative for achieving ovarian suppression. Normal estrogen production by the ovaries is regulated by the pulsatile production of LHRH by the hypothalamus. LHRH stimulates gonadotropin-releasing

hormone (GnRH) production by the pituitary, and this induces estrogen production from the ovaries of a premenopausal woman. LHRH agonists such as goserelin bind to the GnRH receptors with strong affinity, causing an initial surge in estrogen production (which can cause the so-called tumor flare that may occur clinically), followed by a blockade of the physiologic pulsatile and ongoing effects of natural LHRH. The patient is therefore rendered medically menopausal, but the suppressed ovarian function is reversible. This potential for restoring fertility is attractive, but the impact on cancer control is uncertain. The evidence from several prospective randomized trials evaluating ovarian ablation/ovarian suppression is summarized in Table 54.6.

Chemotherapy for Breast Cancer

The earliest studies of chemotherapy for breast cancer involved perioperative administration of medications that are considered inferior to the effective agents currently available, and the goal of these early investigations was to eliminate dissemination of cancer cells that might have occurred in conjunction with surgical manipulation of tumors. The NSABP B-01⁶⁶ trial (conducted nearly 40 years ago) therefore involved intravenous thiotepa versus placebo administered at the time of radical mastectomy and over the first 2 days postoperatively. Not surprisingly, this regimen failed to produce any improvements in outcome for the entire group of treated patients, but the subset of highest risk women (those with four or more metastatic nodes) did experience some overall survival advantages. Subsequent trials conducted during the 1970s and 1980s revealed the power of cyclophosphamide and combination chemotherapy (CTX) regimens in reducing breast cancer relapse rates as well as mortality risks.

Until fairly recently, the two regimens of cyclophosphamide/methotrexate/fluorouracil and cyclophosphamide/doxorubicin/fluorouracil, delivered in every-3-week cycles, have been the most commonly employed regimens for adjuvant therapy of breast cancer. During the late 1990s, the taxanes emerged as an alternative and highly effective agent against breast cancer. Furthermore, the development of active and tolerable bone marrow supportive therapy in the form of granulocyte colony-stimulating factors has opened the door to dose-dense regimens allowing safe delivery of higher cumulative CTX doses within shorter time frames. Selecting the appropriate cases for the various regimens has been challenging, but as shown in Table 54.7, several Phase III studies have successfully addressed many of the pertinent issues.

Collectively, these studies suggest that adjuvant CTX regimens that include a taxane as well as doxorubicin appear to be most reasonable for node-positive breast cancer patients. This conclusion is supported by findings from the CALGB 9344, NSABP B-28, and BCIRG 001 Phase III studies. These three trials all randomized node-positive patients to receive doxorubicin-based combinations versus doxorubicin CTX plus a taxane, and all three demonstrated an outcome advantage for the taxane arms. The CALGB 9741 and 9344 trials also revealed superiority of dose-dense therapy (9741), but no outcome advantage for increased doses of doxorubicin (9344). Questions regarding superiority of one taxane versus the other (paclitaxel versus docetaxol) remain unanswered.

TABLE 54.6. Prospective randomized trials of ovarian ablation/ovarian suppression.

Study	N	Eligibility profile	Median follow-up (years)	Treatment arms	Outcome
Scottish Trial 1993 ¹⁹⁶	332	Premenopausal Node-positive Any ER status	Maximum 12	CMF OA	No significant difference in 8-year OS (hazard ratio 1.12; 95% CI 0.76–1.63) but ovarian ablation better in cases with ER >20fmol/mg
Roche 1996 ^{197a}	162	Premenopausal Node-positive ER and PR-positive	7	Surgical or radiotherapeutic OA FAC × 6	7-year DFS 83% for OA vs. 55% for FAC (significant on univariate, but not multivariate analysis after accounting for number of metastatic nodes) 7-year OS 84% for OA vs. 74% for FAC (not significant)
Ejlertsen 1999 ¹⁹⁸	732	Premenopausal ER-positive Node-positive and/or tumor >5 cm	5.7	OA CMF × 9	5-year DFS 67%; OS 78% 5-year DFS 66%; OS 82% (no significant difference in DFS or OS)
Rutqvist 1999 ^{199b}	2,631	Premenopausal	4.3	Goserelin × 2 years alone Tamoxifen × 2 years alone Goserelin and tamoxifen × 2 years No adjuvant endocrine therapy	Event-free hazard benefit in favor of goserelin use (relative risk, 0.77; 95% CI, 0.66–0.90)
Boccardo 2000 ²⁰⁰	244	Premenopausal ER-positive	6.3	CMF OA/OS ^c + tamoxifen	No significant difference in DFS or OS
Schmid 2002 ²⁰¹	589 ^d	Premenopausal Node-positive ER-positive		CMF Leuprolin	No significant difference in DFS or OS
IBCSG 2001 ²⁰²	174	Premenopausal Node-positive ER-positive s/p therapeutic ovarian ablation	4.1	Tamoxifen × 5 years AC × 4, then tamoxifen × 5 years	No significant difference in DFS or OS
Jonat 2002 ²⁰³ and Kauffmann 2003 ²⁰⁴ (ZEBRA Study)	1,614	Premenopausal Node-positive (any ER status ^e)	7.3	CMF × 6 Goserelin × 2 years	No significant difference in DFS or OS for ER-positive disease; CMF better for ER-negative disease

Jakesz 2002 ²⁰⁵	1,034	Premenopausal ER-positive	5	CMF × 6 Goserelin × 3 years + tamoxifen × 5 years	5-year DFS 76% 5-year DFS 81% (<i>P</i> = 0.37; significant in favor of endocrine therapy)
Love 2002 ²⁰⁶	709	Premenopausal Operable breast cancer (node positive or tumor >2cm size)	3.6	Oophorectomy + tamoxifen × 5 years Observation	5-year DFS 75%; 5-year OS 78% 5-year DFS 58%; 5-year OS 70% (<i>P</i> < 0.05; significant for DFS and OS in favor of adjuvant therapy)
Castiglione- Gertsch 2003 ²⁰⁷	1,063	Premenopausal Node-negative (any ER status ^f)	7	Goserelin × 2 years CMF × 6 CMF × 6 + goserelin × 1.5 years	DFS significantly superior in favor of CMF for ER-negative tumors (5-year DFS 84% for CMF alone and 88% for CMF + goserelin vs. 73% for goserelin alone) DFS similar for all three arms in ER-positive tumors (5-year DFS 81% for either goserelin or CMF alone; and 86% for CMF + goserelin)
Arriagada 2003 ²⁰⁸	926	Premenopausal Operable breast cancer (Any ER status ^g)	9.5	OA/OS + CTX ^h CTX ^h	10-year DFS 48%; 10-year OS 65% 10-year DFS 49%; 10-year OS 68% (no significant differences in DFS or OS)
Davidson 2003 ²⁰⁹	1,504	Premenopausal Node-positive ER-positive	9.6	FAC × 6 FAC × 6 + goserelin × 5 years FAC × 6 + goserelin + tamoxifen × 5 years	9-year DFS 57%; 9-year OS 70% 9-year DFS 60%; 9-year OS 73% 9-year DFS 68%; 9-year OS 76% ^h

OA, ovarian ablation; CMF, cyclophosphamide, methotrexate, 5-fluorouracil; ER, estrogen receptor; PR, progesterone receptor; FAC, 5-fluorouracil, doxorubicin, cyclophosphamide; CTX, chemotherapy; DFS, disease-free survival; OS, overall survival; CI, confidence interval.

^aTrial closed in 1989 because of poor accrual, with 153 evaluable patients.

^bPooled results from similar trials conducted by the Cancer Research Campaign; the Breast Cancer Trials Group; the Stockholm Breast Cancer Study Group; the South-East Sweden Breast Cancer Group; and the Gruppo Interdisciplinare Valutazione Interventi in Oncologia (GIVIO); adjuvant chemotherapy use varied by individual protocols and participating centers.

^cSurgical oophorectomy, 6 patients; radiotherapeutic oophorectomy, 31 patients; goserelin, 87 patients.

^dReported data on 227 evaluable patients from interim analysis.

^eApproximately 20% of participants were ER negative; these were evenly distributed between the two trial arms.

^fApproximately 30% of participants were ER negative; these were evenly distributed between the two trial arms.

^gApproximately 24% of participants were ER negative; these were evenly distributed between the two trial arms; the adjuvant CTX delivered included an anthracycline in 77%; OA/OS was via irradiation or LHRH agonists.

^hOutcome differences not significantly different, but trends favoring OS in women who did not become amenorrheic with CTX, and favoring tamoxifen in women who did become amenorrheic.

TABLE 54.7. Table of selected Phase III trials evaluating adjuvant chemotherapy.

Study	Eligibility	N	Median follow-up	Randomization	DFS	OS
CALGB 9344 ²¹⁰	Node-positive	3,121	69 months	AC	65%	77%
				AC + paclitaxel	70%	80%
				Significance	<i>P</i> = 0.0023	<i>P</i> = 0.0064
NSABP B-28 ²¹¹	Node-positive	3,060	64 months	AC	72%	85%
				AC + paclitaxel	76%	85%
				Significance	<i>P</i> = 0.008	<i>P</i> = 0.46
BCIRG 001 ²¹²	Node-positive	1,491	55 months	TAC	75%	87%
				FAC	68%	81%
				Significance	<i>P</i> = 0.001	<i>P</i> = 0.008
CALGB ^a 9741 ²¹³	Node-positive	2,005	36 months	Conventional (q 3 weeks) ACP	75%	90%
				Dose-dense (q 2 weeks) ACP + G-CSF	82%	92%
				Significance	<i>P</i> = 0.010	<i>P</i> = 0.013

CALGB, Cancer and Leukemia Group B; NSABP, National Surgical Adjuvant Breast Project; BCIRG, Breast Cancer International Research Group; TAC, taxol (paclitaxel), adriamycin (doxorubicin), cytoxin (cyclophosphamide); AC, adriamycin (doxorubicin), cytoxin (cyclophosphamide); FAC, fluorouracil, adriamycin (doxorubicin), cytoxin (cyclophosphamide); ACP, adriamycin (doxorubicin), cytoxin (cyclophosphamide), paclitaxel (taxol).

^aThe CALGB Trial 9741 also evaluated sequential adriamycin × 4 followed by paclitaxel × 4 followed by cytoxin × 4 versus concurrent adriamycin and cytoxin × 4 followed by paclitaxel × 4 and found no significant effect on outcome based on these schedule variations.

Radiation Therapy for Breast Cancer

Radiation therapy and surgery are the primary modalities for treatment of locoregional manifestations of breast cancer. Radiation therapy alone can sterilize some breast tumors, but at the expense of excessively toxic doses. The standard rationale is therefore to rely on surgery to control grossly apparent breast lesions and to utilize irradiation to eliminate residual microscopic disease. Results from the Phase III studies of BCT summarized in Table 54.3 demonstrate the success of this approach. Adjuvant breast radiation delivered after surgical lumpectomy will effectively decrease the incidence of in-breast tumor recurrences. Most trials, however, have demonstrated equivalent overall survival rates following lumpectomy regardless of whether radiation was delivered. This finding suggested that breast cancer outcome was largely determined by ability to control progression of micrometastases and that irradiation would make a marginal or negligible contribution to survival. In contrast, the Guy's Hospital BCT Trials⁶⁷ used a breast XRT regimen that would be considered inferior to contemporary radiation schedules, and this resulted in significantly inferior survival rates. Level I evidence therefore supports the inclusion of appropriate radiation therapy (5,000–6,000 rads) into the management of conservatively treated breast cancer patients.

A recent meta-analysis⁶⁸ of Phase III clinical trials involving breast irradiation has motivated additional consideration of the survival benefits associated with radiation therapy in BCT patients. Vinh-Hung and Verschraegen pooled the outcomes of 13 trials involving more than 8,000 patients. The mortality hazard for patients treated by lumpectomy without radiation therapy was 1.086 (95% confidence interval, 1.003–1.175). This corresponds to a possible 8% survival benefit conferred by radiation.

The issue of postmastectomy chest wall irradiation (PMRT) has generated extensive controversy over the past few decades. Clinical trials conducted thus far have failed to render a consistent answer to the question of whether sterilization of microscopic disease on the chest wall of a mastectomized patient yields a worthwhile outcome advantage to all breast

cancer patients. The EBCTCG studied this question indirectly in their meta-analysis of radiation for early-stage breast cancer patients.^{69,70} Although this study revealed a reduced breast cancer mortality risk associated with adjuvant XRT (by 13%), it was at the expense of a 21% increase in nonbreast cancer-related mortality. This pooled analysis, however, involved studies whose primary design involved mastectomy versus BCT, systemic therapy versus no systemic therapy, and variable axillary management strategies. This heterogeneity precludes the ability to draw well-defined conclusions.

Table 54.8 summarizes the results from Phase III prospective randomized trials conducted internationally that have contributed data regarding PMRT in women whose management has also included ALND as well as adjuvant systemic therapy. The results of these trials suggest that patients with four or more metastatic axillary lymph nodes represent the subset most likely to derive a benefit from PMRT, primarily because of their inherently increased risk for chest wall recurrence (range, 20%–40%). The ability to reduce locoregional relapses (to rates of 6%–14%) in these patients with the delivery of PMRT appears to improve the overall survival as well. The National Cancer Institute, the American Society of Clinical Oncology, and the American Society of Therapeutic Radiation Oncology have all issued position statements recommending PMRT for breast cancer patients with four or more metastatic nodes.

The Danish Breast Cancer Group^{71,72} reported survival benefits from PMRT in women with one to three metastatic axillary nodes as well; however, this trial has been criticized because of the surgical treatment rendered. The average number of nodes retrieved from the ALND specimens (six) was somewhat lower than would be expected in a standard level I and II dissection. This finding prompts the concern that inadequate regional surgery may have contributed to the increased incidence of locoregional failures. Unfortunately, a clinical trial designed by the Radiation Therapy Oncology Group designed to address the question of PMRT in patients with one to three metastatic axillary lymph nodes was recently closed because of poor accrual, and this question therefore remains unanswered.

TABLE 54.8. ^aDFCI Trial patients with 1–3 nodes positive received CMF adjuvant chemotherapy; patients with four or more positive nodes received AC adjuvant chemotherapy.

^bAll SECSG Trial patients had at least 4 positive nodes.

Primary Chemotherapy for Breast Cancer

Implementation of preoperative chemotherapy protocols (also commonly referred to as neoadjuvant or induction chemotherapy) revolutionized the management of locally advanced breast cancer (LABC) cases, and this approach is now considered the standard of care for patients with bulky breast and/or axillary disease. Early skepticism regarding this treatment sequence was based on concerns that preoperative chemotherapy would exert an adverse effect on (i) surgical complication rates, (ii) the prognostic value of the axillary nodal status, and (iii) overall survival as a consequence of delayed surgery. Nonetheless, the generally dismal results of treating LABC with primary surgery, radiation alone, or chemotherapy alone motivated investigations of multimodality therapy, and the benefits as well as the safety of preoperative downstaging of disease to improve respectability became apparent.

Broadwater et al.⁷³ demonstrated comparable operative morbidity among nearly 200 LABC patients treated with mastectomy, approximately half of whom received preoperative doxorubicin-based chemotherapy. The induction chemotherapy patients in fact had a lower rate of postoperative seroma

formation. Danforth et al.⁷⁴ similarly reported that preoperative chemotherapy had no adverse effect on surgical complication rates and did not result in delayed delivery of any postoperative cancer care. Most patients will be ready to undergo surgery approximately 3 weeks after the last chemotherapy treatment, when the absolute neutrophil and platelet counts have normalized (greater than 1,500 and 100,000, respectively).

McCready et al.⁷⁵ confirmed that the axillary nodal status retains its prognostic value in the neoadjuvant chemotherapy setting. Their study of 136 LABC undergoing modified radical mastectomy following induction chemotherapy revealed that patients with no axillary metastases in the postchemotherapy mastectomy specimen had an excellent outcome, with nearly 80% surviving 5 years. In contrast, less than 10% of patients with 10 or more positive nodes survived 5 years, and patients with an intermediate number of residual metastatic nodes had an intermediate survival rate.

The third issue, regarding induction chemotherapy and its relative impact on breast cancer survival in comparison to conventional postoperative adjuvant therapy, remains controversial. It is clear, however, that preoperative treatment and deferral of surgery do not increase rates of unresectabil-

ity. On the contrary, approximately 80% of patients will have at least 50% shrinkage of the primary tumor mass, and only 2% to 3% will have signs of progressive disease.⁷⁶⁻⁷⁸ Fears that the surgeon will lose a "window of opportunity" to resect chest wall disease are therefore unfounded, and preoperatively treated patients are likely to be rendered improved operative candidates. A surgical resection is essential in accurately documenting chemotherapy response and in achieving durable locoregional control of disease, as the clinical assessment of response will overestimate the actual pathologic extent by two- to threefold.^{79,80}

The induction CTX benefits of tumor downstaging and the ability to rapidly identify chemoresistant disease by *in vivo* observation motivated expanded applications of this treatment to the setting of early-stage disease. Accordingly, outcomes from prospective clinical trials have now been reported in which preoperative chemotherapy has been compared directly to postoperative chemotherapy in women with LABC as well as early-stage disease. Some of these Phase III clinical trial results are shown in Table 54.9.⁸¹⁻⁸⁸ All have demonstrated overall survival equivalence for the two treatment sequences, confirming the oncologic safety of the neoadjuvant approach.

Subset analyses of the Phase III studies, however, reveal that patients found to have a complete pathologic response (pCR) do have a statistically significant survival benefit, substantiating the concept that primary breast tumor response is a reliable surrogate for chemoeffect on micrometastases. In the NSABP B-18 trial,⁸⁸ patients with stage I-III breast cancer who were randomized to receive four cycles of doxorubicin and cytosine preoperatively and who experienced a pCR had a 5-year overall survival of 86%, which was statistically superior to the outcome seen in all other study participants. Similarly, the University of Texas M.D. Anderson Cancer Center⁸⁹ reported an overall survival rate of 89% for pCR patients treated on preoperative chemotherapy protocols designed specifically for LABC, and this outcome also represented a statistically significant benefit compared to patients with a lesser response. Unfortunately, both studies found that only 12% to 13% of patients experience a pCR when treated with a doxorubicin-based regimen, and this proportion is simply insufficient in yielding a survival benefit for the entire pool of preoperatively treated patients. Predictors of a pCR include relatively smaller size primary breast tumors, estrogen receptor negativity, and high-grade lesions.⁸⁹ The latter two features probably characterize rapidly cycling tumors that may be particularly sensitive to chemotherapy effects.

The ability to downsize the primary breast tumor, thereby facilitating attainment of a margin-negative lumpectomy with a smaller-volume lumpectomy, is a major advantage of the neoadjuvant CTX sequence. A feasibility study reported by Singletary et al.⁹⁰ addressed many of the concerns that induction CTX might leave a field of microscopic satellite lesions, with a resulting increased risk of margin failure and/or excessive local recurrence rates. The Singletary study involved a pathology review of the mastectomy specimens in 143 LABC cases that had been treated with preoperative CTX; approximately one-quarter had adequate shrinkage of tumor and adequate eradication of disease in surrounding breast tissue as well as skin, such that they would have been candidates for successful lumpectomy. Table 54.9 demonstrates the overall comparability of local recurrence rates in subse-

quent clinical trials of women receiving BCT with versus without neoadjuvant CTX.

The NSABP B-18 trial^{87,88,91} randomized more than 1,500 women with stages I-III breast cancer to receive preoperative versus postoperative chemotherapy. This study demonstrated a statistically significant increase in breast conservation therapy utilization for the preoperative chemotherapy arm (68% versus 60%). With a median follow-up of 72 months, the local recurrence rates were 7.9% and 5.8% (no statistically significant difference) following BCT in the preoperative and postoperative chemotherapy arms, respectively. The conversion rate to BCT eligibility was greatest in the patients with T3 tumors at diagnosis. The NSABP also reported that local recurrence was somewhat higher in the subset of lumpectomy patients who were downstaged to become BCT eligible in comparison to the BCT patients who were BCT candidates at presentation.⁸⁸ However, this subset of downstaged BCT cases was predominantly composed of T3 tumors, and because local recurrence is one manifestation of underlying tumor biology, it would be expected that the more advanced stage lesions might have increased local recurrence rates regardless of surgery type and treatment sequence. Also, radiation boost doses were not consistently used in the lumpectomy patients, and tamoxifen therapy was only used in patients over 50 years of age. Both these interventions, if implemented uniformly, might have influenced local recurrence rates in downstaged tumors. Last, the NSABP requires that margin-negative lumpectomies be free of any tumor cells at an inked margin; a more-aggressive approach to margin control might be necessary for lumpectomies in tumors that have been downsized by preoperative CTX.

Newman et al.⁹² analyzed a series of 100 patients treated at the M.D. Anderson Cancer Center on a prospective protocol of preoperative sequential taxotere and adriamycin-based chemotherapy in patients with stage I-III breast cancer. These investigators reported that 34% of patients initially ineligible for BCT were converted to lumpectomy candidates with this preoperative chemotherapy regimen. Final pathology review of all surgical specimens revealed that clinical assessment of BCT eligibility following induction chemotherapy was inaccurate for invasive lobular cancers, multicentric disease, and diffuse microcalcifications. Difficulties with assessment of chemoresponse in lobular cancers have also been noted by Mathieu et al.⁹³

Induction chemotherapy is a reasonable and safe treatment approach for patients with breast cancer of any stage if the clinician is certain that chemotherapy would be recommended in the postoperative setting. The risk of overtreatment can be minimized by obtaining multiple diagnostic core biopsy specimens to confirm that a lesion is predominantly invasive, as it would clearly be inappropriate to treat large-volume or palpable DCIS tumors (with or without microinvasion) with CTX in any setting. Patients presenting with multiple tumors or extensive calcifications on initial mammogram should be counseled that preoperative chemotherapy will not convert them to BCT eligibility, regardless of extent of their primary tumor shrinkage. If the tumor is not associated with any microcalcifications, then a radiopaque clip should be inserted (preferably under ultrasound guidance) either before delivery of the neoadjuvant CTX or within the first couple of cycles. In the event that the patient should have a complete clinical response to the preoperative chemotherapy, this clip will serve

as the target for subsequent mammography-assisted wire localization lumpectomy when the patient is ready for surgery. Lesions associated with microcalcifications have an inherent target for subsequent localization.

There is ongoing debate regarding the optimal method for integrating sentinel node staging of the axilla into induction CTX protocols. The standard treatment sequence for neoadjuvant CTX patients involves a percutaneous needle biopsy for establishment of the cancer diagnosis, delivery of chemotherapy, breast/axillary surgery, followed by irradiation in selected cases, and endocrine therapy for hormone receptor-positive disease. It was therefore logical for initial investigations to evaluate the results of sentinel lymph node biopsy performed after the delivery of preoperative CTX and concomitantly with the breast surgery. Concerns arose early in these discussions that the lymphatic mapping concept might be compromised by the following:

- i. Lymphatic obstruction by tumor emboli from the relatively larger tumors that are more likely to be managed with neoadjuvant CTX;
- ii. CTX effect on axillary metastases might not be uniform; and/or
- iii. CTX might obliterate intramammary lymphatic channels.

Any combination of these factors could result in higher rates of sentinel node nonidentification or false negativity. Studies reported by Bedrosian et al.⁹⁴ and Chung et al.⁹⁵ documented the accuracy of lymphatic mapping for T2 and T3 breast

cancers. Breslin et al.⁹⁶ reported the first series of patients undergoing sentinel lymph node biopsy and completion ALND after neoadjuvant CTX in a 2000 study from the M.D. Anderson Cancer Center, and these investigators demonstrated that the lymphatic mapping technology is indeed feasible in these cases, but accuracy rates are optimized when the surgical team has progressed through the learning curve of mapping in the setting of CTX-treated axillary tissue.

As shown in Table 54.10, several other investigators have now reported varying success rates with lymphatic mapping performed after delivery of neoadjuvant CTX. Identification rates range from 85% to 97%, and false-negative sentinel nodes are identified in 0% to 33% of cases. One feature supporting the biologic rationale for this approach is the persistent observation that even after neoadjuvant CTX, the sentinel node is frequently the isolated site of axillary metastases. A meta-analysis of reported studies conducted by Xing et al.⁹⁷ revealed an overall accuracy of 95% for sentinel node biopsy in this setting.

Nonetheless, the suboptimal false-negative results have prompted many surgeons to perform sentinel node biopsy for axillary staging before delivery of neoadjuvant CTX. The disadvantage to this approach is that some women will be subjected to unnecessary ALNDs, because the node-positive patients identified at presentation will be committed to a completion ALND after induction CTX, despite the fact that the sentinel node(s) may have been the only sites of disease for some cases, and for others the CTX may have eliminated any residual axillary metastases.

Management of Ductal Carcinoma In Situ

Because DCIS is largely a disease whose manifestations are confined to in-breast pathology, management strategies focus on various combinations of local therapy: mastectomy, lumpectomy, and breast irradiation. Axillary metastases are sufficiently rare with DCIS that nodal staging with the conventional level I/II lymph node dissection and its associated risk of lymphedema is generally considered unnecessary. However, in cases of extensive DCIS, where the risk of coexisting invasive disease is significant, information regarding the axillary nodal status becomes more relevant. The advent of lymphatic mapping and sentinel lymph node biopsy has greatly facilitated the handling of this dilemma. Adjuvant systemic therapy provides no survival benefit for pure DCIS because of the exceedingly low risk of micrometastases. However, hormonally active medical therapies such as selective estrogen receptor modulators and aromatase inhibitors exert a suppressive effect on abnormal proliferative activity in the breast, and these agents can therefore be useful in contributing to local control of disease as well as prevention of new breast primary cancerous events. Table 54.11⁹⁸⁻¹⁰³ summarizes the results reported by Phase III studies designed to compare DCIS treatment options.

Local Therapy

Mastectomy was the standard management approach for DCIS until approximately 25 years ago. During the 1980s, two developments provided the impetus for expanded surgical options in the treatment of this condition: (i) publication of prospective, randomized clinical trials from the United States and from Europe confirming the safety of breast conservation therapy as management for early-stage invasive breast cancer; and (ii) implementation of widespread screening mammography programs and the resulting increased rates of detection for localized foci of DCIS. Despite concerns that DCIS represented a diffuse pattern of disease in the breast, it became increasingly difficult for clinicians to support the paradox of offering breast-sparing treatment to women with invasive palpable breast cancer while women with mammographically detected DCIS were penalized with a routine recommendation for mastectomy. Hence, breast conservation strategies were explored and have been proven to be oncologically safe for appropriately selected DCIS cases.

Nonetheless, mastectomy remains a reasonable treatment option for DCIS, resulting in prolonged disease-free survival. Advances in plastic surgery techniques for immediate or delayed breast reconstruction have further improved the results achieved by mastectomy for DCIS. In certain clinical scenarios, mastectomy remains the preferred approach:

1. Patients with diffuse, suspicious-appearing microcalcifications in the breast
2. Inability to obtain margin control by lumpectomy and/or reexcision(s)
3. Patients with a contraindication to chest wall irradiation (XRT) or who lack access to an XRT facility, in cases in which it has been determined that breast XRT would be a necessary adjunct to lumpectomy
4. Patients with a primary personal preference for mastectomy
5. Patients with multiple, clinically apparent foci of DCIS that are not amenable to resection within a single margin-negative lumpectomy
6. Suboptimal tumor-to-breast size ratio, where a margin-negative lumpectomy will yield an unacceptable cosmetic result (as defined by the patient)

Mastectomy and lumpectomy have never been directly compared in a prospective, randomized trial designed for DCIS patients. However comparable survival has been confirmed by indirect comparisons from retrospective studies and from DCIS patients who were incidentally included in the NSABP B-06 trial.⁹⁸ The B-06 trial was designed to evaluate the outcome of approximately 1,800 stage I and II breast cancer patients randomized to treatment by breast conservation therapy (with versus without breast irradiation) or by mastectomy. Centralized pathology review subsequently identified 78 cases of DCIS that were randomized as well⁹⁸ and equally divided between the three study arms. The overall survival for all three arms was similar (approximately 96% at 6 years), but the addition of breast irradiation to lumpectomy decreased local recurrence (LR) from 43% to 7% (see Table 54.11).

As shown by Table 54.11, lumpectomy alone results in consistently higher rates of LR (range, 20%–43%) in comparison to patients treated by lumpectomy and breast radiation (range, 7%–12%). Commonly cited risk factors for LR have included suboptimal margin control, young age at diagnosis, and high-grade tumors with comedo-necrosis. Although margin status is frequently implicated in risk for developing LR, there is no consensus regarding the optimal extent of a negative margin. Furthermore, as noted in a meta-analysis of BCT for DCIS by Boyages et al.,¹⁰⁴ studies published before 1998 often neglected to include margin status in their analyses. In the more-recent studies, a negative margin was variously defined as a minimum of 1, 2, or 3 mm of microscopically normal tissue at the inked lumpectomy borders.

Another consistent finding between studies was that approximately half of all locally recurrent lesions are in the form of invasive disease. The decision to be treated by breast preservation therefore involves a different category of risk that is assumed by the DCIS patient compared to the patient undergoing lumpectomy for invasive cancer. In the latter case, the risk for distant micrometastases is present from the time of diagnosis, and decisions regarding the need for adjuvant systemic therapy are addressed at that time. In the former case, however, there would be no need to consider treatment of micrometastases, because DCIS biologically would not be expected have the ability to extend beyond the local tissue environment of the breast. The development of a local recurrence alters this prognostically favorable situation, and affected patients then face the risk of breast cancer mortality from distant spread. The proportion of invasive LR was similar for the patients treated by lumpectomy alone versus lumpectomy and XRT. Because the risk of LR is lower for the radiated patients, however, the assumption would be that radiation reduces the incidence of a potentially life-threatening pattern of disease progression. One could further postulate that mastectomy is the safest treatment for DCIS patients because of the exceptionally low rate of LR. Although low, this risk is not nonexistent,^{105,106} indicating

that rare forms of DCIS do possess a biologically aggressive nature (or that an occult focus of invasion was present in the breast). Despite this concern, the Phase III clinical trials summarized in Table 54.11 reveal similarly high overall survival rates for DCIS patients treated by lumpectomy with or without breast irradiation.

Because of the expense, inconvenience, and potential adverse effects of XRT, several investigators have attempted to identify subsets of DCIS patients with sufficiently low-risk lesions that they could routinely be treated by lumpectomy alone. The obvious candidates would be small-volume, low-grade DCIS with widely negative margins on lumpectomy. Some groups have developed grading systems that stratify DCIS patients based on the risk of developing LR. The most popular of these is the Van Nuys Prognostic Index (VNPI), developed by Silverstein et al.¹⁰⁷ and based on the detailed pathology analyses and follow-up of several hundred DCIS patients. This index utilizes a point system to categorize patients on the basis of nuclear grade (with versus without necrosis); extent of DCIS (15 mm or less versus 16–40 mm versus more than 40 mm); and margin width (10 mm or more versus 1–9 mm versus less than 1 mm). Cumulative points resulting in scores of 3 or 4 identify patients who should be safely managed by lumpectomy only, whereas scores of 8 or 9 would be indications for mastectomy. Intermediate scores would be consistent with safe treatment by lumpectomy and XRT. This index was recently modified to include age (less than 40 versus 40–60 versus more than 60 years).¹⁰⁸ Several studies have been unable to validate the accuracy of the VNPI in predicting LR. A major disadvantage to the VNPI is that it was developed by retrospective review of treated patients and therefore has some inherent biases. Despite the difficulties in developing a reproducible and accurate scoring system for DCIS, an international and multidisciplinary panel of DCIS experts convened a consensus panel several years ago, and collectively decreed that all pathology reports on DCIS should include a description of morphology, nuclear grade, and necrosis.¹⁰⁹

Several investigative groups have implemented prospective clinical trials designed to evaluate the long-term results of treating highly selected subsets of DCIS patients by lumpectomy alone. One such study, conducted by the Dana-Farber/Harvard Cancer Center, utilized DCIS grade 1 or 2, size up to 2.5 cm, and final margins of at least 1 cm as eligibility criteria. After accrual of 157 patients (of an accrual goal of 200), the early closure of this study was recently reported¹¹⁰ because of an excessive LR rate. At a median follow-up of 40 months, 13 patients experienced a LR (9 were invasive recurrences), corresponding to a 5-year rate of 12.5% and a per annum rate of 2.5% per patient-year. A Phase 3 clinical trial implemented by the Radiation Therapy Oncology Group (RTOG), which randomizes small, low-grade DCIS to lumpectomy with versus without XRT and with versus without tamoxifen, is currently under way.

Regional Treatment and Management of the Axilla

Past studies of mastectomy performed for DCIS revealed axillary metastases in approximately 2% of DCIS cases. It is commonly assumed that these are related to a focus of invasive disease in the breast that was overlooked on pathologic tissue sampling. This low risk of detecting nodal disease and the

wish to minimize risk of lymphedema prompted most surgeons to abandon the routine practice of performing a conventional level I/II ALND in DCIS patients. For those patients requiring a mastectomy because of diffuse DCIS, the need for axillary staging becomes more relevant because of the associated increased risk of coexisting microinvasion. In these cases the standard approach was to include a level I ALND with the mastectomy.

Integration of the lymphatic mapping technology into breast cancer surgery during the past decade presented a novel and minimally invasive method for detecting axillary metastases. Several investigators have now reported their findings from series of DCIS patients undergoing sentinel lymph node biopsy, with interesting results. Intra et al.¹¹¹ found axillary metastases in 7 of 223 (3.1%) DCIS patients, and Pendas et al.¹¹² reported a 6% rate of sentinel node positivity in 87 DCIS cases. These increased rates of upstaging patients previously thought to have preinvasive DCIS are inconsistent with established overall long-term survival rates of 98% for DCIS patients. It must be noted, however, that in both these series the majority of sentinel node disease was micrometastatic, detected by immunohistochemistry, and completion ALNDs rarely demonstrated additional metastases in nonsentinel nodes. The biologic significance of axillary metastases in this setting is therefore questionable. Given this uncertainty, the current standard of care is to defer axillary staging by lymphatic mapping in DCIS cases managed with breast preservation unless invasion is detected in the lumpectomy specimen, in which case the patient can be returned to the operating room for a subsequent sentinel lymph node biopsy. In contrast, it is not technically feasible to perform a lymphatic mapping procedure after the breast has been removed, and a different approach must be used for DCIS patients undergoing mastectomy. If there is a significant likelihood of a coexisting invasive focus, based on prior biopsy findings, or based on extent of DCIS, it is therefore reasonable to perform the lymphatic mapping procedure concomitantly with the mastectomy. Immunohistochemistry should not be routinely performed for these cases outside of a clinical trial.

Medical Therapy for DCIS

Because of the known prevalence of ER expression in DCIS lesions, and because of tamoxifen's known ability to suppress breast ductal proliferative activity, it has been reasonable to explore utilization of this selective ER receptor modulator as adjuvant therapy for DCIS. As shown in Table 54.11, the NSABP's B-24 study¹⁰¹ randomized 1,800 DCIS cases to treatment by lumpectomy and XRT followed 5 years of tamoxifen versus placebo. At a median follow-up of 74 months, tamoxifen was found to result in a significantly lower risk of both ipsilateral and contralateral breast cancer events. There were 130 breast cancer events in the placebo arm versus 84 in the tamoxifen arm, consistent with a 37% reduction for the tamoxifen patients ($P = 0.0009$). There was no requirement for margin control in this trial and, interestingly, there were fewer ipsilateral breast cancer events in the tamoxifen-treated arm even among those patients with involved margins. The pattern of benefit conferred by tamoxifen in NSABP B-24 was also notable, with most of the risk reduction occurring in contralateral breast events. Tamoxifen reduced the risk of contralateral invasive and noninvasive disease by 52% ($P = 0.01$).

For the ipsilateral breast there was a significant reduction in invasive recurrences, by 44% ($P = 0.03$), but the reduction in recurrent DCIS was only by 18% ($P = 0.43$).

Another prospective randomized trial conducted in the United Kingdom¹¹³ (commonly called the UK Trial) had a two-by-two factorial design and evaluated the relative contributions of breast irradiation and tamoxifen therapy to the outcome of DCIS patients treated with lumpectomy. This study found that although both approaches are effective in decreasing risk of local recurrence, tamoxifen had only marginal benefit in patients receiving breast XRT. The UK Trial has been criticized because of its design, which allowed for some bias because patients were allowed to self-select regarding adjuvant therapy to some extent.

Allred et al. conducted a meticulous study of the ER expression in DCIS lesions from the NSABP tamoxifen-treated arm and reported a close association between the pattern of hormone receptor positivity and likelihood benefit from tamoxifen.¹¹⁴ With a median follow-up of 104 months, the rate of LR for ER-positive DCIS was 10%, compared to 23% for the ER-negative lesions. It should be noted, however, that Allred et al. utilized a very specific grading and interpretation of ER staining by immunohistochemistry. Their findings with regard to DCIS and tamoxifen are biologically plausible; however, whether their methods can be widely replicated for standardized clinical practice warrants further study.

The ATAC Trial yielded provocative results regarding the activity of the aromatase inhibitor anastrozole for adjuvant management ER-positive postmenopausal breast cancer. This trial randomized more than 9,000 early-stage breast cancer patients to receive anastrozole, tamoxifen, or the combination of anastrozole with tamoxifen, as systemic adjuvant therapy. The risk of contralateral new breast cancers was reduced to a significantly greater degree in the anastrozole compared to the tamoxifen arm (odds ratio, 0.42; $P = 0.007$).⁵¹ These findings prompted the design and implementation of NSABP B-35, a Phase 3 trial that randomizes postmenopausal DCIS patients treated by breast conservation therapy to receive adjuvant tamoxifen versus anastrozole for the prevention of additional breast cancer events.¹¹⁵

Breast Cancer Risk Reduction

Until recently, the primary message of breast health awareness programs has been that "early detection is a woman's best protection" against breast cancer because there was no way to prevent the disease. Currently, however, tamoxifen is U.S. Food and Drug Administration (FDA) approved for chemoprevention of breast cancer in high-risk women, and numerous investigators are evaluating other medications that may decrease the risk of breast cancer. Data have also become available regarding the efficacy of surgical strategies to reduce breast cancer risk.

The ability to hormonally manipulate breast tissue and thereby reduce proliferative changes that would otherwise evolve into cancer has been recognized over the past several decades. Women using tamoxifen for a unilateral breast cancer were seen to have a 40% lower risk of second primary/contralateral breast cancer compared to breast cancer patients not treated with tamoxifen. These data motivated implemen-

tation of the first large-scale chemoprevention trial conducted in the United States, the National Surgical Adjuvant Breast Project (NSABP) P-1 study,¹¹⁶ a prospective, placebo-controlled randomized study of tamoxifen in 13,880 high-risk women. Eligibility criteria to participate in the P-1 Study included age at least 60 years; a 5-year Gail model breast cancer risk estimate of more than 1.66%; and history of lobular carcinoma in situ (LCIS). After 54 months median follow-up, the trial was unblinded early because of the magnitude of difference in breast cancer incidence between the treated and control arms of the study, revealing that tamoxifen lowered breast cancer risk by 49%. It therefore now considered the standard of care to evaluate breast cancer risk factor information in women and to counsel high-risk women about the options of chemoprevention.

Unfortunately, however, making a commitment to 5 years of tamoxifen is not easy, as several potentially severe adverse reactions can be associated with this therapy. Tamoxifen effects on estrogen receptors in the uterus, vascular system, and central nervous system increase risks of uterine cancer, thromboembolic phenomena (deep vein thrombosis and pulmonary emboli), and vasomotor symptoms (e.g., hot flashes, night sweats), respectively. Partially offsetting these risks are tamoxifen's estrogen agonist effects on the skeletal system and lipid profile, resulting in a reduced incidence of osteoporosis and lower serum cholesterol levels. NSABP P-1 study participants in the premenopausal age range appeared to be relatively protected from adverse tamoxifen effects,¹¹⁶ however, the safety of tamoxifen during fetal development has not been established, and chemoprevention with this agent is therefore contraindicated in women who are contemplating pregnancy.

Complicating the chemoprevention decision process further is the fact that tamoxifen will only reduce the incidence of estrogen receptor-positive tumors. Tamoxifen has no impact on the occurrence of estrogen receptor-negative disease, a potentially significant issue in counseling women who harbor mutations in one of the breast cancer susceptibility genes. Subset analysis of genetically tested NSABP P-1 participants demonstrated that tamoxifen does not reduce breast cancer risk in BRCA-1 mutation carriers; however, it does appear to offer some chemoprevention benefit in BRCA-2 mutation carriers.¹¹⁷ This finding is consistent with prior studies revealing that BRCA-2 mutation-associated tumors are similar in histopathology to sporadic breast cancer, whereas BRCA-1 cancers are more likely to be estrogen receptor negative and aneuploid.

The ideal SERM would retain antiproliferative activity in the breast, but without subjecting the patient to the negative risks. Toward this end, the (NSABP) is currently accruing to the second chemoprevention trial, the Study of Tamoxifen and Raloxifene (STAR). STAR randomizes high-risk postmenopausal women to receive either tamoxifen or raloxifene, a SERM that is presently FDA approved for treatment of osteoporosis. Preliminary evidence indicates that raloxifene has similar breast cancer risk reduction activity compared to tamoxifen, but with a lower incidence of uterine neoplasia. Premenopausal women are ineligible for STAR participation because of the absence of data on raloxifene effects in young, ovulating women.

One theory of breast carcinogenesis proposes that risk of malignant transformation is related to lifetime exposure of

breast tissue to cyclic extremes in the levels of circulating hormones. Accordingly, it is postulated that stabilization of estrogen levels will decrease the incidence of mammary neoplasia. Studies of gonadotropin-releasing hormone agonists in conjunction with low-dose hormone replacement therapy are therefore under way as a means of testing this hypothesis, and preliminary results have shown that this approach can successfully decrease mammographic density;¹¹⁸ however, longer follow-up is needed to evaluate actual chemoprevention efficacy.

Recent data on the efficacy of aromatase inhibitors for adjuvant therapy in breast cancer have revealed that these agents also possess significant chemoprevention activity.¹¹⁹ Table 54.12^{116,119-128} summarizes reported data on the risk-reducing strength of various medical therapies.

Premenopausal prophylactic oophorectomy and prophylactic mastectomy are additional options as surgical strategies for breast cancer risk reduction. Surgical menopause before age 35 years is an established protective factor against breast cancer risk. Availability of BRCA testing has resulted in the identification of women from hereditary breast-ovarian cancer families, and these women are especially motivated to consider prophylactic removal of the ovaries. Published case-control data (level II evidence) by Rebbeck et al.¹²⁹ and Kauff et al.¹³⁰ have confirmed that prophylactic oophorectomy in this setting can decrease breast cancer incidence by approximately 50%. Premature menopause, however, is associated with an increased risk of osteoporosis and atherosclerotic cardiovascular disease. Interestingly, the breast cancer protection afforded by prophylactic oophorectomy was not diminished by hormone replacement therapy in the Rebbeck et al. study.

Prophylactic mastectomy is a dramatic and extreme maneuver to decrease breast cancer risk, yet only recently has its efficacy in high-risk women been documented. Early reports of prophylactic mastectomy in humans^{131,132} demonstrated a 1% to 2% failure rate, but these studies were flawed by limited follow-up and by the inclusion of many women who were probably at low risk for developing breast cancer. Women at risk for hereditary breast cancer would potentially be most susceptible to a failed prophylactic mastectomy, as in these cases any microscopic amount of residual breast tissue would harbor the germ-line predisposition for malignant transformation.

Hartmann et al.¹³³ have made valuable contributions to our understanding of the efficacy of prophylactic mastectomy through their meticulous scrutiny of the Mayo clinic database. This analysis yielded 639 prophylactic mastectomy patients with documented increased risk on the basis of family history of breast and/or ovarian cancer. These high-risk patients were further stratified into very-high (214 patients) and moderately-high risk (425 patients) subsets based on extent of family history. Outcome regarding number of subsequent breast cancers occurring among the very high risk subset was compared to the number of breast cancers developing among the female siblings of these patients. For the moderate-risk patients, efficacy of the prophylactic surgery was evaluated by calculating the number of expected cancers based on summing of the individual Gail model risk estimates for the entire group. Survival analyses were performed by projecting anticipated longevity based on population-based data. With a median follow-up of approximately 14

years, 7 breast cancers were detected in the prophylactic mastectomy patients (3 in the very high risk subset and 4 in the moderate-risk subset), consistent with a 90% reduction in breast cancer risk and mortality in both categories of high-risk patients.

Subsequent study of the Hartmann database¹³⁴ reported results of prophylactic mastectomy in women who were also found to be BRCA mutation carriers and confirmed an equivalent magnitude of breast cancer risk reduction. Similarly, Meijers-Heijboer et al.¹³⁵ reported outcome for 76 BRCA mutation carriers followed prospectively after having undergone prophylactic mastectomy and found no tumors developing with an average follow-up of nearly 3 years. Hence, reliable evidence does indicate that prophylactic mastectomy will effectively and substantially reduce the incidence of breast cancer in high-risk women, although the protection conferred is not complete.

Metastatic Breast Cancer

Goals of Therapy

Although few if any patients with metastatic breast cancer are cured by treatment, many will remain in remission for prolonged periods and enjoy acceptable quality of life. Treatment modestly prolongs survival, perhaps by 20% to 30% proportionally, and palliation is achieved for many if not all patients.¹³⁶⁻¹⁴⁰

Taken together, these considerations suggest that judicious, serial application of available therapies should result in the main goals of treatment of metastatic disease: palliation and modest survival prolongation. To achieve these goals, the clinician needs to first assess the patient's status in regard to diagnosis, prognosis, and prediction.

Diagnosis

Certain constellations of abnormalities may be so compelling that tissue confirmation of a new finding suggestive of metastatic disease is not required. However, it is strongly recommended that a biopsy of a suspicious lesion be performed to document that one is, in fact, dealing with metastatic breast cancer and not a benign lesion or a second, primary cancer. Such biopsies can be performed by fine-needle aspiration, core needle biopsy, or excision, depending on the circumstances. Biopsy of a metastatic lesion also permits reanalysis of the patient's tumor for predictive factors.

Prognosis

Chemotherapy is more likely to induce a clinical response than endocrine therapy or trastuzumab. However, chemotherapy is also usually more likely to have more toxicity, and so either endocrine or trastuzumab treatment is preferred as first therapy for estrogen receptor- or HER2-positive metastatic disease, respectively. However, chemotherapy is indicated as first-line therapy for patients with evidence of rapidly progressive visceral metastases, especially if there is evidence of substantial end-organ dysfunction, such as elevated liver function tests (especially bilirubin) and/or pulmonary symptoms, regardless of predictive factors.

TABLE 54.12. Phase III trials of breast cancer chemoprevention.

Study	Primary chemoprevention study?	N	Eligibility criteria	Age range (years)	Randomization	Intended treatment duration (years)	Median follow-up	Breast cancer hazard
Royal Marsden ^{120,121}	Yes	2,471	High risk, family history	30–70	Tam vs. placebo	5–8	70 months	1.06 (0.7–1.7) Tam. vs. placebo
NSABP P-01 ^{116,120}	Yes	13,388	≥1.67% 5-year risk LCIS Age >60 years	35	Tam vs. placebo	5	54.6 months	0.51 (0.39–0.66)
Italian Tamoxifen Study Group ^{120,122–124}	Yes	5,408	S/p hysterectomy	35–70	Tam vs. placebo	5	81.2 months	All: 0.75 (0.48–1.18) No HRT: 0.99 (0.59–1.68) HRT: 0.36 (0.14–0.91)
IBIS ^{120,125}	Yes	7,139	RR *0.132	35–70	Tam vs. placebo	5	50 months	0.68 (0.50–0.92)
Tamoxifen Chemoprevention Overview Analysis ¹²⁰	Yes, collective review	28,406	NA	NA	Tam vs. placebo	NA	70.6 × 10 ³ women-years	0.62 (0.54–0.72)
MORE ^{120,126}	No	7,705	Postmenopausal; osteoporosis	Median, 66.5	Raloxifene vs. placebo	4	3 years	0.28 (0.17–0.46)
STAR ²⁵⁰	Yes	Accrual goal 19,000	Postmenopausal; ≥1.67% 5-year risk LCIS	Accrual not yet completed	Tam vs. raloxifene	5	Accrual not yet completed	NA

ATAC ¹¹⁹	No	9,366	Postmenopausal, early-stage breast cancer	Mean, 64 years	Arimidex vs. Tam vs. Tam + arimidex	5	33.3 months	0.42 (0.22–0.79)

Prediction

For most patients, careful selection of the optimal therapy can result in considerable and often relatively long-lasting palliation. Expression of estrogen and progesterone receptors (ER, PgR) is highly predictive of response to endocrine treatments.^{141,142} HER-2 is the protein product of the *erbB-2* gene, a member of the epidermal growth factor receptor family that consists of four members: epidermal growth factor receptor (EGFR, also called HER1), HER2 (also called *erbB-2* and *c-neu*), HER3, and HER4. HER2 is amplified and/or overexpressed in 25% to 40% of breast cancers, and the humanized monoclonal anti-HER2 antibody, trastuzumab, appears to be effective only in patients with HER2-positive breast cancer.¹⁴³⁻¹⁴⁵

There are no good predictive factors for individual chemotherapy agents. Chemotherapy resistance assays have been studied for more than two decades, but none of these technologies has been shown in rigorous studies to be sufficiently accurate for routine clinical use.¹⁴⁶⁻¹⁴⁸ Therefore, selection of specific chemotherapy is empiric. For example, patients who relapse within 1 year of adjuvant therapy are very unlikely to respond to the same agents again. Moreover, cumulative toxicities, especially cardiac failure with the anthracyclines, may preclude additional treatment even if the agent is likely to be effective.

Selection of Therapy: Local Versus Systemic

Local therapies (surgery, radiation, hyperthermia) often preclude concurrent systemic therapy and therefore are most appropriate for patients who have isolated metastases and/or who have impending crises, such as long bone fracture, spinal cord metastases, or intracranial metastases.

Systemic Therapy: Endocrine Therapy

For most patients with metastatic disease, selection of systemic therapy is preferable. Patients with ER- and/or PgR-positive tumors should receive endocrine therapy. There is no role for combined endocrine and chemotherapy; there are some preclinical and adjuvant data suggesting that they may be antagonistic.^{149,150} Regardless, because palliation is the goal, if endocrine treatment alone is appropriate it is more likely to induce palliation. If not, then there is no reason to use it, and chemotherapy should be initiated alone.

For the past 20 years, tamoxifen has been the first-line endocrine treatment of choice, because it is equally or more effective and has fewer side effects than previously available therapies. However, because most hormone receptor-positive patients receive tamoxifen in the adjuvant setting, second-line endocrine therapy, in fact, becomes "first line" if patients recur on tamoxifen. Several prospective randomized trials have demonstrated that for postmenopausal women with ER-positive metastatic breast cancer, the selective aromatase inhibitors are more effective with fewer side effects than older second-line therapies, such as megestrol acetate or aminoglutethimide¹⁵¹⁻¹⁵⁴ (Table 54.13). Recently, similar studies have demonstrated that survival is superior for women treated with AIs compared to tamoxifen as first line therapy for metastatic disease^{136,155,156} (Table 54.13). Because they do not inhibit ovarian estrogen production, aromatase inhibitors should not be used in premenopausal women.

Fulvestrant, similar to tamoxifen, binds to the ER. However, instead of modulating ER dimerization and binding to estrogen response elements in the nucleus, fulvestrant prevents dimerization and induces downregulation of the receptor. Prospective randomized trials have demonstrated that fulvestrant is as effective as anastrozole as second-line therapy and, recently, more effective than tamoxifen as first-line therapy¹⁵⁷⁻¹⁵⁹ (see Table 54.13).

Premenopausal women with hormone receptor-positive metastatic breast cancer are probably best treated with ovarian function cessation, either by surgical oophorectomy or by chemical cessation of ovary function with the use of luteinizing hormone-releasing hormone antagonists such as goserelin. Addition of either tamoxifen, an aromatase inhibitor, or fulvestrant to ovarian cessation appears to improve outcome, but the side effects are greater. However, because the aromatase inhibitors appear more effective than tamoxifen in postmenopausal women, it is not unreasonable to combine ovarian ablation with an aromatase inhibitor.^{160,161}

Side effects of endocrine treatments are generally related to antiestrogenic effects, including hot flashes, moodiness, and vaginal dryness and dyspareunia. The aromatase inhibitors all seem to have a small rate of arthralgias and of gastrointestinal upset. Because tamoxifen has estrogenic properties in the liver, it increases thrombogenesis, with consequent increased risk of deep venous thrombosis and cerebral vascular accident. Long-term use of aromatase inhibitors is associated with increased risk of osteoporosis and fracture, whereas tamoxifen has estrogenic effects in bone and is therefore protective from this effect. However, in women with metastatic disease, this is rarely an issue because they rarely remain on the agent for more than a few months due to progression, and they are frequently treated with bisphosphonates (see following).

Systemic Therapy: Chemotherapy

Of the common solid tumor malignancies, breast cancer is one of the most sensitive to chemotherapy, although, as noted, metastatic breast cancer exhibits a fundamental pattern of resistance that ultimately, and nearly universally, leads to death. Nonetheless, responses, and one therefore hopes improvement in symptoms, occur in 20% to 60% of patients when treated with single-agent alkylating agents, antimetabolites (purine and pyrimidine analogues), anthracyclines and anthraquinones, and taxanes. Of these, the anthracyclines (doxorubicin, epirubicin) and taxanes (paclitaxel, docetaxel) appear to have the highest single-agent activity.

Through the 1980s, combination chemotherapy was widely applied in metastatic breast cancer, cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) and cyclophosphamide, doxorubicin (adriamycin), and 5-fluorouracil (CAF).^{162,163} In the 1990s, use of sequential single-agent therapy was more widely applied to avoid overlapping toxicities of combination therapy.¹⁶⁴⁻¹⁶⁹ Results of two recently published studies have suggested a modest survival advantage for combination therapy using either docetaxel and capecitabine or paclitaxel and gemcitabine.^{138,170} These two studies notwithstanding, in the absence of rapidly progressive visceral disease, it seems just as reasonable to treat patients with single-agent chemotherapy, offering the next therapy if the first is either ineffective or intolerable.

TABLE 54.13. Prospective randomized trials of endocrine therapy for metastatic breast cancer.

<i>Comparison</i>	<i>Reference</i>	<i>Clinical benefit*</i>	<i>TTP (HR for progression)</i>	<i>Overall survival (HR for death)</i>
Selective aromatase inhibitors versus aminoglutethimide				
Letrozole vs. aminoglutethimide	153	36.3% 28.9% (NS)	0.72 (<i>P</i> = 0.008)	0.64 (<i>P</i> = 0.002)
Selective aromatase inhibitors versus megestrol acetate				
Anastrozole vs. megestrol acetate	151	42.2% 40.3% (NA)	0.94 (NS)	0.78 (<i>P</i> = 0.025)
Letrozole vs. megestrol acetate	152	34.5% 31.7% (NS)	0.80 (<i>P</i> = 0.07)	0.82 (<i>P</i> = 0.15)
Letrozole vs. megestrol acetate	251	26.7% 23.4% (NA)	0.99 (NS)	0.92 (<i>P</i> = 0.49)
Exemestane vs. megestrol acetate	252	37.4% 34.6% (NS)	0.82 (<i>P</i> = 0.04)	NA (<i>P</i> = 0.04)
One selective aromatase inhibitor versus another				
Letrozole vs. anastrozole	253	27% 23%	1.0 (<i>P</i> = 0.92)	0.95 (<i>P</i> = 0.62)
Selective estrogen receptor downregulator versus selective aromatase inhibitor				
Fulvestrant vs. anastrozole	158	42.2% 36.1% (<i>P</i> = 0.26)	0.92 (<i>P</i> = 0.43)	NA
Fulvestrant vs. anastrozole	157	44.6% 45% (NS)	0.98 (<i>P</i> = 0.84)	NA
Selective aromatase inhibitors versus tamoxifen (selective estrogen receptor modulator)				
Anastrozole vs. tamoxifen	254	56.2% 55.5% (NS)	0.99 (<i>P</i> = 0.94)	NA
Anastrozole vs. tamoxifen	255	59% 46% (<i>P</i> = 0.01)	0.69 (<i>P</i> = 0.005)	NA
Letrozole vs. tamoxifen	155	49% 38% (<i>P</i> = 0.001)	0.70 (<i>P</i> = 0.0001)	NA
Exemestane vs. tamoxifen	156	57% 42% (<i>P</i> = NA)	NA	NA

In summary, chemotherapy can induce quite satisfactory palliation, in spite of its side effects, if applied judiciously. There does not appear to be an optimal regimen, schedule, or dose, although general guidelines can be drawn from a number of well-performed prospective randomized trials.

Novel Targeted Therapies

Trastuzumab is a humanized monoclonal antibody that selectively binds HER2. Phase II trials have shown it to induce responses in 10% to 25% of patients with HER2-positive breast cancers.^{144,171,172} Perhaps more importantly, a single prospective randomized clinical trial has demonstrated that response rates, progression-free survival, and even overall survival are improved by chemotherapy (either CAF or paclitaxel) plus trastuzumab versus chemotherapy alone.¹³⁹

These exciting findings have led to combination studies of trastuzumab with several chemotherapeutic agents, with the suggestion of increased response rates than might be expected from historical controls.¹⁷³⁻¹⁷⁵

There are two important caveats regarding trastuzumab therapy. First, in the pivotal metastatic trial, congestive heart failure was observed in more than 25% of patients treated with combination doxorubicin and trastuzumab and in more than 10% of those who received paclitaxel and trastuzumab.¹³⁹ Currently combination therapy with trastuzumab and an anthracycline should be considered contraindicated. Second, HER2 is most commonly evaluated in breast cancer tissue by immunohistochemistry (IHC). The only IHC test for HER2 testing that is approved by the FDA is the so-called Herceptest. Substantial data suggest that, using the recommended readout scale of 0-3+, only those

patients whose tumors are read as "3+" are likely to benefit from trastuzumab.¹⁷⁶ Likewise, it also appears that HER2 amplification, which is evaluated by fluorescent in situ hybridization (FISH), is also an accurate predictor of benefit from trastuzumab.¹⁷⁶ A reasonable algorithm is to perform IHC first. Patients with tumor HER2 scores of 0–1+ are unlikely to benefit, whereas those who are 3+ are good candidates for trastuzumab. For patients whose tumors are 2+, FISH should be performed to distinguish those who should receive trastuzumab from those who should not.

Other novel therapies that appear to have some benefit include bevacizumab, a monoclonal antibody directed against vascular endothelial growth factor (VEGF) and the orally available inhibitors of the EGFR-family tyrosine kinases.^{177–179} However, none of these has been studied in a sufficiently rigorous manner to determine if it has a role in routine clinical care.

Monitoring Patients with Metastatic Breast Cancer

Palliative therapy should be continued so long as it appears to be successful and tolerated, as determined by history, physical examination, radiographs, and serologic/blood testing. Commonly a patient is followed for several cycles of therapy, lasting weeks to months, until progression is obvious and therapy should be changed. During this period of time, the patient may have been exposed to the toxicities of the therapy needlessly, if it was of little or no value in reducing the cancer burden.

Serial plain radiographs, computerized tomography, magnetic resonance imaging, and bone scintigraphy can provide evidence of response or, more importantly, progression. It is critical that the clinician be aware of causes of false-positive evidence of progression, in particular the so-called scintigraphic healing flare associated with response of bone metastases and conversion from lytic to sclerotic lesions. Because more than 50% of patients with metastases may have bone-predominant or bone-only metastases, monitoring may be quite difficult.

The value of positron emission tomography for monitoring metastatic breast cancer has not been shown in prospective, well-designed clinical trials, although this technology appears to have substantial promise. Serial circulating tumor markers, in particular carcinoembryonic antigen (CEA) and products of the MUC1 gene (identified by the commercially available assays CA 15-3 or CA 27.29), appear reasonably accurate for monitoring patients with metastatic disease.¹⁸⁰ However, approximately 25% of patients may experience a false-positive increase, or "tumor marker spike," during the first 30 to 60 days of therapy, and the clinician also needs to be aware of other reasons for nonmalignant tumor marker elevation, for example, as observed with acute hepatic dysfunction. Recently, results of a prospective clinical trial have suggested that circulating tumor cell (CTC) levels, as evaluated by an automated immunomagnetic technique, may be strongly associated with clinical outcome of patients with metastatic breast cancer.^{181,182} These data, and the potential benefits of changing therapy very early for patients with elevated CTC, require validation in future studies.

In summary, high levels of evidence support the benefits of careful application of systemic therapies for patients with metastatic disease. Prospective randomized clinical trials

have demonstrated the benefits of various endocrine treatments for those with hormone receptor-positive disease, for specific chemotherapeutic regimens for patients with very poor prognosis or those with hormone-refractory metastases, and for the use of trastuzumab alone or in combination with chemotherapy for patients with HER2-positive breast cancer. Ongoing research offers promise to further improve quality of life and even survival for patients who suffer with distant disease, and it is hoped that future investigations may even result in cure rates approaching those of Hodgkins' disease, non-Hodgkins' lymphoma, and testicular cancer.

Thyroid and Parathyroid

Gerard M. Doherty

Thyroid and parathyroid diseases combine the focuses of endocrinology and oncology, as one must consider both the hormonal function effects of the tumor and its treatment and the management of the malignancy, or potential malignancy. This chapter addresses the malignant forms of thyroid and parathyroid diseases and their epidemiology, diagnosis, treatment, and follow-up.

Thyroid Nodule

A palpable solitary nodule caused by a carcinoma in the neck is often impossible to distinguish from a benign nodule. However, a hard and firm consistency in especially a relatively fast growing nodule indicates a higher risk for malignancy than a soft slowly growing nodule, and multinodular disease is associated with lower risk of malignancy compared with a solitary nodule.¹ A solitary nodule is best investigated by fine-needle aspiration (FNA), as well as ultrasound (Figure 55.1). FNA, however, is limited in its ability to differentiate benign from malignant disease for follicular tumors, because the diagnostic criteria rely on thorough examination of capsular invasion. Ultrasound-guided FNA may improve the diagnostic yield of FNA, but interpretation problems of the aspirate remain.

FNA biopsy has a sensitivity and specificity of 95% and 97.5%, respectively, in the diagnosis of thyroid cancer. The diagnostic accuracy of FNA cytology is more than 95% for papillary thyroid cancer (PTC). FNA cytology in patients with PTC commonly shows psammoma bodies, papillary structure, and the nuclear features of PTC (Figure 55.2). The FNA cytology may be suspicious or indeterminate, including follicular and Hürthle cell neoplasms, and in such cases patients should undergo thyroidectomy because about 20% prove to be thyroid cancer. In cases in which the FNA biopsy is nondiagnostic the FNA should be repeated; this is important because about 10% of these neoplasms are malignant.

Diagnostic ¹³¹I- or technetium-thallium scintigraphy was used in the past to identify hypofunctional areas in the thyroid corresponding to a palpable lesion—*cold* nodules. However, this method has very low specificity and should only be used for patients with suppressed thyroid-stimulating hormone (TSH). There is no indication for scintigraphy in a euthyroid patient with a thyroid nodule.

There are no available diagnostic approaches that can distinguish follicular carcinoma from follicular adenoma, other than diagnostic lobectomy and histologic evaluation. There-

fore, for follicular thyroid neoplasms by cytology, diagnostic lobectomy is generally indicated. If the thyroid nodule is large or otherwise suspicious for a carcinoma, the patient should have a total thyroidectomy, at the discretion of the surgeon and the patient.

Thyroid Cancer

Epidemiology

Thyroid cancer is the most common endocrine malignancy; it also has the highest mortality among endocrine neoplasms. According to estimates by the American Cancer Society, about 23,600 new cases of thyroid cancer will occur in 2004 in the United States and about 1,460 people will die of thyroid cancer. In addition, although thyroid cancer is more common in women than in men (M:F ratio, 5,960:17,640), death from thyroid cancer occurs in a higher proportion of the men (M:F, 620:840).² The lifetime risk of developing thyroid carcinoma is 0.33% for men and 0.9% for women, according to U.S. Surveillance, Epidemiology and End Results (SEER) data estimates.³ Thyroid cancers have a wide range of aggressiveness, from relative indolence for most papillary thyroid cancer (PTC) to near-uniform lethality for anaplastic thyroid cancer. Fortunately, PTC accounts for about 80% of all thyroid cancer cases in iodine-sufficient areas and is associated with a relatively good prognosis.

Significant advances in our knowledge of the molecular biology, diagnosis, and prognosis of thyroid cancer have been made over the past three decades. The treatment of differentiated thyroid cancer remains controversial, with debates among experts regarding the most appropriate extent of thyroidectomy, the use of postoperative radioactive iodine ablation, and the need for thyroid hormone for TSH suppression. In addition, the understanding of the molecular changes leading to papillary thyroid cancer and medullary thyroid cancer have created optimism that specific therapies will be developed.

Follicular Cell-Derived Thyroid Cancer

The normal thyroid gland consists mainly of follicular cells. These specialized cells concentrate iodide from circulating blood through the sodium iodide symporter (NIS), synthesize thyroid hormone and thyroglobulin, and respond to thyroid-stimulating hormone (TSH) by both growth and hormone

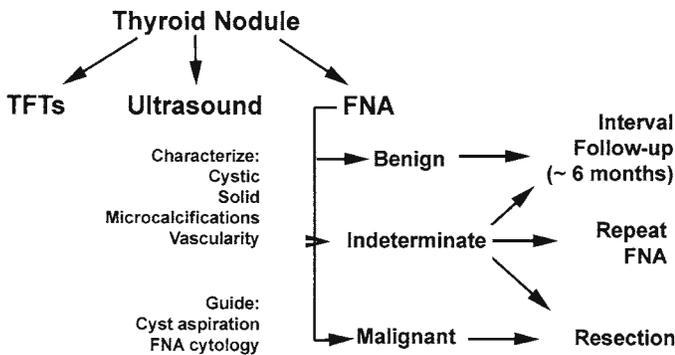

Figure 55.1. Algorithm for the evaluation of a solitary thyroid nodule. All patients should have thyroid function tests. Ultrasound is extremely helpful in the characterization of the nodule, and in the guidance of percutaneous interventions. Fine-needle aspiration cytology is the mainstay of thyroid nodule assessment and is very reliable. Thyroid scintigraphy does not have a place in the routine evaluation of a thyroid nodule unless the patient is hyperthyroid.

release. Follicular cell-derived thyroid cancer (FCDDTC) cells lose some of the normal signals that control cell growth and division, but often maintain some of the functions of normal thyroid follicular cells. The function that is most frequently lost is the ability to synthesize thyroid hormone. Very few thyroid carcinomas make thyroid hormone or cause hyperthyroidism. However, the NIS is present and functional in most FCDDTC, and forms the basis for the use of radioiodine therapy in its management. Most FCDDTC also retain the ability to synthesize thyroglobulin, which allows the use of serum levels of thyroglobulin after treatment as a tumor marker for follow-up. Finally, most FCDDTC continue to express the TSH receptor and to respond to TSH with growth and increased thyroglobulin release. This understanding is important in the treatment of FCDDTC, as suppression of TSH with thyroid hormone can decrease the recurrence rate. In addition, during follow-up, administration of TSH can increase the sensitivity of thyroglobulin tumor marker measurement.

FCDDTC includes several related histologic and clinical subtypes. The main types are papillary thyroid cancer (about 80%), follicular thyroid cancer (about 15%), and Hürthle cell cancer. A variety of subcategories also exist, some of which have prognostic implications (Table 55.1).

Papillary Thyroid Carcinoma

CLINICAL FEATURES

Almost all patients (98% or more) who present with clinical evidence of PTC present with a mass located in the thyroid

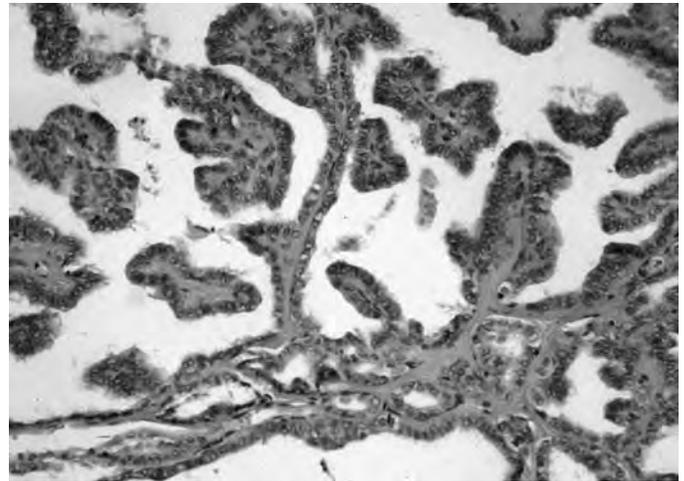

Figure 55.2. Papillary thyroid cancer histology. The classic papillary thyroid cancer has thin vascularized stalks lined by follicular cell-derived thyroid cancer (FCDDTC) cells with typical nuclear changes. These can be diagnosed on cytology by the nuclear changes and by the fragments of papillary architecture that are sometimes identifiable.

gland (67%), a mass associated with cervical lymphadenopathy (13%), and only with cervical lymphadenopathy (20%).⁴ Children and young adults more frequently present with palpable nodal metastases.⁵ The peak incidence of PTC is in the third and fourth decade of life, and there is a female-to-male ratio of 3:1. Depending on the series and whether prophylactic neck node dissection was performed, the rate of cervical node metastases is 11% to 80%. Most studies from the United States report a rate of 30% to 40% cervical node metastases when therapeutic neck node dissections are done.⁶ Distant metastasis is less common (2%–14%). The most common sites of distant metastases are to the lung and bone, and less commonly to the soft tissue, central nervous system, and liver.

Papillary thyroid cancer is the most common tumor that occurs in patients with Graves' disease, accounting for about 75% of the thyroid cancers associated with Graves' disease.⁷ Some investigators report more-aggressive thyroid cancers in patients with Graves' disease whereas others do not.^{7,8} Confounding factors that cloud the debate regarding whether patients with Graves' disease have more-aggressive tumors are (1) whether the thyroid cancer was diagnosed clinically or on histologic evaluation, (2) whether surgical or medical treatment was used, (3) history of radiation to the head and neck, and (4) level of microscopic histologic evaluation for the presence of thyroid cancer. The similarity of the thyroid-stimulating antibodies, present in Graves' patients, and TSH

TABLE 55.1. Histologic variants of follicular cell-derived thyroid carcinoma.

<i>Variants with similar clinical behavior</i>	<i>Variants with more aggressive behavior</i>
Follicular variant of papillary	Tall cell
Minimally invasive follicular thyroid carcinoma (FTC)	Diffuse sclerosing
Encapsulated	Columnar
Solid/trabecular	Oxyphil (Hürthle)
	Oncocytic papillary thyroid cancer (PTC) (similar to Hürthle)
	Clear cell FTC
	InsularMixed MTC/FTC (behaves like medullary thyroid carcinoma, MTC)

is clearly documented. The fact that TSH promotes tumor growth, invasion, angiogenesis, and inhibits apoptosis in vitro supports the possibility that thyroid cancer may be more aggressive in these patients. It appears that patients who present with clinical evidence of thyroid cancer and who have Graves' disease have more-aggressive tumors, whereas patients with occult thyroid cancers who are treated for Graves' disease have an excellent prognosis.

PATHOLOGIC FEATURES

PTC is typically firm with an irregular border, has a whitish color, and may contain microcalcifications. However, there is variation in the tumor gross characteristics related to the different morphologic variants of PTC. For example, the encapsulated follicular variant of PTC may have a well-defined margin with a fleshy appearance similar to a follicular adenoma. Depending on the evaluation of the entire thyroid gland, a microscopic examination, and the thickness of histologic section, up to 80% tumor multicentricity is reported for PTC. Carcangiu and associates found 22% of PTC were multifocal on routine histologic examination whereas Katoh et al., on thin (0.5- μ m) microscopic section evaluation, found 78% of PTC were multifocal.^{4,9} Overall, most studies report 20% to 30% of PTC are multicentric. Vascular invasion by PTC is uncommon compared with follicular thyroid cancer, occurring rarely.

The presence of papillae and unique nuclear features are the defining characteristic of PTC. The papillae appear as fibrovascular stalks lined by the neoplastic epithelial follicular cells. The nuclear features are hyperchromatic nuclei, absent nucleoli, nuclear grooves, and intranuclear inclusions. Several variants of PTC exist, and their diagnosis is established by the presence of these distinct nuclear features of PTC. Some variants behave similar to typical PTC whereas others have a more-aggressive behavior. In 1960, Lindsay made the initial observation that some "follicular carcinoma" had papillae and a less-aggressive clinical course than typical follicular carcinoma.¹⁰ Subsequent studies confirmed these observations, and the follicular variant of PTC is now regarded as a variant of PTC. This variant is characterized by the presence of ground-glass (clear nucleoli) nuclei and may have some or no papillary elements on histology. The micropapillary, "occult," or "minimal" variant of PTC is smaller than 10mm by definition and is commonly found incidentally. Patients with occult PTC (less than 1 cm) have a near-normal life expectancy. The encapsulated variant of PTC accounts for about 10% of all PTC and is characterized by a total surrounding fibrous capsule that may have focal invasion but has the nuclear features consistent with PTC. In the solid/trabecular variant of PTC are foci of solid and/or trabecular growth pattern in most (more than 50%) or all of the tumor with the typical nuclear features of PTC. The presence of this morphologic variant is important to recognize to avoid misclassification as a poorly differentiated thyroid cancer.

The tall cell variant of PTC has a typical appearance with the height of the follicular cells greater than twice the width with an intense eosinophilic cytoplasm lining the glandular and papillary structures.¹¹ In this variant, nuclear grooves and intranuclear invaginations are commonly present. Hazard and Hawk observed that these tumors occurred in older patients

and were larger in size (greater than 5cm), with frequent extrathyroid extension and a higher incidence of vascular invasion.¹² Studies by Johnson et al. and Moreno-Egea et al. comparing patients with the tall cell variants to patients with typical PTC, which matched patients for age and gender, found a higher recurrence rate and mortality in patients with the tall cell variant of PTC.^{11,14} Vickery and associates were the first to describe the diffuse sclerosing variant of PTC, which is characterized by dense intrathyroidal lymphocytic invasion, severe fibrosis, squamous metaplasia, and numerous psammoma bodies involving one or both thyroid lobes.^{15,16} Importantly, this morphologic variant was associated with a slightly worse prognosis and occurred more frequently in children. Compared with typical PTC, most subsequent studies have shown a higher rate of nodal and distant metastases, and also a higher recurrence rate for the diffuse sclerosing variant, but not a significant difference in mortality. According to the World Health Organization thyroid histologic classification, oxyphil or Hürthle cell carcinomas that display classic papillary architecture on histology are considered a variant of PTC. Herrera and associates have reported that this morphologic variant compared with typical PTC is associated with a higher recurrence rate and mortality.¹⁷

RISK FACTORS AND ASSOCIATED HEREDITARY CONDITIONS

Several hereditary conditions and environmental factors increase the risk of developing thyroid cancer. A history of radiation exposure increases the risk of developing differentiated thyroid cancer. Most of the external radiation exposure was used in children to treat them for tinea capitis, hypertrophic thymus, tonsillitis, acne, and external otitis in the 1940s and 1950s. Large case-control retrospective studies by Shore et al. and Ron et al. confirmed the increased risk of thyroid cancers and benign thyroid nodules in children exposed to low-dose therapeutic radiation.¹⁸⁻²¹ Shore and colleagues reported among 2,650 children exposed to therapeutic low-dose radiation, there is an increased relative risk of 45 for malignant thyroid tumors and a relative risk of 15 for benign thyroid tumors. Ron and associates found a relative risk of 4 for malignant thyroid tumors and 2 for benign thyroid tumors in a cohort of 10,834 children exposed to therapeutic radiation for tinea capitis. A linearly increased risk of thyroid cancer to dose of radiation exposure has been observed with an even higher risk among those exposed at a young age. A minimum 3- to 5-year latency period has been observed between radiation exposure and tumor development. The number of cases continues to increase for at least three decades after exposure and then decreases. About 90% of the radiation-associated thyroid cancers reported have been PTC. Today, radiation-induced thyroid cancer accounts for about 9% of all thyroid cancers. In addition to age and dose of radiation exposure, other environmental or genetic factors may play a role in which individuals develop thyroid neoplasm. Perkel and associates, in a study of 286 sib pairs, reported a significant ($P = 0.05$) familial concordance for thyroid neoplasms (benign and malignant) but not for thyroid cancer.²² Schneider et al. have followed 2,634 children in Chicago and 40% have developed thyroid neoplasms (all types) and 12% thyroid cancer.²³ The use of low-dose radiation treatment in patients with benign conditions has been

abandoned in the past 40 years because of the recognized increased risk for thyroid cancer.

Radiation exposure from diagnostic radiation or therapeutic high-dose external-beam radiation accounts for the medical-related exposure in patients today. Investigations in children exposed to nuclear fallout accidents in the Marshall Islands, Nevada test sites, and Chernobyl clearly document an increased risk of thyroid cancer among patients exposed to acute ionized radiation.²⁴⁻²⁶ As in the studies of patients exposed to low-dose therapeutic radiation, age at exposure and dose of radiation exposure were significant factors in the increased relative risk. Other risk factors such as dietary, sex hormones, goitrogens, and environmental factors have also been identified but not all studies show an increased risk of thyroid cancer (Table 55.2). Epidemiologic studies show that both high-iodine and low-iodine diets can increase the risk of thyroid cancer.

Patients with familial adenomatous polyposis (FAP) have an increased risk of benign and malignant thyroid neoplasms^{27,28}; they can develop either papillary or follicular tumors.

DIAGNOSIS OF PAPILLARY THYROID CANCER

The majority of patients with PTC present with a neck mass originating from the thyroid gland or from a cervical node metastasis. When there is significant local tumor invasion, patients may have local symptoms such as hoarseness, changes to the singing voice, or difficulty swallowing. A careful history and physical examination with emphasis on a history of head and neck radiation or familial thyroid disorders is important. If a patient has had previous neck surgery or has had any change in his or her voice, indirect or direct laryngoscopy can evaluate the status of the vocal cords. Although hyperfunctioning PTC are rare, careful evaluation for symptoms or signs of hypothyroidism with serum TSH level determination should be done.

A diagnosis of PTC is usually established by fine-needle aspiration (FNA). FNA cytology is highly accurate for diagnosing PTC. Simultaneous thyroid ultrasonography may be used during FNA biopsy, especially if the thyroid nodule is cystic, to obtain cellular element from the solid component (Figure 55.3).

Intraoperative frozen section in patients with PTC is not necessary for patients with PTC by cytologic examination. In patients who have enlarged lymph nodes or when there is a question of lymph node metastases, a frozen section can be helpful in confirming nodal metastases and for confirming the diagnosis intraoperatively.

TABLE 55.2. Risk classification systems for patients with papillary follicular cell-derived thyroid cancer (FCDTC).

System	Prognostic factors included
AGES	Age, tumor grade, extrathyroidal invasion, distant metastases, tumor size
AMES	Age, extrathyroidal invasion, distant metastases, tumor size
EORTC	Gender, tumor histology type, extrathyroidal invasion, distant metastases
MACIS	Age, extrathyroidal invasion, distant metastases, completeness of resection, tumor size

EORTC, European Organization for Research and Treatment of Cancer.

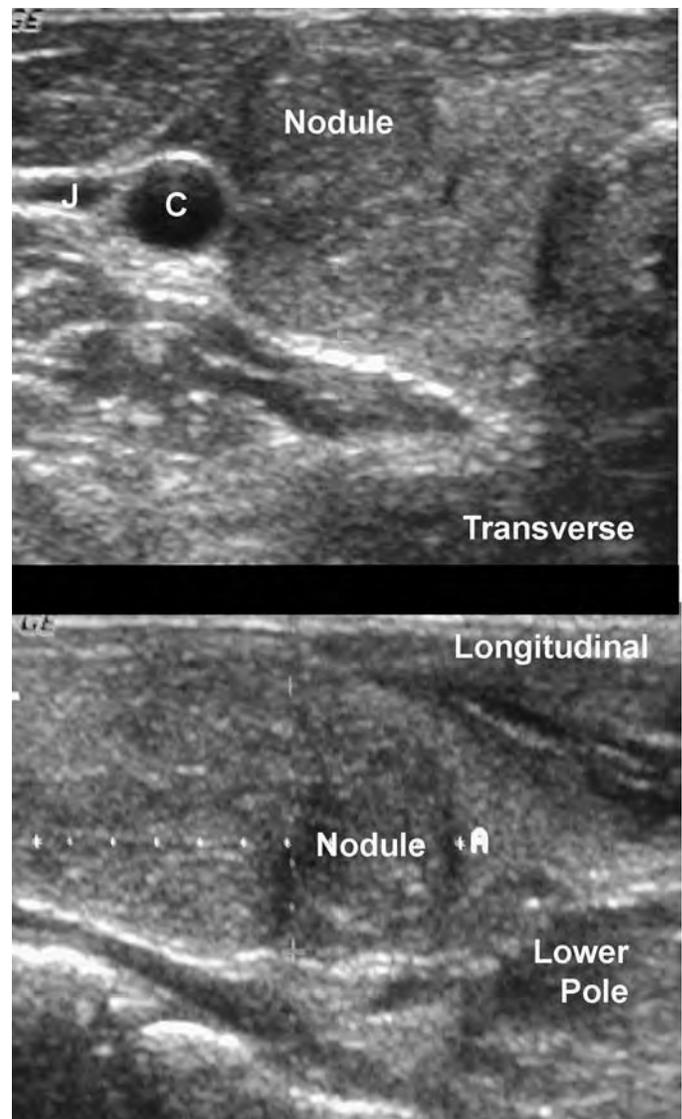

Figure 55.3. Thyroid ultrasound. Ultrasound is extremely useful for the characterization of cervical anatomy and thyroid nodules. This nodule in the lower pole of the right lobe of the thyroid gland is well circumscribed, slightly hypoechoic, and deforms the surface of the thyroid gland. Upon resection, this was a tall cell carcinoma of the thyroid. J, jugular vein; C, carotid artery.

TREATMENT OF PAPILLARY THYROID CANCER

Controversy remains regarding optimal treatment of patients with differentiated thyroid cancer. The controversy persists because there are no prospective randomized control studies evaluating the merit of extent of thyroidectomy, postoperative radioactive iodine therapy, and TSH suppressive therapy. Such a trial would require a large multicenter trial with a long follow-up time required because of the relatively good prognosis and low incidence of thyroid cancer.

EXTENT OF THYROIDECTOMY

Thyroidectomy is safe and effective and it is the primary treatment in patients with PTC. In patients who have bilateral lobe tumors, extrathyroidal tumor extension, and/or high-risk PTC, there is a general consensus that total thyroidectomy is warranted. However, in low-risk patients con-

flicting points of view by experts persist. Generally, three surgical approaches have been advocated among experts: (1) thyroid lobectomy or hemithyroidectomy (total removal of one lobe and isthmus), (2) near-total (total lobectomy and subtotal resection on the contralateral side leaving less than 1g thyroid tissue), and (3) total thyroidectomy. The most important reasons for performing a total or near-total thyroidectomy in patients with PTC are (1) a lower dose of radioactive iodine can be used to identify and ablate residual thyroid cancer, and (2) the serum thyroglobulin level following total thyroidectomy is a more accurate marker of recurrent/persistent PTC. Up to 80% of PTC are multicentric and tumor foci may occur in the contralateral lobe, thus representing a potential site of recurrence. There is about a 1% risk of a differentiated thyroid cancer progressing to anaplastic thyroid cancer, which is uniformly lethal. Hay et al. from the Mayo clinic also specifically studied local recurrence and nodal and distant metastases in patients with low-risk PTC based on the AMES prognostic classification system, finding those patients who had unilateral procedure (lobectomy only) had a higher local recurrence rate (14%) and nodal metastases (19%) than those patients treated with bilateral procedures.²⁹ However, there was no significant difference in survival rate and distant metastases.

Although advocates of lesser procedures contend that there is a higher risk of complications after total thyroidectomy, numerous surgeons with experience in total thyroidectomy report complication rates of less than 2%. The risk of complication from thyroidectomy depends primarily on the extent of thyroid disease, the experience of the surgeon, and anatomic variation of the parathyroid glands, recurrent laryngeal nerves, and external laryngeal nerves. The most common and serious complications of thyroidectomy are injury to the recurrent laryngeal nerves or parathyroid glands. It seems obvious that the risk of complication is higher with total thyroidectomy because of dissection on the side contralateral to the tumor. However, comparable complication rates for total thyroidectomy, near-total thyroidectomy, and lesser procedures are achieved by many surgeons.^{30,31} Even among the less than 2% of patients who had complications, these patients were more likely to have more-invasive tumors involving the recurrent laryngeal nerve. Although the evidence suggests that total thyroidectomy should be associated with little or no higher complication rate than lesser procedures, these data are based upon the outcomes of experienced surgeons. The public policy issue of whether it is preferable to advocate a less-effective approach (lobectomy) that is more applicable by the occasional thyroid surgeon is made moot if patients are cared for by those with experience performing these operations.

Total thyroidectomy is the treatment of choice for virtually all patients with PTC when postoperative radioactive iodine is considered. This group includes virtually all patients except those with the very best prognosis, that is, small tumor (less than 1cm), confined to the thyroid without evident metastases, in an otherwise healthy woman under 45 years. Even in patients with low-risk PTC, total or near-total thyroidectomy is associated with a lower recurrence rate and mortality.^{6,29} Serum thyroglobulin levels after total thyroidectomy are a more accurate marker for follow-up of patients with PTC, and postoperative radioactive iodine scanning and ablation is more effective. If a total thyroidectomy

cannot be performed without injury to the recurrent laryngeal nerve or parathyroid glands, a near-total thyroidectomy can be done with a small amount of thyroid tissue left behind that can subsequently be ablated with radioactive iodine.

LYMPH NODE DISSECTION

Up to 80% of patients with PTC have cervical lymph node metastases; however, the prognostic significance of lymph node metastases is controversial. Patients with PTC and matted lymph nodes or tumor extending through the lymph node capsule have a worse prognosis.^{6,32,33} When patients are matched for age and sex, lymph node metastases also appears to be associated with a higher recurrence rate. Patients with PTC treated with prophylactic node dissection compared with only therapeutic node dissection (removal of palpable enlarged lymph nodes) have essentially the same survival rate. Even though up to 80% of patients with PTC have occult cervical lymph node metastases, most of these metastases can be ablated with radioactive iodine treatment postoperatively and some do not appear to grow. Lymph node dissection during thyroidectomy has a higher complication rate, probably because it is associated with more tumor, especially around the parathyroid glands. Therapeutic lymph node dissection with removal of the ipsilateral central neck nodes and perithyroid lymph nodes (Delphian node and lymph nodes medial to the carotid sheath) is important for clinically involved nodes. If there are clinically involved lateral neck nodes, then a compartment-based resection, rather than a "node-plucking" operation, has a better rate of control of the nodal disease. A functional modified radical neck dissection removing all fibrofatty tissue with lymph nodes but preserving all motor (phrenic, vagus, and spinal accessory nerves) and sensory nerves as well as the sternocleidomastoid muscle and internal jugular vein unless invaded by tumor is the best approach. Contralateral lymph node dissection should also be performed for gross evidence of lymph node metastases. The superior mediastinal lower nodes and periesophageal nodes are often involved, and can often be removed through the cervical excision.

RECURRENT AND PERSISTENT PTC

Most patients with PTC are diagnosed with persistent or recurrent disease by an elevated serum Tg level and/or by a positive radioactive iodine scan. Some patients with recurrent PTC may have an elevated Tg with a negative radioactive iodine scan. In this situation, a therapeutic dose of ¹³¹I (100–200mCi) may help some patients by showing uptake (diagnostic benefit) or by response to this therapy (therapeutic benefit).³⁴ Local recurrences are often associated or precede distant metastases in patients with PTC; an evaluation for metastatic disease is important to define the extent of the recurrence. When recurrent PTC is identified in the neck by radioiodine scan, computed tomography (CT) scan, magnetic resonance imaging (MRI), or ultrasound with a positive FNA biopsy, a neck dissection can eliminate disease. Patients with solitary metastases (usually to the bone and rarely to the lung, which tend to be multiple) can benefit from operative resection. About two-thirds of patients with lung or bone metastases from differentiated thyroid cancer respond to ¹³¹I therapy. In patients who are not operative candidates, and for most patients after resection of isolated metastasis to bone, external-beam radiation can be helpful in local tumor control

or for symptomatic relief. In those patients with PTC that fail ^{131}I ablation or external-beam radiotherapy and who are not surgical candidates, cytotoxic chemotherapy may be useful in patients with progressive PTC.³⁵

Follicular Thyroid Carcinoma

CLINICAL FEATURES

The clinical presentation of follicular thyroid carcinoma (FTC) is very similar to PTC. Most patients present with a mass in the thyroid. However, FTC is less likely to be associated with cervical lymph node metastases than is PTC, so it is unusual to have a lateral neck mass as the presenting sign. FTC can be associated with distant metastases, particularly in older patients. In contrast to patients with follicular adenoma, patients with follicular thyroid cancers are more likely to have local symptoms; these can include difficulty swallowing, dysphonia, stridor, or pain. Patients can also present with evidence of distant metastases, most typically metastases in the bone, lung, brain, or liver. Apparently because of its propensity for vascular invasion, follicular tumors often metastasize via hematogenous pathways, and only rarely via cervical lymph nodes as would be more typical of papillary cancer. Biopsy at these distant sites may demonstrate relatively benign-appearing follicular tumor; however, by its behavior it has defined itself as an invasive malignant variety. Thus, follicular cancers typically present as a slowly growing solitary thyroid mass in a middle-aged to older person. About 25% of the patients have extrathyroidal invasion at the time of presentation. Between 10% and 33% of patients have distant metastasis at the time of initial diagnosis.

Most follicular cancers are nonfunctional ("cold") by radioiodine thyroid scan. Occasionally, a follicular cancer retains the ability to concentrate iodine to a degree similar to adjacent thyroid tissue ("warm") or even to a greater degree than the normal thyroid ("hot"). The rare "functional" thyroid cancer is nearly always a follicular carcinoma rather than a papillary tumor.

Follicular thyroid cancers can occur in any age group, but the median age of groups with follicular cancers is typically higher than groups with papillary cancers. The median age at presentation is in the sixth decade of life. Similar to papillary cancer, the female to male ratio is between 2:1 and 5:1.³⁶

PATHOLOGIC FEATURES

The important features that distinguish FTC from follicular adenomas are vascular and capsular invasion.³⁷ Follicular carcinomas can appear very similar to follicular adenoma on cytology and gross examination and therefore impossible to identify by either the cytologist, surgeon, or pathologist before complete pathologic assessment. The well-differentiated follicular carcinomas are identified by signs of minimal invasion such as microscopic evidence of capsule discontinuity. Other follicular tumors may be less differentiated, widely invading surrounding thyroid or even extrathyroidal tissues. The tumor cells vary in their histologic differentiation, but are generally bland, monomorphic cells lacking nuclear changes typical of PTC. Thus, follicular carcinoma cells can appear differentiated and may resemble normal

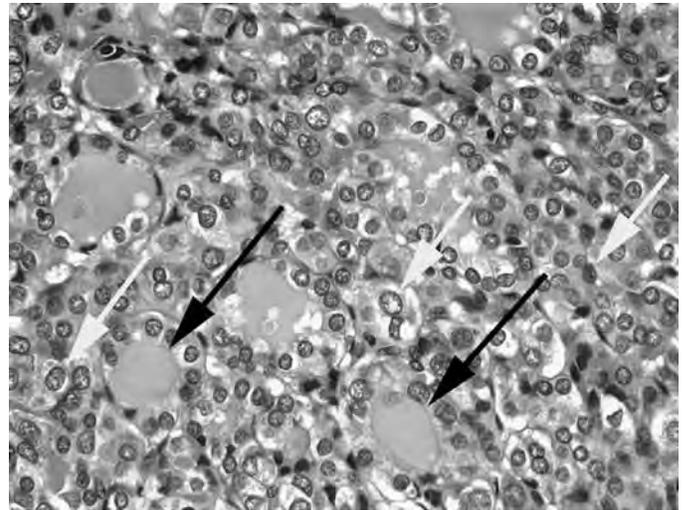

Figure 55.4. Follicular variant of papillary thyroid cancer. This variant has the follicular architecture of follicular thyroid carcinoma (FTC) (black arrows) without papillary structures, but has the nuclear features of papillary thyroid cancer (PTC) (white arrows) with nuclear grooves, clearing, and clumped chromatin.

thyroid tissue even when recurrent or metastatic; this can be misinterpreted as a "thyroid remnant" and not treated properly. The precise histologic pattern may be described as follicular, trabecular, or solid or display combinations of these. In the widely invasive forms, the tumor demonstrates areas of solid growth, frequent mitoses, and atypical cells. Signs of dedifferentiation are frequent as the disease proceeds.

Tumors with a mix of papillary and follicular features often show follicular differentiation, expressing follicular structures, but have nuclear features of papillary carcinoma (for example, psammoma bodies, or nuclear grooves or pseudoinclusions) (Figure 55.4). They can be difficult to diagnose on cytology, but once recognized they have the clinical course and prognosis of PTC rather than FTC.

RISK FACTORS AND ASSOCIATED HEREDITARY CONDITIONS

In areas with sufficient intake of iodine, most of the differentiated thyroid carcinomas are papillary. In areas with iodine deficiency and endemic goiter, the total incidence of thyroid carcinoma is similar, with a relative increase in follicular thyroid carcinoma that are sometimes even more frequent than papillary carcinomas. A substantial intake of vegetables from the cruciferous family that block iodine uptake (goitrogenic food) can contribute to these findings. The stimulatory factor in the low-iodine areas leading to thyroid tumors appears to be TSH, although no clear correlation has been documented. Nevertheless, iodine supplementation coincides with an increase in the incidence of papillary carcinomas, with reduction in follicular and especially poorly differentiated and anaplastic carcinomas.³⁸ External radiation has not been associated with follicular carcinoma. Investigations after the Chernobyl accident generally support these earlier findings, although there are occasional reports of follicular thyroid carcinomas.³⁹ Nearly all follicular thyroid carcinomas are sporadic, but may in rare cases also be associated with familial colon polyposis or Gardner's syndrome, as well as Cowden's syndrome.

TREATMENT OF FOLLICULAR THYROID CANCER

Surgical resection is the only available method for FTC in the thyroid. As for PTC, the choice of hemithyroidectomy or total thyroidectomy as the procedure of choice for FTC has been debated. Hemithyroidectomy or total thyroidectomy with extirpation of central lymph nodes without radioiodine are both adequate for survival outcomes in patients with invasive follicular carcinoma confined to the thyroid, that is, T1–T2N0M0.

However, for larger tumors (above T2), total thyroidectomy with at least central lymph node dissection is appropriate for a number of reasons. This treatment allows postoperative ¹³¹I ablation, as well as diagnostic scintigrams for follow-up. Arguments against total thyroidectomy have been increased risk for surgical complications such as injury to the recurrent laryngeal nerve or permanent hypoparathyroidism. However, for experienced surgeons, total thyroidectomy is a safe procedure, with minor complication rates. Therefore, in T3–4 tumors, a more-extensive treatment is mandatory. Although follicular tumors metastasize to lymph nodes in the neck less frequently than papillary tumors (approximately 35% versus 67%), therapeutic modified neck dissection should be performed when clinically apparent disease is present, followed by postoperative ¹³¹I diagnostic procedures and radioiodine ablation therapy.

Hürthle Cell Carcinoma

Hürthle cell carcinoma is a variant of follicular carcinoma, which is sometimes called an oxyphilic or oncocytic carcinoma. These tumors may be remarkably similar on gross examination but are microscopically characterized by an acidophilic cytoplasm with small pyknotic central nuclei. It is important to distinguish these tumors from each other, because the oncocytic carcinomas have a much lower capacity for uptake of iodine, which makes postoperative diagnostic and therapeutic ¹³¹I scintigrams difficult. They have a natural history and prognosis similar to FTC, which supports similar treatment.⁴⁰

Postoperative Management of Differentiated Thyroid Carcinoma

PROGNOSIS

FCDTc is the direct cause of death of more patients than all other endocrine malignancies combined. Nevertheless, with a crude mortality rate of only around 7%, the vast majority of patients with FCDTC are either cured, or lives with cancer, often for many years.

Overall recurrence rates after apparent surgical cure of the primary tumor range from 10% to 35%,^{41,42} depending on histologic subtype and stage at diagnosis.^{41–45} Recurrence may sometimes occur many years after the initial, apparently successful, treatment.⁴⁶ Thyroid carcinomas exhibit among the widest range of malignant potential of any human cancer. They range from the almost benign, incidentally discovered, papillary microcarcinoma, which probably has no impact on long-term survival, to extremely aggressive poorly differentiated carcinomas with a median life expectancy of only a few months. Within the FCDTC group, life expectancy and the likelihood of cure vary widely.

There have been many attempts to identify prognostic factors for patients with FCDTC. Unfortunately, there are no randomized, prospective trials of any aspect of thyroid cancer management, largely because of the relative rarity of the tumor, its generally slow clinical course with long survivorship, and the difficulty and expense of mounting large multicenter studies over prolonged periods. Nevertheless, a great deal of information is available from large retrospective reviews from a number of centers that can be used to influence all aspects of management of the patient with differentiated thyroid cancer (DTC). To select appropriate therapy and follow-up, and to provide prognostic information to the patient, the initial step in the postoperative care of the patient with FCDTC is to categorize the patient's risk of recurrence and death from disease.

AMERICAN JOINT COMMITTEE ON CANCER (AJCC) STAGING

Pathologists apply the pTNM classification system to tumors of all types, providing a convenient shorthand method to describe the tumor extent (Table 55.3).⁴⁷ Using this system, the tumor is assessed according to the size of the primary tumor mass, with T1 representing tumors of 1 cm or less, T2 those between 1 and 4 cm in maximum diameter, T3 those greater than 4 cm, and T4 represents tumors of any size exhibiting local extrathyroidal invasion. The presence (N1) or absence (N0) of lymph node spread, and the presence (M1) or absence (M0) of distant metastases are similarly easily defined at the time of the original diagnosis, and the pTNM classification is generally straightforward to determine within a few hours of operation. Although the prognosis for many tumor types is determined largely or exclusively by the extent of disease, described efficiently by the pTNM classification, FCDTC are unique, in that the strongest influence on prognosis is patient age at diagnosis. As a result, the AJCC staging system uses patient age in defining stage for follicular cell-derived thyroid carcinoma.

In this staging system, all patients under the age of 45 with FCDTC have stage I disease unless they have evidence of distant metastases, which makes them stage II. More-advanced stages are restricted to patients over the age of 45, with locally invasive tumors (stage III), or with evidence of nodal (stage III) or distant (stage IV) metastases. The pTNM system is the most widely accepted tool to describe the extent of disease for staging in thyroid carcinoma. The AJCC stage correlates well with outcome of FCDTC, in both retrospective and prospectively collected data, with stage I and II disease exhibiting a less than 1% overall mortality at 5 years.⁴⁸ In contrast, more-advanced stages of disease, limited to those patients over the age of 45 with locally invasive or metastatic disease, carry a less-favorable prognosis. For stage III disease, the 5-year mortality was 6% for PTC and 18% for FTC, whereas stage IV disease had a 5-year mortality in excess of 50% in both tumor types.

Despite its simplicity and utility, however, the AJCC staging does not provide all the information a clinician may need to adequately classify a patient with DTC and to assist in making therapeutic decisions. It does not use several additional independent prognostic variables and may therefore risk misclassification of a significant number of patients. For this reason, several other classification schemes remain in clinical use that may permit more accurate decision making, at least for patients with FCDTC.

TABLE 55.3. American Joint Committee on Cancer (AJCC) thyroid cancer staging.

Primary tumor (T)			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
T1	Tumor 2 cm or less in greatest dimension limited to the thyroid		
T2	Tumor more than 2 cm but not more than 4 cm in greatest dimension limited to the thyroid		
T3	Tumor more than 4 cm in greatest dimension limited to the thyroid or any tumor with minimal extrathyroid extension (e.g., extension to sternothyroid muscle or perithyroid soft tissues)		
T4a	Tumor of any size extending beyond the thyroid capsule to invade subcutaneous soft tissues, larynx, trachea, esophagus, or recurrent laryngeal nerve		
T4b	Tumor invades prevertebral fascia or encases carotid artery or mediastinal vessels		
<i>All anaplastic carcinomas are considered T4 tumors.</i>			
T4a	Intrathyroidal anaplastic carcinoma—surgically resectable		
T4b	Extrathyroidal anaplastic carcinoma—surgically unresectable		
Regional lymph nodes (N)			
NX	Regional lymph nodes cannot be assessed.		
N0	No regional lymph node metastasis		
N1	Regional lymph node metastasis		
N1a	Metastasis to Level VI (pretracheal, paratracheal, and prelaryngeal/Delphian lymph nodes)		
N1b	Metastasis to unilateral, bilateral, or contralateral cervical of superior mediastinal lymph nodes		
Distant metastasis (M)			
MX	Distant metastasis cannot be assessed		
M0	No distant metastasis		
M1	Distant metastasis		
Stage grouping ^a			
Papillary or Follicular			
Under 45 years			
Stage I	Any T	Any N	M0

CLINICOPATHOLOGIC PROGNOSTIC SCHEMES FOR FCDTC

For patients with FCDTC, age at initial treatment, tumor size, the presence of extrathyroidal invasion, and the presence of distant metastases at diagnosis are the most important risk factors for recurrence and for cause-specific mortality. However, unlike almost any other cancer type, the presence of lymph node metastases in PTC has little influence on cause-specific mortality from this disease, although it increases the risk of locoregional recurrence.

Several other factors, not included in the AJCC staging scheme, are also independent prognostic variables in rigorous multivariate analyses, including tumor grade in PTC, which is rarely assessed in routine histologic examination; extent of microinvasion of capsule or of blood vessels in FTC; DNA aneuploidy in Hürthle cell cancer and PTC, but not in nonoxyphilic FTC; delay to initial surgical intervention; and completeness of surgical resection of the primary tumor. These prognostic factors are not of equal importance in predicting mortality or recurrence, with the most predictive factors generally being regarded as the presence of distant metastases, the age of the patient, and the extent of the tumor.⁴⁹

Several prognostic systems have been developed that include a number of these variables, weighted according to their importance in predicting outcomes, in multivariate analyses, of retrospectively analyzed large cohorts of patients (see Table 55.2). Each of these schemes permits classification of patients with FCDTC (particularly PTC, the most common type) into low-, medium-, and high-risk groups, accurately predicting long term outcome for these patients. Each of the prognostic schemes includes a slightly different group of variables, weighted in slightly different ways. However, all have certain features in common, and all include both tumor and patient variables, emphasizing the likely importance of host-tumor interaction in the behavior of this group of cancers.

Almost all the schemes, except the Ohio State University system, include the patient's age as an important variable predicting outcome. The size of the primary tumor, its histologic type, the presence of extrathyroidal invasion, and the presence of distant metastases are almost universally included. Controversy remains about the importance of nodal metastases and of patient gender. Tumor grade (and DNA ploidy in certain tumor types) is almost certainly an important independent prognostic variable but is rarely assessed.

The MACIS score (named for its predictive variables of Metastases, Age, Completeness of surgical excision, local Invasion, and tumor Size) was derived from a retrospective review of almost 1,800 patients with PTC treated at one institution over a period of up to 50 years (median, 17 years follow-up).⁵⁰ Approximately half of the patients (from 1940 to 1964) were selected to represent the "training" group, and a formal multivariate analysis was performed on this group to identify the independently predictive prognostic variables from the data set. Each of these variables had a significant predictive value on outcomes in univariate analysis, but also remained significantly correlated with outcome in multivariate analysis.

The MACIS equation was generated to weight the importance of each of the predictive variables, generating a single score for patient classification (Table 55.4). This equation was tested on the remaining 1,015 patients in the original data set

TABLE 55.4. The MACIS score.

Metastasis	
Age	
Completeness of resection	
Invasion (local)	
Size (primary tumor)	
MACIS = 3.0 (for distant metastases at presentation)	
+ 3.1 (for age less than 40 years) or (0.08 × age)	
+ 1.0 (for incomplete tumor resection)	
+ 1.0 (if locally invasive)	
+ 0.3 × tumor size (in centimeters)	
	20-year cause-specific mortality
MACIS score	
<6.0	<2%
6–6.99	11%
7–7.99	44%
>8	76%

(the "test group"), and on the group as a whole, and proved to be a reliable predictor of outcome over a 20-year period in these patients.⁵⁰

A MACIS score of less than 6.0, representing the lowest risk group, carries a less than 1% cause-specific 20-year mortality risk from PTC and encompasses more than 80% of all patients presenting with PTC. A score between 6.0 and 6.9 has an 11% 20-year mortality; scores between 7.0 and 7.9 have a mortality rate of 44%; and scores of 8.0 and over (fortunately, a rare occurrence, affecting less than 5% of this group of patients) have a predicted disease-specific mortality of 76% at 20 years. This broad range of outcomes is predicted rapidly and easily at the bedside on the day after primary surgery, using data that should be available in every case from the operative and pathology reports, and from simple, universally available preoperative screening tests.

The other prognostic systems provide a similar rapid, accurate assignment of risk group category. The choice of prognostic scheme remains a matter more of preference than of science; however, it appears rational to use some system, in addition to the AJCC classification, to assign prognosis and guide therapeutic decisions for patients. Such classification allows accurate identification of the majority (80%–85%) of patients with FCDTC at low risk of cause-specific mortality. These patients can be reassured and managed with less-intensive intervention. More-intensive follow-up, and perhaps more-aggressive adjuvant therapy, can then be targeted to the higher-risk patients, the minority who are most likely to benefit from a more-aggressive management strategy.

PREDICTING DISEASE RECURRENCE

Recurrence of FCDTC is considerably more likely than death. The recurrences carry significant physical and psychologic morbidity and increase the likelihood of subsequent mortality. Recurrent disease is often predictable, and follows the patterns of spread observed at diagnosis. These vary with the type of FCDTC; PTC exhibits early spread to (and frequent recurrence in) regional lymph nodes, and less frequently distant spread, principally to the lungs and later to skeleton. Hürthle cell cancer follows a similar pattern, although perhaps more frequently exhibiting distant metastases.

Typical nonoxyphilic FTC, however, less often involves lymph nodes, spreading preferentially by a hematogenous route to lungs, bones, and brain. Metastatic spread to other organs has also been reported.

Local recurrence occurs mainly within the thyroid bed, ipsilateral to the primary tumor site, as a result of incomplete surgical resection, local invasiveness of the primary tumor, or failure of adjunctive therapy to destroy persistent microscopic tumor deposits. Local recurrence at sites other than the thyroid bed may result from unrecognized local spread of the tumor within the thyroid remnant or multifocal tumor that has been incompletely removed or ablated.

Regional recurrence also occurs frequently in the central compartment lymph nodes, often as a result of incomplete initial surgical exploration. These nodes are involved in up to 25% of patients with PTC at the time of diagnosis, and adequate primary surgery should include their resection, at least ipsilateral to the tumor. Jugular chain lymph nodes may also commonly be the site of regional recurrence, presumably as a result of unrecognized micrometastases present at the time of the original diagnosis. Adequate assessment of the jugular chain nodes is essential before and during the primary surgery. Preoperative ultrasound before the initial operation may provide the most sensitive method of detection of affected nodes, to enable therapeutic node dissection to potentially decrease the recurrence rate.⁵¹

The development of distant metastases, fortunately, is rare in FCDTC but heralds a poor prognosis, particularly for older patients, with cause-specific mortality rates of up to 60% at 10 years for stage IV disease.⁴⁵ By contrast, the presence of distant metastases, particularly micrometastases in the lungs, in young patients need not signal an imminent demise, with long-term survivorship being the norm, justifying their classification as stage II disease.

The risk factors for the development of distant metastatic disease in PTC mirror those established for mortality.^{52,53} The age of the patient, the size of the tumor, and the presence of local invasion or incomplete surgical resection dominate the models. In addition, however, the involvement of lymph nodes with PTC, particularly those in the jugular chains, at the time of diagnosis, substantially increases the risk of future regional recurrences. The role of lymph node metastases in the prediction of distant spread remains controversial. For FTC, the presence of vascular invasion within the primary tumor, and possibly extensive capsular invasion, substantially increases the subsequent risk of developing distant metastases.

POSTOPERATIVE ADJUVANT THERAPY

Two major forms of adjuvant therapy are commonly used following surgical treatment of FCDTC: radioactive iodine and thyroid hormone suppression of TSH. The availability of radioactive iodine (in the form of ¹³¹I) as an effective adjuvant, its ease of use, and perhaps misconceptions regarding its efficacy, have resulted occasionally in complacency regarding the initial surgical treatment of these tumors. The importance of the primary surgical procedure cannot be overstated. Although the adjuvant therapies do have important impacts and roles, the long-term outcome for the patient depends largely on the adequacy of resection, particularly for patients at higher-than-average risk of death or recurrence.

THYROID HORMONE

The suppression of TSH by administration of suprathreshold doses of thyroid hormone is probably the most widely used adjuvant therapy for FCDTC. In use for more than 40 years, this treatment is based on the belief that suppression of TSH removes an essential growth factor for cells of thyroid follicular origin, thus delaying or preventing the regrowth of the cancer. However, firm evidence that TSH-suppressive therapy is truly effective in the postoperative management of DTC is hard to obtain, in the absence of any randomized prospective trials.

Initially, the goal of TSH suppression therapy was to attain an absent response to intravenous TRH administration, assessed on a first-generation TSH radioimmunoassay, consistent with essentially complete suppression of the pituitary thyrotrope. With the development of more-sensitive TSH assays in the 1980s, it became possible simply to maintain an undetectable TSH, measured using a sensitive (second-generation) immunometric TSH assay, with a lower limit of detection of around 0.1 mU/L. Since the advent of "ultrasensitive" TSH assays (third- and fourth-generation), with lower limits of detection of 0.01 mU/L, 0.001 mU/L, or less, it has become possible to titrate the dose of thyroid hormone in the majority of patients to achieve levels of TSH within prespecified ranges. Unfortunately, there are not good data to help with decision making, so that the "desirable range" for TSH is speculative at the present time.

The contemporary data to support TSH suppression are limited. A recent retrospective, multicenter study of 683 patients, stratified by the National Thyroid Cancer Treatment Cooperative Study (NTCTCS) stage, who had been treated and followed at 14 institutions over a 10-year period, showed a significantly reduced risk of disease progression (defined as cause-specific mortality or recurrence) in stage III and IV patients with FCDTC treated with suppressive doses of thyroid hormone.⁵⁴ No such difference in outcome was observed in stage I and II patients.

The use of suprathreshold doses of thyroid hormone may, however, carry some risk of adverse consequences.^{55,56} A small proportion of patients experience hyperthyroid symptoms of tremor, anxiety, sleep disturbance, heat intolerance, and palpitations, which can be intolerable and can sometimes require reductions in thyroid hormone dosage. The impact of TSH suppression on bone turnover is also a concern, particularly in postmenopausal women, who have an increased risk of osteoporosis. The danger of this is probably negligible in premenopausal women, although it remains unclear whether estrogen replacement after menopause is equally protective. The possible impact of TSH suppression on bone health in men remains unknown.

A suppressed TSH is also a risk factor for the development of atrial fibrillation (AF), with its consequent increased risk of cerebrovascular events.⁵⁶ TSH suppression increases the odds ratio for the development of AF by threefold over baseline. This finding was based on prospectively collected data from the Framingham cohort and did not distinguish between endogenous and exogenous sources of thyroid hormone as the cause of the suppressed TSH. Because triiodothyronine (T₃) is the active hormone at the cardiac level, and because T₃ concentrations are somewhat lower for any given concentration of TSH when exogenous thyroxine is the source of thyroid hormone excess, the actual risk may be somewhat lower than indicated from the Framingham data. Nevertheless, the

potential for significant morbidity exists, and may not be balanced by an improvement in outcome of the FCDTC, at least for stage I and II patients.

The recent guidelines of the National Comprehensive Cancer Network (Version 1.2003 available at http://www.nccn.org/physician_gls/f_guidelines.html) make no distinction regarding the level of TSH suppression between patients with cancers of varying risk. However, the joint recommendations of the American Association of Clinical Endocrinologists (AACE) and the American Association of Endocrine Surgeons (AAES) suggest a stratified approach, according to either AJCC stage or patient risk as assessed by one of the clinical prognostic schemes.⁵⁷ One approach, then, is for patients at low-risk (MACIS score less than 6.0, or AJCC stage I PTC), whose life expectancy is essentially normal, and whose lifetime risk of recurrence is less than 5%, the serum TSH is maintained at or just below the lower limit of the normal range. Because the risk of tumor recurrence in these low-risk patients falls to less than 1% in the 20 years beyond the first 5 postoperative years, the thyroid replacement can be adjusted to allow the TSH to rise into the lower third of the normal range after 5 recurrence-free years. This strategy avoids the potential morbidity associated with long-term TSH suppression. Lifelong monitoring of thyroid hormone status, by annual measurement of serum TSH concentration, is recommended.

Patients at intermediate risk of tumor recurrence include those patients with PTC whose MACIS score lies between 6.0 and 6.9, AJCC stages I and II, or stage III with only lymph node metastases, and patients with minimally invasive FTC. These groups almost certainly warrant rather more aggressive management than the low-risk patients. The TSH should be maintained in the subnormal range, without achieving frank hyperthyroidism. The target TSH concentration is below 0.1 mU/L, ideally in the range between 0.05 and 0.1 mU/L.

High-risk patients, including those with widely invasive FTC or Hürthle cell cancer, or PTC with MACIS scores over 7.0, stage IV disease, or stage III disease with local (extrathyroidal) invasion, should maintain virtually complete TSH suppression (TSH less than 0.05 mU/L). These patients may experience hyperthyroid symptoms when TSH suppression is achieved, although this may be transient. The potential for morbidity must be recognized, and these patients should have screening and monitoring of bone density, at least in postmenopausal women, with appropriate prophylactic and therapeutic management of bone disease.

RADIOACTIVE IODINE THERAPY

The majority (75% or more) of FCDTC retain the capacity to take up and concentrate iodine, although frequently rather less efficiently than normal thyroid tissue, as is evident from the fact that most thyroid carcinomas are "cold" nodules on preoperative thyroid scintigraphy. This residual differentiated function permits radioactive isotopes of iodine to be used for both the detection and treatment of residual thyroid follicular cells.⁴³

Administered orally, iodine isotopes are absorbed rapidly and reliably from the upper gastrointestinal (GI) tract, circulate transiently in the bloodstream, and are concentrated in tissues that express a functional sodium iodide transporter (NIS); these include normal and cancerous thyroid tissue, salivary gland, breast, stomach, and colon. The NIS is also

expressed in the kidney, which transports as well as filters iodine, and circulating iodine is excreted rapidly through the urine and stool. The uptake of iodine into both normal and cancerous thyroid tissue is dependent on TSH, which causes upregulation of expression, and possibly increased function, of NIS.

Radioactive isotopes of iodine (¹³¹I, ¹²⁹I) emit gamma rays, which can be detected using an appropriate detection apparatus (a gamma-camera), thus permitting imaging of iodine-concentrating tissues, and thereby the detection of residual or metastatic thyroid tissue, provided there has been sufficient prior stimulation with TSH. Although γ -rays are high energy, their tissue absorption is low, and the majority of these particles pass through the cell and surrounding tissue. Although ideal for imaging purposes, treatment of residual thyroid carcinoma with radioactive iodine depends on β -particle emission, the major emitted particle released by the decay of ¹³¹I β -particles have moderately high energy travel and only short distances, less than 1 cm, before interacting with surrounding tissue. The resulting ionization and generation of superoxide radicals causes DNA damage, including double-strand DNA breaks; this activates the p53 pathway (commonly intact in differentiated thyroid carcinoma) and leads to apoptosis of the affected cell.

RADIOIODINE REMNANT ABLATION

Postoperative ablation of any remnant thyroid by treatment with 30 to 100mCi of ¹³¹I is often used to "complete" the initial surgical treatment in FCDTC.⁴³ Controversy remains about the optimal dose required to achieve this. A typical dose is between 30 and 75 mCi. Most often, radioactive iodine is administered 4 to 6 weeks after surgery, with the patient in a hypothyroid state, to maximize TSH-stimulated iodine uptake and whole-body iodine retention. Some authorities advocate a low-iodine diet during preparation for ¹³¹I treatment and scanning. Hypothyroidism may be achieved by avoiding thyroid hormone replacement therapy postoperatively, and waiting for at least 4 weeks for endogenous hormone concentrations to fall. Alternatively, initial substitution for 4 weeks with triiodothyronine (Cytomel) followed by 2 weeks of withdrawal can be used and may shorten the duration of symptomatic hypothyroidism. After confirmation of a serum TSH elevated to at least 30mIU/L, and a negative serum pregnancy test in women of childbearing potential, oral ¹³¹I is administered, most often in an outpatient setting.

There is little doubt that even quite substantial remnants of normal thyroid tissue can be eliminated by this approach. Whether small amounts of residual thyroid carcinoma are also eliminated by these remnant ablative doses is uncertain, because carcinoma cells may be several orders of magnitude less efficient than normal follicular cells in the accumulation of iodine.⁵² Many groups regard remnant ablation as a necessary first step before proceeding, at a later date, to higher-dose treatment of known residual (or recurrent) disease.

Elimination of a postsurgical remnant has three goals. First, this may destroy residual normal thyroid tissue, making subsequent neck and whole-body scans easier to interpret, because areas of more subtle uptake (for example, in metastatic tumor within regional lymph nodes) might otherwise be overshadowed. Second, it may simplify interpretation of serum thyroglobulin (Tg) concentrations, because residual normal thyroid tissue otherwise contributes, to some degree,

to the production of Tg, particularly in the stimulated state (i.e., with elevated TSH). Third, it may make subsequent therapeutic doses of radioiodine more effective, as there will be no competition for the dose from normal thyroid tissue.

There are few data to ascertain whether remnant ablation with ^{131}I improves the outcome of patients with thyroid carcinoma. No randomized trials have been reported of radioactive iodine therapy, and none are in progress. The understanding of the risks and benefits of this widely used therapeutic approach is based entirely on observational, retrospectively analyzed, nonrandomized studies.

In low-risk patients who have had adequate primary operations, with small intrathyroidal papillary tumors (pT1–2, stage I disease), ^{131}I ablation provides no detectable benefit with respect to either cause-specific survival or the risk of recurrent disease.⁵⁸ Even in those patients with regional nodal involvement, ^{131}I does not further improve the already very low-risk of either death or recurrence in these otherwise low-risk patients. It is also extremely difficult to detect improvements in survival rates that approach 100%.

The possible benefit of such ablation in higher-risk patients, without evidence of residual disease, continues to stimulate heated debate. These arguments are fueled by apparently contradictory data from a few major centers. On the one hand are data from Mazzaferri, showing that 30-year recurrence rates, in patients with tumors larger than 1.5 cm, were halved (from 38% to 16%) in the 350 patients who received ablation with ^{131}I , compared with the 802 who did not.⁵⁹ Similarly, cause-specific 30-year mortality rates fell from 8% to 3%, with no deaths observed in patients who received ^{131}I in whom there was no evidence of residual disease. This view is shared by DeGroot and by the M.D. Anderson group.^{60,61}

Contradicting this view are data reported by Hay, which have failed to show any significant benefit of ^{131}I ablation in patients with adequate primary surgery, including selective node dissection, in whom no evidence of residual disease was detected.⁴⁵ Analysis of a total of 1,542 patients with PTC, treated at Mayo Clinic, of similar stage to those reported by Mazzaferri, showed recurrence rates (16.6% versus 19.1%; $P = 0.89$) and mortality rates (5.9% versus 7.8%; $P = 0.43$) that were no different with or without ^{131}I remnant ablation.

The recurrence rates reported in this Mayo Clinic study are considerably lower than other reports, even in the absence of routine ^{131}I ablation. This finding may reflect the completeness of surgical excision of the primary tumor and emphasizes the importance of the primary operation in determining outcome. It may be that ^{131}I ablation has proven useful in other studies because of the presence of unrecognized residual disease, almost certainly within regional lymph nodes, the site of the majority of recurrences in several studies. With adequate preoperative assessment (using ultrasound), and careful intraoperative exploration of these affected nodes, the rate of later recurrence may be reduced to the level of the Mayo data and may obviate the need for the radioiodine.

Long-term data show that ablative doses of ^{131}I are safe and are not associated with significant side effects or carcinogenic risk.^{62,63} The financial cost and inconvenience to the patient may outweigh any potential benefit, however, at least in low-risk patients who had undergone adequate primary operation. These data support the highly selective use of ^{131}I remnant ablation as adjunctive therapy following

adequate primary surgery. In contrast, those patients at moderate or high risk of tumor recurrence based on postoperative risk assessment may benefit more, because they require follow-up by isotope scans and by stimulated Tg concentrations, and may need treatment for residual or recurrent disease. FTC, and particularly its Hürthle cell variant, carry somewhat higher risks for recurrent and metastatic disease than PTC, and these patients may be likely to benefit from ^{131}I ablation and treatment.

RADIOIODINE THERAPY FOR LOCALLY RESIDUAL DISEASE

Microscopic residual disease is likely to remain after resection of locally invasive (pT4) tumors, even if adequate clearance of gross residual disease is achieved surgically; this may be detected histologically as tumor presence at the surgical margin at the time of the initial resection, even in some tumors initially thought to be contained within the thyroid. Such microscopic disease increases the risk of true PTC thyroid-bed recurrence, and of cause-specific mortality, at least in older (stage III) patients.⁶⁴ Similarly, invasive Hürthle cell variant FTC is more likely to recur within the thyroid bed and can prove difficult or impossible to eradicate. Treatment with ^{131}I can be effective for the elimination or control of residual disease in some patients. Approximately 75% to 85% of FCDTC concentrate iodine appreciably when sufficiently stimulated by TSH, and adequate doses of orally administered ^{131}I can induce apoptosis in these cells and in surrounding tissue in a radius of up to 2 mm.

Either ^{131}I or external-beam irradiation improved local recurrence and 20-year cause-specific survival rates in patients with microscopic residual disease.^{65,66} Traditionally, treatment of residual disease is a two-step process, with a relatively low dose (30–75 mCi) administered for ablation, and a higher treatment dose (100–200 mCi) given, at a later date, for treatment. There is no empirical evidence that this approach is superior to administration of therapeutic doses on the first occasion. From a diagnostic view, however, a significant thyroid remnant may overshadow the presence of subtler uptake in extrathyroidal tissues, and so the presence of residual disease can be masked on a posttherapy scan.

A few patients present with locally advanced disease, which makes complete surgical resection difficult or impossible, and a small number of these patients have gross residual disease in the neck despite an optimal surgical procedure. An aggressive primary surgical approach for these patients, including partial resection of trachea or esophagus, if necessary, to achieve local control is reasonable, with careful preservation of function. When this is not possible, the presence of gross residual disease is an independent risk factor for both recurrence and cause-specific mortality. Radioactive iodine provides a therapeutic option in this setting, and divided doses of up to 500 mCi may be necessary in an attempt to achieve local control. Some groups advocate even higher total doses of ^{131}I , guided by dosimetry studies, to achieve the maximum dose possible, to a point just short of bone marrow toxicity. Consequences of very high dose ^{131}I therapy include significant permanent xerostomia, dysphagia, bone marrow suppression, and risk of secondary malignancy, including leukemia, lymphoma, transitional cell bladder carcinoma, and colon carcinoma.

Dosimetry has a number of significant potential errors in predicting the radiation dose received by tumor tissue in

response to a dose of ^{131}I . The estimated volume of the residual or recurrent tumor to be treated is, at best, only an approximation. The uptake of iodine may vary from one area of residual tumor to another, and may be heterogeneous within a single focus of recurrence. Additionally, the effective half-life of ^{131}I may vary substantially between patients, and even within a single patient, between the tracer and the therapeutic dose. Finally, the use of a prior tracer dose of ^{131}I , necessary to calculate dosimetry, may result in "stunning" of the tumor tissue, and so decrease the uptake of a subsequent therapeutic dose.⁶⁷ This stunning effect, if it truly exists, may be minimized by using a low (less than 5 mCi) scanning dose of ^{131}I , or ^{123}I (a gamma-emitter), as the tracer. Nevertheless, dosimetry remains a controversial tool in the administration of therapeutic ^{131}I and is used by a minority of practitioners.

Residual or recurrent FCDTC, even in the presence of gross disease, is often slow growing, may be alternatively treated by external-beam irradiation, and may be amenable to local control by intermittent repeat surgical neck exploration. Very high dose ^{131}I therapy (more than 500 mCi) is of unproven efficacy and has significant associated morbidity. External-beam radiotherapy may be a more-effective alternative.

RADIOIODINE THERAPY FOR METASTATIC DISEASE

Metastatic FCDTC may concentrate iodine in up to 80% of cases, and TSH can stimulate this uptake. Treatment with ^{131}I is therefore used widely to treat distant metastases, whether they are present at the time of the original diagnosis or appear at a later time. In the treatment of microscopic pulmonary metastases, ^{131}I appears effectively to minimize further growth, and possibly induce regression, at least in children and young adults.⁵ This approach may lower the serum Tg concentration and reduce or eliminate iodine trapping, although the chest X-ray may never return entirely to normal and later recurrences remain a possibility. Whether ^{131}I improves survival in these cases remains unproven, but seems likely, and certainly long-term survival is expected in younger patients with PTC, treated with adequate surgery and ^{131}I , even when pulmonary metastatic disease exists at presentation.

There are also numerous anecdotal reports and case series that show significant shrinkage of pulmonary and other distant metastases in older patients after effective ^{131}I treatment.⁶⁸ There are no prospective data to show an improvement in survival with this treatment. Larger metastases (greater than ~1 cm in maximum diameter) are significantly less responsive to ^{131}I . Hypoxia within these larger tumor masses induces relative radioresistance, possibly by limiting the production of superoxide radicals, thus reducing the impact of radioactivity on tissue injury.

Initial enlargement of treated metastases occurs commonly, presumably some variable combination of a response to the trophic effect of the elevation of TSH necessary to induce iodine trapping and the edema that occurs in response to effective tumor tissue injury. Such enlargement can cause significant problems from space-occupying lesions in critical locations such as within the brain or adjacent to the spinal cord. Prophylactic steroid administration may be helpful.

The effective ^{131}I dose is lower after the use of recombinant human thyrotropin (rhTSH) than after thyroid hormone withdrawal, however, because hypothyroidism decreases renal ^{131}I clearance, increasing its effective biologic half-life.

This effect does not occur after rhTSH therapy and therefore more attention to dosimetry may be necessary when treating after rhTSH use. The efficacy of ^{131}I therapy after rhTSH stimulation has not been evaluated and currently represents an unlicensed use of this product, except for compassionate use in selected patients.

Alternative therapeutic modalities, including resection and localized external-beam irradiation, may also play a role in the management of metastases from FCDTC, and ^{131}I should be viewed as merely one component of a multimodal therapeutic approach.

POSTOPERATIVE SURVEILLANCE AND FOLLOW-UP

Recurrence rates for FCDTC range from 10% to 35%.⁴¹⁻⁴⁵ The majority of recurrences occur within the first 5 to 10 postoperative years; however, recurrences can occur as long as 25 years after apparently successful primary treatment. Many of the recurrences are easily amenable to treatment, particularly if detected early, before vital structures are compromised. Some form of sensitive surveillance is desirable to detect recurrences before they become clinically apparent.

The vast majority of patients with PTC are at low risk of recurrence, and these patients are unlikely to succumb to their disease. Follow-up surveillance must involve negligible risk, minimal morbidity or discomfort, and must be financially rational. The follow-up should be tailored to the patient's level of risk, with high-risk patients receiving more-intensive assessment, directed to the likely sites of recurrence, whereas low-risk patients should be reassured, and have much less intensive (and less-expensive) follow-up. The clinical staging and risk assessment schemes such as MACIS provide a logical and accurate basis to determine an appropriate follow-up strategy.

ANATOMIC EVALUATION

The majority of recurrences of FCDTC occur in the thyroid bed or within regional lymph nodes in the neck. Ultrasound examination, using high-resolution transducers, permits accurate evaluation of the postoperative neck and is the imaging modality of choice for postoperative surveillance. Recurrent PTC, in particular, has sonographic features that are highly characteristic, with calcifications which result in multiple tiny bright echogenic foci within the tumor deposit. Lymph node architecture by ultrasound is also distinctive for nodal metastases, with enlargement, rounding, and loss of the normally visible, hyperechoic hilar structures. Ultrasound has a major added advantage over other imaging modalities in that ultrasound-guided FNAB can provide cytologic confirmation of the presence of metastatic cancer.

MRI and CT scanning are also widely used to assess the postoperative neck. CT scanning is usually performed without contrast, because the iodine loading from the contrast material otherwise obviates the subsequent use of radioactive iodine therapy. Although either of these techniques can be used to detect recurrences in the neck, their resolution is less good than ultrasound, in part because thyroid carcinoma exhibits similar spin-decay kinetics and similar X-ray density to other soft tissue structures in the neck. The minimum detectable size of recurrent tumor deposits within the neck using these techniques is about 0.5 to 1.0 cm. These techniques are also substantially more

expensive than ultrasound. For these reasons, they are used as specialized tests to answer specific issues with regard to a recurrence, rather than as a surveillance tool, for most patients.

Spiral CT scanning (without contrast) may be useful to detect the pulmonary metastases that can occur in FCDTC. However, although the lung and mediastinum represent the most frequent distant metastatic sites for FCDTC of all types, the majority of patients are at very low risk of this event, and a chest X-ray may be sufficient on a routine basis, to exclude pulmonary metastases, in the majority of low-risk patients. In higher-risk patients, radioactive iodine scanning may prove even more useful than CT scanning because it also provides information regarding the possible future treatment of the detected disease with ^{131}I .

FUNCTIONAL EVALUATION

Isotope Scanning Functional scanning with radioactive iodine (^{131}I or ^{123}I) remains the most widespread, and often the only, postoperative surveillance undertaken. Although less efficient than normal thyroid, the majority of (~80%), but not all, FCDTCs retain the capacity to concentrate iodine and its isotopes. A gamma-camera permits imaging of the neck within 24 hours of ingestion of oral ^{131}I or ^{123}I , whereas whole-body scanning requires clearance of the physiologically accumulated gastrointestinal and renal iodine and therefore requires 48 to 72 hours between administration of the isotope and imaging. Positive imaging demonstrates functional thyroid tissue and implies that it may be amenable to destruction with the beta-emitter ^{131}I .

Whole-body scanning is commonly performed using doses of 1 to 5 mCi ^{131}I . Follicular cell iodide uptake is a TSH-dependent process, in both normal and malignant tissue. Preparation for scanning has traditionally required withdrawal of thyroid hormone therapy for several weeks, to allow high levels of endogenous TSH to develop, thus stimulating uptake.⁶⁹ Serum TSH concentrations of more than 30 mU/L are recommended for scanning and treatment purposes. During the withdrawal of thyroid hormone, which lasts 4 weeks or more, patients develop hypothyroidism, with all its attendant morbidity, and efforts to limit this, by conversion to T_3 (Cytomel) before thyroid hormone withdrawal, are incompletely effective. In addition, a small number of patients are unable to mount an adequate endogenous TSH response because of hypopituitarism, or may be particularly sensitive to the effects of hypothyroidism because of various nonthyroidal illnesses.

Genetic engineering has permitted the large-scale production of recombinant human thyrotropin (rhTSH), and this is now approved for human diagnostic, but not therapeutic, use. Several large studies have been completed, comparing withdrawal scans with rhTSH-stimulated scans.^{69,70} Clearly, patients experience considerably fewer hypothyroid symptoms during rhTSH stimulation, when compared with withdrawal scanning, and patients report higher quality of life scores during the days before the scan. rhTSH, which is administered by intramuscular injection, has limited side effects that are relatively minor for most patients.

The usual dose of rhTSH is two injections on consecutive days, with the second injection administered 24 hours before ingestion of the iodine isotope.⁵⁷ This approach requires some logistic commitment because the whole process of rhTSH

administration followed by scanning requires approximately 5 days to complete. rhTSH fails to trigger urinary iodine retention, and the effective biological half-life of ^{131}I is therefore somewhat lower for rhTSH than for withdrawal scans. This results in rather lower whole-body iodide retention and so marginally poorer quality scans. This problem may be compensated by using higher tracer isotope doses (raising concerns about stunning), or by prolonging the acquisition time in "count-poor" scans, and under these circumstances the detection rate of metastatic disease approaches that of the withdrawal scan.⁵⁷ In carefully controlled, blinded studies of hormone withdrawal versus rhTSH-stimulated scans, a small number of "discordant" scans have been reported, with rather more areas of uptake missed following rhTSH stimulation than after withdrawal scanning in the same patients. The addition of stimulated Tg measurements to the scan itself improves the identification rate of patients with residual or recurrent disease to levels similar to withdrawal scanning. Very few treatment decisions would be altered by this minimal difference in sensitivity, but the approach remains a trade-off of sensitivity for symptom minimization.

Except in a compassionate use setting, rhTSH is not currently approved for treatment with radioiodine, because the difference in renal iodide clearance may make such treatment less effective. Studies of the use of rhTSH for ^{131}I therapy are under way. It has been used in a small number of patients with hypopituitarism, who are unable to mount an endogenous TSH rise with conventional hormone withdrawal.

The precise role for rhTSH-stimulated radioiodine scanning in the routine postoperative follow-up of patients with DTC remains unclear. Although the small difference in sensitivity may have minimal clinical impact, the current inability to follow a positive scan immediately by administration of therapeutic radioiodine remains a significant hurdle to its widespread use. For high-risk patients, in whom therapy with ^{131}I is believed likely to be required, withdrawal scanning seems more appropriate, to allow treatment to follow immediately. In low-risk patients, isotope scanning may not be necessary. Those intermediate-risk patients who might best benefit from this new approach remain to be clearly defined.

Other Functional Scans A variety of other isotopic scanning approaches have been assessed in thyroid cancer detection. The most promising of these is positron emission tomography (PET) scanning, which depends on the tumor uptake and sequestration of fluorodeoxyglucose (FDG) tracer.^{71,72} It provides a combination of functional and anatomic imaging. The precise sensitivity and specificity of this technique for the detection of recurrent thyroid carcinoma remains to be adequately assessed. The initial experiences show that the less well differentiated FCDTC, which are less likely to image with radioiodine scans, are more likely to image with FDG-PET scan. Thus, the thyroglobulin-positive/radioiodine-negative patient in whom a recurrence is suspected may be best imaged with the FDG-PET technique.

Octreotide scanning, using isotope-labeled octreotide and traditional gamma-camera imaging or SPECT (gamma-camera tomography) imaging, can identify tumors expressing the appropriate receptor (type 2 somatostatin receptors). This may be a useful adjunctive method for the detection of some unusual FCDTC that express the somatostatin receptor. At present, however, it has no role in the routine management of FCDTC.

TUMOR MARKER

Serum thyroglobulin (Tg) is a highly specific product of the thyroid follicular cell and is detectable in the circulation of patients with residual normal or abnormal thyroid tissue.⁵⁷ After total thyroidectomy and remnant ablation, an elevated or rising Tg concentration is a highly specific and sensitive marker of recurrent FCDTC. Tg may be produced by residual normal thyroid tissue following surgery, and even after ¹³¹I thyroid remnant ablation, so a low stable level of Tg might not indicate residual disease. A few tumors, particularly those that are high grade and less well differentiated, may not produce large amounts of Tg, making a recurrence without elevated Tg a possibility. Nevertheless, measurement of serum Tg is an important component of a comprehensive surveillance program, allowing detection of early recurrent disease in the majority of such patients, and identifying some patients who might benefit from more-aggressive anatomic imaging.

Tg production and secretion into the circulation are TSH dependent, and Tg concentrations increase following withdrawal of thyroxine therapy, or following stimulation with rhTSH. However, the majority of patients with clinically significant recurrent disease have an elevated Tg level even when on suppressive thyroxine therapy.⁵⁷ It is not clear that TSH-stimulated Tg measurement is worthwhile in the majority of patients at low risk of recurrent disease. Radioactive iodine remnant ablation, discussed previously, lowers basal and stimulated Tg concentrations by ablating a postsurgical thyroid remnant. However, this ablation is often incomplete, even with relatively high doses of ¹³¹I, and the Tg concentration may remain detectable even in this setting. A serum Tg concentration greater than 5 ng/mL (while on suppressive thyroxine therapy) is a useful trigger for further investigation; however, it is not uncommon for patients with Tg concentrations of 5 to 20 ng/mL to have no anatomic or functional evidence of disease and to have stable, nonprogressive Tg levels.

The measurement of serum Tg is complicated, in as many as 20% of patients, by the presence of circulating anti-Tg antibodies as a result of autoimmune thyroiditis.⁵⁷ Depending on the assay, these antibodies may artificially raise or lower the measured Tg concentration and significantly complicate its interpretation. All assays should include screening for anti-Tg antibodies, and their presence should lead to caution in interpretation of the result. Autoantibody titers can wax and wane; even long-term trends in Tg concentrations may not reliably reflect the underlying growth of thyroid tissue in these patients.

Anaplastic Thyroid Carcinoma

Anaplastic thyroid carcinoma (ATC) is extraordinarily aggressive, relentless, and resistant to treatment. Its typical course stands in stark contrast to that observed for FCDTC. Few therapies have discernible value, and those affected typically suffer rapid tumor progression and death.

EPIDEMIOLOGY

ATC consistently has a median age of onset in the seventh decade of life and is characterized by a female preponderance ranging from 55% to 77%. In the comprehensive 1997 SEER report, which did not reexamine histology but which was con-

ducted entirely in the modern immunohistochemical era, ATC accounted for 1.6% of all thyroid carcinomas.⁷³

CLINICAL FEATURES

Patients with ATC typically present with a suddenly enlarging neck mass. Local compressive symptoms are frequent and can include stridor, dysphagia, dyspnea, hoarseness, weight loss, and superior vena cava syndrome. Patients often have distant metastases at presentation that are usually pulmonary but can also involve bone, brain, and soft tissues. Preexistent thyroid conditions are frequent and can include prior benign thyroid nodules, differentiated thyroid carcinoma, goiter, and Graves' disease.⁷³⁻⁷⁵

Multiple retrospective clinical series on ATC document its demographic profile and lethality.⁷³⁻⁷⁵ Gender is not a prognostic factor reliably impacting upon survival, nor is the use of radiation therapy. The presence of distant metastases at diagnosis predicts earlier demise from ATC. Small tumor size, defined as less than 5-6 cm, is associated with improved survival compared with larger tumors. In a careful multivariate analysis, small tumor size (less than T3) was one of only three identified independent prognostic factors; the others were distant metastasis and the use of thyroxine, while surgical resection, radiation therapy (XRT), and radioiodine ablation had no influence on survival.

*TREATMENT OF ANAPLASTIC THYROID CANCER**LOCAL THERAPY*

Surgical resection of ATC does not reliably improve local control or survival. A modern-era large series from M.D. Anderson Cancer Center, after reviewing histology to exclude lymphomas, observed no benefit to radical operation for ATC compared with less-radical resection.⁷⁶ Similarly, a large multivariate analysis also found no survival benefit to operation for ATC.⁷⁷ Resection of ATC may occur in association with better survival, whereas small tumor size is associated with better survival whether ATC is resected or not. Large tumors are impossible to resect, but it does not follow that it is the resection that improves survival.

The significance of focal anaplastic change observed histologically in a differentiated thyroid carcinoma is an occasional observation that may be quite important. In a small recent series, 8 of 65 patients with tall cell or insular carcinoma were found on histologic review to have focal anaplastic carcinoma, defined as a microscopic area or areas of anaplastic dedifferentiation within the primary tumor or nodal metastasis seen only on one slide.⁷⁸ All patients were treated by thyroidectomy, half received subsequent radioiodine ablation, and 4 of 8 patients had distant metastases at presentation. The group with foci of anaplastic change experienced increased mortality compared with patients with tall cell or insular carcinoma by both univariate and multivariate analysis, and 7 of 8 died of disease a mean of 11 months later. The authors concluded that even small anaplastic foci predict a fatal outcome. Another report of 17 patients with ATC noted that complete surgical excision of small ATC foci was the only factor associated with survival longer than 12 months. In ATC, the variables of tumor size and anaplastic foci require further study. Patients noted to have foci of ATC within FCDTC may have a prognosis dictated by the ATC focus. Although the data for this are limited, they are compelling. Unfortunately, there are few treatment options to offer patients with this disease.

Given the poor prognosis observed when microscopic foci of ATC are identified incidentally at thyroidectomy for FCDC, it appears even more difficult to make a case for routine surgical resection of preoperatively identified ATC lesions. After the possibility of ATC is entertained based on history and physical examination, a core needle biopsy establishes the diagnosis in most patients. The role of surgery is limited to open biopsy when needle biopsy fails to obtain enough tissue to differentiate ATC from thyroid lymphoma and securing the airway via tracheostomy when necessary in individual patients. Emergent management of tracheal compression by tumor is occasionally necessary; if the airway is tenuous (less than 4 mm in diameter) on CT imaging, before induction of radiation therapy, a tracheostomy is prudent.

Treatment after diagnosis focuses upon local tumor control in the neck. Conventional local therapy is based upon the reports that once-weekly low-dose doxorubicin (10 mg/m²) given as a radiosensitizer with hyperfractionated radiotherapy can produce local tumor regression.⁷⁹ The radiation therapy is carried out at a fractional dose of 1.6 Gy per treatment twice a day for 3 days per week with a total tumor dose of 5.76 Gy. The initial report appeared to offer a modest survival benefit compared with historical controls that has not been borne out in subsequent studies. Use of radiotherapy in combination with a variety of systemic therapies has also failed to demonstrate a survival advantage. The efficacy of radiotherapy at local control has not yet been tested formally in a trial, but numerous studies have reported substantial rates, with local control typically achieved in more than two-thirds of patients (16%–84%), allowing death from distant metastases.^{79,80} Use of radiation also potentially facilitates the use of an effective systemic therapy should such an agent be identified.

SYSTEMIC THERAPY

There are no known systemic therapies that reduce mortality from ATC. ATC has poor concentration of radioiodine, and this modality has no role in therapy. Some reports have suggested a possible role for paclitaxel.^{81,82} However, the benefit appears limited and the response durations short.

In summary, ATC is a rare rapidly fatal disease for which there is no known effective therapy, in contrast to FCDC. There are few data to support a role for resection in patients diagnosed preoperatively with large ATC tumors. However, there may be a benefit to resection of small ATC (less than 5 cm). Anaplastic foci noted within well-differentiated thyroid cancer portend a poor prognosis. Local irradiation may sometimes provide palliative control of disease in the neck.

Medullary Thyroid Carcinoma

CLINICAL FEATURES

Medullary thyroid carcinomas (MTCs) are 5% to 9% of all thyroid cancers seen in the United States. The cells of origin are the C cells, also called parafollicular cells, derived from the neural crest. C cells are about 1% of the total thyroid mass and are dispersed throughout the gland, with the highest concentration in the upper poles. The C cells have the unique ability to synthesize and secrete calcitonin. Although calcitonin is integral in calcium homeostasis in other vertebrate species, its role in humans is unclear. Calcitonin is used as a

specific tumor marker for MTC. It is extremely useful in the screening of individuals predisposed to the hereditary forms of the disease and in the follow-up of patients who have been treated. C cells are also capable of secreting other hormones, including carcinoembryonic antigen (CEA), histaminase, neuron-specific enolase, calcitonin gene-related peptide, somatostatin, thyroglobulin, thyrotropin-stimulating hormone, adrenocortical-stimulating hormone, gastrin-related peptide, serotonin, chromogranin, and substance P.

The clinical presentation of patients with sporadic MTC is similar to patients with FCDC, in that they usually have a mass in the thyroid gland, and may also have palpable cervical lymph node metastases. Sporadic MTC presents in the third through fifth decades of life, with a roughly equal proportion of men and women. Patients with very large tumor burdens may also have diarrhea as a manifestation of the hormonal function of the tumor. The diagnosis is often suspected based upon cytologic assessment, and the suspicion may be strengthened by an elevated basal serum calcitonin level. However, the presence of an elevated calcitonin level alone is not diagnostic of MTC, even in the presence of a palpable thyroid mass.⁸³

Patients from multiple endocrine neoplasia kindreds (MEN-2a, MEN-2b, and familial medullary thyroid carcinoma) often now present without any thyroid mass or discernible thyroid abnormality. Optimally, they are discovered based on direct genetic testing of the RET protooncogene, leading to presymptomatic therapy.

PATHOLOGIC FEATURES

MTC was recognized as a unique entity by Hazard, Hawk, and Creile in 1959.⁸⁴ Before 1959, MTC was classified as a variant of anaplastic thyroid carcinoma with amyloid stroma. MTCs are well-demarcated, firm, gray-white tumors that may have a gritty consistency. Calcifications may be present on imaging studies. Histologically, the tumors contain uniform polygonal cells with finely granular eosinophilic cytoplasm and central nuclei. The presence of amyloid is a distinctive feature of MTC, although it is not found in all cases. The amyloid is thought to be formed from calcitonin or procalcitonin molecules. In patients with sporadic disease, approximately 70% are solitary and unilateral and 30% are bilateral or multifocal. In patients with RET mutations, 95% are bilateral or multifocal, and only 5% are solitary.⁸⁵ C-cell hyperplasia is associated with MTC, particularly in the familial forms. It is presumed that C-cell hyperplasia is a precursor lesion to MTC.

Tumors that exhibit mixed features of MTC and FTC, or, more rarely, MTC and PTC, are unusual, but do occur.^{86,87} The WHO recognizes the mixed MTC/FTC as a distinct histologic entity, but the clinical implications of this diagnosis are unclear. They should probably be managed in the same way as more-typical MTC. The possibility of successful treatment of such mixed tumors with radioactive iodine has been entertained, but no data exist.

RISK FACTORS AND ASSOCIATED HEREDITARY CONDITIONS

There are no known risk factors for MTC, other than the hereditary syndromes that predispose to it (Table 55.5). The multiple endocrine neoplasia (MEN) type 2 syndromes include MEN 2A, MEN 2B, and familial, non-MEN medullary

TABLE 55.5. Clinical features of sporadic MTC, multiple endocrine neoplasia (MEN) 2A, MEN 2B, and familial, non-MEN medullary thyroid carcinoma (FMTC).

<i>Clinical setting</i>	<i>Features of MTC</i>	<i>Inheritance pattern</i>	<i>Associated abnormalities</i>	<i>Genetic defect</i>
Sporadic MTC	Unifocal	None	None	No germ-line defect
MEN 2A	Multifocal, bilateral	Autosomal dominant	Pheochromocytoma Hyperparathyroidism	Germ-line missense mutations in extracellular cysteine codons of RET
MEN 2B	Multifocal, bilateral	Autosomal dominant	Pheochromocytoma Mucosal neuroma Megacolon Skeletal abnormalities	Germ-line missense mutation in tyrosine kinase domain of RET
FMTC	Multifocal, bilateral	Autosomal dominant	none	Germ-line missense mutations in extracellular or intracellular cysteine codons of RET

thyroid carcinoma (FMTC).⁸⁸ These are autosomal dominant inherited syndromes caused by germ-line mutations in the RET proto-oncogene. The cellular growth and malignant transformation are caused by a gain-of-function mutation, with enhanced intrinsic tyrosine kinase activity (codons 609, 611, 618, 620 of exon 10; codon 634 of exon 11; codon 768 of exon 13; codon 844 of exon 14), or an alteration of substrate recognition (codon 883 of exon 15; codon 918 of exon 16). Medullary thyroid carcinoma (MTC) is the hallmark of these syndromes, with tumors that are multifocal, bilateral, and usually occur at a young age. There is almost complete penetrance of MTC in patients affected by these syndromes; all persons who inherit the disease allele develop MTC. Other features of the syndromes are variably expressed, with incomplete penetrance.

In MEN 2A, patients develop multifocal, bilateral MTC associated with C-cell hyperplasia. Approximately 40% of gene carriers develop adrenal pheochromocytomas, which may also be multifocal and bilateral but not extraadrenal, which are usually associated with adrenal medullary hyperplasia. Hyperparathyroidism develops in 25% to 35% of patients, and is due to hyperplasia, which may be asymmetric, with one or more glands becoming enlarged. The hyperparathyroidism is generally relatively mild compared with MEN 1. Parathyroid carcinoma has been reported in one patient with MEN 2A. Hirschsprung's disease, characterized by the absence of autonomic ganglion cells within the distal colonic parasympathetic plexus, resulting in obstruction and megacolon, is infrequently associated with MEN 2A.

In MEN 2B, 40% to 50% of patients develop pheochromocytomas, and all individuals develop neural gangliomas, particularly in the mucosa of the digestive tract, conjunctiva, lips, and tongue. MEN 2B patients also have megacolon, skeletal abnormalities, and markedly enlarged peripheral nerves. MEN 2B patients do not develop hyperparathyroidism. MTC develops at a very young age (infancy) and appears to be the most aggressive form of hereditary MTC, although its aggressiveness may be more related to the extremely early age of onset, rather than the biologic virulence of the tumor. MTC in patients with MEN 2B is rarely curable once it develops, although it may be preventable by prophylactic thyroidectomy.

Familial, non-MEN medullary thyroid carcinoma (FMTC) is characterized by the development of MTC without any

other endocrinopathies. MTC in these patients has a later age of onset and a more-indolent clinical course than MTC in patients with MEN 2A and MEN 2B. These patients do not develop any of the extrathyroidal manifestations of MEN 2A or 2B.

PROGNOSIS OF MEDULLARY THYROID CANCER

Although the prognosis of sporadic MTC is considered to be favorable, long-term studies report a 5- and 10-year-survival rate of only 80% to 90% and 60% to 80%, respectively.^{89,90} More than 50% of all patients with sporadic MTC eventually die of their disease. TNM tumor stage is the most powerful predictor of prognosis in sporadic MTC. Most patients die of distant metastases (stage IV), which have the single greatest influence on outcome. In addition, patients with lymph node metastases (stage III) have a worse outcome compared with those patients without lymph node metastases. The impact of lymph node metastases on survival is greater than primary tumor size. The often-reported better prognosis of hereditary MTC is most likely biased by those hereditary cases that are diagnosed at an early tumor stage by screening procedures, notably by calcitonin measurement or mutation analysis of the RET proto-oncogene.

TREATMENT OF MEDULLARY THYROID CANCER

Resection is the treatment of choice in MTC. This offers the only prospect of definitive cure, both in primary and in locally recurrent MTC. Whenever feasible, all efforts should be directed at eradicating the tumor.

PRIMARY OPERATION

Localized or Regional Disease Because of the frequent multicentricity of sporadic MTC (20%), total thyroidectomy is appropriate for all cases of sporadic MTC, regardless of primary tumor size. Controversy exists, however, regarding the indication for and the extent of lymph node surgery. The central neck lymph node compartment is involved in at least 33% of patients with tumors of 10mm or less (pT1) in size (Table 55.6).^{91,92} With this frequent involvement of the central neck compartment with small cancers, a dissection of the central neck should be performed for all patients for accurate staging and therapy for micrometastases. In the presence of

TABLE 55.6. Medullary carcinoma of the thyroid: frequency and distribution of nodal metastases.

Tumor size	No. of patients	Central node metastases (patients)	Ipsilateral level II-V metastases (patients)	Contralateral level II-V metastases (patients)
Unilateral tumor				
0–0.9 cm	4	3/4	3/4	1/4
1–1.9 cm	9	8/9	8/9	3/9
2–2.9 cm	5	4/5	3/5	3/5
3–3.9 cm	5	2/5	4/5	3/5
4 cm or larger	9	9/9	8/9	4/9
Total	32	26/32 (81%)	26/32 (81%)	14/32 (44%)
Bilateral tumors (largest size)				
0–0.9	12	8/12	9/12	4/12
1–1.9	7	5/7	6/7	4/7
2–2.9	8	7/8	4/8	5/8
3–3.9	7	7/7	6/7	5/7
4 cm or larger	7	5/7	4/7	2/7
Total	41	32/41 (78%)	29/41 (71%)	20/41 (49%)

Source: Data from Moley and DeBenedetti.⁹²

central neck lymph node metastases, demonstrated preoperatively by ultrasonography or intraoperatively, dissection of at least the ipsilateral neck compartments (levels 2–5) with curative intent is advocated because of the frequent occurrence of lateral neck lymph node metastases (Table 55.6). Contralateral metastases are present in at least 40% of patients, and these compartments may also require dissection, either under the same anesthetic, or subsequently if the calcitonin levels fail to normalize after thyroidectomy with central and ipsilateral dissection.

MTC with Distant Metastases Patients with distant metastases at presentation usually have an unfavorable course that does not warrant extended surgery apart from total thyroidectomy, central lymphadenectomy, and selective removal of symptomatic lymph nodes or tumor masses. Even with widespread disease, patients often have a prolonged survival despite their debilitating symptoms from tumor persistence or progression. Selected procedures may be indicated for symptomatic control. Judicious palliative reoperative resection of discrete symptomatic lesions may provide significant long-term control of symptoms, improving quality of life for patients with metastatic MTC.

REOPERATION

Hypercalcitoninemia after primary surgery is a frequent phenomenon. For patients with locoregional recurrence without detectable distant metastases after inadequate primary surgery, reoperation to try to achieve local control and possibly cure is appropriate. Inadequate primary procedures should not be allowed to eliminate the chance for the patient to be cured, if the remaining disease can be excised. The indication for and the extent of surgery in patients with postoperative hypercalcitoninemia depends on the extent of locoregional recurrence or tumor persistence. Despite the persistence of hypercalcitoninemia, a substantial proportion of patients exhibit neither locoregional nor distant tumor foci by noninvasive imaging techniques.

Locoregional reoperation with curative intent is indicated in patients without demonstrable distant metastases.⁹³ Due to the frequency of bilateral lymph node metastases at reoperation, reoperative procedures should be designed to remove residual disease from the central neck, as well as to accomplish adequate bilateral neck dissection.

Locoregional recurrence after adequate primary surgery can be caused by either local recurrence within the former thyroid bed or locoregional lymph node metastases. It is important to localize the site of recurrence carefully in these patients who have had previous neck clearance. Central neck recurrence should be eradicated because tumor-related complications affecting the tracheoesophageal axis are difficult to manage and cannot be treated effectively by external-beam radiation. Solitary locoregional lymph node recurrence after adequate primary surgery is best treated by selective lymphadenectomy.

PREVENTATIVE RESECTION FOR MEN 2A, 2B, OR FMTC GENE CARRIERS

Individuals with MEN 2A, 2B, and FMTC are virtually certain to develop MTC at some point in their lives (usually before age 30). Therefore, at-risk family members who are found to have inherited a RET gene mutation should have thyroidectomy, regardless of their plasma calcitonin levels.

In a report of preventative thyroidectomy for RET mutation carriers, Wells and colleagues reported a series of 49 children with MEN 2A and MEN 2B.⁹⁴ In this series, 14 children had a prophylactic thyroidectomy based on genetic testing. The average age of the children at the time of surgery was 10.5 years. Postoperative calcitonin levels were all undetectable, and there was no evidence of recurrent MTC with a mean follow-up of 1.3 years. In an interim report of 3-year follow-up of the earliest group of 18 patients, no recurrence of disease was noted.⁹⁵

The finding of carcinoma in the glands of many of these young patients with normal stimulated calcitonin testing

indicates that the operation was therapeutic, not prophylactic. The ideal age for performance of thyroidectomy in those patients found to be genetically positive has not been determined unequivocally. Six years of age is accepted as a reasonable time for thyroidectomy in patients with MEN 2A and FMTC. Patients with MEN2B should undergo thyroidectomy during infancy, because of the aggressiveness and earlier age of onset of MTC in these patients. Follow-up over the next decades will determine whether there is a significant rate of recurrence following preventative thyroidectomy. At present, it is advisable to follow these patients with plasma calcitonin levels every 1 to 2 years. These patients must also continue to be followed for the development of pheochromocytoma and hyperparathyroidism.

EXTERNAL IRRADIATION

MTC is not very sensitive to external irradiation. Some retrospective studies report a reduced risk of local recurrence after radiation; however, operative removal of all tumor should be performed whenever feasible.⁹⁶ External irradiation may have distressing long-term side effects, notably cough and mucous membrane dryness. Scarring in the neck hampers future assessment of local recurrences and renders reoperation more difficult or impossible. When operative treatment has been successful in normalizing the calcitonin level, there is no need for radiation. In the event of locoregional recurrence, reoperation is the preferred treatment. Radiation therapy should be avoided unless local disease is either symptomatic or rapidly progressing and is not amenable to resection. Radiation may be useful in the treatment of symptomatic distant metastases, especially in bone metastases.

CHEMOTHERAPY

Experience with chemotherapy is limited to advanced or metastatic MTC, and no consistent benefit has been shown.⁸⁸ Drugs investigated include cisplatin, cyclophosphamide, dacarbazine (DTIC), doxorubicin, 5-fluorouracil (5-FU), streptozocin, vincristine, and vindesine.

FOLLOW-UP OF MEDULLARY THYROID CANCER

The postoperative follow-up for patients with sporadic MTC primarily consists in monitoring serum calcitonin levels. When an elevated or rising serum calcitonin is identified, further diagnostic workup or therapeutic intervention is indicated, including additional imaging and possibly surgery. The diagnostic workup must differentiate between local and systemic recurrence.

Parathyroid Carcinoma

Parathyroid carcinoma can be difficult to diagnose. At the time of the initial cervical exploration, it may be overlooked due to lack of overt malignant tumor characteristics such as adherence to the trachea, thyroid, recurrent laryngeal nerve, or esophageal wall and/or the presence of lymph node metastases. On microscopic evaluation, unless there is evidence of capsular or vascular invasion, the diagnosis may remain ambiguous. The combined intraoperative findings provided by an experienced surgeon and a meticulous microscopic evaluation are often required to confirm the suspicious diag-

nosis of malignancy. Because the first operation offers the best chance of local tumor control, it is imperative that the surgeon is aware of the clinical course of parathyroid cancer and participates in the management and follow-up.

Clinical Features of Parathyroid Carcinoma

In contrast to benign hyperparathyroidism, patients with parathyroid cancer are younger at diagnosis (44 to 53 years) with equal sex distribution.^{97,98} Clinical symptoms are usually conspicuous in patients with a parathyroid malignancy. The general symptoms are fatigue, both muscular and mental, depression, nausea, vomiting, dehydration, polydipsia, and polyuria. Each of these can be attributed to the marked hypercalcemia usually found in these patients. Skeletal changes occur in approximately 40% to 70% of the patients. Elevated serum alkaline phosphatase levels are common. Nephrolithiasis occurs in about 70%, and nephrocalcinosis with severe renal dysfunction is found in 20% to 50%. Pancreatitis and peptic ulcerations are reported to occur in 10% to 15%. Among 95 patients with the diagnosis of parathyroid cancer, the median serum calcium level was 3.6 mmol/L (range, 2.5–6.1), and 20% had a palpable cervical mass.⁹⁸

The combination of both renal and bone disease is frequently encountered in parathyroid cancer patients in contrast to those with benign hyperparathyroidism (HPT); this should raise the suspicion of cancer. A palpable, usually firm, cervical tumor is present in 30% to 50% of the patients. Thus, a diagnosis of parathyroid cancer should be strongly considered in a patient with a relative rapid onset of symptoms, with laboratory findings consistent with severe primary hyperparathyroidism (pHPT), an elevated serum alkaline phosphatase, and a palpable neck mass.

Treatment of Parathyroid Carcinoma

The most characteristic intraoperative findings are a firm grayish white tumor, grossly adherent to adjacent structures.⁹⁹ Most malignant tumors are larger (more than 2 cm, median weight 4 g), but size or glandular weight alone is not sufficient for diagnosis. The same operative strategy applies to benign and malignant parathyroid neoplasms in making every effort to preserve the capsule of the tumor. When the tumor invades a neighboring structure such as the thyroid gland, the strap muscles, or the esophageal wall, these structures should be removed in continuity with the tumor. When adherent to the recurrent laryngeal nerve that is known to function, an attempt to shave the tumor from the nerve is justifiable and indicated when the diagnosis of carcinoma is questionable. Most functioning nerves can be dissected free from contiguous malignant tumors. If this cannot be accomplished, the nerve may have to be sacrificed, which is preferable to cutting into tumor.

Breaking the tumor capsule can cause tumor seeding and puts the patient at risk for developing local recurrence even if the tumor is benign. Seeding of tumor cells or parathyromatosis can be extremely hard to differentiate from invasive carcinoma. Resection en bloc with the ipsilateral thyroid lobe is frequently required. Several authors and results from the collected international series of parathyroid carcinomas showed that a more extensive procedure including lymph node dissection did not affect prognosis.^{97,98} Lymph node

metastases were a rare finding. Reliance on intraoperative microscopic diagnosis should be avoided because of the difficulties in applying the diagnostic criteria of malignancy in a frozen section. Bilateral exploration for an evaluation of the other glands to rule out a concomitant benign neoplasm or multiglandular disease is recommended.

Parathyroid cancer can follow a variably aggressive course. Even at initial exploration, the macroscopic appearance of the tumor can be misleading. Hypercalcemia from parathyroid carcinoma may have a slow or a rapid onset, although the average time to recurrence is 3 years after initial diagnosis.¹⁰⁰ When signs of acute hypercalcemic crisis are evident, urgent treatment is indicated; this includes rehydration with intravenous saline, restoration of electrolyte balance, loop diuretics, and bisphosphonates.¹⁰¹ Intravenous bisphosphonates (pamidronate) usually have an effect within 48 to 72 hours that may be sustained for up to 3 weeks. The mechanism of action is inhibition of osteoclastic bone resorption. The drug is well tolerated and not associated with any major complications.

Surgical removal of metastatic or recurrent disease is appropriate whenever feasible. The most common locations for recurrent or metastatic disease are the neck and the lungs, followed by the liver and the skeleton. Cervical recurrences may require repeated neck explorations. A lateral approach (anterior to the sternocleidomastoid, and lateral to the strap muscles) is preferred and may prevent damage to a recurrent laryngeal nerve.¹⁰² Patients with lung metastases have been successfully treated or palliated by limited resection.

Prognosis and Follow-Up

Comparative studies have shown that parathyroid cancer can sometimes be controlled by aggressive surgical interventions; when that is not possible, the best palliative drug treatment for maintaining eucalcemia is intravenous bisphosphonate. There is a significant difference in survival in the collected international series of parathyroid carcinomas when comparing the survival of patients with metastatic disease to those without metastases (30% versus 85% after 5 years).⁹⁸ These findings stress the importance of early diagnosis, appropriate initial surgical procedure, and the variability in tumor biology.

Tumors of the Endocrine System

Jeffrey A. Norton

Endocrine cancer includes the thyroid, parathyroid, endocrine gastrointestinal tract, and the adrenal. Cancer of the endocrine system is uncommon. The overall incidence is 11.2 and 4.5 per 100,000 woman and men, respectively.¹ Because ovary and breast are not included under endocrine cancer, thyroid cancer is the most common type, and it is covered in depth in Chapter 55. The remaining types are even less common, with an annual incidence of 1 to 20 per million. This chapter informs the reader about these rare tumors. Further, we characterize the multiple endocrine neoplasia syndromes, several autosomal dominant familial endocrine cancer syndromes that simultaneously affect multiple endocrine glands.

Adrenal Tumors

Adrenal adenoma is a benign neoplasm of adrenal cortical cells. It is not greater than 5 cm in diameter or 100 g in weight. Cellular pleomorphism and necrosis are rare. It may be hormonally functional. Adenomas produce syndromes of hypercortisolism and hyperaldosteronism and not virilization or feminization. Tumors larger than 6 cm that produce sex hormones are usually carcinoma. Pleomorphism, tumor necrosis, and mitotic activity are more common in carcinoma. The prognosis of adrenal cortical adenoma secreting cortisol is excellent, and surgical resection is curative. However, resection of aldosteronomas does not cure hypertension in some patients. Resection is followed by a favorable response in blood pressure and serum level of potassium; however, 30% of patients may develop recurrent hypertension.

Adrenal cortical carcinoma is a malignant neoplasm of adrenal cortical cells. It is rare and is less than 0.2% of all cancer. It occurs at a rate of only 2 per million. Women develop functional adrenal cancer more often than men. Men have nonfunctioning malignant adrenal tumors more often than women. There is a bimodal occurrence by age, with a peak incidence at less than 5 years and a second peak in the fourth and fifth decade. Adrenal cortical carcinomas are greater than 6 cm in size and weigh between 100 and 5,000 g. Areas of necrosis and hemorrhage are common. Invasion and metastases also occur. Microscopically, the appearance is variable. Cells with big nuclei, hyperchromatism, and enlarged nucleoli are all consistent with malignancy. Nuclear pleomorphism is more common in tumors larger than 500 g. Vascular invasion and many mitoses are diagnostic of malignancy.

Adrenal cortical carcinoma is part of Li-Fraumeni, a hereditary syndrome, including sarcoma, breast, and lung cancer. Mutations in the p53 gene occur in these families. Genetic changes are more common in malignant adrenal tumors. The most frequent DNA copy number changes include losses of 1p, 2q, 3p, 3q, 6q, 9p, and 11q. There are also gains and amplifications of 5q, 9q, 12q, and 20q.² Adrenal cortical cancer is associated with rearrangements at the 11p15 locus and IGF-II gene overexpression.³ Insulin-like growth factor (IGF)-II may be a major determinant of progression and a target for future therapies. Predictors of survival include distant metastases, venous, capsular, and adjacent organ invasion, tumor necrosis, mitotic rate, atypical mitosis, and mdm-2 expression.⁴

Adrenal cancers may have tumor-specific mutations in p53 that serve as a marker for the tumor.⁵ Mutations in the p53 gene have been used to diagnose malignancy.⁶ Quantitative nuclear analysis demonstrates that nuclei from adrenal cancers are larger than those in adenomas, and DNA density is diploid in adenomas and aneuploid in carcinomas. Adrenal cancer cells in culture can spontaneously transition between two subtypes by switching expression of two genes, BRG1 and Brm, at the posttranscriptional level. This mechanism allows the cell to adapt to environmental factors that may suppress growth or cause death.⁷ Finally, in general carcinomas produce abnormal amounts of androgens and 11-deoxysteroids. However, this is merely suggestive of malignancy, because only 10% of malignant tumors produce masculinization whereas the rest secrete cortisol, aldosterone, or nothing.

Cushing's Syndrome

Cushing's syndrome, or endogenous hypercortisolism, is caused by (in order of frequency) (a) excessive secretion of adrenocorticotropic hormone (ACTH) by a pituitary tumor, (b) cortisol by an adrenal tumor, or (c) ACTH by an ectopic tumor. Cushing's syndrome is potentially lethal and, if untreated, is associated with excessive mortality.⁸ Determining the cause of the hypercortisolism involves sophisticated testing.

The signs and symptoms of hypercortisolism are ubiquitous and diverse; nearly every organ in the body is affected (Table 56.1). Progressive weight gain is the most common symptom. Obesity is usually truncal. Patients have thin extremities due to muscle wasting. Increased fat in the dorsal neck region combined with kyphosis secondary to osteo-

TABLE 56.1. Signs and Symptoms of hypercortisolism (Cushing's syndrome).

Weight gain
Truncal obesity
Muscle wasting
Osteoporosis
Buffalo hump
Hypertension
Facial rounding
Striae
Hirsutism
Type 2 diabetes mellitus
Menstrual irregularity
Impotency
Dilated blood vessels
Thinning subcutaneous tissue on face
Depression to psychosis
Opportunistic infections

porosis gives the appearance of a "buffalo hump." Serial photographs show a rounding of the face. Blood pressure increases mildly. Striae are reliable clinical signs of Cushing's syndrome. Hirsutism consists of excessive fine hair on face, upper back, and arms. Virilization, including clitoromegaly, deep voice, and balding, suggest carcinoma. Glucose intolerance and hyperglycemia are common, and patients develop type 2 diabetes mellitus. Weakness secondary to muscle atrophy occurs, especially in ectopic ACTH syndrome. Menstrual irregularity or amenorrhea is common in women, whereas men have impotency. In children, the most common presenting signs are obesity and short stature. Dilatation of blood vessels and thinning of the subcutaneous tissue give the face a ruddy appearance. Mental changes vary from mild depression to severe psychosis. Hypokalemia exacerbates the weakness and implies carcinoma or ectopic ACTH syndrome. Immunosuppression associated with hypercortisolemia results in opportunistic infections, including cryptococcosis, aspergillosis, nocardiosis, *Pneumocystis carinii*, and necrotizing fasciitis.

The first diagnostic goal is to unequivocally establish the presence of hypercortisolism (Table 56.2). The next step is to exclude the pituitary as a cause, and the final step is to determine the exact etiology. Urinary excretion of free cortisol is directly proportional to the amount of cortisol in the plasma. Determination of 24-hour urinary free cortisol excretion is the single best test to diagnose hypercortisolism. However, some (5%) patients with mild Cushing's syndrome have been

TABLE 56.2. Workup of Cushing's syndrome.

Step	Goal	Method
1	Diagnose hypercortisolism	24-h urine free cortisol Low-dose dexamethasone
2	Rule out pituitary cause	High-dose dexamethasone MRI of sella Petrosal sinus sampling
3	Find tumor	CT or MRI adrenals Chest CT (ectopic ACTH)

ACTH, adrenocorticotropic hormone.

found to have normal levels of urinary free cortisol. The overnight single-dose (low-dose) dexamethasone test works because patients with hypercortisolism fail to suppress cortisol secretion with low-dose dexamethasone. Normal subjects given 1 mg dexamethasone orally at 11:00 P.M. have plasma cortisol levels less than 5 µg/dL at 8:00 A.M. the next day. Patients with endogenous hypercortisolism do not suppress and have cortisol levels greater than 5 µg/dL. A normal low-dose dexamethasone test and urinary free cortisol (less than 100 µg/day) exclude the diagnosis of hypercortisolism. The standard high-dose dexamethasone suppression test is the most useful test in excluding the pituitary as the cause of hypercortisolism. The expected results are that high-dose dexamethasone (8 mg/day) suppresses urinary levels of free cortisol to less than 50% of baseline levels in patients with pituitary-dependent hypercortisolism (Cushing's disease), but not patients with primary adrenal tumors or ectopic ACTH syndrome. This test diagnoses Cushing's syndrome and determines the cause with an accuracy rate of approximately 95%.

Adrenal computed tomography (CT) can detect normal adrenal glands in most patients. CT can reliably distinguish cortical hyperplasia from tumor. CT has great sensitivity (more than 95%); however, it lacks specificity. CT can be used to image the primary tumor plus local and distant metastases in cancer. Magnetic resonance imaging (MRI) is able to distinguish among adenoma, carcinoma, and pheochromocytoma. Signal loss on chemical shift MRI occurs in adrenal cortical cancer.⁹ In a recent study of 204 patients with adrenal masses, the sensitivity of MRI for distinguishing benign from malignant masses was 89%, specificity was 99%, and accuracy was 94%.¹⁰ Fluorodeoxyglucose-positron emission tomography (FDG-PET) has been studied in 10 patients with adrenal cortical cancer. The sensitivity was 100% and the specificity was 95%. In 3 patients, previously unidentified lesions were seen that modified the treatment plan.¹¹

Conn's Syndrome

An aldosteronoma is a benign adrenal cortical tumor that secretes excessive amounts of aldosterone. Primary aldosteronism is caused by an aldosterone-producing adenoma, idiopathic hyperplasia, or carcinoma. Secondary aldosteronism, which occurs with renal artery stenosis, is diagnosed by an increase in plasma renin activity, whereas primary has low plasma renin levels. Hypertension, hypokalemia, hyperaldosteronism, and decreased plasma renin levels are essential for the diagnosis of primary aldosteronism. Primary hyperaldosteronism is also associated with weakness, muscle cramps, polyuria, and polydipsia. These clinical signs are caused by hypokalemia (K less than 3.5 mEq/L). Hypertension is usually not severe and is mostly diastolic (diastolic pressure more than 90 mmHg) (Table 56.3).

Once the diagnosis of primary aldosteronism is established, the next important consideration is the etiology: hyperplasia versus adenoma. CT can image approximately 90% of aldosteronomas but may miss small tumors (Figure 56.1). The contralateral adrenal cortex is thin. Iodocholesterol scans with ¹³¹I-β-iodomethyl-19-norcholesterol can distinguish between adenoma and hyperplasia. Hyperplasia has symmetrical uptake in both adrenal glands and adenoma has uptake only in the tumor.¹² If the results are inconclusive, sampling of the adrenal veins for aldosterone is indicated.

TABLE 56.3. Diagnosis and localization of hyperaldosteronism.

Step	Goal	Method
1	Diagnose primary hyperaldosteronism	Measure serum K Blood pressure Serum aldosterone and renin
2	Adenoma vs. hyperplasia (IAH)	CT Iodocholesterol scan Adrenal venous sampling
3	Management Adenoma IAH	Laparoscopic adrenalectomy Spironolactone

IAH, idiopathic adrenal hyperplasia.

Adrenal venous sampling may be more sensitive than CT and iodocholesterol scans. However, the latter studies usually make the diagnosis.

The management of primary aldosteronism depends on the etiology. Hyperplasia is best managed medically with spironolactone, amiloride or nifedipine. Aldosteronomas are best removed by laparoscopic adrenalectomy, which is associated with less pain and more rapid recovery than open procedures. Aldosterone-producing carcinomas are rare (less than 2% of adrenal cancers) and should be removed by open adrenalectomy.

Incidentaloma

An incidentaloma is an incidental adrenal mass detected by CT. It occurs in 0.6% of abdominal CT scans. The majority are benign adrenal cortical adenomas. Cancer occurs in 7%. Two diagnostic questions arise with incidentalomas. Is it cancer? Does it secrete excessive hormones? If either answer is yes, surgery is indicated (Figure 56.2).

The initial workup of incidentalomas requires a careful history and physical examination, including blood pressure. Weight gain, weakness, signs of hypercortisolism, hypertension, virilization, feminization, change in menstruation, and evidence of occult malignancy (stool guaiac, Pap smear, anemia) should all be noted. Laboratory evaluation consists of a serum potassium level, 24-hour urine collection for free

cortisol, vanil-mandelic acid (VMA), metanephrines, and catecholamines. A low-dose dexamethasone suppression test is indicated, in addition to urinary free cortisol, to rule out hypercortisolism.¹³ Some patients have normal urinary levels of free cortisol and fail to suppress with low-dose dexamethasone. Similarly, plasma free metanephrines and normetanephrine levels are indicated in addition to urinary catecholamines to exclude a pheochromocytoma.¹³ Hormonal screening for an excess of androgens or estrogens is limited to patients with clinical signs.

Size of an adrenal mass is the single most important criteria for malignancy. Adrenal cancers are generally greater than 6 cm in diameter. Nevertheless, a smaller lesion should not be totally ignored. Most recently, because of decreased morbidity with laparoscopic adrenalectomy, experts have advocated resection for 4-cm incidentalomas, especially in younger patients.¹³

Fine-needle aspiration for cytology of an adrenal mass has limited ability to differentiate benign from malignant primary adrenal lesions. Fine-needle aspiration (FNA) may be catastrophic in a patient with an unsuspected pheochromocytoma, so plasma metanephrine and normetanephrine results are required before needle biopsy. FNA may be complicated by hemorrhage and rupture of tumor. In patients with suspected metastatic disease to the adrenal or lymphoma, FNA is diagnostic.¹⁴

Biochemical assessment should be performed to exclude hormonal function of the tumor. Excessive hormonal secretion (catecholamines, aldosterone, cortisol, sex steroids) is an indication for resection. The size of the tumor is assessed. Size greater than 4 cm is an indication for surgical resection. The incidence of cancer in solid adrenal masses equal to 6 cm is estimated to be between 35% and 98%. Laparoscopic excision of tumors smaller than 6 cm in size is recommended because of less pain and morbidity. Laparoscopic excision of large adrenal tumors (greater than 6 cm) is not recommended because a high proportion of these tumors are malignant. If the mass is smaller than 4 cm and nonfunctional, a repeat follow-up CT examination in 3 to 6 months is indicated to again determine size. If size increases, surgical excision is necessary.

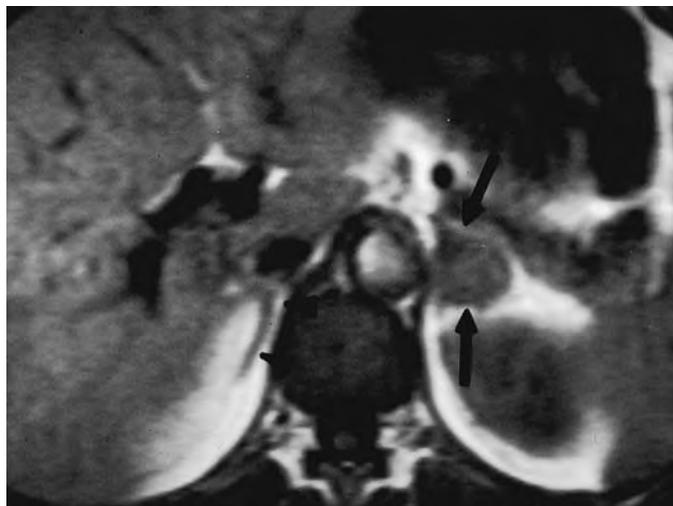

FIGURE 56.1. Computed tomography (CT) of left adrenal aldosteronoma shows a normal right adrenal gland and a small (2-cm) tumor in the left adrenal that was an aldosteronoma.

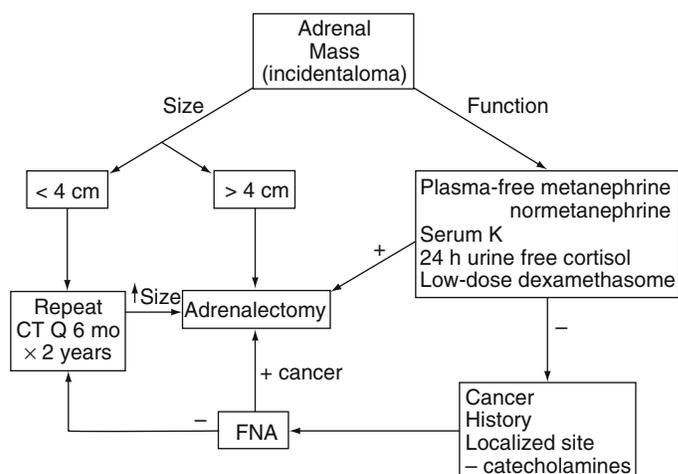

FIGURE 56.2. Flow chart for the management of incidentally discovered adrenal tumors.

TABLE 56.4. Staging of adrenal cancer.

Stage	Tumor size (cm)	Lymph nodes	Local invasion	Distant metastases	Five-year survival (%)
1	Less than 5	–	–	–	More than 80
2	More than 5	–	–	–	50–75
3	Any	+	+	–	50
4	Any	+	+	+	10

Virilization/Feminization

Virilization or feminization may be combined with hypercortisolism, or the tumor may produce only estrogen or testosterone. Sex hormone secretion is often associated with adrenal cancer. In children, the clinical signs of increased androgen production include excessive growth, premature pubic and facial hair, acne, genital enlargement, increased muscle mass, and deep voice. In women, the clinical signs of excess androgen production include hirsutism, acne, amenorrhea, infertility, increased muscle mass, deep voice, and temporal balding. In adult men, hyperestrogenism presents with gynecomastia, decreased sexual drive, impotence, and infertility. In premenopausal women, hyperestrogenism presents with irregular menses. In postmenopausal women, it causes dysfunctional uterine bleeding. The workup includes 24-hour urinary 17-ketosteroids, 17-hydroxysteroids, urinary free cortisol, and, depending on virilization or feminization, serum determination of testosterone or estrogen.

Adrenal Carcinoma

Seventy-five percent of adrenal carcinomas present with excessive glucocorticoid or mineralocorticoid hormone secretion; however, some may be nonfunctional.¹⁵ The mainstay of treatment of adrenal cortical carcinoma is complete surgical resection. If the carcinoma cannot be effectively removed without removing the ipsilateral kidney, concomitant nephrectomy is necessary. CT or MR can image the extent of disease and should include the chest to rule out pulmonary metastases. If the inferior vena cava is involved, imaging studies such as cavography are useful to assess extent of tumor. Tumor size, hemorrhage, and mitotic count each correlate with survival rates for patients undergoing curative resection. Tumors less than 12 cm, mitotic rate less than 6 per high-power field, and absence of hemorrhage are associated with improved survival.¹⁶ Radical, complete resection of all cancer is critical for prolonged survival and potential cure. There is no clearly effective adjuvant therapy.¹⁷ Recurrent or metastatic tumor should also be resected. Recent reports suggest that radiofrequency ablation may be able to control recurrent tumor both inside and outside the liver.¹⁸

Adrenal carcinoma may occur in children. It occurs in children younger than 6 years, with a higher incidence in girls than boys. The median age in children is 4 years. Virilization is the most common presenting feature (93%), followed by hypercortisolism.¹⁹ The overall 5-year survival rate for children with adrenal cancer is 49%, and following complete resection 70%. Adrenal cancer occurs in adults. The second peak age is between 40 and 50 years, and most present with hormonal syndromes. The staging of patients with adrenal carcinoma is as follows: 20% of patients have stage I, II, and III disease at diagnosis, whereas 80% have metastases²⁰ (Table 56.4). Many

patients (70%) present with stage III or IV disease. The definitive treatment for localized disease including stage III is en bloc resection. Even tumor thrombus within the inferior vena cava is not a contraindication to resection.²¹ Surgical resection of localized disease can be curative. The overall 5-year survival rate is between 20% and 35%. In a recent series, the 6-year survival following complete resection of all tumor is 60%.²² Complete resection of recurrent tumor is also useful and, if achieved, it is associated with a 6-year survival of 40%.^{23,24} Patients should undergo monitoring of steroid hormone levels postoperatively to assess for recurrence. CT and MRI are also able to detect local recurrences and pulmonary metastases. If a localized recurrence is detected, it should be removed surgically. Prolonged remissions have been reported after resection of hepatic, pulmonary, and cerebral metastases. Patients with recurrent adrenal cortical carcinoma who can be surgically resected have 5-year survival rates of 50% versus 8% for non-operated cases. Control of recurrent tumor can be achieved by radiofrequency ablation.¹⁸ Palliation of bony metastases may be achieved by radiation therapy.

Op-DDD (mitotane) is the most commonly used chemotherapy drug for adrenal cancer (Table 56.5). It is administered at a dose of 2 to 6 g daily, and the dose is increased until toxicity occurs. Toxicity includes gastrointestinal, neuromuscular, and skin symptoms. Mitotane prolongs bleeding time and inhibits platelet aggregation. A decrease in urinary steroid excretion is seen in most patients. Partial responses occur in one-third of patients and a few complete responses have been reported. Because mitotane inhibits the multidrug-resistant gene, chemotherapy has been given with mitotane. Patients with metastatic adrenal cortical carcinoma have been given etoposide, cisplatin, and mitotane. The response rate was 33% with some complete responses. Further, when combined with etoposide, doxorubicin, and cisplatin, it had an overall response rate of 22% to 54%.^{24,25} Docetaxel and gemcitabine failed to demonstrate a response in 2 patients treated.²⁶ Irinotecan (CPT-11) at 250mg/m² has been ineffective in 12 patients with metastatic adrenal cortical carcinoma who failed other therapies.²⁷

TABLE 56.5. Chemotherapy for adrenal cancer.

Drug	Response rate (%)
Mitotane	30–60
Suramin	15–30
Doxorubicin	19
5-Fluorouracil (5-FU) + doxorubicin + cisplatin	20
Etoposide + doxorubicin + cisplatin	100 (3/3)
Oncovin + cisplatin + epipodophyllotoxin	100 (1/1)
Mitotane + etoposide + doxorubicin + cisplatin	50

Pheochromocytoma

Pheochromocytomas are rare tumors that secrete excessive catecholamines. They arise from chromaffin cells in the adrenal medulla and elsewhere. They occur in about 1 per 100,000 per year.²⁸ In autopsy series, only 0.005% to 0.1% of persons have unsuspected pheochromocytomas. When urinary catecholamines are measured in hypertensive patients, pheochromocytoma is present in only 0.1% of patients.

Pheochromocytomas may be intraadrenal, extraadrenal, benign, or malignant. Early diagnosis and therapy improve the prognosis. Incidence of malignancy is as low as 5% and as high as 46% in different series. Extraadrenal tumors are more likely to be cancerous. Pheochromocytomas may be associated with endocrine and nonendocrine inherited disorders. Bilateral adrenal medullary pheochromocytomas are components of MEN 2a and MEN 2b. Some families have bilateral adrenal pheochromocytomas and no other manifestation of MEN. In other families, only extraadrenal pheochromocytomas have been reported. Pheochromocytomas occur in approximately 25% of patients with von Hippel-Lindau (VHL) disease and in 1% of patients with neurofibromatosis and von Recklinghausen's disease. Further, recent studies indicate that many patients with apparently sporadic pheochromocytomas really have either MEN-2 (RET gene) or VHL. Among 271 patients, 66 (24%) were found to have mutations of VHL and RET. This finding suggests that patients who present with apparently sporadic nonfamilial pheochromocytoma should be screened for RET and VHL mutations as 25% will have them.²⁹ Germ-line mutations in three of the succinate dehydrogenase subunits (SDHD, SDHB, and SDHC) cause susceptibility to head and neck paragangliomas (extraadrenal pheochromocytomas).^{30,31}

Pheochromocytomas cause intermittent, episodic, or sustained hypertension. Pheochromocytomas also cause insulin resistance and diabetes.³² Following resection of the tumor, insulin sensitivity improves.³³ Further, pheochromocytomas may produce other hormones, including ectopic ACTH and Cushing's syndrome. Pheochromocytomas arise from chromaffin cells. Chromaffin cells are widespread and associated with sympathetic ganglia during fetal life. After birth, most chromaffin cells degenerate, and the majority remain in the adrenal medulla; this may explain why approximately 90% of pheochromocytomas are in the adrenal medulla. Extraadrenal pheochromocytomas may arise anywhere, including the carotid body, intracardia, along the aorta (both thoracic and abdominal), and within the urinary bladder. The most common extraadrenal location is the organ of Zuckerkandl that is near the origin of the inferior mesenteric artery to the left of the aortic bifurcation. Data from series of patients with sporadic pheochromocytomas indicate that the right adrenal gland more often harbors a tumor than the left gland. Pheochromocytomas usually measure between 3 and 5 cm in diameter and weigh 100 g. Tumors are tan to gray in color and have a soft consistency. Larger tumors are cystic and have necrosis or calcification. Microscopically, pheochromocytomas are usually arranged in cords or alveolar patterns. Tumors are generally clearly separated from the adrenal cortex by a thin band of fibrous tissue. Extension into the cortex or vascular invasion may occur.

TABLE 56.6. Management of patients with pheochromocytoma.

Step	Goal	Method
1	Diagnosis	24-h urine for vanil-mandelic acid (VMA), metanephrines, and catecholamines: plasma free metanephrine, normetanephrine
2	Localization	CT MRI Metaiodobenzylguanidine (MIBG) scan
3	Preparation	Phenoxybenzamine ± propranolol
4	Resection	Laparoscopic adrenalectomy (open for extraadrenal and/or large tumor)
5	Recurrence	Plasma-free metanephrine, normetanephrine

The pathologic distinction between benign and malignant pheochromocytomas is not clear. The only absolute criterion for malignancy is the presence of secondary tumors in sites where chromaffin cells are not usually present and visceral metastases. Malignant tumors tend to be larger and weigh more. Staining for the nuclear proliferation marker MIB-1 is positive in 50% of malignant pheochromocytomas and negative in benign tumors. Benign pheochromocytomas may demonstrate marked nuclear pleomorphism, whereas, paradoxically, malignant ones demonstrate less. Malignant pheochromocytomas usually have many more mitoses, but capsular and vascular invasion occurs with equal frequency in both. Nuclear DNA ploidy may be a predictive indicator of malignant potential. Flow cytometry has been used to identify tetraploidy, polyploidy, and aneuploidy, which are associated with malignancy. Neuropeptide Y gene expression is more common in benign tumors.

Patients with pheochromocytomas can present with a range of symptoms, from mild labile hypertension to sudden death secondary to severe hypertension, myocardial infarction, or cerebral vascular accident. The classic patient describes "spells" of paroxysmal headaches, pallor, palpitations, hypertension, and diaphoresis. In 50% of patients, the hypertension is intermittent, but it may be sustained. In children, hypertension is sustained. Patients may have lactic acidosis. Patients may have weight loss and hyperglycemia.

The diagnosis of pheochromocytoma is based on measuring catecholamines and metabolites in the urine (Table 56.6), which previously required a 24-hour urine for metanephrines and catecholamines.³⁴ However, plasma free metanephrines and normetanephrines have been used recently to reliably diagnose pheochromocytoma.³⁵ Certainly the blood measurement greatly facilitates the workup, and it is accurate. Measurements of urinary total metanephrines or VMA are not as reliable as plasma free levels of metanephrines and normetanephrine.³⁶ If a pheochromocytoma is suspected, the best study is plasma free levels of metanephrine and normetanephrine.³⁷ Older studies suggest that urinary measurement of catecholamines, VMA, and metanephrine levels are best. It is now clear that plasma free samples have replaced urinary studies as indicated in patients with suspected pheochromocytoma.

CT and MRI are the two nonnuclear medicine procedures of choice to localize pheochromocytomas. Both are noninvasive and sensitive, being able to reliably detect tumors 1 cm in diameter. MRI may be more specific because of findings with different sequences. CT detects more than 95% of

pheochromocytomas, including 9 of 10 bilateral tumors. CT also detects most extraadrenal retroperitoneal tumors. However, MRI is similar and may be better. MRI also imaged all pheochromocytomas demonstrated on CT, plus metastases to the chest, retroperitoneum, and liver that were not seen. Because it has no radiation exposure, MRI can be used to image during pregnancy. In one analysis, CT imaged 16 of 19 pheochromocytomas (84%) whereas MRI imaged 12 of 15 (75%) for comparable sensitivity.³⁸ In addition, MRI successfully imaged an intrapericardial pheochromocytoma and distinguished it from the cardiac chambers and surrounding great vessels, which could not be determined by CT.

The single best technique for localization of pheochromocytomas is nuclear scanning after the administration of labeled metaiodobenzylguanidine (MIBG). The compound is similar to norepinephrine and is taken up by vesicular monoamine transporters.³⁹ The sensitivity of MIBG scanning with ¹³¹I for pheochromocytoma is 100% and the specificity is 95%.⁴⁰ It appears that MIBG scanning is safe, noninvasive, and efficacious for the localization of pheochromocytomas, including those that arise in nonadrenal sites, and malignant disease. Bone metastases are best imaged by bone scan. Because MIBG scan is a total body study, it can image tumors wherever they are including unusual locations.⁴⁰ Although CT and MRI reflect changes in morphology, scintigraphic imaging relies on tissue function. False-positive results with MIBG are rare, which accounts for the high specificity (98% to 100%). False-negative results do occur, which lowers sensitivity. For patients with suspected pheochromocytoma and negative MIBG, ¹⁸F-FDG PET may be useful. Metastases from a predominantly dopamine-secreting pheochromocytoma that did not take up MIBG were imaged with FDG-PET.⁴¹ Further, ¹⁸F-DOPA PET has imaged 17 pheochromocytomas in 17 patients. It is highly sensitive and specific and may be very useful if other studies are negative.⁴¹ It has imaged a malignant bladder pheochromocytoma.⁴² It may be superior to MIBG for localization of metastatic pheochromocytoma.⁴³ It is not commonly available, but it can be useful.⁴⁴

Once the diagnosis is established and the tumor localized, preoperative preparation includes α -adrenergic blockade. Patients are started on phenoxybenzamine, 10mg orally two or three times daily. If tachycardia develops, α -adrenergic blocking agents (propranolol) are added. Propranolol should never be started before α -blockade because unopposed vasoconstriction may worsen hypertension. Phenoxybenzamine increases the total blood and plasma volume and reduces lactic acidosis. Appropriately used calcium channel antagonists and selective α_1 -receptor blockers are also effective and safe.⁴⁵

Small (less than 6cm) intraadrenal pheochromocytomas are removed using laparoscopic techniques.⁴⁶ However, others report that laparoscopic adrenalectomy should still be performed for large tumors (greater than 6cm). They point out that the operative time, blood loss, and length of stay are the same for either small or large adrenal tumors.^{47,48} Laparoscopic procedures appear to decrease pain and shorten the time to recovery.⁴⁹ Most pheochromocytomas are well localized, which facilitates laparoscopic removal. Laparoscopic adrenalectomy for familial pheochromocytomas is especially useful because these tumors are small and within the adrenal gland.⁵⁰ Adrenal cortical-sparing surgery may be indicated for patients with familial pheochromocytomas who require bilat-

eral adrenalectomy.⁵¹ However, iatrogenic pheochromocytomatosis has been described as a possible complication of laparoscopic removal. Numerous tumor cells are deposited throughout the retroperitoneum near the site of the primary tumor, which may have been caused by laparoscopic excision of a malignant tumor or by spilling benign tumor cells at the time of laparoscopic excision. Despite the exact etiology, this is a rare complication that must be considered if it continues to occur.⁵²

Malignant pheochromocytomas are present in approximately 10% of patients with pheochromocytoma. Malignant tumors have high mitotic rate, aneuploidy and high S-phase fraction.⁵³ EM66 is a novel secretogranin II-derived peptide that is present in the chromaffin cells of the human adrenal gland. EM66 has a higher concentrations in benign pheochromocytomas than malignant tumors.⁵⁴ Expression of hTERT, HSP90, and telomerase activity may also be used to detect more-aggressive tumors.⁵⁵ SDHB gene is a tumor suppressor gene. Detection of a germ-line SDHB mutation in patients with apparently sporadic pheochromocytomas appears to be associated with a tumor that is high risk for malignancy and recurrence.⁵⁶

The basic principles in the treatment of malignant pheochromocytoma have been to surgically resect recurrences or metastases whenever possible and to treat hypertensive symptoms by catecholamine blockade. Surgical resection of metastatic and recurrent pheochromocytoma has been shown to prolong survival. Soft tissue masses or bony masses may be treated with radiation therapy if doses of 40Gy or more can be administered.⁵⁷ Serum levels of chromogranin A can be used to measure response to therapy.⁵⁸ Survival data of patients with malignant pheochromocytoma are difficult to obtain because of the rarity and indolence of the tumor. The 5-year survival rate is between 36% and 60%.

Because of the high sensitivity (85%) and specificity (100%) of ¹³¹I-MIBG to image pheochromocytomas, it has been used at higher doses to treat recurrent or metastatic pheochromocytomas. A beneficial response to treatment is observed in 42% to 60% of patients. Paedial remissions as measured by decrease in catecholamine secretion and tumor size have been observed in approximately one-third of patients treated. However, complete responses with ¹³¹I-MIBG have been rare.⁵⁹ Recently, very high dose (800 mCi) ¹³¹I-MIBG resulted in complete antitumor responses in 2 of 12 patients with skeletal and soft tissue metastases from pheochromocytoma and partial responses in most.⁶⁰

Combinations of cyclophosphamide, vincristine, and dacarbazine have been used in patients with metastatic pheochromocytoma. However, the regimen has been abandoned because of toxicity and variability in response rate with few complete responses. Single cases have been reported to have complete responses with cyclophosphamide, vincristine, and dacarbazine (CVD). Long-acting octreotide (sandostatin-LAR) has been used to treat malignant pheochromocytoma without success. Even tumors that were positive on octreoscan did not respond to LAR.⁶¹ Combination chemotherapy with cyclophosphamide, vincristine, dacarbazine, doxorubicin, and epirubicin resulted in a complete response in a single patient with metastatic pheochromocytoma.⁶²

Pancreatic Islet Cell Tumors

Endocrine tumors of the pancreas are classified primarily according to the associated clinical syndrome.⁶³ Signs and symptoms are caused by uncontrolled excessive secretion of hormone. For example, patients with insulinoma have altered mental status, confusion, seizures, and other neuroglycopenic symptoms related to hypoglycemia caused by excessive uncontrolled insulin secretion.⁶⁴ Pancreatic endocrine tumors share a number of common features including similar microscopic appearance, hormonal symptoms, special issues in patients with multiple endocrine neoplasia type 1,⁶⁵ and malignant growth affecting survival. Pancreatic endocrine tumors are usually slow growing, and even patients with extensive tumor may still live for long periods. However, if liver metastases occur, survival will be affected by the malignant nature of the tumor. Effective treatment must address the symptoms associated with the clinical syndrome and the malignant potential of the tumor.

Epidemiology

Endocrine tumors of the pancreas are rare, having an incidence of less than 10 per million people per year.⁶³ Insulinomas are the most common islet cell tumor with a prevalence of approximately 1 per million per year, and gastrinomas are a close second. The remaining islet cell tumors are less common.

Pathology

Pancreatic neuroendocrine tumors arise from cells that have been termed APUDomas (APUD means amine precursor uptake and decarboxylation). Pancreatic neuroendocrine tumors are composed of monotonous sheets of small round cells with uniform nuclei and cytoplasm. Mitotic figures are unusual. Tumors have dense secretory granules. When stained by immunohistochemistry, most pancreatic neuroendocrine tumors are positive for more than one hormone. However, in most instances only one peptide is secreted into the circulation. Pancreatic neuroendocrine tumors are hypervascular, solid, and reddish-brown in color. They occur not only within the pancreas as they have been described in ectopic pancreas tissue.⁶⁶ They are usually solid, but cystic and papillary insulinomas have been described.⁶⁷ Neuroendocrine tumors may have a "rhabdoid" appearance, which means sheets of monotonous tumor cells with uniform round nuclei.⁶⁸ Tumors may be caused by mutations of the tumor suppressor gene *DPC4* located on chromosome 18q21 that have been found in 5 of 9 (55%) nonfunctional pancreatic neuroendocrine tumors.⁶⁹ X-chromosome loss of heterozygosity is common in gastrinomas from women, and its presence indicates more-aggressive growth and behavior.⁷⁰ Aberrant methylation of the *APC* promoter is strongly involved in the molecular pathogenesis of pancreatic neuroendocrine tumors.⁷¹ *Raf-1* activation causes morphologic changes and decrease in secretory granules.⁷² One study showed that methylation of the *p16^{INK4a}* gene is the most common gene alteration in gastrinomas, and it appears to occur early in the time sequence of these tumors and may be a central process in the molecular pathogenesis.⁷³

In general, microscopic pathologic analysis of pancreatic endocrine tumors has failed to predict the growth pattern of the tumor and is not able to determine whether a tumor is benign or malignant. In addition, there is no correlation between histologic pattern and clinical syndrome. At present, the only clear determination of malignancy is detection of metastases, either in lymph nodes or liver. However, lymph node metastases do not negatively affect survival, whereas liver metastases clearly do.⁷⁴ Microscopic invasion of blood vessels and surrounding pancreas is another indicator of malignancy, but it is not as precise as the detection of distant metastatic disease. Because of this, it is unclear exactly which pancreatic neuroendocrine tumors are malignant. The true nature of an individual tumor can only be determined by careful long-term follow-up studies. In general, few (less than 10%) insulinomas are cancerous,⁷⁵ 60% of gastrinomas are malignant (lymph node or liver metastases),⁷⁶ and the majority (50% to 90%) of all other islet cell tumors are malignant. Neuroendocrine tumors of the gut are similar and have a similar prognosis. Five-year survival rates for localized neuroendocrine tumors are approximately 80% or greater, whereas for metastatic tumors the rates decrease to 50%.⁷⁷ Survival of patients with pancreatic neuroendocrine tumors has been shown to decrease when liver metastases occur. However, surgical excision of liver tumors has salvaged some patients and improved prognosis.⁷⁸

Functional (hormone-producing) pancreatic neuroendocrine tumors are usually malignant (except for insulinomas), but patients have an excellent survival. Most patients who undergo surgery to remove tumor have a 5-year survival of more than 75%.⁷⁹ Nonfunctional pancreatic neuroendocrine tumors commonly present as a pancreatic mass lesion. These tumors may be detected incidentally on CT scan ordered for another reason (Figure 56.3). They may cause intestinal bleeding if they invade into the bowel or stomach or they obstruct the splenic vein and cause gastric varices. They may cause gastrointestinal obstruction if they obliterate the lumen of the small bowel or colon. Nonfunctional tumors are distributed evenly throughout the head, body, and tail of the pancreas. The 2-year survival for surgically removed node-negative nonfunctional pancreatic neuroendocrine tumor (NET) is 78%, for node-positive tumors is 72%,

FIGURE 56.3. CT of a large nonfunctional pancreatic neuroendocrine tumor within the head.

and for liver metastases is 36%.⁸⁰ Pancreatic neuroendocrine tumors do not usually obstruct the pancreatic duct, but they can be a cause of focal, recurrent pancreatitis.^{81,82} The size of an individual islet cell tumor does not appear to correlate with the severity of the hormonally mediated symptoms. There is, however, a clear correlation between the size of the tumor and the occurrence of malignancy; the larger the tumor, the greater the probability of metastases, especially liver metastases. Insulinomas, similar to duodenal gastrinomas, are generally small tumors, less than 2 cm. However, duodenal gastrinomas still have a 60% chance of nodal metastases, whereas small insulinomas seldom spread. Glucagonomas, somatostatinomas, pancreatic polypeptidomas, and other islet cell tumors are frequently large at the time of detection, more than 5 cm, and are usually malignant. Most pancreatic endocrine tumors are solitary, encapsulated, and within the pancreas. However, islet cell tumors may also occur in the duodenum and other extrapancreatic locations. Primary gastrinomas have been described within the duodenum (Figure 56.4), pancreas, heart, liver, stomach, and ovary. When metastases occur, they are usually found in peripancreatic lymph nodes (60%) or liver (30%). Late in the course of disease, tumor spreads to lung, bone, and even heart.

Pancreatic endocrine tumors occur in either a nonfamilial (sporadic) form or in a familial form associated with multiple endocrine neoplasia type 1 (see section on MEN-1). The exact proportion of patients with pancreatic islet cell tumors who manifest MEN-1 varies in different series from less than 5% to 25%. The recognition of MEN-1 syndrome is impor-

tant because these patients always have multiple pancreatic neuroendocrine tumors. Furthermore, screening of other family members is indicated. Finally, the presence of one hormonal abnormality in MEN-1 patients may affect another. Primary hyperparathyroidism worsens the manifestations of Zollinger–Ellison syndrome and should be corrected first. Functional islet cell tumors are the second most frequent abnormality in MEN-1 and are present in approximately 80% of individuals. Gastrinomas, insulinomas, glucagonomas, and vasoactive intestinal peptide tumors (VIPomas) occur in decreasing prevalence in MEN-1 patients with gastrinomas in 54% and insulinomas in 20%. In addition to MEN-1, studies suggest that pancreatic islet cell tumors are found more commonly in patients with von Recklinghausen's disease, von Hippel–Lindau syndrome, and tuberous sclerosis. In patients with von Recklinghausen's disease, duodenal somatostatinomas and gastrinomas have been reported. In patients with von Hippel–Lindau syndrome, 17% of patients have pancreatic endocrine tumors, including both adenomas and carcinomas. However, it is unusual for these tumors to be functional and few have a clinical hormonal syndrome. Patients with tuberous sclerosis have insulinomas and nonfunctional pancreatic islet cell tumors.

Specific Islet Cell Tumors

Insulinomas occur in the pancreas and are evenly distributed among the head, body, and tail.⁷⁵ Insulinomas are most often benign, but they can metastasize and be malignant.⁸³ Glucagonomas also occur within the pancreas (Table 56.7). In contrast, primary gastrinomas usually occur within the duodenum (50%), and the second most common site is the pancreas (20%–40%). Further, approximately 80% to 85% of primary gastrinomas are found within the gastrinoma triangle, an area that includes the head of the pancreas and the duodenum.⁸⁴ Vasoactive intestinal peptide-secreting tumors (VIPomas) are usually in the pancreas, but they may also occur within the duodenum. Somatostatinomas are commonly in the pancreas, but may be extrapancreatic. In a recent review of 48 primary somatostatinomas, 56% were in the pancreas and 44% were in the duodenum or jejunum. Similar to glucagonomas, somatostatinomas usually are large, greater than 5 cm, and metastases are present at the time of diagnosis.⁸⁵

Patients with insulinoma or gastrinoma have symptoms of hypoglycemia and ulcer diathesis with or without diarrhea, respectively. The diagnosis is established biochemically based on the results of standardized tests. Insulinoma is diagnosed by a 72-hour fast with the development of neuroglycopenic symptoms. Insulinoma is proven by hypoglycemia (glucose less than 45 mg/dL) and hyperinsulinism (insulin more than 5 μ U/mL). Close supervision is necessary to exclude factitious hypoglycemia, use of medications to falsely decrease blood glucose levels. Zollinger–Ellison syndrome (ZES) is diagnosed by measurement of elevated fasting serum levels of gastrin (more than 100 pg/mL) and elevated levels of basal acid output (BAO greater than 15 mEq/h). All antacid medications should be discontinued during testing as these drugs may falsely elevate serum gastrin levels. The secretin stimulation test is also used to diagnose ZES; 2 U/kg of secretin is given intravenously and serum levels of gastrin are measured before and

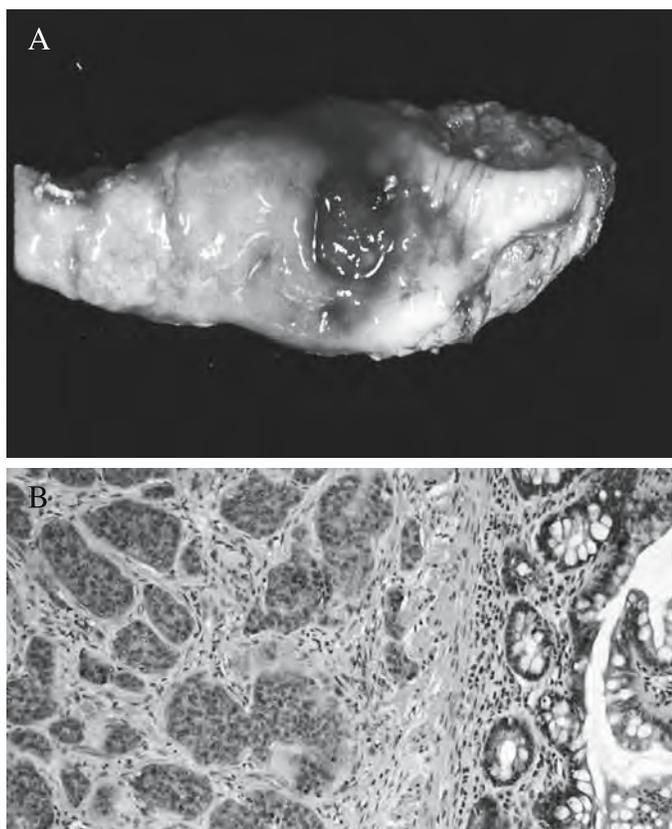

FIGURE 56.4. Gross (A) and microscopic (B) photographs of a duodenal gastrinoma.

TABLE 56.7. Pancreatic neuroendocrine tumor, incidence of multiple endocrine neoplasia (MEN)-1, diagnosis, location, and malignant potential.

<i>Tumor</i>	<i>MEN-1 (%)</i>	<i>Diagnosis</i>	<i>Location</i>	<i>Malignant (%)</i>
Insulinoma	10	Fasting glucose Insulin C-peptide Pro-insulin	Pancreas	5-0
Gastrinoma	20	Fasting gastrin Basal acid output (BAO) Secretin test	Duodenum Pancreas Extrapancreatic Extraintestinal	60
Glucagonoma	Rare	Glucagon	Pancreas	100
Somatostatinoma	Rare	Somatostatin	Pancreas Duodenum Jejunum	100
Vasoactive intestinal polypeptide-secreting tumors (VIPoma)	Rare	VIP	Pancreas Duodenum	60
Ppoma (nonfunctional tumor)	Common	Pancreatic polypeptide	Pancreas	60

after. An increase of 200 pg/mL over basal levels of gastrin is consistent with ZES.

After the diagnosis of insulinoma is made based on the results of the fast, localization studies are used to try to image and identify the insulinoma. CT correctly images approximately 50% of these tumors. In a recent study with multiphasic helical CT, 19 of 30 insulinomas were correctly identified; there were no false positives.⁸⁶ Most experts agree that multiphasic CT is the imaging study of choice for pancreatic neuroendocrine tumors. It can image all large tumors (more than 2 cm) and it images approximately 50% of tumors as small as 1 cm. Tumors appear as a blush on CT because of increased vascularity.⁸⁷ MRI localized 7 of 8 neuroendocrine tumors in one study.⁸⁸ Somatostatin receptor scintigraphy (SRS) is the imaging study of choice for all pancreatic neu-

roendocrine tumors except insulinomas (Figure 56.5). Recent studies suggest that FDG-PET may also be useful, but it is not as good as SRS.⁸⁹ SRS is generally believed to be inaccurate for the localization of insulinomas compared to all other pancreatic neuroendocrine tumors. However, in one recent study it was able to identify most insulinomas, and when combined with endoscopic ultrasound (EUS) it correctly demonstrated 15 of 16 insulinomas.⁹⁰ EUS is able to identify most insulinomas, more preoperatively than all other studies. However, occasionally it may have false-positive results that lead to misguidance of the surgery. Pancreatic nodules and accessory spleens have been confused with insulinoma. EUS is not a substitute for careful preoperative evaluation and biochemical testing that should be done in every patient.⁹¹ EUS specificity can be improved by needle biopsy, which can be done for primary pancreatic tumors or lymph nodes⁹² (Figure 56.6). The best results are seen when one combines thin-section helical CT with EUS. In one study of 18 consecutive patients, this combination identified an insulinoma in each patient.⁹³

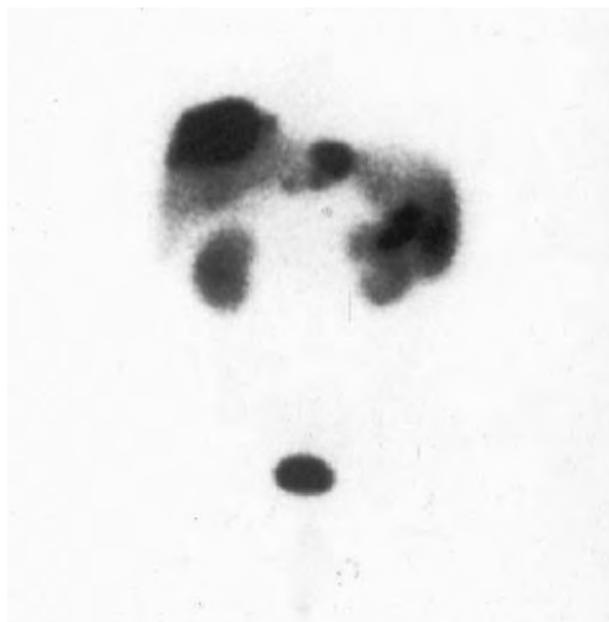

FIGURE 56.5. Somatostatin receptor scintigraphy (octreoscan) of a pancreatic tail neuroendocrine tumor with bilobar liver metastases.

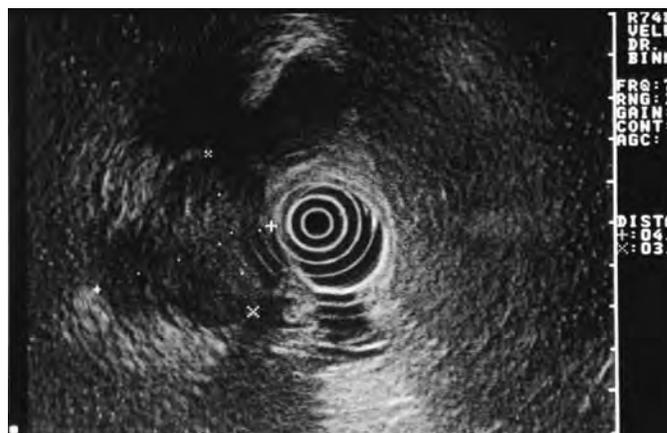

FIGURE 56.6. Endoscopic ultrasound (EUS) of a large nonfunctional neuroendocrine tumor within the head of the pancreas. During EUS, the tumor was aspirated for cells, making the diagnosis of pancreatic neuroendocrine tumor. This tumor is the same tumor seen on CT scan in Figure 56.3.

Because insulinomas are generally benign and located within the pancreas, the goal of surgery is to precisely identify the tumor and remove it preserving as much pancreas as possible. Intraoperative ultrasound has been useful for precise operative localization. It can identify the tumor and its relationship to vital structures such as the common bile duct and the pancreatic duct. It allows the surgeon to decide the best way to remove the tumor and avoid complications. A preoperative calcium angiogram has been shown to localize most (more than 90%) of insulinomas to the head, body, or tail of the pancreas.⁹⁴ Similar studies have been done with secretin injection for gastrinomas. However, recently calcium angiogram has been shown to effectively localize most gastrinomas as well.⁹⁵ Further, modern methods have allowed laparoscopic enucleation of insulinomas based on laparoscopic ultrasound done during the surgery. If it can be done, this procedure results in less pain and more rapid recovery.⁹⁶ However, similar complications such as pancreatic fistula and abscess may occur with laparoscopic pancreatic operations and must be considered. Because of this fact, the length of stay with laparoscopic surgery for NET has not been dramatically different than open operations.^{97,98}

The glucagonoma syndrome is a specific hormonally mediated clinical syndrome that includes a characteristic pruritic migratory red excoriating rash called necrolytic migratory erythema (NME), diabetes mellitus, weight loss, anemia, stomatitis, thromboembolic complications, hypoaminoacidemia, and gastrointestinal and neuropsychiatric disturbances.⁹⁹ Some patients also have evidence of tachycardia, heart failure, and a dilated cardiomyopathy.¹⁰⁰ These signs and symptoms are relieved by resection of the tumor. Infusions of zinc, amino acids, and total parenteral nutrition have each relieved the NME skin rash in certain cases.¹⁰¹ It is most likely caused by a nutritional deficiency related to chronic excess levels of glucagon. CT scan and octreoscan image most glucagonomas. PET scan images some tumors as well.¹⁰² Patients commonly have clinical manifestations of the hypercoagulable state, including pulmonary embolus and deep venous thrombosis.^{103,104}

Vasoactive intestinal polypeptide-secreting tumors (VIPoma) are rare pancreatic neuroendocrine tumors with remarkable symptoms of severe diarrhea.¹⁰⁵ Most tumors that produce VIP are found within the pancreas, but they can also be extrapancreatic. These tumors are usually malignant. Patients may have liver metastases at the time of diagnosis. MRI is the best imaging study to visualize liver neuroendocrine tumor.^{106,107} Octreoscan can also image tumor. VIPoma leads to a syndrome of watery diarrhea, hypokalemia, hypercalcemia, and achlorhydria. It is also called the Verner-Morrison syndrome or the pancreatic cholera syndrome. Dehydration, renal failure, and electrolyte and acid-base abnormalities are so severe that death may ensue if these are not corrected. Octreotide can reverse the diarrhea and correct the fluid-base disturbances and may be lifesaving in some patients. It has few side effects and can be used in the elderly without complications.¹⁰⁸ Interferon-alpha and 5-fluorouracil have been used to treat metastatic VIPoma and have resulted in a dramatic response in one patient.¹⁰⁹

Nonfunctioning pancreatic islet cell tumors are usually large (more than 5 cm), and symptoms are related to tumor mass. Patients may present with incidentally imaged pan-

atic neuroendocrine tumor seen on a CT done for another reason. They may have intestinal bleeding or obstruction or pain. Other less-common functioning islet cell tumors such as those associated with acromegaly (GRFoma), hypercalcemia, or ectopic ACTH production are usually quite large, with liver metastases at diagnosis. Recently, a ghrelin-producing pancreatic neuroendocrine tumor was described. It was not associated with clinical features of acromegaly.¹¹⁰

Radiologic Imaging

Despite the fact that there are numerous studies to image pancreatic neuroendocrine tumors, some patients will still have no imageable tumor. CT has been an excellent study for identifying large tumors within the pancreas and liver. It can reliably visualize tumors that are greater than 2 to 3 cm in diameter; however, smaller tumors may be missed. CT is indicated in all patients with suspected islet cell tumors, especially to exclude liver metastases. Multidetector CT has been able to image many neuroendocrine tumors including those within lymph nodes. When coupled with somatostatin receptor scintigraphy, it can reliably detect the majority of neuroendocrine tumors.¹¹¹ The results with MRI are similar to CT. MRI has the advantage that no radiation is used; however, it is much more expensive and is not routinely recommended unless small liver metastases are a concern. MRI correctly imaged 29 of 31 neuroendocrine tumors in 19 patients.¹¹² Somatostatin receptor scintigraphy (SRS) or octreoscan images neuroendocrine tumors based on the density of type 2 somatostatin receptors. The high density of sst2 on pancreatic neuroendocrine tumors and carcinoid tumors makes radiolabeled somatostatin analogues excellent for tumor imaging. If the tumor is imaged by these analogues, the peptide inhibits tumor growth and hormone secretion, making it useful for treatment. Studies are under way to label octreotide with other isotopes to use it for tumor cell destruction.¹¹³ It is an excellent study at identifying both primary and metastatic tumors. It has a sensitivity and specificity of approximately 85% to 90%. It is the imaging study of choice for nearly all neuroendocrine tumors except insulinomas. However, it must be realized that it may fail to identify small tumors within the duodenum. It has been combined with echo-enhanced power Doppler sonography to better image pancreatic neuroendocrine tumors.¹¹⁴

Endoscopic ultrasound is best for imaging small pancreatic islet cell tumors within the pancreas such as insulinoma. It has a sensitivity and specificity of 85% for pancreatic islet cell tumors. However, it is observer dependent and not all institutions have had excellent results. Occult insulinomas and gastrinomas can be regionally localized by calcium and/or secretin angiogram. Arteries that perfuse the pancreas are injected with an agent that causes the tumor to secrete hormone that can be measured in the hepatic vein. Calcium is used for both insulinoma and gastrinoma, whereas secretin is only for gastrinoma. These studies provide correct regional localization in approximately 90% of patients. These studies provide less information in gastrinoma, because occult tumors are generally within the gastrinoma triangle, and more information in insulinoma that are uniformly distributed throughout the entire pancreas.

Treatment

Treatment should be designed to control the signs and symptoms of excessive hormone secretion and the malignant growth and spread of the tumor. The only curative treatment is complete surgical resection of all tumor. Gastrinomas are most commonly within the duodenum. Duodenotomy (opening the duodenum) identifies more tumors and results in a greater cure rate, indicating that it should be done routinely in all operations for gastrinoma. These tumors are frequently small, most commonly found in the proximal duodenum, and associated with lymph node metastases in 60% of patients.¹¹⁵⁻¹¹⁷

Resection of primary gastrinoma has been shown to decrease the probability of liver metastases. Even localized liver metastases can be removed for apparent amelioration of symptoms and prolongation of survival.¹¹⁸ Serum levels of chromogranin A and secretory hormones can be used to assess curative resection, but minor changes in levels are not sensitive enough to assess tumor regression or progression.¹¹⁹ Repetitive imaging with CT and SRS can be used to follow tumor response to therapy. Aggressive surgery including Whipple pancreaticoduodenectomy has been performed for neuroendocrine tumors (NET) of the pancreas. However, because the prognosis is good with pancreatic neuroendocrine tumors, the operative death rate and morbidity of surgery should be acceptable. A recent report shows that the Whipple for NET had an operative mortality of 10% and a complication rate of 30%. However, the long-term survival was also excellent in that 81% and 70% were alive at 5 and 10 years, respectively.¹²⁰

Chemotherapy treatment is based on tumor differentiation. Differentiation can be assessed by octreoscan and biopsy. Well-differentiated NET are usually positive on SRS, suggesting that somatostatin analogues will be useful in treatment to inhibit both tumor growth and hormone secretion. If the SRS is negative and the tumor is poorly differentiated, chemotherapy treatment is indicated. Drugs such as cisplatin and etoposide are especially useful and have 50% response rates with some dramatic responses.¹²¹ Medical management of the gastric acid hypersecretion in patients with gastrinoma can usually be achieved with 20 to 40mg of omeprazole twice a day. The hypoglycemic symptoms of insulinoma are treated by more-frequent feedings. Drugs such as diazoxide, octreotide, and verapamil may occasionally be helpful. However, in general, the hypoglycemia of insulinoma is unable to be controlled with drugs. The symptoms of glucagonoma (rash) and VIPoma (diarrhea) can be controlled with octreotide, the long-acting somatostatin analogue. Dopamine agonists have been used to treat the hormonal secretion by some pancreatic NET. Elevated serum levels of pancreatic polypeptide and prolactin have been significantly reduced by either cabergoline or bromocriptine.¹²² The malignant tumoral process of islet cell tumors can seldom be controlled with chemotherapy.¹²³ Approximately 30% to 40% of tumors respond to doxorubicin, 5-FU, and streptozotocin as single drugs or in combination. Interferon-alpha has also produced some partial responses. Chemoembolization of liver metastases using interventional radiology techniques and doxorubicin has had a significant partial response rate. However, there have been no complete responses, and it does not appear to prolong survival. Patients with untreated liver

metastases have a 20% 5-year survival. On the other hand, octreotide therapy using long-acting depot slow-release-form sandostatin LAR 20mg IM every 3 weeks or sandostatin LAR 30mg IM every 4 weeks does inhibit tumor growth and progression of NET that have high-density somatostatin receptors. This hormonal treatment plus surgical resection and/or radiofrequency ablation of liver neuroendocrine tumors increases the 5-year survival to 80% to 90%.^{124,125} Liver transplantation has also been used for patients with metastatic liver NET who do not have tumor outside the liver. In general, the results have been good. Patients are seldom cured by liver transplantation as tumor generally recurs. However, the 5-year survival is between 36% and 83%.¹²⁶⁻¹²⁸ Bone metastases are usually treated with external-beam radiation therapy. They have also been successfully treated with indium-labeled pentetretotide.¹²⁹ Patients may live for many years with distant metastases from neuroendocrine tumors because tumor progression may be slow.

Carcinoid Tumors

Carcinoid tumors are neuroendocrine tumors derived from the diffuse neuroendocrine system. They are composed of monotonous sheets of small round cells with uniform nuclei and cytoplasm. Pathologists cannot differentiate benign from malignant tumors based on histology. Malignancy can only be determined based on the detection of metastases to either lymph nodes or distant sites. Carcinoid tumors synthesize numerous bioactive amines and peptides including neuron-specific enolase (NSE), 5-hydroxytryptamine (serotonin), 5-hydroxytryptophan, synaptophysin, chromogranin A and C, substance P, tachykinins, and hormones such as ACTH, calcitonin, and growth hormone-releasing hormone. Carcinoid tumors are fairly common in autopsy series and are present in approximately 21 per million autopsies. Similarly, 1 in 300 appendectomies will have a carcinoid tumor. Carcinoid tumors occur with greater frequency in patients with the MEN-1 syndrome.

Carcinoid tumors generally originate in four sites: bronchus, appendix, rectum, and small intestine (Table 56.8). Carcinoid tumors most commonly occur in the appendix (40%), small intestine (27%), rectum (13%), and bronchus (12%). Carcinoid tumors may also be divided into foregut, midgut, and hindgut. Foregut tumors include the bronchus, stomach, and thymus, which most commonly produce peptide hormones such as ACTH and calcitonin. These tumors also cause the atypical carcinoid syndrome because they secrete 5-hydroxytryptophan and lack the enzyme to convert it to 5-hydroxytryptamine or serotonin. Midgut carcinoid tumors include the appendix and small intestine (Figure 56.7). These tumors most commonly secrete serotonin that causes the typical carcinoid syndrome. However, because the liver metabolizes serotonin, signs and symptoms of the carcinoid syndrome are not present without liver metastases and the release of serotonin into the systemic circulation. Hindgut carcinoid tumors occur in the rectum and generally secrete no hormones.

Foregut carcinoid tumors most commonly occur in the bronchus and are a common cause of ectopic ACTH syndrome (Cushing's syndrome). The tumors occur in the major bronchi. They appear cherry-red on bronchoscopy because of

TABLE 56.8. Carcinoid tumors: location, metastases, and carcinoid syndrome.

Location	Site	Incidence (%)	Metastases (%)	Carcinoid syndrome
Foregut	Stomach	2	22	10
	Duodenum	3	20	3
	Bronchus	12	50	13
	Thymus	2	25	0
Midgut	Jejunum	1	35	9
	Ileum	23	35	9
	Appendix	38	2	Less than 1
	Ovary	Less than 1	6	50
Hindgut	Rectum	13	3	0

increased vascularity. Biopsy is contraindicated because of the risk of uncontrolled hemorrhage. MRI of the chest is the best method to diagnose bronchial carcinoid tumors because it can distinguish a tumor from hilar vessels. Lobectomy is the surgical procedure of choice as 50% have lymph node metastases. Thymic carcinoid tumors are another potential cause of ectopic ACTH syndrome. These tumors are commonly malignant. CT and MRI are excellent studies to image the extent of disease and make the diagnosis. The tumor appears as a mass within the anterior superior mediastinum and the thymus. Radical thymectomy is the procedure of choice. Care should be taken to avoid injury to one or both phrenic nerves.

Stomach carcinoid tumors equal only 3 of every 1,000 gastric neoplasms (Figure 56.8). Recent studies suggest that not all gastric carcinoid tumors are similar. Some are associated with chronic hypergastrinemic states such as achlorhydria and Zollinger–Ellison syndrome. These tumors arise from the enterochromaffin cells (ECL) cells, are small, multiple and seldom malignant (9% overall). These are contrasted to sporadic carcinoid tumors of the stomach, which are large, single, and atypical on histology and are associated with the carcinoid syndrome in 15% to 50% of cases. These tumors cause the syndrome without liver metastases as the bioactive substances can enter the systemic circulation; 55% to 66% of these large gastric carcinoid tumors are malignant based on the detection of nodal or liver metastases.

Midgut carcinoid tumors most commonly occur within the appendix. Most carcinoid tumors occur at the tip of the appendix and are totally removed by an appendectomy.

FIGURE 56.7. CT of an ileal carcinoid tumor (T). (From Norton et al.,⁷⁶ with permission.)

Appendiceal carcinoid tumors are usually smaller than 1 cm in diameter, and simple appendectomy is adequate. Tumors between 1 and 2 cm are more worrisome, especially when present at the base of the appendix. These tumors have a 50% chance of lymph node metastases and are best treated by right hemicolectomy. Tumors greater than 2 cm in size have a high probability of nodal spread and are also treated by right hemicolectomy. However, most appendiceal carcinoids are smaller than 1 cm, at the tip of the appendix, and only require simple appendectomy. Primary small intestinal carcinoid tumors may be multiple and most occur within the ileum. In fact, 40% are within 2 feet of the ileocecal valve. Unlike appendiceal carcinoid tumors, which are usually benign, these tumors are generally malignant. They spread to local lymph nodes and cause a dense fibrotic reaction that distorts the gut and may cause symptoms of small bowel obstruction. This fibrosis may obliterate venous outflow and result in venous mesenteric infarction. The incidence of nodal metastases from ileal carcinoid tumors is dependent on the size of the tumor. If the tumor is less than 1 cm, nodal metastases are present approximately 15% of the time. If the tumor is between 1 and 2 cm, nodal metastases occur 60% to 80% of the time. If the tumor is larger than 2 cm, metastases nearly always occur. Liver metastases also occur and, if present,

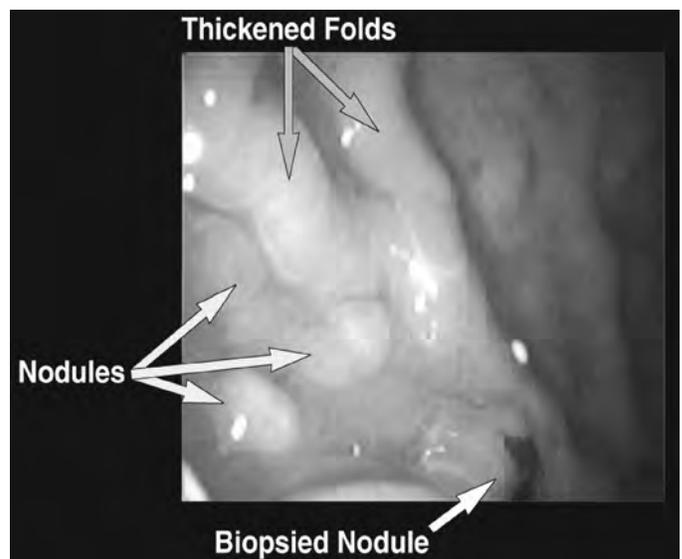

FIGURE 56.8. Multiple stomach carcinoid tumors (nodules) seen on endoscopy. This patient also has thickened gastric folds secondary to Zollinger–Ellison syndrome.

patients have symptoms of the malignant carcinoid syndrome. Duodenal carcinoid tumors may also occur, but most are asymptomatic and are found on endoscopy as an incidental finding. A duodenal carcinoid tumor less than 1 cm is clinically insignificant, whereas approximately one-third of larger tumors spread to lymph nodes. Thus, duodenal carcinoid tumors are rarely clinically significant, but they must be differentiated from gastrinomas and somatostatinomas that can appear like a small duodenal carcinoid. Immunoperoxidase staining for various hormones helps to differentiate the various tumors.

In approximately 1 in every 2,500 sigmoidoscopies, a hindgut carcinoid tumor is identified. Rectal carcinoids occur submucosally on the anterior or lateral walls of the rectum between 4 and 13 cm from the dentate line. Approximately 80% of these tumors are less than 1 cm in size and never metastasize. Tumors greater than 2 cm almost always metastasize. These larger tumors are locally invasive and have a large number of mitoses. Either simple resection with negative margins or low anterior resection is the procedure of choice for rectal carcinoid tumors. Abdominoperineal resection is not recommended as small tumors are seldom malignant and large tumors are usually not cured by surgery. Rectal carcinoid tumors seldom cause the carcinoid syndrome.

Carcinoid Syndrome

The carcinoid syndrome is associated with severe flushing attacks. Flushing attacks are characterized by the sudden onset of a deep red color over the upper part of the body, primarily the neck and face, and an unpleasant feeling of warmth, lacrimation, itching, palpitations, and diarrhea. Flushing spells may be precipitated by stress, certain foods such as cheese or wine, exercise, and drugs. Attacks are generally brief, lasting 2 to 5 minutes, and episodic. Typical flushing attacks are most commonly seen with carcinoid tumors that originate in the midgut and have liver metastases. Diarrhea is also associated with carcinoid syndrome. Ovarian carcinoid tumors also commonly cause the carcinoid syndrome (see Table 56.8). Diarrhea usually occurs with the flushing but it may also occur alone. Typically the stools are watery with the number of movements ranging from 3 to 30 per day. Patients commonly develop wheezing and airway constriction during an attack. Cardiac manifestations are also part of the carcinoid syndrome. The cardiac disease is typically caused by fibrosis that involves primarily the right side of the heart. Fibrous deposits tend to cause constriction of the tricuspid and pulmonic valve that results in regurgitation. In the atypical carcinoid syndrome, the flushing may be prolonged, lasting several days. It is more diffuse over the entire body, and may be a constant red or cyanotic color. The atypical rash

is frequently provoked by food and may be associated with intense pruritis.

In general, the signs and symptoms of the carcinoid syndrome are caused by serotonin (5-HT) secretion by the tumor. Most patients (more than 85%) with the carcinoid syndrome have elevated urinary levels of 5-hydroxyindolacetic acid (5-HIAA), the major metabolite of serotonin. The carcinoid syndrome is diagnosed by measurement of elevated urinary levels of 5-HIAA. It is also important to remember that foregut carcinoid tumors may produce the atypical carcinoid syndrome. These tumors lack the appropriate decarboxylase enzyme to convert 5-hydroxytryptophan to serotonin (5-hydroxytryptamine). Therefore, in patients with the atypical carcinoid syndrome, urinary levels of 5-HIAA may be normal but urinary metabolites of tryptophan are elevated. Further, platelet levels of serotonin will be elevated because platelets have the enzyme to convert 5-hydroxytryptophan to serotonin. However, most patients with carcinoid syndrome have midgut carcinoid tumors with liver metastases, and these patients have elevated urinary levels of 5-HIAA.

Localization Studies

Patients with the carcinoid syndrome typically have a mass in the small bowel on CT with cicatrization and narrowing of the bowel with partial obstruction. These patients usually have liver metastases. Tumor is best imaged by somatostatin receptor scintigraphy that has approximately a 90% sensitivity and specificity for the tumor. SRS is especially useful because it will also image bone and other distant metastases. SRS has been shown to be superior to imaging with MIBG.¹³⁰

Prognosis and Treatment

For all patients with the carcinoid syndrome, the 5-year survival is approximately 25% (Table 56.9). The prognosis varies with the site of origin and extent of disease. Patients with the carcinoid syndrome usually have distant metastases. The most immediate life-threatening complication is the carcinoid crisis that may occur during chemotherapy, surgery, or anesthesia. The crisis only happens in patients with 24-hour urinary 5-HIAA levels greater than 200 mg per 24 hours. The crisis initially presents with upper body flush, hypertension, and tachycardia, and subsequently severe hypotension and death may develop. Treatment with intravenous octreotide (long-acting somatostatin analogue) ameliorates the symptoms and signs and can be lifesaving.

The manifestations of the carcinoid syndrome should be managed medically. The flush is initially controlled by avoiding precipitating agents, diarrhea by antidiarrheal drugs, wheezing by bronchial dilators, and valvular heart disease by

TABLE 56.9. Five-year survival (%) with carcinoid tumors by site and stage.

Location	Site	Primary		
		with no metastasis	Nodal metastases	Distant metastases
Foregut	Bronchus	96	71	11
	Stomach	93	23	0
Midgut	Appendix	99	99	27
	Ileum	75	60	20
Hindgut	Rectum	92	44	7

inotropic drugs and diuretics. However, the syndrome may not be completely controlled by these measures and eventually patients become more symptomatic. At this point, patients are treated by the somatostatin analogue octreotide 100–150 μ g SC TID, which markedly improves all symptoms. After 1 to 2 weeks of octreotide, the patient can be given sandostatin LAR 20–30mg IM every 3 to 4 weeks to control the syndrome long term. Patients who are treated chronically with this drug may become refractory to it and require larger and larger doses. Interferon-alpha has also been used to treat the carcinoid syndrome and may be helpful in some patients.

Carcinoid tumors are best managed surgically. However, in patients with liver or locally advanced tumor, surgery is seldom curative. Patients with distant metastases may have symptoms related to a partial small bowel obstruction that warrant surgery. Further, in some reports aggressive surgery to debulk the primary and metastatic tumor is associated with amelioration of symptoms and prolongation of survival. Hepatic metastases may also be treated with chemoembolization, cryotherapy, radiofrequency ablation, and liver transplantation. Each of these procedures may improve symptoms, but none has been shown to clearly prolong survival. Control of liver metastases by surgery is associated with a 5-year survival of 80%.¹³¹ Chemotherapy with adriamycin, 5-fluorouracil, and streptozotocin has a 30% partial response rate. However, there have been no complete responses and no improvement in survival. Immunotherapy with interferon-alpha has also decreased tumor size and may improve symptoms. In general, patients with carcinoid tumors live for long periods (see Table 56.9), and treatments are used to provide specific goals such as relief of symptoms and prolongation of survival. Recent data continue to document that chemotherapy has not been effective in gastroenteropancreatic neuroendocrine tumors. Somatostatin analogues such as sandostatin LAR in doses of 20–30mg IM every 3 to 4 weeks have been able to control the signs and symptoms of carcinoid syndrome and appear to have decreased tumor growth, causing stabilization of disease.¹³² A prospective trial of interferon-alpha, lantreotide, or both in 80 patients with metastatic carcinoid tumors demonstrated that each of the drugs and the combination had antitumor activity that decreased symptoms and appeared to prolong survival. However, no treatment group was significantly better than the other groups.¹³³ Other investigators have criticized this study based on inadequate numbers of patients and the use of lantreotide instead of other somatostatin analogues.¹³⁴ A new approach that shows promise is based on inhibition of the epidermal growth factor receptor by gefitinib, which induced apoptosis and cell-cycle arrest in *in vitro* studies of malignant neuroendocrine tumors.¹³⁵

Multiple Endocrine Neoplasia

Multiple endocrine neoplasia type 1 (MEN-1) is an inherited endocrine disorder that includes hyperplasia of the parathyroid glands, tumors of the pancreatic islets and anterior pituitary, and occasionally carcinoid tumors and lipomas. It is inherited as an autosomal dominant disorder with variable penetrance, meaning that 50% of the offspring will develop the disease, but each may not express all the components (Table 56.10).

TABLE 56.10. Multiple endocrine neoplasias: genetics and clinical syndromes.

	<i>MEN-1</i>	<i>MEN-2A</i>	<i>MEN-2B</i>	<i>FMTC</i>
Chromosome	11	10	10	10
Gene	Menin	RET	RET	RET
Autosomal dominant	+	+	+	+
Phenotype	—	—	+	—
MTC	—	+	+	+
Virulence of MTC	—	++	++++	+
Pheochromocytoma	—	+	+	—
Pancreatic NET	+	—	—	—
1° HPT	+	+	—	—
Pituitary tumor	+	—	—	—

MEN, multiple endocrine neoplasia; MTC, medullary thyroid carcinoma; FMTC familial medullary thyroid carcinoma; NET, neuroendocrine tumor; 1° HPT, primary hyperparathyroidism.

Genetic Abnormalities in MEN-1

The causative gene in MEN-1 has been mapped to the long arm of chromosome 11 (see Table 56.10). The exact gene has been identified and named *menin*. *Menin* is a tumor suppressor gene, but its exact function is unknown.¹³⁶ Screening for the presence of disease should begin during the second or third decade of life. Individuals at risk should be questioned and examined for kidney stones, lipomas, hypercortisolism, hypoglycemia, peptic ulcer disease, headaches, acromegaly, and visual field defects. Blood levels of calcium, glucose, prolactin, gastrin, and pancreatic polypeptide are measured.

Parathyroid Hyperplasia in MEN-1

Primary hyperparathyroidism (HPT) is the most common endocrine disorder in patients with MEN-1.^{137,138} The manifestations are similar to those seen in non-MEN-1 patients with HPT and include asymptomatic hypercalcemia, weakness, fatigue, kidney stones, and bone pain from decreased bone density. The prevalence of HPT in MEN-1 increases with age and is nearly 100% after age 50. The age of onset is 25 years, which is younger than sporadic HPT. Primary hyperparathyroidism is diagnosed by measurement of elevated serum levels of total calcium, ionized calcium, and parathyroid hormone (PTH). The intact PTH assay has seldom given false-positive results and is very specific for HPT. These patients always have parathyroid hyperplasia, but at surgery there can be some asymmetry in size.¹³⁹ The operation of choice is currently three and one-half gland parathyroidectomy. Half the most normal-appearing parathyroid gland is left intact and marked with a clip. The cervical thymus should also be removed, as supernumerary glands may occur and are usually within the thymus.

Pancreatic Islet Cell Tumors in MEN-1

MEN-1 patients also develop pancreatic or duodenal neuroendocrine tumors. Tissue microdissection techniques show that pancreatic neuroendocrine tumors in MEN-1 originate from the ductal acinar system and not the islets.¹⁴⁰ Endoscopic ultrasound has been used in MEN-1 patients to detect pancreatic neuroendocrine tumors at an early stage before the development of metastases. EUS was able to diagnose the

presence of pancreatic neuroendocrine tumors in 14 of 15 MEN-1 patients before they had signs or symptoms of islet cell tumors.¹⁴¹ These tumors may be malignant, and there is a correlation between the size of the tumor and the chance of metastases.¹⁴² Pancreatic islet cell tumors may be non-functional or produce excessive hormones that cause a characteristic clinical syndrome. The most common functional islet cell tumor in MEN-1 is gastrinoma. Moreover, any islet cell tumor can occur in patients with MEN-1, including gastrinoma, insulinoma, glucagonoma, VIPoma, GRFoma, somatostatinoma, and nonfunctional tumor or PPoma.

Surgery is indicated to remove a potentially malignant islet cell tumor and ameliorate hormonal effects. At surgery these patients commonly have multiple pancreatic islet cell tumors and also multiple duodenal neuroendocrine tumors.¹⁴³ Recent studies indicate that tumors that produce insulin, glucagon, and VIP are more commonly within the pancreas, whereas tumors that secrete gastrin are usually within the duodenum.¹⁴⁴ The goal of surgery is to remove tumor without excessive morbidity and mortality. Surgical resection seldom cures patients of Zollinger–Ellison syndrome,¹⁴⁵ but it reduces the probability of liver metastases. The concept of early diagnosis of pancreatic neuroendocrine tumors in MEN-1 patients is not supported by the low cure rate and the fact that MEN-1 patients with resected metastatic tumors have the same survival as patients with resected localized tumors.¹⁴⁶

Pituitary Tumors in MEN-1

The most common pituitary tumor in MEN-1 is a prolactinoma. Elevated serum levels of prolactin are diagnostic and are used as a screening study. Prolactinomas cause galactorrhea and impotence. Pituitary tumors in MEN-1 may also secrete other hormones including corticotropin (ACTH), growth hormone, and thyroid stimulating hormone (TSH). These tumors are associated with Cushing's disease, acromegaly, and hyperthyroidism, respectively. Biochemical diagnosis of each is based on recognition of the clinical signs and symptoms. MRI or CT of the sella and visual field examination are ordered for patients suspected to have pituitary tumors. Bitemporal hemianopsia may occur when large tumors compress the optic chiasm.

Pituitary adenomas that produce prolactin are usually treated with bromocriptine. Pituitary tumors can also be removed surgically or less commonly are treated with irradiation.

Less-Common Tumors in MEN-1

Less-common tumors that may occur with MEN-1 include bronchial or thymic carcinoids, intestinal carcinoids, gastric carcinoids, lipomas, benign adenomas of the thyroid gland, benign adrenocortical adenomas, and rarely adrenocortical carcinomas. Carcinoid tumors should be removed surgically when identified. Cortical adenomas of the thyroid gland and benign cortical adenomas of the adrenal cortex usually require no treatment, unless there is evidence of excessive hormonal function. Lipomas are usually large and should be excised when symptomatic. Adrenal cortical carcinomas commonly present with signs and symptoms of hypercortisolism and are identified as a large adrenal tumor on CT (6 cm). Surgical resection is the treatment of choice.

Multiple Endocrine Neoplasia Type 2A, 2B, and Familial Medullary Thyroid Carcinoma

Multiple endocrine neoplasia type 2A (MEN-2A) is an autosomal dominant inherited endocrine syndrome that is characterized by medullary thyroid carcinoma (MTC), adrenal pheochromocytoma(s), and parathyroid hyperplasia (see Table 56.10). Multiple endocrine neoplasia type 2B (MEN-2B) is an autosomal dominant inherited endocrine syndrome that is characterized by MTC, adrenal pheochromocytoma(s), and a characteristic phenotype that includes mucosal neuromas, puffy lips, bony abnormalities, marfanoid habitus, intestinal ganglioneuromas, and corneal nerve hypertrophy.¹⁴⁷ Unlike MEN-2A, parathyroid disease is not associated with MEN-2B. Familial medullary thyroid carcinoma (FMTC) is characterized by an autosomal dominant inheritance of only medullary thyroid carcinoma without any other endocrine abnormalities.¹⁴⁸

Gene Defect in MEN-2

The gene for MEN-2A, MEN-2B, and FMTC has been localized to the pericentromeric region of chromosome 10 (see Table 56.10). The responsible gene is a transmembrane protein kinase receptor called RET.^{149,150} RET is an oncogene in that mutations enhance cellular growth. The exact mechanism by which RET enhances cellular growth is unknown. Recent studies have detected missense mutations in RET in all individuals with MEN-2A, MEN-2B, and FMTC.^{149,150} MEN-2A and FMTC mutations have been identified within the extracellular portion of the molecule, whereas MEN-2B mutations have been identified within the intracellular domain.

Medullary Thyroid Carcinoma

In patients with MEN-2A, MTC generally appears between the ages of 5 and 25 years before the development of pheochromocytoma or primary hyperparathyroidism.¹⁵⁰ Recently, detection of RET mutations in the peripheral white blood cells of patients from kindreds with MEN-2A has been used as a screening procedure to diagnose an affected individual.^{150,151} Because 100% of individuals with MEN-2A will develop MTC, total thyroidectomy has been performed when RET mutations are detected. Before thyroid surgery, it is important to rule out the presence of a pheochromocytoma by measuring 24-hour urine levels of VMA, metanephrines, and total catecholamines. When total thyroidectomy has been performed based solely on genetic testing, either premalignant C-cell hyperplasia or in situ MTC has been identified.

Individuals with MEN-2B have a characteristic phenotype.¹⁴⁷ These patients have prognathism, puffy lips, poor dentition, mucosal neuromas, corneal nerve hypertrophy, and multiple bony abnormalities. The presence of MEN-2B can be ascertained by the observation of corneal nerve hypertrophy on slit-light examination. Patients with MEN-2B usually have locally advanced MTC at presentation.¹⁴⁷ These patients are seldom cured by thyroidectomy and usually die of the MTC.

Individuals with FMTC have the best prognosis.¹⁴⁸ In these patients, MTC occurs at an older age and patients seldom die of MTC. Thus, in the three different familial settings, although the same oncogene is affected, the virulence of the MTC is different. The most virulent form is MEN-2B,

the intermediate form is MEN-2A, and the least virulent is FMTC. Total thyroidectomy is indicated for the familial types of MTC as each involves both lobes of the gland.

Pheochromocytoma in MEN-2A and 2B

Individuals with either MEN-2A or MEN-2B may develop bilateral benign intraadrenal pheochromocytomas.¹⁵⁰ The diagnosis of pheochromocytoma is made by detection of elevated 24 hour urinary levels of VMA, metanephrines, or total catecholamines. Urinary metanephrines are the single best diagnostic study. Imaging studies can identify which adrenal gland is involved. CT, MRI, and MIBG scan each have utility. Both MRI and CT can image pheochromocytomas as small as 1 cm. There is controversy as to the extent of adrenalectomy in patients with MEN-2. Some recommend bilateral adrenalectomy for all individuals with biochemical evidence of pheochromocytoma, because studies have shown that 70% are bilateral and sudden death can be caused by an untreated pheochromocytoma. Others remove only the adrenal gland in which a tumor is seen. If a unilateral adrenalectomy is performed, careful follow-up is warranted as some patients may develop another tumor in the contralateral gland. Recent studies have demonstrated that laparoscopic adrenalectomy is the method of choice to remove these tumors. Resection should be performed after the patient has been prepared preoperatively with alpha-adrenergic-blocking drugs such as phenoxybenzamine. Adrenal surgery should be performed before thyroidectomy.

Parathyroid Disease in MEN-2A

Patients with MEN-2A may also develop symptomatic primary hyperparathyroidism (HPT).¹⁵² The diagnosis is ascertained by measurement of elevated serum levels of calcium and parathyroid hormone. HPT is caused by multiple gland disease or parathyroid hyperplasia (see Table 56.10). The proper surgical treatment is three and one-half gland parathyroidectomy.

Gastrointestinal Manifestations of MEN-2A or MEN-2B

Some individuals with MEN-2A may also have Hirschsprung's disease. Recent evidence suggests that Hirschsprung's disease is also associated with RET mutations; however, these mutations are inactivating for RET. Individuals with MEN-2B commonly complain of severe constipation, and megacolon or diverticulosis has been described. MEN-2B patients are known to have abnormal gut motility secondary to intestinal ganglioneuromatosis. Constipation should be treated as symptoms arise. As the MTC becomes metastatic, patients may develop severe secretory diarrhea. MTC can secrete a wide variety of peptide hormones that cause diarrhea. Octreotide has been used to inhibit the diarrhea in this setting.

Sarcomas of Bone

Randy N. Rosier and Susan V. Bukata

Sarcomas of bone have a number of distinguishing features that set them apart from primary cancers of many other organ systems. First, they are extremely rare in comparison with other types of cancer, a fact that has impeded the ability of treatment in this field to evolve rapidly in an evidence-based manner because of the small numbers of patients available for studies. Progress in this field has been possible only with multicenter and oncology group trials that can provide sufficient numbers of patients for study. Even so, clinical trials are generally limited to prospective case series at best, and much of the literature is based on retrospective case series. True controlled randomized prospective trials are extremely rare. Nevertheless, a number of clinically useful observations defining the behavior of these tumors and their responses to treatments have derived from the analyses of the numerous case series that have been published, and these results and the associated levels of evidence are reviewed here.

Bone sarcomas are generally characterized by a solitary primary focus with initial local growth being followed by hematogenous patterns of metastasis, with the lungs as the most common initial metastatic site. Metastases to other bones also can occasionally occur, although lymphatic, central nervous system, and other solid organ metastases are distinctly rare. The annual incidence of primary bone malignancies is less than 3,000 cases/year in the United States, excluding marrow cell malignancies such as lymphoma and myeloma.¹ The majority of bone sarcomas fall into three histogenic types: osteosarcoma, Ewing's sarcoma, and chondrosarcoma. Osteosarcoma and Ewing's sarcoma preferentially affect children and young adults, whereas chondrosarcoma is seen more commonly in later adulthood. Far less common sarcomas of bones include fibrosarcoma, malignant fibrous histiocytoma, and extremely rare lesions such as adamantinoma. Because of the extreme rarity and lack of clinical trials with these uncommon lesions, the following material focuses on the three most common tumor types.

Bone sarcomas typically evolve in a single focus, with local centrifugal growth and invasion of the bone and surrounding soft tissues. Although metastases are typically pulmonary in location, metastases within a single bone (so-called skip metastases²) or to other bones can occur occasionally.³ Before the advent of chemotherapy, treatment was generally by surgical amputation proximal to the lesion, and the prognosis for these sarcomas was extremely poor. Use of chemotherapy, in particular for osteosarcoma and Ewing's sarcoma, has markedly improved survival in comparison with

historical results. While osteosarcoma and chondrosarcoma are relatively resistant to radiation, Ewing's sarcoma is radiosensitive, and radiation has been used as both a primary or adjuvant treatment for this disease in the past.⁴ However, because of late recurrences in bone at the primary site and other complications such as pathologic fracture, the treatment paradigm for this disease has evolved over the past two decades to surgical resection and adjuvant chemotherapy, similar to the approach for osteosarcoma.⁵ For chondrosarcoma, because of resistance to both chemotherapy and radiation, surgery remains the only method of treatment.⁶

In addition to the use of adjuvant chemotherapy and radiation, the treatment of bone sarcomas has evolved surgically during the past two to three decades as well. There has been a progressive and well-supported change from amputations to limb-sparing types of surgical procedures for the majority of bone sarcomas.^{5,7} A number of factors have contributed to this change, many related to technologic advances. Examples include accurate imaging techniques such as magnetic resonance imaging (MRI), which enable far better assessment of the anatomic location of the tumor than was available previously; free tissue microvascular transfers, enabling coverage of problematic soft tissue defects; and availability of osteochondral allografts and complex prosthetic bone and joint replacement devices for limb reconstruction. These advances have dramatically enhanced the ability to perform limb salvage procedures with preservation of limb function while not compromising treatment of the malignancy. Instruments for limb functional outcomes assessment have been developed⁸ and are widely used to evaluate local treatment outcomes, in addition to the traditional measures of disease presence or absence, quantification of disease extent, and performance status.

There are currently two slightly different staging systems used by orthopedic oncologists for bone sarcomas.⁹ The surgical staging system of Enneking^{10,11} is based on the grade, anatomic extent, and presence of metastases, and has been widely used by musculoskeletal oncologists for many years. It has been adopted by the Musculoskeletal Tumor Society and is also known as the MSTS staging system.⁹ The staging correlates well with survival and facilitates surgical planning for the primary lesion. Tumors are graded as either low or high grade (stage I or II, respectively), and as either confined to a single anatomic compartment (A) or involving more than one anatomic compartment (B). Stage III refers to any tumor with metastases. More recently, the American Joint Committee on Cancer has developed a bone tumor staging system

TABLE 57.1. Musculoskeletal Tumor Society staging system.

Stage	Grade	Local extent	Metastases
I-A	Low	Intracompartmental	None
I-B	Low	Extracompartmental	None
II-A	High	Intracompartmental	None
II-B	High	Extracompartmental	None
III	Any	Any	Present, any site

Data from Enneking et al.¹⁰

that is also in use, the major differences being that tumor size is considered as well as location of metastases.⁹ Tables 57.1 and 57.2 outline the bone sarcoma staging systems. Several considerations borne out by both staging systems are that higher-grade tumors, tumors with metastases, and large or anatomically more extensive tumors have worse prognoses. In a recent comparison of the two staging systems, no significant difference in prognosis prediction was found, indicating that at present either system remains acceptable.⁹

Clinical presentation of bone sarcomas usually involves pain, often at rest or at night, and presence of swelling or a mass at the primary site. Systemic symptoms are rare. Occasionally pathologic fracture can occur, although this is fortunately relatively uncommon, presumably because bone sarcomas are generally quite painful and may cause the patient to seek medical attention before bone destruction is sufficient to cause fracture. The most useful study in developing differential diagnosis of the lesion remains the radiograph of the primary site. Osteosarcomas usually exhibit destructive patterns with disorganized bone formation, periosteal reaction, and often extension into the adjacent soft tissues. Ewing's sarcomas tend to have a permeative lytic pattern on radiographs, with periosteal reaction and also with soft tissue extension. Chondrosarcomas may be identified or suspected because of the combination of a destructive radiographic appearance with presence of calcifications. Three-dimensional imaging, generally with MRI, enables evaluation of the anatomic extent, the soft tissue involvement, and proximity to critical neurovascular structures, and helps to determine feasibility of limb-sparing surgical treatment of the tumor. Diagnosis is most commonly achieved by needle biopsy, although occasionally an open biopsy may be necessary to obtain adequate tissue for definitive diagnosis. Biopsy is best performed by an experienced orthopedic oncologist who will ultimately provide the surgical treatment of the primary tumor, because placement of the biopsy site has important anatomic considerations relevant to the definitive resection, and outcomes have been shown to be better in

TABLE 57.2. The American Joint Committee on Cancer (AJCC) staging system for bone tumors.

Stage	Grade	Local extent	Metastases
IA	Low	≤8 cm	None
IB	Low	≥8 cm	None
IIA	High	≤8 cm	None
IIB	High	≥8 cm	None
III	Any	Any	Skip metastases
IVA	Any	Any	Pulmonary metastasis
IVB	Any	Any	Other metastases

Data from *AJCC Cancer Staging Manual*, sixth edition (2002), published by Springer-Verlag New York, www.springer-ny.com.

this circumstance.¹² Additional staging studies besides the imaging of the primary lesion should include computed tomographic (CT) scan of the lungs to detect pulmonary metastases and a whole-body bone scan to help identify bony metastases or skip metastases. Following confirmation of diagnosis and staging, either surgical treatment (for chondrosarcoma) or preoperative adjuvant chemotherapy (for osteosarcoma or Ewing's sarcoma) is initiated. For those tumors treated with adjuvant chemotherapy, surgical resection and reconstruction (if feasible) is carried out after several cycles of preoperative "neoadjuvant" treatment. Following surgical treatment, chemotherapy is resumed for a predetermined number of cycles, depending on the protocol in use. Metastatic pulmonary lesions persisting after chemotherapy or appearing later during posttreatment follow-up may be resected by thoracotomy with salvage of some patients.¹³

After successful completion of therapy, patients are monitored periodically with radiographs and other local imaging modalities at the primary site, as well as with chest CT scans and bone scans. The role of positron emission tomography (PET) scans in evaluation and follow-up of bone sarcomas is still in evolution, and this modality is not yet a component of most standardized protocols. PET scan activity has been shown in chondrosarcoma to correlate with grade and outcome,¹⁴ although CT scans have been shown to be superior to PET scans in detection of pulmonary metastasis of osteosarcoma.¹⁵ PET scan activity has also been shown to correlate with response to chemotherapy for bone sarcomas.¹⁶ However, the role of PET scans in diagnosis and follow-up of bone sarcomas remains to be determined.

Osteosarcoma

Osteosarcoma is by definition a sarcoma composed of bone-forming cells and is the most common of the primary bone sarcomas. Osteosarcoma is characterized by the production by the tumor cells of the matrix of bone, osteoid, which may mineralize to a variable extent. Osteosarcomas may also contain other tissues of mesenchymal origin, such as cartilage and fibrous tissue. Osteosarcoma most commonly affects individuals in the second and third decades and preferentially involves the major long bones, that is, the femur, tibia, and humerus, although essentially any bone can be involved. There are a number of histologic variants of osteosarcoma, including typical central high-grade osteosarcoma, telangiectatic osteosarcoma, parosteal osteosarcoma, periosteal or juxtacortical osteosarcoma, fibroblastic osteosarcoma, chondroblastic osteosarcoma, intramedullary low-grade osteosarcoma, and secondary osteosarcoma (most commonly arising in irradiated bone or in Paget's disease).¹⁷ Parosteal osteosarcomas are low-grade lesions with low metastatic potential arising adjacent to the periosteum, usually of the posterior distal femur, proximal tibia, or of the proximal humerus. These tumors differ from most other osteosarcoma subtypes in that the treatment is generally surgical resection alone.¹⁸ Studies of prognosis versus histogenic subtypes of osteosarcomas have shown that telangiectatic and fibroblastic osteosarcomas have a relatively better prognosis and chondroblastic variants a worse prognosis.¹⁹⁻²²

The approach to treatment of osteosarcoma for the past two decades has consisted of induction multiagent chemotherapy, surgical resection (whether amputation or

limb salvage surgery with reconstruction), and then postoperative chemotherapy. The approach arose from the Rosen T10 protocol, which produced markedly enhanced survival compared with the prior dismal historical results of amputation alone.²³ Although a number of different protocols have been used, the most commonly included drugs in the multiagent regimens have been doxorubicin, methotrexate, cisplatin, cyclophosphamide, and ifosfamide (Table 57.3).^{13,24-38} Although other agents have been employed, there has not been a dramatic difference among protocols in outcomes. The recent evidence in the literature is summarized in Table 57.3. Many series consist of small numbers of patients, and most are retrospective or prospective case series, with true randomized clinical trials being extremely rare except for a few Phase III comparative studies. Overall, however, the survival rates with this tumor have not changed dramatically beyond original chemotherapeutic protocols. Comparative studies have determined that local recurrence and survival rates do not differ whether the patient has had limb salvage or amputation.⁵ Some of the major advances in the past decade relate to improved ability to salvage functional extremities, with custom and modular prosthetics, enhanced soft tissue reconstructions, and allografting technologies. Recent develop-

ments in lengthening prosthetics have enabled salvage of extremities in younger children, despite a relatively high complication rate.^{39,40} However, prevention and treatment of metastatic disease remain the major challenges.

Evidence from the literature summarized in Table 57.3 and site-specific evidence presented in Table 57.4⁴¹⁻⁴⁵ lead to consensus on a number of issues, which are summarized by the following:

1. Prognosis is worse with metastasis or with local recurrence.
2. Good response to neoadjuvant chemotherapy (greater than 90% necrosis) is associated with a better prognosis.
3. Pelvic and spinal primary sites are associated with a worse prognosis.
4. Older patients have a worse prognosis with osteosarcoma.
5. Pathologic fracture is not associated with a worse prognosis and is no longer believed to be an absolute indication for amputation.
6. Outcome varies among osteosarcoma subtypes.
7. Aggressive treatment with multiagent chemotherapy and surgical resection carries a better prognosis than less-aggressive approaches.

Overall survival with osteosarcoma treated with multiagent chemotherapy and surgery has remained in the 60% to 70% range over the past two decades. Limb salvage has become more prevalent and has not shown an adverse effect on survival, even in the context of pathologic fracture.^{5,39,40,46-49} Survival in relapsed or metastatic osteosarcoma is distinctly worse (see Table 57.3) and ranges from 18% to 55%. The prognosis is worse in axial skeletal locations, such as the spine and pelvis (see Table 57.4),^{41,43-45} which may relate in part to the technical difficulty of obtaining wide surgical margins in these locations. Prognosis for skip metastases has also been extremely poor.²

There has been considerable interest in identifying prognostic markers in osteosarcoma. The RB and p53 genes have long been associated with the pathogenesis and growth dysregulation in osteosarcoma but have not found utility prognostically.⁵⁰ Multidrug resistance genes, such as MDR1 (P-glycoprotein), a cellular detoxifying plasma membrane efflux pump that can confer chemotherapeutic resistance on tumor cells, have been fairly widely investigated in osteosarcoma. However, the issue of prognostic relevance remains unresolved, with some studies showing correlation with prognosis^{51,52} whereas others have not.^{53,54} Bone morphogenetic proteins (BMPs) have been studied, with findings of BMP4 and 7 expression in all osteosarcomas and BMP6 in chondroblastic subtypes.^{55,56} Other markers that have been investigated include Her2/neu,^{57,58} tenascin,⁵⁹ ezrin,⁶⁰ LRP5,⁶¹ and telomerase.⁶² Although one study suggested overexpression of Her2/neu correlated with poor prognosis,⁵⁷ a more-recent study has contradicted that finding.⁵⁸ Tenascin, ezrin, LRP5, and telomerase have each been found to correlate with metastasis and worse prognosis in recent single studies.⁵⁹⁻⁶²

A number of newer agents have been tested for activity against osteosarcoma, including carboplatin, ecteinascidin, liposomal doxorubicin, etoposide, gemcitabine, interleukin 12, topotecan, paclitaxel, and the combination of retinoic acid and interferon alpha, generally in the setting of metastatic and/or recurrent tumor refractory to standard regimens.^{38,63-72}

Although the studies have been small, ecteinascidin, topotecan, and paclitaxel have exhibited minimum activity.^{64,67,71} Ifosfamide, etoposide, and carboplatin have been evaluated in several studies and antitumor efficacy demonstrated, although results are similar to previous multiagent regimens.^{34,63,65,69,73} Gemcitabine and interleukin 12 have shown activity against metastatic disease in animal models,^{70,74} but interleukin 12 has not been evaluated in clinical trials, and response to gemcitabine in one Phase II trial with refractory disease was modest.⁶⁶ Preoperative intraarterial cisplatin has demonstrated improved survival of 92% in a single clinical study,²⁶ whereas in another study with intraarterial carboplatin the 3-year survival was similar to other multidrug protocols at 71%.³⁸ Unfortunately, overall the results with newer agents have not shown promise of significantly altering the treatment outcomes with this disease, and further studies are needed.

Ewing's Sarcoma

Ewing's sarcoma is an aggressive, non-matrix-producing primary bone sarcoma that affects individuals mainly in the second and third decades. Many of these tumors are characterized by presence of a specific chromosomal translocation (11:22), resulting in an abnormal transcription factor, EWS-FLI-1, which may contribute to their pathogenesis. Ewing's sarcoma can occur in the soft tissues as well, and both bone and soft tissue lesions often exhibit features of neuroectodermal differentiation, previously termed peripheral neuroectodermal tumors (PNET).⁴ The presence of neural differentiation features has not been shown to affect outcome.^{75,76} Currently, the term Ewing's sarcoma family of tumors (ESFT, or EFT) is used to encompass the variations of this sarcoma. Ewing's sarcoma is characterized by a permeative pattern of bone destruction, often associated with a periosteal reaction and soft tissue mass. As with other bone sarcomas, the presenting complaint is usually pain at the site

of the primary lesion. Involvement of the major long bones is most common, although pelvic, spinal, and rib primary sites also occur.⁷⁷ Metastases are hematogenous and usually pulmonary, with bone as a much less common metastatic site. Diagnosis is generally accomplished by needle biopsy, although occasionally an open surgical biopsy may be necessary. The use of immunohistochemistry to identify markers of neural differentiation, cell-surface markers such as CD99, and the specific fusion protein, EWS-FLI-1, which results from the characteristic chromosomal translocation found in most cases of the disease, has made diagnosis more accurate with small tissue specimens.⁷⁸⁻⁸¹ The staging studies are similar to those of other bone sarcomas, with magnetic resonance imaging (MRI) of the primary site for surgical planning, CT scan of the chest to assess pulmonary metastasis, and whole-body bone scanning to rule out bone metastases.⁷⁷

Treatment consists of multiagent chemotherapy regimens similar to those used for osteosarcoma, followed by surgical resection and reconstruction if feasible, with or without local radiotherapy, depending on the response of the tumor to neoadjuvant therapy and achievement of wide surgical margins. This regimen represents a shift in approach over the past two decades as previously chemotherapy with local radiation was the most common treatment paradigm. However, late recurrences in irradiated bone in the past led to increasing use of surgical treatment of primary lesions, with improved results.⁸²⁻⁸⁵ In unresectable lesions in difficult locations, such as the spine, chemotherapy with adjuvant radiation treatment remains an acceptable alternative to surgical treatment. Postoperative chemotherapy is then utilized, as for osteosarcoma, with subsequent follow-up using MRI, CT, and bone scan assessments periodically to monitor for recurrent disease.

The published clinical studies of Ewing's family tumors are summarized in Table 57.5^{75,82-84,86-101} and Table 57.6,¹⁰²⁻¹⁰⁷ and the issues of consensus based on evidence presented in these studies are as follows:

1. Surgical treatment of the primary lesion is associated with a better prognosis than radiotherapy alone.
2. The prognosis of patients presenting with metastatic disease is much worse than those without.
3. Late complications such as relapse and second malignancies occur and must be monitored through long-term follow-up.
4. Addition of etoposide and ifosfamide improves outcome in patients without metastasis but not in those with metastasis at presentation.
5. Pathologic fracture is not associated with worse prognosis and does not necessarily mandate amputation.
6. Chemotherapeutic response of tumor to neoadjuvant chemotherapy is highly correlated with outcome.
7. Prognosis in spinal and pelvic locations is worse than with extremity tumors.
8. Tumor volume is inversely correlated with outcome.
9. Improved survival with stem cell transplantation has not been as yet demonstrated.

The problems associated with interpretation of the data on Ewing's tumors relates in large part to the rarity of the disease. Thus, most of the reported evidence is at the case series level, with few randomized trials. In addition, much of the literature is based on relatively small numbers of cases, with patient and treatment heterogeneity. Furthermore,

many reported series have been collected over significant periods of time, introducing the confounding variables of changing treatment paradigms and diagnostic and staging technologies. As can be seen from Table 57.5, reported overall survival rates at 5 years generally are in the range of 50% to 70% for nonmetastatic disease presentation and 20% to 30% for metastatic disease, thus reinforcing the strong prognostic significance of early metastasis. Longer time to relapse has also correlated with improved survival.⁹² Surgical treatment of the primary has yielded better outcomes than radiotherapy alone in several studies,^{64,83,100,102,108,109} leading to the current shift in paradigm favoring surgical resection whenever possible. Incorporation of surgical treatment for relapsed disease has also been shown to improve survival.^{92,110,111} Pathologic fractures occur in Ewing's tumor, particularly in the femur, but have had similar outcomes to disease without fracture whether or not amputation was undertaken.^{112,113}

Additional factors that have been found in some studies to correlate with a worse prognosis include tumor volume greater than 100 mL,^{94,113,114} nonextremity sites such as the spine and pelvis,^{102,103,106,115} elevated serum lactate dehydrogenase (LDH) levels,^{76,82,116} and systemic symptoms such as fever and anemia.¹¹⁶ Apart from the presence of metastatic disease, however, the strongest predictor of prognosis is response to neoadjuvant chemotherapy.^{85,94,97,107,113,116,117}

A number of issues remain controversial, such as the prognostic significance of age at diagnosis, concerning which conflicting data have been reported.^{97,118} The treatment of metastatic disease does not appear to have improved much over time despite numerous changes in chemotherapeutic protocols, although the value of surgical treatment of the primary lesion has been well supported.^{64,83,100,119} Several studies have reported on improved outcomes in nonmetastatic patients with more-recent protocols incorporating ifosfamide and etoposide over previous protocols that did not incorporate these agents.^{87,101,120} Some experimental drug regimens evaluated in recent small Phase II studies for relapsed disease include cyclophosphamide + topotecan and irinotecan.^{64,121} Although the cyclophosphamide/topotecan study yielded a 35% response rate, further study of larger numbers of patients will likely be needed to determine the possible role of this regimen. Responses in the irinotecan study were minimal,¹²¹ and a Phase II study of pyrazoloacridine yielded no responses.¹²²

Although allogeneic and autologous stem cell transplantation for relapsed or advanced disease have not shown improved outcomes over chemotherapy alone,^{93,95} a high rate of tumor cell contaminants in autologous stem cells has been reported^{93,123} and may be a contributing factor to failures.
