Women with low-grade/indolent lymphomas, relatively normal complete blood counts, and without impending organ compromise may be safely observed until delivery or disease progression. In the aggressive histologic subtypes of NHL, treatment with CHOP should be instituted promptly. Successful treatment of Burkitt's lymphoma requires high-dose methotrexate. Patients presenting with this disease in the first trimester should have a therapeutic abortion.⁹²

Symptom Management During Cancer Treatment

A great concern to patients, families, and the care team is which drugs can be used during pregnancy for symptom control. Pain management and control of nausea are as important in the pregnant as the nonpregnant patient. Physicians may need to manage anxiety or depression in young women with a newly diagnosed cancer. Bracken and Holford¹⁰⁰ performed a case-control study of deliveries with ($n = 1,427$) and without ($n = 3,001$) congenital malformations in Connecticut between 1974 and 1976. They examined prescription drug use in each trimester for cases and controls. Three classes of agents were found associated with congenital malformations when used in the first trimester of pregnancy: narcotic analgesics, tranquilizers, and antidepressants. Antiemetics were not associated with congenital malformations in their study. Recent retrospective and prospective studies have shown that a newer class of antidepressants, that is, the selective serotonin reuptake inhibitors, may be safer than the antidepressants studied previously.¹⁵ Table 99.4 lists many of the drugs commonly used for symptom control in cancer, along with their FDA risk classification.¹⁵

Dolasetron and ondansetron, selective serotonin subtype 3 receptor antagonists used in the treatment of chemotherapy-associated nausea and vomiting, are considered class B agents by the FDA. Neither causes fetal harm in rats or rabbits, but only ondansetron has been studied in pregnant women.¹⁵ Prochlorperazine readily crosses the placenta and has been used to treat nausea and vomiting in pregnancy. It is considered safe for this indication when used occasionally and in low doses.¹⁵

Acetaminophen is routinely used during all stages of pregnancy for pain relief and to control fever.^{15,18} Pregnant women also frequently use salicylates. There is a theoretical risk of

TABLE 99.4. Drugs used in symptom management by pharmacologic type and FDA fetal risk category.

Anesthetics	Lidocaine (B)
Antihistamines	Chlorpheniramine (B) Cyproheptadine (B) Diphenhydramine (B) Meclizine (B) Promethazine (C)
Analgesics and antipyretics	Acetaminophen (B) Phenacetin (B)
Antidepressants	Amitriptyline (C) Amoxapine (C) Bupropion (B) Citalopram (C) Desipramine (D) Doxepin (C) Fluoxetine (C) Imipramine (D) Mirtazapine (C) Nortriptyline (D)
Narcotic analgesics (D) NSAIDs	Aspirin (D) Celecoxib (D) Diflunisal (D) Ibuprofen (D) Ketoprofen (D) Antiemetics Dimenhydrinate (B) Dolasetron (B) Droperidol (C) Doxylamine (A) Meclizine (B) Granisetron (B) Metoclopramide (B) Ondansetron (B) Prochlorperazine (C)

prostaglandin inhibitors, such as aspirin, causing premature closure of the ductus arteriosus, resulting in cardiovascular abnormalities. However, no adverse fetal outcomes have been reported after exposure to low-dose aspirin.¹⁵ Ibuprofen and other nonsteroidal antiinflammatory drugs (NSAIDs) are without apparent teratogenicity, but may have reversible fetal effects when used in the third trimester.¹⁵ NSAIDs cause decreased urine output and reduced amniotic fluid volume after prolonged usage.¹⁰¹ Meperidine and morphine are not associated with fetal abnormalities,¹⁷ nor are codeine, propoxyphene, oxycodone, or hydrocodone.¹⁰⁰ Maternal addiction to narcotics with subsequent neonatal narcotic withdrawal syndrome has been well described.¹⁵

Depression may be controlled with selective serotonin reuptake inhibitors, such as fluoxetine and sertraline. Fluoxetine does not have teratogenic effects and may be used in pregnancy. Sertraline is also an option, has a shorter half-life, and may be preferred over fluoxetine.¹⁵ The effects of the anxiolytic benzodiazepines, including diazepam and lorazepam, on the human embryo and fetus are controversial. A number of studies have reported an association with congenital defects while other studies have not.¹⁵ The risk, if present, appears to be low. Neonatal withdrawal has followed continuous use of diazepam during pregnancy, and a dose-related sedation of the infant is apparent if the drug is used close to delivery.¹⁵

Fatigue is a common symptom during chemotherapy and may be exacerbated by anemia. Epoetin alpha, recombinant

human erythropoietin, is indicated for chemotherapy-associated anemia. The drug has been studied in pregnant patients with renal disease and other disorders and does not appear to present a major risk to the fetus.¹⁵ It should be recalled, however, that mild anemia is physiologic during pregnancy and that iron deficiency is common. The latter should be corrected before epoetin alpha is added.

Conclusion

The coincidence of pregnancy and cancer poses challenges for caregivers, patients, and families. The survival of two patients, the mother and the fetus, is at risk. Randomized controlled trials are not available to guide practice. Even more than in other areas of oncology, the patient's personal values and religion may play a role in choosing the appropriate course of treatment. All options, including delaying treatment or abortion to allow immediate treatment, must be carefully considered. Patients must be given the best estimates of risks to mother and fetus for each possible treatment strategy.

In general, diagnostic imaging to accomplish anatomic staging does not increase fetal risk and may aid in appropriate maternal risk assessment. Therefore, staging should not be neglected in the pregnant patient. Radiation therapy can be used as a treatment modality, either when treatment planning is carefully performed to minimize fetal risk, or when sacrifice of the fetus is anticipated. Fetal doses of ionizing radiation less than 5cGy do not appear to cause fetal injury, whereas more than 10cGy exposure in early pregnancy is teratogenic. Chemotherapy during the first trimester of pregnancy poses the greatest risk of fetal loss and birth defects. Risks decrease thereafter, depending on the specific drugs employed and the timing during the pregnancy. During the third trimester, chemotherapy is associated with fetal growth restriction, whereas peripartum chemotherapy poses a risk for myelosuppression in the newborn. Supportive care needs should not be ignored during pregnancy, and analgesics, antidepressants, and antiemetics can and should be used.

Survivorship*

Survivorship Research: Past, Present, and Future

Julia H. Rowland

Origins of Cancer Survivorship Research

In 1884, an official ceremony was held and the cornerstone laid for an ornate and turreted building in New York City that would for many years house the first cancer treatment center in the country. The site, located on the upper west side of Central Park, then a virtual wilderness area on the larger island of Manhattan, was selected because the belief at the time was that cancer was contagious. The rounded design of the towers, where patient beds were to be located, was intended to discourage the risk of germs, which were thought to lurk in corners. Named The New York Cancer Hospital, this institution would later be moved in 1948 to its current east side location where it was, until 1960, called the Memorial Hospital for Cancer and Allied Diseases. The history of this leading center for cancer care and research, known today as the Memorial Sloan-Kettering Cancer Center, a sprawling multisite enterprise, is illustrative of where we have come in viewing cancer.¹

At the turn of the 20th century, cancer was largely incurable, poorly understood, and associated with treatments that were often as dire as the disease itself. By midcentury, with the advent of anesthesia, antibiotics, and the introduction of multimodal cancer therapies, the number of individuals living longer (beyond 5 years) with cancer had slowly increased. However, it was not until the latter part of the 1900s that the nationally estimated 5-year cancer prevalence figures (prevalence being defined as the number of people alive at a given point in time with a history of cancer) reached 50%. From an evidence perspective, this event, which occurred between 1974 and 1976,² might in hindsight be considered a turning point in what would soon become the field of cancer survivorship. Arguably, without substantial numbers of survivors, issues of “survivorship” would never have become of interest; the focus of research would have remained, as it had in the past, largely on trying simply to enable an individual to become a survivor, not what the future of that person’s life might be like.

The first glimpse at this new world came from pediatric oncology where, seemingly overnight, a death sentence was being converted into long-term cure. This point is well illustrated in the steady upward curve in pediatric cancer survival rates from 1950 to 1998 depicted in Figure 100.1. Introduction in the late 1960s of therapies to prevent central nervous system relapse in survivors of childhood lymphoblastic leukemia (ALL) was among several key treatment changes that would lead to a revised perspective on this disease (Figure

100.2). Because ALL is the most common form of childhood cancer, accounting today for approximately 30% of cancer cases diagnosed in children before the age of 14,³ the impact of this breakthrough produced a dramatic shift in 5-year survival rates for pediatric cancer as a whole. It also spawned the first generation of articles calling for attention by the medical community to issues that went beyond merely curing a child to those affecting his or her quality of life after treatment.⁴⁻⁶ This same process was slower to evolve in the adult cancer arena.

Development of Survivorship Researcher and Assessment Tools

Others, and most notably Jimmie Holland,^{7,8} have written in detail about the confluence of both medical and societal factors that led to the recognition of the field of psychosocial oncology. Three elements essential to the growth of the field were the change within the medical community toward disclosing a cancer diagnosis, training of a cadre of researchers to address posttreatment issues related to quality of life (QOL), and development of assessment tools to measure and describe the survivorship experience. Of these, the movement toward disclosing a cancer diagnosis was the most critical.

Throughout most of the 1960s, the practice in the United States was not to tell patients their diagnosis, “never tellers” constituting an estimated 90% of physicians surveyed in a report by Oken.⁹ A report published by Novack and colleagues revealed that this policy reversed in the course of a brief 10 years. By 1977, 97% of physicians stated that they told patients they had cancer at the time of diagnosis.¹⁰ This change in practice was important because it opened the door for researchers to approach and ask patients directly about their understanding of their illness and its impact on their lives. The shift in candor about a cancer diagnosis was consequent to growing attention in the United States to patients’ rights, particularly in the health arena. However, physicians’ willingness to adopt this practice was also a reflection of the greater optimism about survival prospects for those diagnosed with cancer. It should be noted that sharing the diagnosis is not a universal practice. In many countries around the world, including several industrialized nations, physicians still hide this information, sometimes at the request of family members.¹¹⁻¹³ In Third World countries, where access to curative therapies is more limited and hence prognosis is grim,

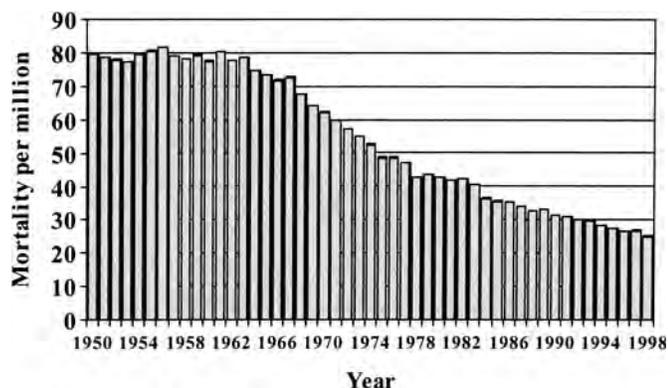

FIGURE 100.1. Remarkable past progress: childhood cancer mortality, 1950–1998.

protecting patients from learning their diagnosis is considered more humane.¹⁴ Even in many European countries, cancer still carries a significant social stigma. As part of its year-long study of cancer survivorship in the United States, the President's Cancer Panel held a meeting in Lisbon, Portugal, in May 2003. The purpose of this meeting was "to learn about the health services and survivorship activities in diverse European nations and health systems that might benefit survivors in this country".¹⁵ The Panel found that the term survivor was rarely used, and in some countries no linguistic equivalent existed. It was common for European survivors, the testimony from many of whom is included in transcripts and the final report from this meeting,¹⁵ to feel they could not publicly reveal their cancer history, or discuss their illness experience, even with family. In contrast to the situation in the United States, few prominent Europeans have disclosed their status as cancer survivors.

Early pioneers in the field of psychosocial oncology often came from mental health or nursing backgrounds. Few,

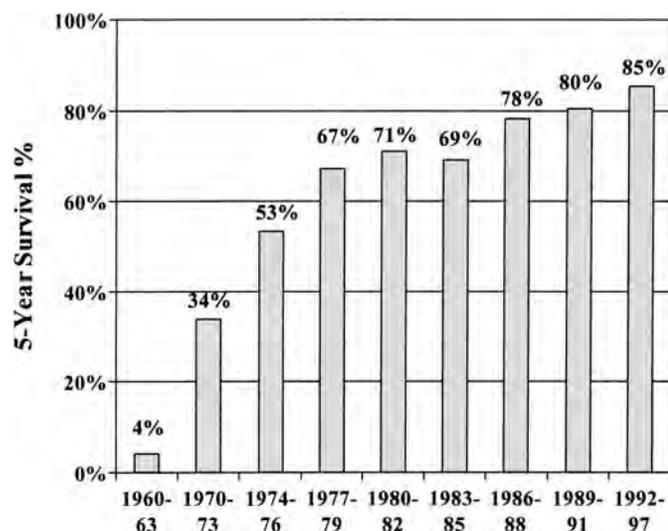

FIGURE 100.2. Remarkable past progress: childhood acute lymphoblastic anemia (ALL) survival rates, 1960–1997.

however, had formal training in psycho-oncology, as dedicated educational programs in this field did not appear until the late 1970s and early 1980s.^{7,16} Today, a number of the National Cancer Institute (NCI)-designated clinical and comprehensive cancer centers offer 2- to 3-year training programs for MDs and PhDs who wish to specialize in this area of research or care. Many also provide access to courses in psychosocial aspects of cancer research to a diversity of healthcare professionals. It also is increasingly common to see position openings for psychosocial oncology specialists announced on association-based online listserves, such as that supported by the American Psychological Association's Division 38 Health Psychology forum.

Paralleling the expertise of the early researchers, the tools used for QOL assessment of survivors' outcomes were drawn initially from the psychiatric or mental health field. Examples of frequently used instruments included the Hopkin's Symptom Checklist (better known to many as the SCL-90),¹⁷ the Profile of Mood States,¹⁸ and the Center for Epidemiologic Studies Depression Scale (CES-D).¹⁹ It quickly became apparent that these measures were not well suited to the cancer survivor population, which, although experiencing distress, generally did not report symptoms at psychiatric or pathologic levels. At the same time, teasing apart symptoms that might be caused by the effects of treatment (e.g., fatigue/lack of energy, sleep disruption, problems concentrating) from signs of emotional distress created a challenge to score interpretation.²⁰⁻²² Further, many of the experiences of those treated were poorly captured by the questions asked in these tools. Frustration with the limits of these more-generic tools resulted in the birth of cancer-specific measurements, an enterprise that, although starting slowly, burgeoned in the 1980s to produce many of the QOL measures, or at least their sophisticated variants, most commonly used today.²³⁻²⁶

Role of Advocacy in the Growth of the Field

DEFINING THE DOMAIN

The shift in focus and language to recognition of people with a history of cancer as "survivors" and their health and social outcomes as constituting "survivorship research" has its own history. In 1985, a young pediatrician working for the Public Health Service, Fitzhugh Mullan, wrote about his experience of living with cancer in a short piece for the *New England Journal of Medicine*. He referred to his journey as the "Seasons of Survival" and in his text first gave name to issues of survivorship.²⁷ In October 1986, he and an intrepid group of about two dozen fellow survivors, cancer healthcare providers and advocates, met in Albuquerque, New Mexico, and established the National Coalition for Cancer Survivorship (NCCS).²⁸ The standard medical definition of a survivor at the time of that gathering, and the only definition commonly applied, held that only those individuals who remained disease free for a minimum of 5 years could be labeled as survivors. At the founding NCCS meeting, the group declared that a person should be viewed as, and was entitled to call himself or herself, a survivor, "from the moment of diagnosis and for the balance of his or her life, regardless of the ultimate cause of death."

The group's argument for advancing this new definition was that it was only by endorsing such thinking that survivors would be able to significantly alter the prevailing medical culture. Specifically, they sought to encourage the cancer practitioner community to move away from its more narrow focus on starting treatment as quickly as possible to one that recognized that a person's unique needs, desires, and ultimate health and life outcomes must be acknowledged in this process. Ideally this would start on day 1, after diagnosis. Although controversial at the time, and certainly not uniformly embraced even today, this broader definition of a cancer survivor has taken hold, at least in the United States. In a search of *Pub Med* from 1981 to 1985, the 5-year period before the founding of the NCCS, 28 research articles (among humans, published in English), were identified using the terms cancer survivorship. Using the same approach to examine the "hits" in 5-year increments since then yielded the following: 1986–1990, 1,700 citations; 1991–1995, 8,417; 1996–2000, 10,574; 2001 to current (with 16 months still remaining to come during this 5-year period), 7,673. Although many of the citations identified would not be classified by many as addressing issues related to living with or beyond cancer (i.e., many still focus on survival, not survivorship), the numbers speak for themselves. On the public side, since 1987 the first Sunday in June has been celebrated as National Cancer Survivors' Day. Many of the large cancer centers in major cities now hold their own "Cancer Survivors Day" celebrations, often in association with special presentations by survivors, scientists, and advocates. The most significant evidence that the field of cancer survivorship had finally come into its own was the creation of an Office of Cancer Survivorship within the world's premier cancer research center, the U.S. National Cancer Institute.

A BRIEF HISTORY OF THE OFFICE OF CANCER SURVIVORSHIP

Had NCCS members decided to stop at endorsing a new definition of survivor, it is not clear how rapidly the broader field of survivorship research might have progressed. Fortunately, they were not content to merely draw attention to the needs of those living with a history of cancer. NCCS members began to advocate for specific resources to further identify and address these needs. In anticipation of what would become the first NCCS Congress, held in Washington, D.C., in November 1995, the Coalition sought the input of scores of researchers, clinicians, and survivors on what questions remained unanswered, who should be charged with addressing these, and how best were we going to achieve optimal cancer care for all. Response to this inquiry was combined in a white paper entitled *Imperatives for Quality Cancer Care: Access, Advocacy, Action & Accountability*. In spring 1996, Ellen Stovall, Executive Director for NCCS, gave a copy of this document to the director of the NCI, Dr. Richard Klausner. After reading this paper, Dr. Klausner called for the creation of the Office of Cancer Survivorship (OCS).

Formally inaugurated at a ceremony held in the Rose Garden of the White House in October 1996, the OCS was established in recognition of the growing population of cancer survivors and their unique and poorly understood needs.²⁹ The overall mission of the office is to enhance the length and quality of survival of all those diagnosed with cancer. The

OCS achieves this by serving as a focus for the support and direction of research that will lead to a clearer understanding of, and the ultimate prevention of, or reduction in, the adverse psychosocial, physical, and economic outcomes of cancer and its treatment. Survivorship research is seen as encompassing the medical, functional, and health-related QOL of children and adults diagnosed with cancer, as well as that of their families. It also includes within its domain issues related to healthcare delivery, access, and follow-up care as they relate to survivors. Because considerable work had been done in elucidating the needs and care of those newly diagnosed and in active treatment, particular emphasis in creating the OCS was placed on developing and supporting research that addresses the health and well-being of individuals who are posttreatment or in remission. The OCS also has as its purview a commitment to educating healthcare providers, as well as survivors themselves, about issues and practices critical to their patients (or in the case of survivors, their own) optimal well-being. Finally, the OCS works to foster and promote the training of the next generation of survivorship researchers and clinicians.

In 2001, members of the OCS, the NCI Director's Consumer Liaison Group, and a number of community researchers and advocates independently suggested that NCI leadership consider advancing cancer survivorship as an area for special focus along with other previously identified topics such as Genes and the Environment, Cancer Imaging, Research on Tobacco and Tobacco-Related Cancers, and Cancer Communications. This recommendation met with approval and elevated Cancer Survivorship to special status in NCI's Fiscal Year 2004 and 2005 budgets^{31,32} (pp 88–93 and 66–71, respectively). Successful adoption of cancer survivorship as an extraordinary opportunity for investment by the NCI was in significant measure due to the specific intercession of Dr. Andrew von Eschenbach. Dr. von Eschenbach's appointment as NCI Director by the President of the United States brought to the Institute in February 2002, for the first time, a cancer survivor as its director. Throughout his leadership, Dr. von Eschenbach has been outspoken about his own cancer experience as a three-time survivor and an unflagging champion for survivorship research.

The breadth of attention to cancer survivorship as an area of public health interest is reflected in a number of recent events at the national level. These events include the release in 2002 by the Institute of Medicine's National Cancer Policy Board of its report *Childhood Cancer Survivorship: Improving Care and Quality of Life* (the adult cancer companion for which is expected to appear in late 2005)³²; the decision by the President's Cancer Panel to pursue cancer survivorship as a theme for its planned hearings in 2003 and 2004, the report from which activities, *Living Beyond Cancer: Finding a New Balance*, was released at the annual meetings of the American Society of Clinical Oncology held in New Orleans in June 2004³³; and the publication in April 2004 of *A National Action Plan for Cancer Survivorship: Advancing Public Health Strategies* by the Centers for Disease Control and Prevention (CDC) and the Lance Armstrong Foundation.³⁴ The latter two initiatives bear the important contribution of Lance Armstrong. Lance, seven-time winner of the world's most grueling bicycle race, the Tour de France, an accomplishment achieved after his diagnosis with and treatment for metastatic testicular cancer, was nominated in 2002 by President

Bush to serve as one of three members of the President's Cancer Panel. The foundation that bears his name underwrote the CDC effort to produce the *National Action Plan* document. During this same period, 2002–2004, five separate bills were introduced in Congress that included language identifying cancer survivorship as an area warranting more attention and funds from the U.S. Department of Health and Human Services (DHHS); one of these would have formally authorized the office by an act of Congress. None of these bills ultimately became law. However, the fact that they were put forward (with others of similar intent likely to follow) is strong evidence that the nation acknowledges that it is not enough for our scientists to find a cure for cancer; we must also, as a country, ensure the quality of the lives of those treated. In the Congressional appropriations document for 2003 (Senate Report 107-216; Department of Labor, Health and Human Services, and Education, and Related Agencies Appropriation Bill), members of the Senate wrote “. . . More must be done to improve the understanding of the growing cancer survivorship population, including determinations of the physiological and psychological late effects, prevalence of secondary cancers, as well as further development of effective survivorship interventions. The Committee supports an aggressive expansion of the NCI Office of Cancer Survivorship activities . . .”.

Function of Survivorship Research in Cancer Control and Care

The world of cancer survivorship research has expanded far beyond that originally envisioned. In the early 1970s, the function of such research was largely limited to describing the “terrain” of survival. By the early 1980s, researchers sought not simply to elucidate the impact of cancer on the lives of individuals and their families but to use this information to develop interventions to help survivors cope better with their illness.^{35,36} In the case of pediatrics, the findings from survivorship research were being used to refine cancer therapies so as to reduce their associated morbidity without diminishing the gains achieved in reduced mortality.³⁷ As we race into the new millennium, this vision, along with the approach to as well as application of survivorship research, has vastly expanded and come to encompass the entire cancer control continuum (Figure 100.3). Originally occupying just one part of the continuum, cancer survivorship research and care now have the potential to address and affect issues along the entire continuum. For example, with more young survivors expected to live full or lengthened lifetimes, they need to be counseled to reduce the risk of (primary prevention) and screened for (secondary prevention) other unrelated malignancies for which they would be at risk across the course of life/normal aging.³⁸

Clinically, the primary function of survivorship research is fivefold. Information about survivors is critical if we are to help patients make decisions now about treatment options that will affect their future; understand the action of and tailor therapies to maximize cure while minimizing adverse treatment-related effects; develop and disseminate evidence-based interventions that reduce cancer morbidity as well as mortality and facilitate adaptation among cancer survivors; improve quality of care and control costs; and equip the next generation of physicians, nurses, and other healthcare profes-

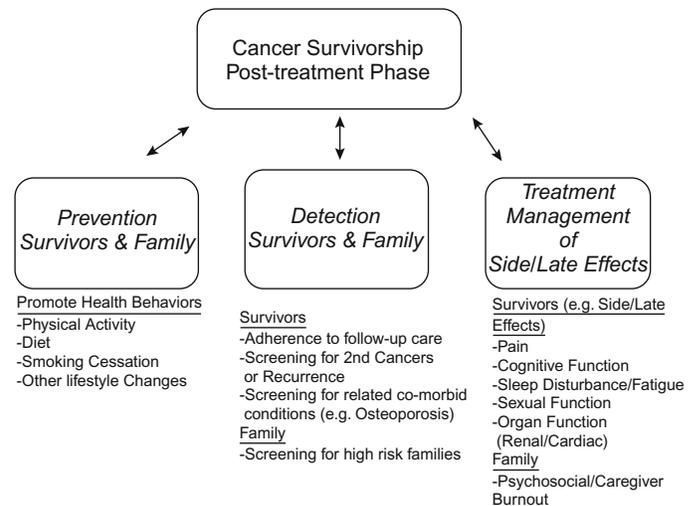

FIGURE 100.3. Aspects of cancer survivorship interventions.

sionals to provide not just the science but also the art of comprehensive cancer medicine.

The New Generation of Survivors: Who are They?

Profile of the Current Survivor Population

“The new population of survivors hanging in there can be found everywhere . . . in offices and factories, on bicycles and cruise ships, on tennis courts and beaches, and in bowling alleys. You see them in all ages, shapes, sizes, colors, usually unremarkable in their appearance, sometimes remarkable for the way they learn to live with disabilities.” (Natalie Davis Spingarn,³⁹ p. 69)

In 1982, Natalie Davis Spingarn became one of a feisty vanguard of cancer survivors, and vocal patient advocates, to publish a book about their encounter with cancer. Her volume, titled *Hanging in There, Living Well on Borrowed Time*,³⁹ chronicled her experience of being diagnosed as a young woman (under age 50) and living long term with metastatic breast cancer. A journalist and investigative reporter by training, Natalie provided information often hard for fellow cancer travelers to find and encouraged them to become active participants in their care, a quite provocative message for those more comfortable operating in the paternalistic model of care of the times. In 1999 she published an update of this journey in a book titled *The New Cancer Survivors: Living with Grace, Fighting with Spirit*.⁴⁰ In this second volume she describes what she recognized as a new and emerging generation of survivors who come from all walks of life, seek an equal or at a minimum a partnership role in their health-related decision making and care, and expect to be treated as whole persons, not as a particular disease (cancer) or body site (breast patient).

The main driver behind interest in issues of cancer survivorship is necessarily the growing population of survivors. Cancer survival in the United States has risen steadily over the past three decades for all cancers combined. When Nixon declared “the war” on cancer in 1971, there were only

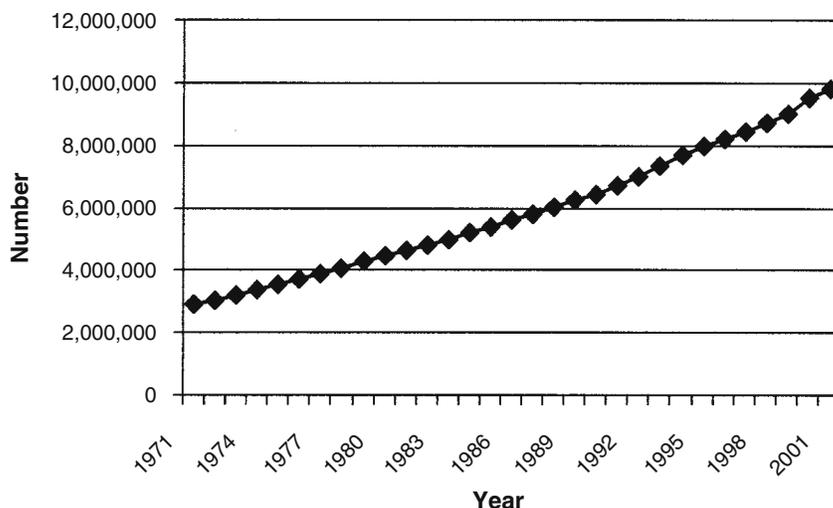

FIGURE 100.4. Estimated number of cancer survivors in the United States from 1971 to 2001. U.S. estimated prevalence counts were estimated by applying U.S. populations to Surveillance Epidemiology and End Results (SEER) 9 Limited Duration Prevalence proportions. Populations from January 2000 were based on the average of the July 1999 and July 2000 population estimates from the U.S. Bureau of Census. (Source: November 2002 submission.)

3 million survivors. Today, there are approximately 22.4 million cancer survivors worldwide; an estimated 9.8 million of these live in the United States alone, representing between 3% and 4% of the population (Figure 100.4).⁴¹ In the absence of other competing causes of death, current figures indicate that for adults diagnosed during 1995 to 2000, 64% could expect to be alive in 5 years; this is up from 50% estimated for those diagnosed during 1974 to 1976. The relative 5-year survival rate for those diagnosed as children (less than 19 years of age) is even higher. Of children diagnosed with cancer between 1974 and 1976, while 80% survived beyond 1 year, little more than half (56%) were still alive 5 years later. Today, 79% of childhood cancer survivors will be alive at 5 years, and the 10 year survival is approaching 75%. If these trends in survival continue, we may reasonably expect to reach the 2010 *Healthy People* goal of 70% 5-year survival for all those diagnosed with cancer.

Of the 9.8 million survivors in the United States, an impressive 14% were diagnosed 20 or more years ago (Figure 100.5). More women than men are survivors. The higher proportion of men who are within 5 years of diagnosis is

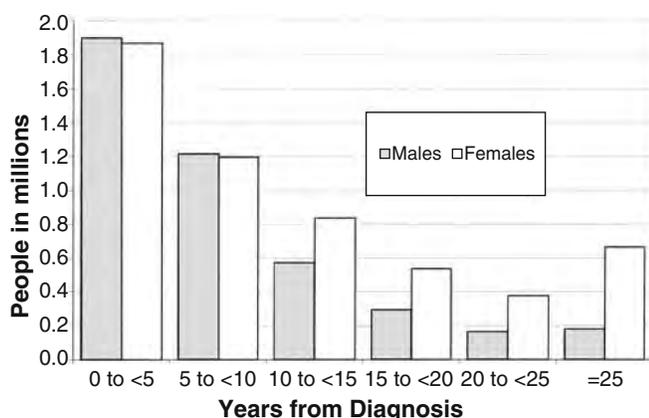

FIGURE 100.5. Estimated number of persons alive in the United States diagnosed with cancer on January 1, 2001, by time from diagnosis and gender (invasive/first primary cases only; $n = 9.8$ million survivors). U.S. prevalence counts were estimated by applying U.S. populations to SEER-9 Limited Duration Prevalence proportions. Populations from January 2001 were based on the average of the July 2000 and July 2001 population estimates from the U.S. Bureau of Census. (Source: November 2003 submission.)

consistent with the larger number of males versus females diagnosed annually with cancer. At the other end of the survivorship continuum, more women survive longer than men due to the higher proportion found to have more readily detected and treatable cancers (e.g., breast, gynecologic), the fact that fewer women ($n = 80,660$) than men ($n = 93,110$) develop lung cancer or die of it (females, 68,510 versus males, 91,930) annually,³ and the generally lower all-cause mortality rate among women versus men in this country.

Of the prevalent cancer population, the largest constituent group comprises breast cancer survivors (22%), followed by survivors of prostate cancer (17%), colorectal cancer (11%), and gynecologic cancer (10%) (Figure 100.6). Consistent with the fact that cancer is a disease associated with aging [median age of cancer patients at diagnosis based on

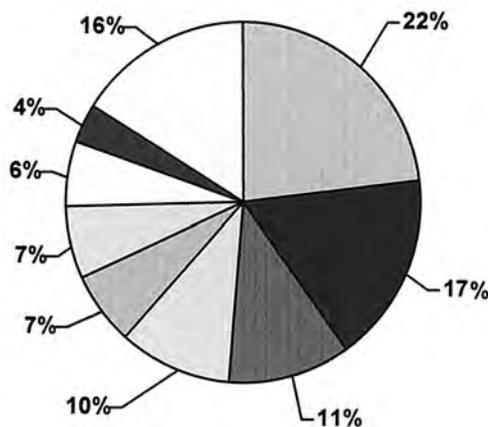

FIGURE 100.6. Estimated number of persons alive in the United States diagnosed with cancer by site. Starting *clockwise from 12:00 position*: female breast (22%), prostate (17%), colorectal (11%), gynecologic (10%), other genitourinary (GU, bladder and testis) (7%), hematologic [Hodgkin's Disease (HD), non-Hodgkin's lymphoma (NHL), leukemia] (7%), melanoma (6%), lung (4%), and other (16%). U.S. Estimated Prevalence counts were estimated by applying U.S. populations to SEER 9 for All Races, White, and Black, SEER 11 for Asian/Pacific Islander, and SEER 11 (excluding Hawaii and Detroit for Hispanic) Limited Duration Prevalence proportions. Populations from January 2001 were based on the average of the July 2000 and July 2001 population estimates from the U.S. Bureau of Census. (Source: November 2003 submission.)

SEER (Surveillance, Epidemiology, and End Results) 12 data from 1997 to 2001 was 67 years; an estimated 56.8% of new cancers are diagnosed in patients 65 and older),⁴² the majority (61%) of our survivors are aged 65 or older, while 33% are between ages 40 and 64, 5% are aged from 20 to 39 years, and fewer than 1% are 19 or younger. It is currently estimated that one of every six persons over the age of 65 is living with a history of cancer. Although it is unknown what impact the use of chemopreventive agents such as tamoxifen will have on the larger figures for breast cancer incidence, as past and future advances in cancer detection, treatment, and care diffuse into clinical practice, the number of survivors can be expected to increase. Fewer deaths from cardiovascular disease and the aging of the population will contribute to this trend.

Projected Population of the Future

Realization that the world's population is aging is sobering.⁴³ In 2011, the first members of the baby boomer generation (those born between 1946 and 1964) will turn 65. It is estimated that by the year 2030 one in five individuals will be age 65 or older and 40% will be from minority groups. At the same time, it is recognized that older cancer patients tend to be in poorer health (34% versus 10% of the general population), often have two or more chronic medical conditions (16% versus 4%), report functional limitations (nearly 70% versus less than 30%), and experience more limitations in activities of daily living (ADL) or instrumental ADL (17% versus 3%).⁴⁴ Given these figures, it is clear that planning for the care and ongoing health of our aging population, many of whom will become cancer survivors, constitutes a critical public health challenge for the future.⁴³

The OCS includes family or caregivers as "secondary" survivors in its definition of survivors. This concept reflects the growing appreciation of the critical role they play in a loved one's or family member's illness. The American Cancer Society (ACS) in its *Facts and Figures* publication for 1996 estimated that three of every four families would have an affected family member. Recent data on caregiving in America suggest that 21% of those over the age of 18 provide unpaid care for an adult 18 and older. The second most common reason for a recipient to need care, after old age, is cancer.⁴⁵ Data obtained from cancer survivors identified by the National Health Interview Survey in 1992 indicated that approximately 24% of adult cancer survivors (1.3 million) had a child 18 years of age or younger living in the home.⁴⁶ To date, relatively little is known about the impact of living with someone who has cancer on other family members in general; even less is known about cancer's impact on the current or future health behaviors and well-being of younger and potentially highly vulnerable family members.

With advances in our understanding of genomics and proteomics and the application of novel delivery systems, many project that future antineoplastic therapies will be more targeted to cancer cells and less toxic to normal tissue, resulting in significant reductions in treatment-associated morbidity. This is not to say cancer therapy will be entirely benign, as few pharmacological treatments are ever entirely without side effects. Monitoring for the novel, potentially subtle, and late-appearing or unexpected effects of newer

approaches to cure represents a challenge to future researchers. Of equal importance will be our ability to assess the impact of delivery of these molecularly targeted treatments. Many agents will be administered orally, shifting the responsibility for delivery and monitoring away from the medical team and to the patient. Appreciating the obstacles faced by patients and families to understand and adhere to regimens will be critical if we are to understand not just drug effectiveness but also survivors' QOL and health-related outcomes.

Domains of Survivorship Research: Multidimensionality

In the early era of research on the psychosocial and physical impact of cancer, the common practice was to use global (e.g., Karnofsky) or summary scores representing overall function across a range of activities of daily living activities (e.g., FLIC, functional living index-cancer; LASA, linear analog self assessment). Perhaps unique to cancer QOL studies (as opposed to those for other chronic illnesses) is their history of emphasis on the importance of patient-based outcomes. What was quickly apparent in instrument selection and development was the need for patient (versus physician)-based measures.⁴⁷⁻⁴⁹ The few clinician-rated scales still commonly in use represent measures to assess patient status for clinical trials (e.g., ECOG, Eastern Collaborative Oncology Group, status) or were designed for use when a patient might be too sick to complete a self-assessment, e.g., the Spitzer Quality of Life Index.⁵⁰

As clinicians began looking more closely at patient-focused outcomes and more behavioral scientists joined the field of inquiry, four primary areas of QOL impact emerged: physical (symptoms), functional (capacity to engage in activities of daily living), emotional (mood/affective and cognitive status), and social (role functioning and/or support, financial burden). Examples of early scales with these four domains include the Quality of Life Index⁵¹ and the Sickness Impact Profile.⁵² These four domains remain at the core of contemporary scales.

An early challenge for the field was the need to develop and test cancer-specific tools. As already noted, initial studies of mental health outcomes for survivors relied heavily on the use of instruments borrowed from the psychiatric arena, for example, the Hopkins Symptom Checklist (SCL-90) and the Profile of Mood States (POMS). Even when studies became more sophisticated and expanded to include such domains as sexual functioning, the available measures (e.g., Derogatis Sexual Functioning Inventory) were often poorly designed to assess cancer patients' functioning or unique areas or types of dysfunction. It is of note that the recent interest in examining benefit finding among survivors led clinical researchers to reflexively go back to the psychiatric literature for tools (e.g., posttraumatic stress scale, civilian version; posttraumatic growth inventory) before realizing that they would need to develop measures better suited to capturing the cancer experience.

The most recent generation of cancer-specific measures is designed to assess domains of well-being that represent newer foci of attention. These measures include, for example, items or scales to assess fatigue, cognitive dysfunction, and

menopausal or hot flash symptoms, as well as bowel and urologic status in colorectal, select gynecologic, and prostate cancer survivors. (See the Cancer Outcomes Measurement Working group-generated publication for an excellent review of current measurement tools.⁵³) The two newest areas of attention in measurement development are long-term survivorship scales⁵⁴⁻⁵⁶ and measures of postcancer health behaviors.⁵⁷⁻⁶⁰ Curiously, although fear of recurrence is probably the single most common concern of those living with a history of cancer, efforts to create instruments designed specifically to measure this domain have languished.⁶¹⁻⁶³

There has been considerable debate as to whether current measures assess QOL or simply health-related quality of life (HRQOL).^{64,65} Many argue that individual QOL is intangible and almost impossible to meaningfully measure. Although the majority of survivorship researchers today use the terms QOL and HRQOL interchangeably, when pressed most agree that our common assessment tools are most accurate in providing (and often specifically designed to generate or elicit) information on survivors' perception of their health-related quality of life than QOL per se. One of the more recently appreciated challenges to the field of QOL assessment among cancer survivors is interpreting the impact cancer has over time in individuals' lives. Cancer researchers are (re)learning what others have reported for decades,⁶⁶ that humans are incredibly adaptable and, given time and support, can adapt to considerable limitations. The manifestation of this resilience is seen in what researchers now refer to as "response shift" in subjects' report of functioning and well-being when measured over time.⁶⁷ In this paradigm, respondents, as they accommodate to a loss or disability, are less likely to report being upset by it, even though the impairment may continue to cause the same level of, and sometimes greater, disability over time. Trying to make sense of this phenomenon while teasing out what health-promoting interventions may or may not be most helpful for survivors' recovery has become a respected field of inquiry in itself.

Trends in Survivorship Research

Past

The historical research on survivorship has been well reviewed by others.^{35,36} General themes have evolved over time. In the early era of survivorship research, most studies focused on the psychological impact of cancer or the delineation of specific sequelae of treatment (e.g., impact of stomas, lymphedema, amputation).^{68,69} As the number of survivors grew and length of survival increased, attention expanded to include examination of the social (interpersonal, family, work, school) and sexual well-being of survivors.^{6,70-72} By the mid-1980s, researchers, responding to the observation by many survivors that they continued to reexperience aspects of the events associated with their diagnosis and treatment, began to conceptualize cancer as a "traumatic event." A new wave of studies sought to determine the extent to which cancer produced symptoms of posttraumatic stress disorder (PTSD).^{73,74} In pursuing this path, investigators began to hear from survivors, particularly in studies that contained

qualitative analyses or open-ended formats, that cancer also caused them to recognize the positive aspects of their lives. The consequence of this observation is that a current trend in research is to examine the role of benefit finding in promoting and/or mediating and moderating survivorship outcomes.⁷⁵⁻⁷⁷

Since the establishment of psychosocial oncology as a field of its own in the early 1970s, clinical researchers have actively sought to take what they learned in their surveys and apply it to interventions that would reduce cancer's toll on survivors and their families. Relatively little of this research, however, was designed exclusively to meet the needs of those posttreatment.^{78,79} This picture is slowly changing.

Present

Since 2000, the NCI's Office of Cancer Survivorship has conducted annual analyses of the number and types of grants in the area of cancer survivorship funded across the National Institutes of Health. (These data are updated and posted yearly online.⁸⁰) Included in this analysis are grants that examine the health or behavior of individuals after treatment for cancer or that of their family members. Excluded from this review are studies that consider patients solely during active treatment or early posttreatment (less than 2 months follow-up) or survivors with recurrent or advanced disease. When the OCS was originally established in 1996, only 24 National Institutes of Health (NIH) grants could be identified that met these narrower criteria. In the philosophy of "build it and they will come," the NCI's commitment to this area of science, with the creation of the OCS, appears to have been successful.

Judging by the numbers, the research community is slowly being enticed to advance its expertise to tackle issues further along the cancer control continuum. In fiscal year 2003 (encompassing October 2002 through September 2003), the period for which most complete data exist, a total of 179 grants were identified as addressing survivorship issues. Of these, 154 (86%) were funded through the NCI. The remainder were supported by the National Institute for Nursing Research ($n = 14$), National Institutes of Mental Health ($n = 5$), National Institute on Aging ($n = 4$), and the National Institute of Dental and Craniofacial Research ($n = 2$). That many grants end up at institutes other than the NCI reflects the fact that many of the issues faced by survivors (e.g., depression, aging, family challenges, pain syndromes) are not always unique to cancer. In keeping with past patterns, the majority of studies supported were descriptive or analytic in nature (54%). However, 42% of the funded research projects contained an intervention component designed to improve the psychosocial well-being, physical status, and/or health behaviors of survivors and/or their family members. This latter figure is important as it denotes the transition that is occurring in the research arena away from mere identification of problems (discovery) to the development and testing of interventions designed to reduce posttreatment morbidity and mortality (development). Most of the studies continue to be unique to or include samples of breast cancer survivors ($n = 79$, 44%), who, for a variety of reasons, have historically been the focus of the majority of the psychosocial research conducted in cancer.⁸¹ Other leading cancer sites

represented in this work include hematologic, prostate, and colorectal.

A clear testament to the success of the NCI's efforts to grow in survivorship research, and the readiness of the research community to pursue questions in this area, is reflected in the response to its request for applications (RFA) for studies addressing long-term cancer survivorship (defined as studies among cancer survivors diagnosed 5 or more years ago). In 1997 the OCS presented its first such RFA (CA 97-018), which attracted 79 applications. In 2003, the RFA was reissued (CA 04-003). A total of 125 applications were received in response to this second call. Of the 125 grants received, 50 (40%) were from investigators new to the field of cancer survivorship research.

One of the reasons that the NCI reissued the Long-Term Survivors RFA was that without this impetus few investigators appeared willing to take on the additional challenges of studying individuals years posttreatment. A review of the research portfolio conducted before the RFA reissuance revealed that only 27 of 126 grants analyzed were studying survivors 5 or more years postdiagnosis; 21 of these were developed in response to the initial RFA. Critical barriers to long-term survivorship research include finding this population, obtaining access to them, including negotiating the many hurdles consequent to the recently implemented Health Insurance Portability and Accountability Act (HIPAA) regulations, developing tools that measure outcomes of relevance to the long-term survivorship experience, identifying appropriate control or comparison groups, and coordinating a team invested in addressing these issues.

Future

Staff at the American Cancer Society took advantage of the opportunity to poll investigators engaged in behavioral, psychosocial, and policy research in cancer about their current interests and expectations for future research foci when compiling a directory of these individuals in 1997 and again when they updated the directory for release in 2002.⁸² Addressing psychosocial issues and treatment and outcomes remained key interest areas over time, a finding not altogether surprising given the target survey participants. However, two important areas for future research emerged in this report: the need to address special populations, a future direction voiced by members of all five of the disciplines represented (behavioral scientist, epidemiologist, nurse, physician, psychologist), and growing attention to health education and communication. Interesting in this study was the low endorsement of interest in survivorship research. Less than 10% said they were engaged in this type of research in 1997 (7.3%), and only 1.5% in 2002. However, in 2002, 11.7% thought it was going to be an important area of research in the future.

Ongoing analysis of the NIH-wide survivorship portfolio highlights a number of areas where our knowledge is lacking. Two of these areas echo themes identified for future targeting by Nehl and colleagues⁸²: (1) the exploration of outcomes for our diverse population of survivors, specifically those from ethnoculturally diverse backgrounds, those from low-income or low educational backgrounds, rural survivors, elderly survivors, and survivors from common cancer sites under-

represented in the literature (lung, colorectal, gynecologic, hematologic)⁸³; and (2) effective communication about survivorship-related issues. To these, four more areas are added, including (3) research on the impact of cancer on the family or caregiver; (4) studies addressing the economic impact of cancer on survivors and survivorship; (5) assessment of the nature, delivery, and outcomes of follow-up care to survivors; and (6) measurement tool development, including that which would enable us to compare survivors with those without a cancer history while also controlling for other comorbid illness states.

As the field of survivorship research has matured, change has occurred not only in the focus of the research being conducted but also in how and by whom this research is being carried out. The typical published cancer survivorship study has evolved from a largely descriptive outcome report based on a small single institution sample^{84,85} to one involving multidisciplinary teams accruing large cohorts and applying complex outcome and intervention assessments.^{86,87} A concrete measure of the growing sophistication of this body of research is the expectation by standing members of study sections (peer review groups) to see power analyses, detailed rationales for measurement choices, adequate representation by appropriate diverse scientific experts, and demonstrated sensitivity to the unique needs and experience of the target survivor group in grants submitted for review, with general impatience with studies that appear to "rediscover" what is already documented. Table 100.1 provides an overview of some of these trends over time.

Looking to the future, it is expected that a healthy balance needs to be maintained between the identification of problematic long-term and late effects of cancer and our ability to address these. The roughly 60%/40% split in current NIH-funded research between studies aimed at identifying problem areas and those designed to develop and test interventions that reduce the negative effects of cancer is probably a reasonable balance. With respect to the intervention arena, two new trends are of note. It is increasingly apparent that to be successful this research must (a) attempt to explain the biopsychosocial interaction between what is being delivered and its impact on health outcomes^{88,89} and (b) control or account for the costs associated with its delivery.⁹⁰ Although psychoneuroimmunology (PNI) research in cancer is by no means new,⁹¹⁻⁹³ attention to mind-body links is expanding as researchers seek to explain what is going on inside the proverbial "black box," in particular, in the context of psychosocial interventions that might mediate or moderate the impact of these trials on cancer recurrence or survival. Further, although drug interventions are relatively low cost, most psychosocial or behavioral interventions are labor intensive and hence more expensive to deliver. Despite this, there is good evidence to suggest they can reduce medical costs.⁹⁴ In recognition of this, investigators are working hard to design interventions that can be either self-administered,^{90,95} delivered readily by available healthcare staff with minimal training,⁹⁶ and/or, the newest piece in these models, made available online.^{97,98} This last point is critical if we are to have any hope of taking into the broader community interventions that hold the promise of significantly reducing the burden of cancer on individuals and society.

TABLE 100.1. Trends in cancer survivorship research design.

	<i>Past</i>	<i>Present</i>	<i>Future</i>
Target samples	Generally small convenience samples, often single institution based and mainly white, middle class, and middle age; largely breast cancer, or mixed, some colorectal, gynecologic; also pediatric, but largely leukemia	Moderate to large samples; often multiinstitutional; some clinical trials and population- or registry-based; increasing diversity of survivor groups by age and site (especially prostate, Hodgkin's disease, other gynecologic); still limited ethnocultural, income, and geographic diversity; more focus on family/caregivers	Mix of large (e.g., cohort, population-based) and moderate size; largely multiinstitutional; greater representation of more diverse cancer sites and previously neglected populations (e.g., by ethnic/income/geographic/age groups); more use of clinical trials samples
Team	Physicians, nurses, and some mental health professionals	Multidisciplinary teams; behavioral scientists leading in many areas; nurses with strong role as well; increasing role of advocates/survivors in research design	Truly multidisciplinary teams; attention to addition of basic scientists and psychoneuroimmunology (PNI) researchers to understand mind-body implications and impact of research findings for recurrence/survival, risk, and treatments; customary role for advocates/survivors in research
Basic design	Descriptive; limited interventions; often atheoretical and exploratory in nature; almost exclusively cross-sectional designs	Increase in hypothesis- and model-driven designs; complex multicomponent interventions growing; replication studies appearing; longitudinal studies increasing	Sophisticated model building and hypothesis testing; emphasis on building on prior studies, including research to take interventions to different audiences, settings, deliverers; intervention designs incorporating biologic markers and/or economic and health services endpoints or outcomes; longitudinal/cohort research
Topic	Focus almost exclusively on documenting dysfunction: distress, disability, impairment; a few coping studies; limited risk modeling	HRQOL instrument development; shift to evaluate both benefits and deficits of illness; modeling of risk for poor outcomes; examining role of caregivers in survivor outcomes and vice versa; growing attention to treatment effects and focused attention to specific problems, e.g., sexual dysfunction, fatigue, cognitive impairment; beginning attention to health after treatment	HRQOL development for long-term survivors (including comparison to other chronic illness groups and controlling for comorbid conditions); identifying/describing late, as yet unknown effects of cancer and novel problems associated with newer treatments and risk for these; targeting and tailoring interventions to survivors; identifying who may need what delivered by whom and when in the course of care; establishing the unique human and economic burden of cancer (versus other chronic illnesses); health promotion, follow-up care studies

HRQOL, health-related quality of life.

Challenges for the Future

Looking to the future, investigators face a number of challenges in advancing cancer survivorship research.⁹⁹ These challenges can be seen as falling into three broad categories: (1) identifying the most salient topics for study, (2) creating or enhancing the resources necessary to conduct the research, and (3) developing ways to make use of what is discovered.

Discovery

One of the greatest challenges to engaging in survivorship research is keeping up with the rapid pace of change in cancer treatments and care, as is particularly well illustrated in the context of breast cancer. In the past 10 years we have seen the uptake into standard practice of the use of sentinel node biopsies (replacing axillary node dissections), neoadjuvant (presurgical administration of) chemotherapy for large tumors, dose-intense and dense regimens of adjuvant chemotherapy with their greater attendant exposure to growth factors, testing for Her2 and consideration of herceptin, autologous tissue implants (over saline or silicone implants) for breast reconstruction, and aromatase inhibitors

in the adjuvant setting, as well as a shift away from use of stem cell transplant as a treatment option. Each of these alterations in practice has implications for QOL outcomes for women treated. For example, elimination for many women of the need for axillary node dissection may result in far fewer women developing lymphedema as a consequence of their breast cancer therapy.^{100,101} Nevertheless, greater exposure to more-intense chemotherapy regimens will likely increase the number of women at risk for persistent problems with pain (related to the accompanying use of growth factors)¹⁰² and memory problems (or chemo brain).¹⁰³ Meanwhile, continued changes in the healthcare delivery system are transforming significantly the availability of and access to resources that have been shown to buffer the adverse effects of care (e.g., access to social support, information and education, and rehabilitation services). In an effort to control rising medical costs and respond to diminished insurance reimbursements, many hospitals and medical centers have sought to decrease the number of patient hospitalizations and length of stay, eliminate or downsize the types of support services as well as the number of social workers in their systems, and shift the delivery of oncology care largely to the outpatient setting.^{104,105} Third-party payers in turn have placed constraints on

patients' ability to use specialized providers and/or services. Combined, these changes in the delivery of cancer care have put enormous pressure on cancer survivors and their family members or caregivers to be more self-sufficient or in some cases to do without the support or services they might wish to have in facilitating optimal recovery.¹⁰⁶ This burden is borne disproportionately by minority and underserved members of our society.¹⁰⁷ Curiously, while research consistently shows that providing education and support is important for survivors' capacity to cope with cancer, access to this help is diminishing.

The implication of these changes for researchers is that what may have been critically important for one cohort of survivors may be less relevant to the next generation of individuals treated. For example, body image was a major focus of research in early studies of breast cancer outcomes when mastectomy was the treatment of choice.⁶⁸ Today, most women have a choice (often involving several options) in how to treat the breast and deal with the cosmetic impact of breast cancer. As a consequence, body image disruption is less salient as either an outcome or research issue. Of more concern is how breast cancer treatment may alter sexual function and/or menopausal symptoms, given that more than 50% of women diagnosed now receive some form of adjuvant chemotherapy or hormonal therapy.¹⁰⁸ Increasingly, researchers are finding themselves caught between the need to identify emerging chronic or late effects of newer therapies and chronicling and addressing the long-term effects of older ones. This dilemma can become problematic if, at review, scientific peers around the table cannot see the relevance of long-term outcomes studies (given this picture), or when forced to make a choice about limited funding dollars, opt to support studies about current therapies only.

Some of the more recently identified "hot" areas of symptom research include a focus on memory problems, fatigue, weight gain, long-term cardiac health, osteoporosis, and persistent pain syndromes (associated with exposure to taxanes and/or use of growth factors). Interest in all these concerns has occurred in direct response to survivors' accounts of specific problems with these conditions (e.g., memory problems, fatigue, weight gain, pain), or clinicians' concerns about known potential toxicities of treatment (e.g., second malignancies, cardiac dysfunction, osteoporosis). As already observed, the recent advances in modern computer and laboratory technology and the associated explosion of discovery in the molecular sciences lend hope that future therapies can be designed to have fewer adverse effects on healthy tissue. Nevertheless, listening carefully to patients' experience of these new approaches is critical if we are to identify and evaluate in future generations of survivors the impact of cancer on health.

On a larger scale, with so many individuals living longer following a diagnosis of cancer, growing attention is being given to researching the efficacy of more generic interventions in improving the future health of survivors, not merely in diminishing their current symptoms. There is a growing movement in particular to develop interventions that include elements with the potential to be generalized to other non-cancer conditions. Two good examples of this are the work being done by Antoni and colleagues in the area of stress management^{109,110} and that of Courneya and colleagues on delivery of physical activity interventions.^{111,112} With the baby boomers fast entering the years of greatest cancer risk, under-

standing the role of comorbidities on cancer outcomes and care is critical to both evaluating and reducing the burden of cancer.^{43,44,113,114} At the same time, a pressing need continues for us to understand the enormous and growing divide between survival—and necessarily the survivorship experience—of our communities of color, low income, low education, and rural status, versus the Caucasian and Asian survivor populations about whom we have the most data.^{83,115}

Development

To accomplish any of this work will take some very specific resources and infrastructure or capacity building. First is access to relevant study samples. A continuing challenge for many researchers is identifying and reaching long-term survivors, in particular those diagnosed more than 5 years earlier.¹¹⁶ Tumor registries can help,¹¹⁷ but loss to follow-up is common. Clinical trials groups, an obvious place to partner to obtain long-term follow-up data, also often lose track of their participants over time.¹¹⁸ The introduction of new federal privacy laws (Health Insurance Portability and Accountability Act, or HIPAA), by requiring individual consent for the conduct of specific studies and data sharing, has made access to survivors and their medical records even more cumbersome. This problem is not unique to the United States.¹¹⁹ Establishment of the NCI-supported Childhood Cancer Survivor Study cohort currently provides a rich resource for survivorship information generated from its ascertained sample of roughly 14,000 survivors of childhood cancer diagnosed between 1978 and 1986 and the companion sample of more than 3,800 siblings.¹²⁰ To date, no such repository exists for survivors of adult cancer.

A second critical need is a steady flow of researchers. Despite the fact that the field of psycho-oncology (or psychosocial oncology), and the more-specific area of posttreatment survivorship research, has grown steadily in the past two decades, the number of researchers devoted to this science is still very limited. Further, there continue to be only a handful of training centers across the country devoted to the education and support of the next generation of researchers invested in survivorship research. With the recent creation of the American Society of Psychosocial Oncology (APOS), now independent from the older International Psycho-Oncology Society, there is hope that this picture may change. Further, the advances in computer technology, use of self-training programs for credit, and online access to a world of expertise may help close this gap in investigator resources. In this regard, APOS and the American Society of Clinical Oncology are pioneering efforts to promote the pursuit of continuing education by members in this and related symptom management and assessment domains.^{121,122} Further, colleagues around the world are beginning to develop programs that promise to ensure a future cadre of talented clinicians and researchers.^{123,124}

A third area of necessary development is on the provider side. Some in the pediatric oncology community have been heard to lament that fewer physicians are choosing to pursue careers in this specialty, assuming (incorrectly) that with survival figures already so high, few challenges or opportunities remain to make breakthroughs in this field. Adult oncology, by contrast, continues to offer diverse challenges; one of these being to better understand the long-term and late conse-

quences of treatment as a way to improve cancer diagnosis, treatment, and care. Inadequate support for young physicians to engage in research remains a barrier to ensuring more oncologists will seek to expand their expertise in the survivorship arena. In a 2002 review of professional education and training in cancer survivorship commissioned by the National Cancer Policy Board (NCPB), Roger Winn found that although oncology textbooks were beginning to incorporate pieces about this aspect of care (in particular, the incidence and pathophysiology of chronic or late effects), often the material was fragmented and provided few guidelines for evaluation and care. There were, however, notable exceptions to this, including the Harris et al. volume *Diseases of the Breast*, and the monograph produced for the benefit of its members by the American Association of Family Practitioners on *Cancer Survivors*.

The picture in nursing appears to be quite different. Nurses were among the leaders in pioneering psychosocial research and QOL instrument development in cancer.^{51,54-56} In a review also commissioned in 2002 by the NCPB, Betty Ferrell and Rose Virani found that all the major nursing textbooks of oncology nursing had sections or information on cancer survivorship and addressing late and long-term effects of disease. The Oncology Nursing Society has had a Special Interest Group in this area for several years.

Engaging the entire medical community (including nurses, primary care physicians, mental health professionals, and rehabilitation specialists) is necessary to ensure that we ask the right questions in survivorship research and use the best approaches to conduct this science. All this activity will require fiscal resources. Already there has been a rapid growth in the number of federal dollars being expended on survivorship research. This amount of money remains small, nevertheless, when compared to that being invested in cancer biology, detection, and treatment. In 2003, the OCS supported \$17 million in grant-related research; NCI-wide investment in survivorship research, broadly defined to include studies among individuals across the survivorship continuum from diagnosis to end of life, was estimated at \$160 million, less than 4% of the NCI budget for that year. Further, the end of the doubling of the NIH budget with FY 2004 and expected spending limits projected for the near future threaten to make competition for this still-nascent area of research a critical source of challenge.

On the positive side, a number of additional funders committed to supporting research on survivors' outcomes have appeared on the scene; these include the Lance Armstrong Foundation, the Avon Foundation, the Susan G. Komen Foundation, and the California Breast Cancer Research Program. Recently reframed as constituting a public health issue,³⁴ cancer survivorship is also beginning to appear on the agenda of the Center for Disease Control and Prevention. In addition, as noted earlier, Congress has put forward a number of bills in the past 2 years indicating their intention that the NIH in general and NCI in particular continue to invest in this science. The creation of the Office of Cancer Survivorship at the NCI provided a critical infrastructure and platform from which to oversee, track, and direct cancer survivorship research at the Federal level. Its existence within the NCI serves as a reminder of the importance of this aspect of the cancer control continuum both across NCI and nationally. Staff from the CDC, National Association of American

Cancer Registries, ACS, NCI, and American College of Surgeons recently put forward recommendations for elements of the framework necessary to move cancer control forward in the next 20 years.¹²⁵ Similarly, members of NCI's Division of Cancer Control and Population Sciences have outlined where we need to go in the future to advance quality of cancer care across the continuum.¹²⁶

Delivery

The final challenge faced is how best to disseminate and use the information gleaned from the growing body of cancer survivorship research. To date, this process has been painstakingly slow, in particular in the adult oncology arena. Delivering on what we already know represents, both historically¹²⁷ and at the present time, the least developed area of cancer survivorship research and constitutes one of the most significant challenges for the future.¹²⁸⁻¹³⁰ This problem is well illustrated in a recent publication of the Institute of Medicine (IOM) entitled *Meeting the Psychosocial Needs of Women with Breast Cancer*.¹³¹ In this volume, the multiple authors provide a wealth of evidence indicating that we already understand the kinds of problems faced by women treated for this disease, the handful of risk factors that increase risk for poor QOL, and the types of interventions that may help improve women's outcomes. Translating this into practice remains the biggest hurdle. This need includes educating healthcare providers about the psychosocial and behavioral effects of cancer and training them to incorporate psychosocial concerns into standard treatment planning and posttreatment monitoring, as well as designing and funding healthcare delivery systems that support this activity.¹²⁸ It is of note that, even in the nation's comprehensive cancer centers, programs for survivors who have completed their cancer therapy remain limited.¹³² In addition, in many of these centers, researchers engaged in survivorship research are not routinely connected with the clinics or care centers.

These same kinds of struggles play out differently in the area of childhood cancer. In pediatrics, attention to the "total child" and his or her family is simply part of standard care.¹³³ Further, most pediatric care, whether in the cancer or non-cancer setting, is designed around promoting normal development and preventing or minimizing risk of disease. Pediatric oncologists, perhaps because of the dramatic advances made in curing childhood cancers, have been at the forefront of efforts to tailor therapies to reduce morbidity without compromising cure. For example, once trials began to show that use of central nervous system prophylaxis dramatically altered the survival for children with ALL in the late 1960s and early 1970s, clinicians quickly turned their attention to finding less-toxic ways to provide this coverage that would eliminate the need for or reduce the dose of cranial radiation to which children would be exposed.³⁷ Equivalent evidence for this approach in adult oncology is harder to identify. The movement away from more-radical excisions to greater tissue-sparing approaches to surgery, as seen in breast and colorectal cancer, are good examples of efforts to modify treatment to improve QOL without adversely affecting cure. These surgical oncology examples notwithstanding, the general trend in adult oncology remains heavily focused on delivering more, not less, treatment, even if the length of time over which these therapies are administered is shrinking.

More recently, both the pediatric and adult oncology communities have engaged in efforts to decide how best to follow themselves, or engage the larger adult healthcare delivery system to care for, the growing population of young and maturing adults previously treated as children.^{134,135} The Children's Oncology Group (COG) has taken a leadership role in shaping this effort. In spring 2004 COG publicly released the first set of comprehensive, long-term follow-up guidelines.¹³⁶ Unique to this document is its attention to the long-term and late sequelae of curative therapies. Unlike currently available guidelines for adult survivors who are posttreatment (e.g., as developed by ASCO, American Society of Clinical Oncology, and NCCN, National Comprehensive Cancer Network) that focus exclusively on cancer surveillance, the childhood cancer follow-up guidelines are constructed around identification and management of risk-based, exposure-related problems that may be screened for and potentially addressed after treatment. Largely unknown is how nononcology professionals view and care for the survivors in their patient population.¹³⁷ What evidence we have suggests that many survivors are not receiving care that might be expected for peers without a cancer history.^{38,59,138,139} In this regard, data from two NCI-led SEER-based research studies on hematologic (non-Hodgkin's lymphoma, NHL) and selected solid tumor (breast, colorectal, prostate, gynecologic) survivors' experience of posttreatment care that will be available starting in 2005 should be informative.

A final criterion for the success of what one might call the cancer survivorship research enterprise is whether it is having an impact on the outcomes of present and future survivors and/or their families and caregivers. This aspect of survivorship research is as yet the least developed of all. Benchmarks for success exist in other realms of cancer control. For example, one can track the reduction in smoking rates to assess prevention efforts, the uptake of screening modalities (e.g., mammography, colonoscopy) by the appropriate populations to monitor inroads in promoting early detection, and survival curves to determine global cancer control. However, it is not clear what the markers of success are for improved survivorship (not to be confused with survival) outcomes.¹⁴⁰ Should this be return to school for children? Return to work for younger adults? Self-reported QOL compared to the general population for cohorts of survivors? Decrease in medical care use among survivors receiving a supportive intervention? If we have learned anything from survivors it is that being disease free does not mean being free of your disease. It is not enough to cure or enable individuals to live long term with a chronic illness without attending to what they are being returned. Because so many cancer survivors are older and present with a history of other comorbid conditions and experience, determining and alleviating what may be the unique burden of cancer is an area that remains to be fully addressed.^{44,113,114,141} At a minimum, we need to be able to provide more than an estimate of the number of individuals who are living beyond a diagnosis of cancer. Finding ways to quantify how those individuals are faring in the main, and where they are on the cancer trajectory (i.e., recently diagnosed, in active treatment, posttreatment, living with or dying of progressive disease) is critical, particularly if we are to establish benchmarks against which to measure our progress. Efforts to do this are under way in Europe¹⁴² and here in the United States.^{143,144}

In summary, the evidence is clear that cancer survivorship, once merely a nascent field, is fast entering its adolescence, its pace of maturation driven by the progress made in controlling the many diseases we call cancer. Although still modest for most cancers, the body of research identifying the long-term and late effects of illness, as detailed in Chapter 101 by Aziz in this volume, is growing rapidly. At the same time, investment in the study of interventions to eliminate or reduce adverse cancer- or treatment-related outcomes is increasing. The cancer advocacy community has matured and provides an invaluable resource for ensuring continued attention to survivorship issues.¹⁴⁵⁻¹⁴⁷ However, it is becoming apparent daily that improvements in cancer survivors' outcomes will likely be affected most by what happens to our healthcare delivery system in the years to come. We already know a great deal about what harms or helps those diagnosed and treated for cancer; delivering on the promise of care that conforms to that knowledge should be our most significant overarching goal for the foreseeable future.

Late Effects of Cancer Treatments

Noreen M. Aziz

Background and Significance

With continued advances in strategies to detect cancer early and treat it effectively, along with the aging of the population, the number of individuals living years beyond a cancer diagnosis can be expected to continue to increase. Statistical trends show that, in the absence of other competing causes of death, 64% of adults diagnosed with cancer today can expect to be alive in 5 years.¹⁻⁴ Relative 5-year survival rates for those diagnosed as children (age less than 19 years) are even higher, with almost 79% of childhood cancer survivors estimated to be alive at 5 years and 75% at 10 years.⁵

Survival from cancer has seen dramatic improvements over the past three decades, mainly as a result of advances in early detection, therapeutic strategies, and the widespread use of combined modality therapy (surgery, chemotherapy, and radiotherapy).⁶⁻¹⁰ Medical and sociocultural factors such as psychosocial and behavioral interventions, active screening behaviors, and healthier lifestyles may also play an integral role in the length and quality of that survival.¹¹

Although beneficial and often lifesaving against the diagnosed malignancy, most therapeutic modalities for cancer are associated with a spectrum of late complications ranging from minor and treatable to serious or, occasionally, potentially lethal.^{2,6,12-15} While living for extended periods of time beyond their initial diagnosis, many cancer survivors often face various chronic and late physical and psychosocial sequelae of their disease or its treatment. Additionally, as the number of survivors and their length of survival expand, long-term health issues specific to cancer survival are also fast emerging as a public health concern. Questions of particular importance to cancer survivors include surveillance for the adverse sequelae, or late and long-term effects, of treatment; the development of new (second) cancers; and recurrence of their original cancer. One-fourth of *late deaths* occurring among survivors of childhood cancer during the extended survivorship period, when the chances of primary disease recurrence are negligible, can be attributed to a treatment-related effect such as a second cancer or cardiac dysfunction.¹⁶ The most *frequently observed* medical sequelae among pediatric cancer survivors include endocrine complications, growth hormone deficiency, primary hypothyroidism, and primary ovarian failure. Also included within the rubric of late effects are second cancers arising as a result of genetic predisposition (e.g., familial cancer syndromes) or the mutagenic effects of therapy. These factors may act independently or synergistically. Synergistic effects of mutagenic agents

such as cigarette smoke or toxins such as alcohol are largely unknown.^{2,6,12}

Thus, there is today a greater recognition of symptoms that persist after the completion of treatment and which arise years after primary therapy. Both acute organ toxicities such as radiation pneumonitis and chronic toxicities such as congestive cardiac failure, neurocognitive deficits, infertility, and second malignancies are being described as the price of cure or prolonged survival.^{2,6,12} The study of late effects, originally within the realm of pediatric cancer, is now germane to cancer survivors at all ages because concerns may continue to surface throughout the life cycle.^{2,6} These concerns underscore the need to follow up and screen survivors of cancer for toxicities such as those mentioned and also to develop and provide effective interventions that carry the potential to prevent or ameliorate adverse outcomes.

The goal of survivorship research is to focus on the *health and life* of a person with a history of cancer *beyond* the acute diagnosis and treatment phase. Survivorship research seeks to examine the causes of, and to prevent and control the adverse effects associated with, cancer and its treatment and to optimize the physiologic, psychosocial, and functional outcomes for cancer survivors and their families. A hallmark of survivorship research is its emphasis on understanding the integration/interaction of multidisciplinary domains.

This chapter presents definitional issues relevant to cancer survivorship; examines late effects of cancer treatment among survivors of pediatric and adult cancer; and articulates gaps in knowledge and emerging research priorities in cancer survivorship research relevant to late effects of cancer treatment. It draws heavily from pediatric cancer survivorship research because a paucity of data continue to exist for medical late effects of treatment for survivors of cancer diagnosed as adults. Research on late effects of cancer treatment began in the realm of pediatric cancer and continues to yield important insights for the impact of cancer therapies among those diagnosed as adults.

Definitional Issues

Fitzhugh Mullan, a physician diagnosed with and treated for cancer himself, first described cancer survivorship as a concept.¹⁷ Definitional issues for cancer survivorship encompass three related aspects:^{2,6} (1) *Who is a cancer survivor?* Philosophically, anyone who has been diagnosed with cancer

is a survivor, from the time of diagnosis to the end of life.⁽¹⁾ Caregivers and family members are also included within this definition as secondary survivors. (2) *What is cancer survivorship?* Mullan described the survivorship experience as similar to the seasons of the year. Mullan recognized three seasons or phases of survival: acute (extending from diagnosis to the completion of initial treatment, encompassing issues dominated by treatment and its side effects); extended (beginning with the completion of initial treatment for the primary disease, remission of disease, or both, dominated by watchful waiting, regular follow-up examinations, and, perhaps, intermittent therapy); and permanent survival (not a single moment; evolves from extended disease-free survival when the likelihood of recurrence is sufficiently low). An understanding of these phases of survival is important for facilitating an optimal transition into and management of survivorship. (3) *What is cancer survivorship research?* Cancer survivorship research seeks to identify, examine, prevent, and control adverse cancer diagnosis and treatment-related outcomes (such as late effects of treatment, second cancers, and quality of life); to provide a knowledge base regarding optimal follow-up care and surveillance of cancer survivors; and to optimize health after cancer treatment.^{2,6}

Other important definitions include those for long-term cancer survivorship and late versus long-term effects of cancer treatment. Generally, *long-term cancer survivors* are defined as those individuals who are 5 or more years beyond the diagnosis of their primary disease and embody the concept of permanent survival described by Mullan. *Late effects* refer specifically to unrecognized toxicities that are absent or subclinical at the end of therapy and become manifest later with the unmasking of hitherto unseen injury caused by any of the following factors: developmental processes; the failure of compensatory mechanisms with the passage of time; or organ senescence. *Long-term effects* refer to any side effects or complications of treatment for which a cancer patient must compensate; also known as persistent effects, they begin during treatment and continue beyond the end of treatment. Late effects, in contrast, appear months to years after the completion of treatment. Some researchers classify cognitive problems, fatigue, lymphedema, and peripheral neuropathy as long-term effects while others classify them as late effects.¹⁸⁻²¹

This chapter focuses largely on the *physiologic* or *medical* long-term and late effects of cancer treatment. Physiologic sequelae of cancer treatment can also be further classified as follows:

- a. System-specific (e.g., organ damage, failure, or premature aging, immunosuppression or issues related to compromised immune systems, and endocrine damage);
- b. Second malignant neoplasms (such as an increased risk of recurrent malignancy, increased risk of a certain cancer associated with the primary malignancy, and/or increased risk of secondary malignancies associated with cytotoxic or radiologic cancer therapies (this topic is not covered in detail in this chapter as it is reviewed comprehensively elsewhere in this book); and
- c. Functional changes such as lymphedema, incontinence, pain syndromes, neuropathies, fatigue, cosmetic changes

such as amputations, ostomies, and skin/hair alterations, and comorbidities such as osteoporosis, arthritis, and hypertension.

Late and Long-Term Effects of Cancer and Its Treatment: Overview and Generalizations

Consequent to the phenomenal success in treating cancer effectively and detecting it early, we are faced today with an increasing population of individuals who, although cancer free for many years, have issues and concerns regarding the persistent (chronic) and the late (delayed) effects of cancer therapies on their health, longevity, and quality of life. The long-term impact of cancer and its treatment can include premature mortality and long-term morbidity. The two most frequent causes of premature mortality in disease-free cancer survivors are (1) cardiac disease and (2) second malignant neoplasms.^{22,23} The subject of late effects among children treated for cancer has been the topic of numerous reviews.^{21,24-28} To varying degrees, it has been shown that disease- or treatment-specific subgroups of long-term survivors are at risk of developing adverse outcomes. These adverse consequences of cancer treatment include early death, second neoplasms, organ dysfunction (e.g., cardiac, pulmonary, gonadal), reduced growth and development, decreased fertility, impaired intellectual function, difficulties obtaining employment and insurance, and a decreased quality of life. This chapter summarizes selected aspects of the spectrum of outcomes relating to the late effects of therapy among individuals (adults, children, and adolescents) treated for cancer.

Generalizations About Late Effects

Several generalizations can be made.^{2,6,29} It is now possible to anticipate certain types of late effects on the basis of specific therapies to which the survivor was exposed, the age of the survivor at the time of treatment, combinations of treatment modalities used, and the dosage administered. There are differences in susceptibility between pediatric and adult patients. Generally, chemotherapy results in acute toxicities that can persist whereas radiation leads to sequelae that are not apparent immediately and surface after a latent period. Combinations of chemotherapy and radiation therapy are more often associated with late effects in the survivorship period.^{2,6,29}

Toxicities related to chemotherapy, especially those of an acute but possibly persistent nature, may be related to proliferation kinetics of individual cell populations as these drugs are usually cell cycle dependent. Thus, organs or tissues most susceptible are those with high cell proliferation (turnover) rates such as the skin (epidermis), bone marrow, gastrointestinal mucosa, liver, and testes. Theoretically, the least susceptible organs and tissues are those that replicate very slowly or not at all and include muscle cells, neurons, and the connective tissue.^{2,6,29}

Issues Unique to Certain Cancer Sites

Late effects have been studied in greater depth for certain cancer sites. The examination of late effects for childhood cancers such as acute lymphoblastic leukemia, Hodgkin's

⁽¹⁾From the National Coalition for Cancer Survivorship.

disease, and brain tumors have provided the foundation for this area of research. A body of knowledge on late effects of radiation and/or chemotherapy is subsequently being developed for adult sites such as breast cancer. For example, recent studies have evaluated and reported on the development of neurocognitive deficits after chemotherapy for breast cancer, a late effect that was initially observed among survivors of childhood cancer receiving cranial irradiation and/or chemotherapy. Late effects of bone marrow transplant have been studied for both adult and childhood cancer survivors, as have sequelae associated with particular chemotherapeutic regimens such as those for Hodgkin's disease or breast cancer.

Chemotherapeutic drugs for which late effects have been reported most frequently include adriamycin, bleomycin, vincristine, methotrexate, cytoxan, and many others (Table 101.1).

The side effects of radiotherapy, both alone and in conjunction with chemotherapy, have been reported fairly comprehensively for most childhood cancer sites associated with good survival rates. It is important to bear in mind that most cancer treatment regimens consist of chemotherapy in conjunction with surgery and/or radiation, and multidrug chemotherapeutic regimens are the rule rather the exception. As such, the risk of late effects must always be considered in light of all other treatment modalities to which the patient has been exposed.

Special Considerations of Primary Diagnosis and Treatment in Childhood

Cancer therapy may interfere with development in terms of physical and musculoskeletal growth, neurocognitive/intellectual growth, and pubertal development. These effects may be most *notable* during the adolescent growth spurt, even though they occur during the childhood period. These specific sequelae are covered in greater detail in the chapter by Bhatia et al. (see Chapter 102) and are not discussed here. A brief classification follows.

- a. Alterations in physical growth
 - i. Linear growth effects³⁰⁻³²
 - ii. Impact of early puberty on growth^{33,34}
 - iii. Hypoplasia³⁵
- b. Alterations in intellectual development³⁶⁻³⁹
- c. Altered pubertal development⁴⁰
- d. Obesity⁴¹⁻⁴³

Special Considerations of Primary Diagnosis and Treatment During Adulthood

Some late effects of chemotherapy may assume special importance depending on the adult patient's age at the time of diagnosis and treatment. Diagnosis and treatment during the *young adult or reproductive years* may call for a special cognizance of the importance of maintaining reproductive func-

TABLE 101.1. Possible late effects of radiotherapy and chemotherapy.

<i>Organ system</i>	<i>Late effects/sequelae of radiotherapy</i>	<i>Late effects/sequelae of chemotherapy</i>	<i>Chemotherapeutic drugs responsible</i>
Bone and soft tissues	Short stature; atrophy, fibrosis, osteonecrosis	Avascular necrosis	Steroids
Cardiovascular	Pericardial effusion; pericarditis; CAD	Cardiomyopathy; CHF	Anthracyclines Cyclophosphamide
Pulmonary	Pulmonary fibrosis; decreased lung volumes	Pulmonary fibrosis; interstitial pneumonitis	Bleomycin, BCNU Methotrexate, adriamycin
Central nervous system (CNS)	Neuropsychologic deficits, structural changes, hemorrhage	Neuropsychologic deficits, structural changes Hemiplegia; seizure	Methotrexate
Peripheral nervous system		Peripheral neuropathy; hearing loss	Cisplatin, vinca alkaloids
Hematologic	Cytopenia, myelodysplasia	Myelodysplastic syndromes	Alkylating agents
Renal	Decreased creatinine clearance Hypertension	Decreased creatinine clearance Increased creatinine Renal filtration Delayed renal filtration	Cisplatin Methotrexate Nitrosoureas
Genitourinary	Bladder fibrosis, contractures	Bladder fibrosis; hemorrhagic cystitis	Cyclophosphamide
Gastrointestinal	Malabsorption; stricture; abnormal LFT	Abnormal LFT; hepatic fibrosis; cirrhosis	Methotrexate, BCNU
Pituitary	Growth hormone deficiency; pituitary deficiency		
Thyroid	Hypothyroidism; nodules		
Gonadal	Men: risk of sterility, Leydig cell dysfunction. Women: ovarian failure, early menopause	Men: sterility Women: sterility, premature menopause	Alkylating agents Procarbazine
Dental/oral health	Poor enamel and root formation; dry mouth		
Ophthalmologic	Cataracts; retinopathy	Cataracts	Steroids

CAD, coronary artery disease; CCF, congestive cardiac failure; LFT, liver function tests; BCNU, carmustine.

tion and the prevention of second cancers. These are also key issues for children whose cancers are diagnosed during childhood.

Cancer patients diagnosed and treated during *middle age* may need specific attention to sequelae such as premature menopause, issues relating to sexuality and intimacy, pros and cons of using estrogen replacement therapy (ERT), prevention of neurocognitive, cardiac, and other sequelae of chemotherapy, and the prevention of coronary artery disease and osteoporosis. It has been reported that sexual dysfunction persists after breast cancer treatment, despite recovery in other domains, and includes vaginal discomfort, hot flashes, and alterations in bioavailable testosterone, luteinizing hormone, and sex hormone-binding globulin.⁴⁴ Menopausal symptoms such as hot flashes, vaginal dryness, and stress urinary incontinence are very common in breast cancer survivors and cannot be managed with standard estrogen replacement therapy.⁴⁵ The normal life expectancy of survivors of early-stage cancers during these years of life underscores the need to address their long-term health and quality of life issues.

Although *older patients* (65 years and over) bear a disproportionate burden of cancer, advancing age is associated with increased vulnerability to other age-related health problems and concurrent ailments such as diabetes, chronic obstructive pulmonary disease, heart disease, arthritis, and/or hypertension. Any of these could potentially affect treatment choice, prognosis, and survival. Hence, cancer treatment decisions may need to be made in the context of the older individual's preexisting health problems (comorbidities). Measures that can help evaluate the existence, nature, and severity of comorbidities among older cancer patients in a reliable manner are needed. Currently, there is little information on how comorbid age-related conditions influence treatment decisions, the subsequent course of the disease, the way that already-compromised older cancer patients tolerate the stress of cancer and its treatment, and how concomitant comorbid conditions are managed.⁴⁶

Review of Late and Long-Term Effects by Organ System or Tissues Affected⁽²⁾

System-Specific Physiologic Sequelae⁽³⁾

CARDIAC SEQUELAE

The heart may be damaged by both therapeutic irradiation and chemotherapeutic agents commonly used in the treatment for cancer. Several types of damage have been reported, including pericardial, myocardial, and vascular. Cardiac damage is most pronounced after treatment with the anthracycline drugs doxorubicin and daunorubicin, used widely in the treatment of most childhood cancers and adjuvant chemotherapy for breast and many other adult cancers. An additive effect has also been reported when anthracyclines are

used in conjunction with cyclophosphamide and radiation therapy. Anthracyclines cause myocardial cell death, leading to a diminished number of myocytes and compensatory hypertrophy of residual myocytes.⁴⁷ Major clinical manifestations include reduced cardiac function, arrhythmia, and heart failure. Chronic cardiotoxicity usually manifests itself as cardiomyopathy, pericarditis, and congestive heart failure.

Cardiac injury that becomes clinically manifest during or shortly after completion of chemotherapy may progress, stabilize, or improve after the first year of treatment. This improvement may either be of a transient nature or last for a considerable length of time. There is also evidence of a continuum of injury that will manifest itself throughout the lives of these patients.⁴⁸ From a risk factor perspective, patients who exhibit reduced cardiac function within 6 months of completing chemotherapy are at increased risk for the development of late cardiac failure.⁴⁹ However, a significant incidence of late cardiac decompensation manifested by cardiac failure or lethal arrhythmia occurring 10 to 20 years after the administration of these drugs has also been reported.⁵⁰

In a recent study of Hodgkin's disease (HD) survivors, investigators reported finding cardiac abnormalities in the majority of the participants.⁵¹ This is an important finding especially because the sample consisted of individuals who did not manifest symptomatic heart disease at screening and described their health as "good." Manifestations of cardiac abnormalities included (a) restrictive cardiomyopathy (suggested by reduced average left ventricular dimension and mass without increased left ventricular wall thickness); (b) significant valvular defects; (c) conduction defects; (d) complete heart block; (e) autonomic dysfunction (suggested by a monotonous heart rate in 57%); (f) persistent tachycardia; and (g) blunted hemodynamic responses to exercise. The peak oxygen uptake (VO_{2max}) during exercise, a predictor of mortality in heart failure, was significantly reduced (less than 20 mL/kg/m²) in 30% of survivors and was correlated with increasing fatigue, increasing shortness of breath, and a decreasing physical component score on the SF-36. Given the presence of these clinically significant cardiovascular abnormalities, investigators recommend serial, comprehensive cardiac screening of HD survivors who fit the profile of having received mediastinal irradiation at a young age.

Congestive cardiomyopathy is directly related to the total dose of the agent administered; the higher the dose, the greater the chance of cardiotoxicity. Subclinical abnormalities have also been noted at lower doses. The anthracyclines doxorubicin and daunorubicin are well-known causes of cardiomyopathy that can occur many years after completion of therapy. The incidence of anthracycline-induced cardiomyopathy, which is dose dependent, may exceed 30% among patients receiving cumulative doses in excess of 600 mg/m². A cumulative dose of anthracyclines greater than 300 mg/m² has been associated with an 11-fold-increased risk of clinical heart failure, compared with a cumulative dose of less than 300 mg/m², the estimated risk of clinical heart failure increasing with time from exposure and approaching 5% after 15 years.

A reduced incidence and severity of cardiac abnormalities was reported in a study of 120 long-term survivors of acute lymphoblastic leukemia (ALL) who had been treated with lower anthracycline doses (90–270 mg/m²), compared with previous reports in which subjects had received moderate

⁽²⁾Common to both children and adults depending on cancer site and treatment(s) received.

⁽³⁾These include organ damage, failure, or premature aging resulting from chemotherapy, hormone therapy, radiation, surgery, or any combination thereof.

anthracycline doses (300–550 mg/m²).^{52,53} Twenty-three percent of the patients were found to have cardiac abnormalities, 21% had increased end-systolic stress, and only 2% had reduced contractility. The cumulative anthracycline dose within the 90 to 270 mg/m² range did not relate to cardiac abnormalities. The authors concluded that there may be no safe anthracycline dose to completely avoid late cardiotoxicity. A recent review of 30 published studies in childhood cancer survivors found that the frequency of clinically detected anthracycline cardiac heart failure ranged from 0% to 16%.⁵⁴ In an analysis of reported studies, the type of anthracycline (e.g., doxorubicin) and the maximum dose given in a 1-week period (e.g., more than 45 mg/m²) was found to explain a large portion of the variation in the reported frequency of anthracycline-induced cardiac heart failure.

Cyclophosphamide has been associated with the development of congestive cardiomyopathy, especially when administered at the high doses used in transplant regimens. Cardiac toxicity may occur at lower doses when mediastinal radiation is combined with the chemotherapeutic drugs mentioned above. Late onset of congestive heart failure has been reported during pregnancy, rapid growth, or after the initiation of vigorous exercise programs in adults previously treated for cancer during childhood or young adulthood as a result of increased afterload and the impact of the additional stress of such events on marginal cardiac reserves. Initial improvement in cardiac function after completion of therapy appears to result, at least in part, from compensatory changes. Compensation may diminish in the presence of stressors such as those mentioned earlier and myocardial depressants such as alcohol.

The incidence of subclinical anthracycline myocardial damage has been the subject of considerable interest. Steiner et al. found 23% of 201 patients who had received a median cumulative dose of doxorubicin of 450 mg/m² had echocardiographic abnormalities at a median of 7 years after therapy.⁵⁵ In a group of survivors of childhood cancer who received a median doxorubicin dose of 334 mg/m², it was found that progressive elevation of afterload or depression of left ventricular contractility was present in approximately 75% of patients.⁴⁷ A recent review of the literature on subclinical cardiotoxicity among children treated with an anthracycline found that the reported frequency of subclinical cardiotoxicity varied considerably across the 25 studies reviewed (frequency ranging from 0% to 57%).⁵⁶ Because of marked differences in the definition of outcomes for subclinical cardiotoxicity and the heterogeneity of the patient populations investigated, it is difficult to accurately evaluate the potential long-term outcomes within anthracycline-exposed patient populations or the potential impact of the subclinical findings.

Effects of radiation on the heart may be profound, and include valvular damage, pericardial thickening, and ischemic heart disease. Patients with radiation-related cardiac damage have a markedly increased relative risk of both angina and myocardial infarction [relative risk (RR), 2.56] years after mediastinal radiation for Hodgkin's disease in adult patients, whereas the risk of cardiac death is 3.1.⁵⁷ This risk was greatest among patients receiving more than 30 Gy of mantle irradiation and those treated before 20 to 21 years of age. Blocking the heart reduced the risk of cardiac death due to causes other than myocardial infarction.⁵⁸

In general, among anthracycline-exposed patients, the risk of cardiotoxicity can be increased by mediastinal radiation,⁵⁹ uncontrolled hypertension,^{60,61} underlying cardiac abnormalities,⁶² exposure to nonanthracycline chemotherapeutic agents (especially cyclophosphamide, dactinomycin, mitomycin C, dacarbazine, vincristine, bleomycin, and methotrexate),^{63,64} female gender,⁶⁵ younger age,⁶⁶ and electrolyte imbalances such as hypokalaemia and hypomagnesaemia.⁶⁷ Previous reports have suggested that doxorubicin-induced cardiotoxicity can be prevented by continuous infusion of the drug.⁶⁸ However, Lipshultz et al. compared cardiac outcomes in children receiving either bolus or continuous infusion of doxorubicin, and reported that continuous doxorubicin infusion over 48 hours for childhood leukemia did not offer a cardioprotective advantage over bolus infusion.⁶⁹ Both regimens were associated with progressive subclinical cardiotoxicity, thus suggesting that there is no benefit from continuous infusion of anthracyclines.

Chronic cardiotoxicity associated with radiation alone most commonly involves pericardial effusions or constrictive pericarditis, sometimes in association with pancarditis. Although a dose of 40 Gy of total heart irradiation appears to be the usual threshold, pericarditis has been reported after as little as 15 Gy, even in the absence of radiomimetic chemotherapy.^{70,71} Symptomatic pericarditis, which usually develops 10 to 30 years after irradiation, is found in 2% to 10% of patients.⁷² Subclinical pericardial and myocardial damage, as well as valvular thickening, may be common in this population.^{73,74} Coronary artery disease has been reported after radiation to the mediastinum, although mortality rates have not been significantly higher in patients who receive mediastinal radiation than in the general population.⁵⁸

Given the known acute and long-term cardiac complications of therapy, prevention of cardiotoxicity is a focus of active investigation. Several attempts have been made to minimize the cardiotoxicity of anthracyclines, such as the use of liposomal-formulated anthracyclines, less-cardiotoxic analogues, and the additional administration of cardioprotective agents. The advantages of these approaches are still controversial, but there are ongoing clinical trials to evaluate the long-term effects. Certain analogues of doxorubicin and daunorubicin, with decreased cardiotoxicity but equivalent antitumour activity, are being explored. Agents such as dexrazoxane, which are able to remove iron from anthracyclines, have been investigated as cardioprotectants. Clinical trials of dexrazoxane have been conducted in children, with encouraging evidence of short-term cardioprotection⁷⁵; however, the long-term avoidance of cardiotoxicity with the use of this agent has yet to be sufficiently determined. The most recent study by Lipshultz et al. reported that dexrazoxane prevents or reduces cardiac injury, as reflected by elevations in troponin T, that is associated with the use of doxorubicin for childhood ALL without compromising the antileukemic efficacy of doxorubicin. Longer follow-up will be necessary to determine the influence of dexrazoxane on echocardiographic findings at four years and on event-free survival.⁷⁶

Another key emerging issue is the interaction of taxanes with doxorubicin. Epirubicin–taxane combinations are active in treating metastatic breast cancer, and ongoing research is focusing on combining anthracyclines with taxanes in an effort to continue to improve outcomes following adjuvant therapy.⁷⁷ Clinically significant drug interactions have been

reported to occur when paclitaxel is administered with doxorubicin, cisplatin, or anticonvulsants (phenytoin, carbamazepine, and phenobarbital), and pharmacodynamic interactions have been reported to occur with these agents that are sequence- or schedule dependent.⁷⁸ Because the taxanes undergo hepatic oxidation via the cytochrome P-450 system, pharmacokinetic interactions from enzyme induction or inhibition can also occur. A higher than expected myelotoxicity has been reported. However, there is no enhanced doxorubicinol formation in human myocardium, a finding consistent with the cardiac safety of the regimen.⁷⁹ Investigators have suggested that doxorubicin and epirubicin should be administered 24 hours before paclitaxel and the cumulative anthracycline dose be limited to 360 mg/m², thereby preventing the enhanced toxicities caused by sequence- and schedule-dependent interactions between anthracyclines and paclitaxel.⁷⁸ Conversely, they also suggest that paclitaxel should be administered at least 24 hours before cisplatin to avoid a decrease in clearance and increase in myelosuppression. With concurrent anticonvulsant therapy, cytochrome P-450 enzyme induction results in decreased paclitaxel plasma steady-state concentrations, possibly requiring an increased dose of paclitaxel. A number of other drug interactions have been reported in preliminary studies for which clinical significance has yet to be established.⁷⁸

The human epidermal growth factor receptor (HER) 2 is overexpressed in approximately 20% to 25% of human breast cancers and is an independent adverse prognostic factor. Targeted therapy directed against this receptor has been developed in the form of a humanized monoclonal antibody, trastuzumab. Unexpectedly, cardiac toxicity has developed in some patients treated with trastuzumab, and this has a higher incidence in those treated in combination with an anthracycline.^{80,81} Both clinical and *in vitro* data suggest that cardiomyocyte HER2/erbB2 is uniquely susceptible to trastuzumab.⁸² Trastuzumab has shown activity as a single agent in metastatic breast cancer both before chemotherapy and in heavily pretreated patients, and its use in combination with an anthracycline or paclitaxel results in a significant improvement in survival, time to progression, and response.⁸⁰ The HER2 status of a tumor is a critical determinant of response to trastuzumab-based treatment; those expressing HER2 at the highest level on immunohistochemistry, 3+, derive more benefit from treatment with trastuzumab than those with overexpression at the 2+ level. Interactions between the estrogen receptor and HER2 pathway has stimulated interest in using trastuzumab in combination with endocrine therapy. Current clinical trials are investigating the role of this agent in the adjuvant setting.

NEUROCOGNITIVE SEQUELAE

Long-term survivors of cancer may be at risk of neurocognitive and neuropsychologic sequelae. Among survivors of childhood leukemia, neurocognitive late effects represent one of the more intensively studied topics. Adverse outcomes are generally associated with whole-brain radiation and/or therapy with high-dose systemic or intrathecal methotrexate or cytarabine.⁸³⁻⁸⁵ High-risk characteristics, including higher dose of central nervous system (CNS) radiation, younger age at treatment, and female sex, have been well documented. Results from studies of neurocognitive outcomes are directly

responsible for the marked reduction (particularly in younger children) in the use of cranial radiation, which is currently reserved for treatment of very high risk subgroups or patients with CNS involvement.⁸⁶

A spectrum of clinical syndromes may occur, including radionecrosis, necrotizing leukoencephalopathy, mineralizing microangiopathy and dystrophic calcification, cerebellar sclerosis, and spinal cord dysfunction.⁸⁷ Leukoencephalopathy has been primarily associated with methotrexate-induced injury of white matter. However, cranial radiation may play an additive role through the disruption of the blood-brain barrier, thus allowing greater exposure of the brain to systemic therapy.

Although abnormalities have been detected by diagnostic imaging studies, the abnormalities observed have not been well demonstrated to correlate with clinical findings and neurocognitive status.^{88,89} Chemotherapy- or radiation-induced destruction in normal white matter partially explains intellectual and academic achievement deficits.⁹⁰ Evidence suggests that direct effects of chemotherapy and radiation on intracranial endothelial cells and brain white matter as well as immunologic mechanisms could be involved in the pathogenesis of central nervous system damage.

Neurocognitive deficits, as a general rule, usually become evident within several years following CNS radiation and tend to be progressive in nature. Leukemia survivors treated at a younger age (*i.e.*, less than 6 years of age) may experience significant declines in intelligence quotient (IQ) scores.⁹¹ However, reductions in IQ scores are typically not global, but rather reflect specific areas of impairment, such as attention and other nonverbal cognitive processing skills.⁹² Affected children may experience information-processing deficits, resulting in academic difficulties. These children are particularly prone to problems with receptive and expressive language, attention span, and visual and perceptual motor skills, most often manifested in academic difficulties in the areas of reading, language, and mathematics. Accordingly, children treated with CNS radiation or systemic or intrathecal therapy with the potential to cause neurocognitive deficits should receive close monitoring of academic performance. Referral for neuropsychologic evaluation with appropriate intervention strategies, such as modifications in curriculum, speech and language therapy, or social skills training, implemented in a program tailored for the individual needs and deficits of the survivor should be taken into consideration.⁹³ Assessment of educational needs and subsequent educational attainment have found that survivors of childhood leukemia are significantly more likely to require special educational assistance, but have a high likelihood of successfully completing high school.^{37,94} However, when compared with siblings, survivors of leukemia and non-Hodgkin's lymphoma (NHL) are at greater risk of not completing high school. As would be anticipated from the results of neurocognitive studies, it has been shown that survivors, particularly those under 6 years of age at treatment, who received cranial radiation and/or intrathecal chemotherapy were significantly more likely to require special education services and least likely to complete a formal education.^{86,95,96}

Progressive dementia and dysfunction have been reported in some long-term cancer survivors as a result of whole-brain radiation with or without chemotherapy, and occur most often in brain tumor patients and patients with small cell

lung cancer who have received prophylactic therapy. Neuropsychologic abnormalities have also been reported after CNS prophylaxis utilizing whole-brain radiation for leukemia in childhood survivors. In fact, cognitive changes in children began to be recognized as treatments for childhood cancer, especially ALL, became increasingly effective. These observations have resulted in changes in treatment protocols for childhood ALL.^{97,98}

Several recent studies have reported cognitive dysfunction in women treated with adjuvant therapy for breast cancer.^{99,100} In one study,¹⁰¹ investigators compared the neuropsychologic performance of long-term survivors of breast cancer and lymphoma treated with standard-dose chemotherapy who carried the epsilon 4 allele of the apolipoprotein E (APOE) gene to those who carry other APOE alleles. Survivors with at least one epsilon 4 allele scored significantly lower in the visual memory (P less than 0.03) and the spatial ability (P less than 0.05) domains and tended to score lower in the psychomotor functioning (P less than 0.08) domain as compared to survivors who did not carry an epsilon 4 allele. No group differences were found on depression, anxiety, or fatigue. The results of this study provide preliminary support for the hypothesis that the epsilon 4 allele of APOE may be a potential genetic marker for increased vulnerability to chemotherapy-induced cognitive decline.

Although cranial irradiation is the most frequently identified causal factor in both adults and children, current work in adults indicates that cognitive problems may also occur with surgery, chemotherapy, and biologic response modifiers.¹⁰²⁻¹⁰⁴ These findings need to be validated in prospective studies along with the interaction between treatment with chemotherapeutic agents, menopausal status, and hormonal treatments. Emotional distress also has been related to cognitive issues in studies of patients beginning cancer treatment.

Patients have attributed problems in cognition to fatigue, and others have reported problems with concentration, short-term memory, problem-solving, and concerns about "chemobrain" or "mental pause."¹⁰⁵ Comparisons across studies are difficult because of different batteries of neuropsychologic tests used, and differences among patient samples by diagnosis, age, gender, or type of treatment received, and, finally, inconsistency in the timing of measures in relation to treatment landmarks. Despite these methodologic issues, studies have shown impairments in verbal information processing, complex information processing, concentration, and visual memory.¹⁰⁶⁻¹⁰⁹

Current studies indicate that cognitive deficits are often subtle but are observed consistently in a proportion of patients, may be durable, and can be disabling.¹¹⁰ Deficits have been observed in a range of cognitive functions. Although underlying mechanisms are unknown, preliminary studies suggest a genetic predisposition. Cognitive impairment may be accompanied by changes in the brain detectable by neuroimaging. Priorities for future research include (1) large-scale clinical studies that use both a longitudinal design and concurrent evaluation of patients with cancer who do not receive chemotherapy—such studies should address the probability and magnitude of cognitive deficits, factors that predict them, and underlying mechanisms; (2) exploration of discrepancies between subjective reports of cognitive dysfunction and the objective results of cognitive testing; (3) studies of cognitive

function in patients receiving treatment for diseases other than breast cancer, and in both men and women, to address the hypothesis that underlying mechanisms relate to changes in serum levels of sex hormones and/or to chemotherapy-induced menopause; (4) development of interventions to alleviate these problems; and (5) development of animal models and the use of imaging techniques to address mechanisms that might cause cognitive impairment.

ENDOCRINOLOGIC SEQUELAE

THYROID

Radiation exposure to the head and neck is a known risk factor for subsequent abnormalities of the thyroid. Among survivors of Hodgkin's disease and, to a lesser extent, leukemia survivors, abnormalities of the thyroid gland, including hypothyroidism, hyperthyroidism, and thyroid neoplasms, have been reported to occur at rates significantly higher than found in the general population.¹¹¹⁻¹¹⁴ Hypothyroidism is the most common nonmalignant late effect involving the thyroid gland. Following radiation doses above 15 Gy, laboratory evidence of primary hypothyroidism is evident in 40% to 90% of patients with Hodgkin's disease, NHL, or head and neck malignancies.^{113,115,116} In a recent analysis of 1,791 5-year survivors of pediatric Hodgkin's disease (median age at follow-up, 30 years), Sklar et al. reported the occurrence of at least one thyroid abnormality in 34% of subjects.¹¹⁴ The risk of hypothyroidism was increased 17 fold compared with sibling control subjects, with increasing dose of radiation, older age at diagnosis of Hodgkin's disease, and female sex as significant independent predictors of an increased risk. The actuarial risk of hypothyroidism for subjects treated with 45 Gy or more was 50% at 20 years following diagnosis of their Hodgkin's disease. Hyperthyroidism was reported to occur in only 5%.

HORMONES AFFECTING GROWTH

Poor linear growth and short adult stature are common complications after successful treatment of childhood cancers.¹¹⁷ The adverse effect of CNS radiation on adult final height among childhood leukemia patients has been well documented, with final heights below the fifth percentile occurring in 10% to 15% of survivors.^{43,118,119} The effects of cranial radiation appear to be related to age and gender, with children younger than 5 years at the time of therapy and female patients being more susceptible. The precise mechanisms by which cranial radiation induces short stature are not clear. Disturbances in growth hormone production have not been found to correlate well with observed growth patterns in these patients.^{31,120} The phenomenon of early onset of puberty in girls receiving cranial radiation may also play some role in the reduction of final height.^{33,121} In childhood leukemia survivors not treated with cranial radiation, there are conflicting results regarding the impact of chemotherapy on final height.¹²²

HORMONAL RATIONALE FOR OBESITY

An increased prevalence of obesity has been reported among survivors of childhood ALL.¹²³⁻¹²⁵ Craig et al. investigated the relationship between cranial irradiation received during treatment for childhood leukemia and obesity.¹²⁶ Two hundred thirteen (86 boys and 127 girls) irradiated patients and 85 (37

boys and 48 girls) nonirradiated patients were enrolled. For cranially irradiated patients, an increase in the body mass index (BMI) *Z* score at the final height was associated with female sex and lower radiation dose but not with age at diagnosis. Severe obesity, defined as a BMI *Z* score greater than 3 at final height, was only present in girls who received 18 to 20 Gy irradiation at a prevalence of 8%. Both male and female nonirradiated patients had raised BMI *Z* scores at latest follow-up, and there was no association with age at diagnosis. The authors concluded that these data demonstrated a sexually dimorphic and dose-dependent effect of cranial irradiation on BMI. In a recent analysis from the Childhood Cancer Survivor Study, Oeffinger et al. compared the distribution of BMI of 1,765 adult survivors of childhood ALL with that of 2,565 adult siblings of childhood cancer survivors.¹²⁷ Survivors were significantly more likely to be overweight (BMI, 25–30) or obese (BMI, 30 or more). Risk factors for obesity were cranial radiation, female gender, and age from 0 to 4 years at diagnosis of leukemia. Girls diagnosed under the age of 4 years who received a cranial radiation dose greater than 20 Gy were found to have a 3.8-fold-increased risk of obesity.

GONADAL DYSFUNCTION

Treatment-related gonadal dysfunction has been well documented in both men and women following childhood malignancies.¹²⁸ However, survivors of leukemia and T-cell non-Hodgkin's lymphoma treated with modern conventional therapy are at a relatively low risk of infertility and delayed or impaired puberty. Treatment-related gonadal failure or dysfunction, expressed as amenorrhea or azoospermia, can lead to infertility in both male and female cancer survivors, and may have its onset during therapy.¹²⁹ Infertility can be transient, especially in men, and may recover over time after therapy. Reversibility is dependent on the dose of gonadal radiation or alkylating agents. Ovarian function is unlikely to recover long after the immediate treatment period because long-term amenorrhea commonly results from loss of ova. Cryopreservation of sperm before treatment is an option for men,¹³⁰ but limited means are available to preserve ova or protect against treatment-related ovarian failure for women.^{131–133} A successful live birth after orthotopic autotransplantation of cryopreserved ovarian tissue has been recently reported.^{134–137} A reasonable body of research on topics relating to the long-term gonadal effects of radiation and chemotherapy exists^{138–161} and provides a basis for counseling patients and parents of the anticipated outcomes on pubertal development and fertility. For greater detail on this topic, please see Chapter 90.

Among survivors of adult cancer, the risk of premature onset of menopause in women treated with chemotherapeutic agents such as alkylating agents and procarbazine or with abdominal radiation therapy is age related, with women older than age 30 at the time of treatment having the greatest risk of treatment-induced amenorrhea and menopause, and sharply increased rates with chemotherapy around the age of 40 years. Tamoxifen has not been associated with the development of amenorrhea so far.¹⁶² Cyclophosphamide at doses of 5 g/m² is likely to cause amenorrhea in women over 40, whereas many adolescents will continue to menstruate even after more than 20 g/m².¹⁶³ Although young women may not become amenorrheic after cytotoxic therapy, the risk of early

menopause is significant. Female disease-free survivors of cancer diagnosed at ages 13 to 19 who were menstruating at age 21 were at fourfold-higher risk of menopause compared to controls.¹⁴⁰

FERTILITY AND PREGNANCY OUTCOMES

Fertility The fertility of survivors of childhood cancer, evaluated in the aggregate, is impaired. In one study, the adjusted relative fertility of survivors compared with that of their siblings was 0.85 [95% confidence interval (CI), 0.78, 0.92]. The adjusted relative fertility of male survivors (0.76; 95% CI, 0.68, 0.86) was slightly lower than that of female survivors (0.93; 95% CI, 0.83, 1.04). The most significant differences in the relative fertility rates were demonstrated in male survivors who had been treated with alkylating agents with or without infradiaphragmatic irradiation.¹⁶⁴

Fertility can be impaired by factors other than the absence of sperm and ova. Conception requires delivery of sperm to the uterine cervix and patency of the fallopian tubes for fertilization to occur and appropriate conditions in the uterus for implantation. Retrograde ejaculation occurs with a significant frequency in men who undergo bilateral retroperitoneal lymph node dissection. Uterine structure may be affected by abdominal irradiation. Uterine length was significantly reduced in 10 women with ovarian failure who had been treated with whole-abdomen irradiation. Endometrial thickness did not increase in response to hormone replacement therapy in 3 women who underwent weekly ultrasound examination. No flow was detectable with Doppler ultrasound through either uterine artery of 5 women and through one uterine artery in 3 additional women.^{165,166} Similarly, 4 of 8 women who received 1,440 cGy total-body irradiation had reduced uterine volume and undetectable uterine artery blood flow.¹⁶⁷ These data are pertinent when considering the feasibility of assisted reproduction for these survivors.

Pregnancy Most chemotherapeutic agents are mutagenic, with the potential to cause germ cell chromosomal injury. Possible results of such injury include an increase in the frequency of genetic diseases and congenital anomalies in the offspring of successfully treated childhood and adolescent cancer patients. Several early studies of the offspring of patients treated for diverse types of childhood cancer identified no effect of previous treatment on pregnancy outcome and no increase in the frequency of congenital anomalies in the offspring.^{168–170} However, a study of offspring of patients treated for Wilm's tumor demonstrated that the birth weight of children born to women who had received abdominal irradiation was significantly lower than that of children born to women who had not received such irradiation,¹⁷¹ a finding that was confirmed in several subsequent studies.^{172–174} The abnormalities of uterine structure and blood flow reported after abdominal irradiation might explain this clinical finding.

Prior studies of offspring of childhood cancer survivors were limited by the size of the population of offspring and the number of former patients who had been exposed to mutagenic therapy. Several recent studies that attempted to address some of these limitations did not identify an increased frequency of major congenital malformations,^{175–180} genetic disease, or childhood cancer^{181,182} in the offspring of former pediatric cancer patients, including those conceived

after bone marrow transplantation.¹⁸³ However, there are data suggesting a deficit of males in the offspring of the partners of male survivors in the Childhood Cancer Survivor Study cohort,¹⁸⁴ as well as an effect of prior treatment with doxorubicin or daunorubicin on the percentage of offspring with a birth weight less than 2,500g born to female survivors in the Childhood Cancer Survivor Study who were treated with pelvic irradiation.¹⁸⁵

PULMONARY SEQUELAE

The *acute* effects of chemotherapy on the lungs may be lethal, may subside over time, may progress insidiously to a level of clinical pulmonary dysfunction, or may be manifested by abnormal pulmonary function tests. Classically, high doses of bleomycin have been associated with pulmonary toxicity. However, drugs such as alkylating agents, methotrexate, and nitrosoureas may also lead to pulmonary fibrosis, especially when combined with radiation therapy. Radiation is thus an important contributor to pulmonary sequelae of chemotherapy.¹⁸⁶ Alkylating agents can injure the lung parenchyma, cause restrictive lung disease by inhibiting chest wall growth, and lead to thin anteroposterior chest diameters even 7 years after completion of therapy. Bleomycin may cause pulmonary insufficiency and interstitial pneumonitis.¹⁸⁷

Pulmonary fibrosis can cause late death in the survivorship period. Among children treated for brain tumors with high doses of nitrosourea and radiotherapy, 35% died of pulmonary fibrosis, 12% within 3 years and 24% after a symptom-free period of 7 to 12 years.¹⁸⁸ The risk for overt decompensation continues for at least 1 year after cessation of therapy and can be precipitated by infection or exposure to intraoperative oxygen. In terms of long-term outcomes, a recent study noted that 22% of Hodgkin's disease patients with normal pulmonary function tests at the end of therapy (three cycles each of mechlorethamine (nitrogen mustard), vincristine, procarbazine, prednisone (MOPP) and adriamycin (doxorubicin), bleomycin, vinblastine, dacarbazine (ABVD) or two cycles of each plus 2,550cGy of involved-field radiotherapy) developed abnormalities with follow-up of 1 to 7 years.

The long-term outcome of pulmonary toxicity is determined by factors such as the severity of the acute injury, the degree of tissue repair, and the level of compensation possible. Pulmonary dysfunction is usually subclinical and may be manifested by subconscious avoidance of exercise owing to symptoms. Premature respiratory insufficiency, especially with exertion, may also become evident with aging. Recent aggressive lung cancer treatment regimens consisting of surgery, radiation, and chemotherapy may well put patients at high risk for decreased pulmonary function and respiratory symptoms.

GENITOURINARY TRACT

Several drugs such as cisplatin, methotrexate, and nitrosoureas have been associated with both acute and chronic toxicities such as glomerular and tubular injury.¹⁸⁹ Glomerular injury may recover over time whereas tubular injury generally persists. Hemodialysis to counteract the effects of chronic renal toxicity may be warranted for some patients. Ifosfamide may cause Fanconi's syndrome with glycosuria, phosphaturia, and aminoaciduria, and may affect glomerular

filtration. Hypophosphatemia may result in slow growth with possible bone deformity if untreated.

Radiation therapy may cause tubular damage and hypertension as a result of renal artery stenosis, especially in doses greater than 20Gy, especially among children.¹⁹⁰ Radiation and chemotherapy may act synergistically, the dysfunction occurring with only 10 to 15 Gy.

The bladder is particularly susceptible to certain cytotoxic agents. Acrolein, a metabolic by-product of cyclophosphamide and ifosfamide, may cause hemorrhagic cystitis, fibrosis, and occasionally diminished bladder volume. An increased risk of developing bladder cancer also exists. Radiation may lead to bladder fibrosis, diminished capacity, and decreased contractility, the severity proportional to dose and area irradiated. The resultant scarring may diminish urethral and ureteric function.

GASTROINTESTINAL/HEPATIC

There are few studies describing long-term effects to this system, either due to underdetection or to a longer latency period than for other organs. Hepatic effects may result from the deleterious effects of many chemotherapeutic agents and radiotherapy. Transfusions may increase the risk of viral hepatitis. Hepatitis C has also been identified in increasing numbers of survivors, 119 of 2,620 tested. Of these patients, 24 of 56 who agreed to participate in a longitudinal study underwent liver biopsy. Chronic hepatitis was noted in 83%, fibrosis in 67%, and cirrhosis in 13%. Fibrosis and adhesions are known to occur after radiotherapy to the bowel.

COMPROMISED IMMUNE SYSTEM

Hematologic and immunologic impairments can occur after either chemotherapy or radiation and are usually acute in nature. They are temporally related to the cancer treatment. Occasionally, persistent cytopenias may persist after pelvic radiation or in patients who have received extensive therapy with alkylating agents. Alkylating agents may cause myelodysplastic syndrome or leukemia as a late sequela. Immunologic impairment is seen as a long-term problem in Hodgkin's disease, relating to both the underlying disease and the treatments used. Hodgkin's disease patients are also at risk for serious bacterial infections if they have undergone splenectomy.

PERIPHERAL NEUROPATHIES

These effects are particularly common after taxol, vincristine, and cisplatin. However, despite the frequent use of such chemotherapeutic agents, few studies have characterized the nature and course of neuropathies associated with these drug regimens or dose levels.^{191,192} Peripheral neuropathy may or may not resolve over time, and potential residual deficits are possible. Clinical manifestations include numbness and tingling in the hands and feet years after completion of cancer treatment.

Second Malignant Neoplasms and Recurrence

Second malignant neoplasms occur as result of an increased risk of second primary cancers associated with (a) the primary

malignancy or (b) the iatrogenic effect of certain cancer therapies.¹⁹³⁻¹⁹⁶ Examples include the development of breast cancer after Hodgkin's disease, ovarian cancer after primary breast cancer, and cancers associated with the HNPCC gene. Survivors of childhood cancer have an 8% to 10% risk of developing a second malignant neoplasm within 20 years of the primary diagnosis^{197,198}; this is attributable to the mutagenic risk of both radiotherapy and chemotherapy.¹⁹⁹⁻²¹³ This increased risk may be further potentiated in patients with genetic predispositions to malignancy.²¹⁴⁻²²⁰ The risk of secondary malignancy induced by cytotoxic agents is related to the cumulative dose of drug or radiotherapy (dose dependence). The risk of malignancy with normal aging results from the risk of cumulative cellular mutations. Compounding the normal aging process by exposure to mutagenic cytotoxic therapies results in an increased risk of secondary malignancy, particularly after radiotherapy, alkylating agents, and podophyllotoxins. Commonly cited secondary malignancies include (a) leukemia after alkylating agents and podophyllotoxins²²¹; (b) solid tumors such as breast, bone, and thyroid cancer in the radiation fields in patients treated with radiotherapy²²²; (c) bladder cancer after cyclophosphamide; (d) a higher risk of contralateral breast cancer after primary breast cancer; and (e) ovarian cancer after breast cancer. Please refer to Chapter 111 for a detailed discussion of this significant issue.

Ancillary Sequelae

LYMPHEDEMA

Lymphedema can occur as a persistent or late effect of surgery and/or radiation treatment, and has been reported most commonly after breast cancer treatment, incidence rates ranging between 6% and 30%.²²³ Lymphedema can occur in anyone with lymph node damage or obstruction to lymphatic drainage. Women undergoing axillary lymph node dissection and high-dose radiotherapy to the axilla for breast cancer are regarded as the highest risk group. Clinically, lymphedema symptoms may range from a feeling of fullness or heaviness in the affected limb to massive swelling and major functional impairment. Recommendations from the American Cancer Society conference on lymphedema in 1998 emphasize the need for additional research on prevention, monitoring, early intervention, and long-term treatment. Treatments suggested encompass multiple treatment modalities including skin care, massage, bandaging for compression, and exercise. Intermittent compression pumps were recommended only when used as an adjunct to manual approaches within a multidisciplinary treatment program, and routine use of medications such as diuretics, prophylactic antibiotics, bioflavonoids, and benzopyrones was discouraged in the absence of additional research. The impact of sentinel node biopsy in lieu of extensive axillary node dissection procedures for breast cancer on the incidence of lymphedema is not known at this time. A recent review by Erickson et al. found that arm edema was a common complication of breast cancer therapy, particularly when axillary dissection and axillary radiation therapy were used, and could result in substantial functional impairment and psychologic morbidity.²²⁴ The authors note that although recommendations for "preventive" measures (e.g., avoidance of trauma) are anecdotally available, these measures have not been well studied. They found that nonpharmacologic treat-

ments, such as massage and exercise, have been shown to be effective therapies for lymphedema, but the effect of pharmacologic interventions remains uncertain.

FATIGUE

Fatigue has been reported as persistent side effect of treatment in many studies.²²⁵⁻²²⁸ This is especially true among patients who have undergone bone marrow transplant.²²⁹ Treatment-related fatigue may be associated with various factors such as anemia, infection, changes in hormonal levels, lack of physical activity, cytokine release, and sleep disorders.²³⁰ The impact of exercise interventions on fatigue is a promising area of research. Fatigue is an important influence on quality of life for both the patient and the family and needs to be managed effectively.

SEXUALITY AND INTIMACY

Sexuality encompasses a spectrum of issues ranging from how one feels about one's body to the actual ability to function as a sexual being and has been reported as a persistent effect of treatment. In a recent study on breast, colon, lung, and prostate cancer survivors, issues related to sexual functioning were among the most persistent and severe problems reported. Preexisting sexual dysfunction may also be exacerbated by cancer and its treatment.²³¹ Please refer to Chapter 90 for further details.

Surgical and Radiation-Induced Toxicities

Surgical effects include increased risk of infections and physiologic compromise associated with nephrectomy (lifestyle changes to prevent trauma to remaining kidney), splenectomy (increased risk for sepsis resulting from encapsulated bacteria), and limb amputation.

Radiation therapy may especially exert effects on the musculoskeletal system and soft tissues among children and young adults, causing injury to the growth plates of long bones and muscle atrophy, osteonecrosis, and fractures.^{2,5} Short stature can occur as a result of direct bone injury or pituitary radiation and resultant growth hormone deficiency. Chronic pain, the result of scarring and fibrosis in soft tissues surrounding the joints and large peripheral nerves, is a particularly distressing problem among patients who have received moderately high doses of radiation. Soft tissue sarcomas, skin cancers at previously irradiated sites, and pregnancy loss due to decreased uterine capacity in young girls after abdominal radiation are also possible.

Cancer Survivors, Healthcare Utilization, and Comorbid Conditions

Cancer survivors are high healthcare utilizers affecting distinct healthcare domains.^{232,233} Data clearly show that cancer survivors are at greater risk for developing secondary cancers, late effects of cancer treatment, and chronic comorbid conditions. Exposures leading to these risks include cancer treatment, genetic predisposition and/or common lifestyle factors.²³⁴⁻²³⁶ Although the threat of progressive or recurrent disease is at the forefront of health concerns for a cancer sur-

vivor, increased morbidity and decreased functional status and disability that result from cancer, its treatment, or health-related sequelae also are significant concerns. The impact of chronic comorbid conditions on cancer and its treatment is heightened more so among those diagnosed as adults and those who are elderly at the time of diagnosis.

Presented next is a brief overview of some factors potentiating the risk for chronic comorbid conditions among cancer survivors. A brief discussion of the major comorbid illnesses observed among survivors is also presented.

Metabolic Syndrome-Associated Diseases: Obesity, Diabetes, and Cardiovascular Disease

Obesity is a well-established risk factor for cancers of the breast (postmenopausal), colon, kidney (renal cell), esophagus (adenocarcinoma), and endometrium; thus, a large proportion of cancer patients are overweight or obese at the time of diagnosis.^{237,238} Additional weight gain also can occur during or after active cancer treatment, an occurrence that has been frequently documented among individuals with breast cancer, but recently has been reported among testicular and gastrointestinal cancer patients as well.^{239,240} Given data that obesity is associated with cancer recurrence in both breast and prostate cancer, and reduced quality of life among survivors, there is compelling evidence to support weight control efforts in this population.^{14,15,241} Also, gradual weight loss has proven benefits in controlling hypertension, hyperinsulinemia, pain, and dyslipidemia and in improving levels of physical functioning, conditions that reportedly are significant problems in the survivor population.^{14,15,21,242} Accordingly, the ACS Recommendations for Cancer Survivors list the “achievement of a healthy weight” as a primary goal.¹⁴

Obesity represents one of several metabolic disorders that are frequently manifest among cancer survivors, disorders that are grouped under the umbrella of “the metabolic syndrome” and include diabetes and cardiovascular disease (CVD). Insulin resistance is the underlying event associated with the metabolic syndrome, and either insulin resistance, co-occurring hyperinsulinemia, or diabetes have been reported as health concerns among cancer survivors.^{243–245} As Brown and colleagues observed,²³⁴ diabetes may play a significant role in the increased number of noncancer-related deaths among survivors; however, its role in progressive cancer is still speculative.

Although there is one study that suggests that older breast cancer patients derive a cardioprotective benefit from their diagnosis and/or associated treatments (most likely tamoxifen),²⁴⁶ most reports indicate that CVD is a major health issue among survivors, evidenced by mortality data that show that half of noncancer-related deaths are attributed to CVD.¹⁰ Risk is especially high among men with prostate cancer who receive hormone ablation therapy, as well as patients who receive adriamycin and radiation treatment to fields surrounding the heart.²⁴⁷ Although more research is needed to explore the potential benefits of lifestyle interventions specifically within survivor populations, the promotion of a healthy weight via a low saturated fat diet with ample amounts of fruits and vegetables and moderate levels of physical activity is recommended.^{14,15}

Osteoporosis

Osteoporosis and osteopenia are prevalent conditions in the general population, especially among women. Despite epidemiologic findings that increased bone density and low fracture risk are associated with increased risk for breast cancer,^{248–256} clinical studies suggest that osteoporosis is still a prevalent health problem among survivors.^{257–260} Data of Twiss et al.²⁵⁸ indicate that 80% of older breast cancer patients have T-scores less than -1 and thus have clinically confirmed osteopenia at the time of their initial appointment. Other cancer populations, such as premenopausal breast and prostate cancer patients, may possess good skeletal integrity at the onset of their disease, but are at risk of developing osteopenia that may ensue with treatment-induced ovarian failure or androgen ablation.

Decreased Functional Status

Previous studies indicate that functional status is lowest immediately after treatment and tends to improve over time; however, the presence of pain and co-occurring diseases may affect this relationship.²⁶¹ In the older cancer survivor, regardless of duration following diagnosis, the presence of comorbidity, rather than the history of cancer per se, correlates with impaired functional status.²⁶² Cancer survivors have almost a twofold increase in having at least one functional limitation; however, in the presence of another comorbid condition, the odds ratio increases to 5.06 (95% CI, 4.47–5.72).²⁶³ These findings have been confirmed by other studies in diverse populations of cancer survivors.^{264–266} A cost analysis by Chirikos et al.²⁶⁶ indicates that “the economic consequence of functional impairment exacts an enormous toll each year on cancer survivors, their families and the American economy at large.”

Grading of Late Effects

The assessment and reporting of toxicity, based on the toxicity criteria system, plays a central role in oncology. Grading of late effects can provide valuable information for systematically monitoring the development and/or progression of late effects.²⁶⁷ Although multiple systems have been developed for grading the adverse effects⁽⁴⁾ of cancer treatment, there is, to date, no universally accepted grading system.³ In contrast to the progress made in standardizing acute effects, the use of multiple late effects grading systems by different groups hinders the comparability of clinical trials, impedes the development of toxicity interventions, and encumbers the proper recognition and reporting of late effects. The wide adoption of a standardized criteria system can facilitate comparisons between institutions and across clinical trials.

⁽⁴⁾Any new finding or undesirable event that may or may not be attributed to treatment.

Some adverse events are clinical changes or health problems unrelated to the cancer diagnosis or its treatment.

A definitive assignment of attribution cannot always be rendered at the time of grading.

Multiple systems have been developed and have evolved substantially since being first introduced more than 20 years ago.²⁶⁸ Garre et al. developed a set of criteria to grade late effects by degree of toxicity as follows: grade 0 (no late effect), grade 1 (asymptomatic changes not requiring any corrective measures, and not influencing general physical activity), grade 2 (moderate symptomatic changes interfering with activity), grade 3 (severe symptomatic changes that require major corrective measures and strict and prolonged surveillance), and grade 4 (life-threatening sequelae).²⁶⁹ The SPOG (Swiss Pediatric Oncology Group) grading system has not been validated so far. It also ranges from 0 to 4: grade 0, no late effect; grade 1, asymptomatic patient requiring no therapy; grade 2, asymptomatic patient, requires continuous therapy, continuous medical follow-up, or symptomatic late effects resulting in reduced school, job, or psychosocial adjustment while remaining fully independent; grade 3, physical or mental sequelae not likely to be improved by therapy but able to work partially; and grade 4, severely handicapped, unable to work independently).²⁷⁰

The National Cancer Institute Common Toxicity Criteria (CTC) system was first developed in 1983. The most recent version, CTCAE v3.0 (Common Terminology Criteria for Adverse Events version 3.0) represents the first comprehensive, multimodality grading system for reporting *both* acute and late effects of cancer treatment. This new version requires changes in two areas: (1) application of adverse event criteria (e.g., new guidelines regarding late effects, surgical and pediatric effects, and issues relevant to the impact of multimodal therapies); and (2) reporting of the *duration* of an effect. This instrument carries the potential to facilitate the standardized reporting of adverse events and a comparison of outcomes between trials and institutions.

It is important to be aware that tools for grading late effects of cancer treatment are available, to validate them in larger populations, and to examine their utility in survivors of adult cancers. Oncologists, primary care physicians, and ancillary providers should be educated and trained to effectively monitor, evaluate, and optimize the health and well-being of a patient who has been treated for cancer. Additional research is needed to provide adequate knowledge about symptoms that persist following cancer treatment or those that arise as late effects, especially among survivors diagnosed as adults. Prospective studies that collect data on late effects will provide much needed information regarding the temporal sequence and timing of symptoms related to cancer treatment. It may be clinically relevant to differentiate between onset of symptoms during treatment, immediately posttreatment, or months later. Continued, systematic follow-up of survivors will result in information about the full spectrum of damage caused by cytotoxic and/or radiation therapy and possible interventions that may mitigate these adverse effects. We also need to examine the role of comorbidities on the risk for, and development of, late effects of cancer treatment among, especially, adult cancer survivors. Practice guidelines for follow-up care of cancer survivors and evaluation and management of late effects need to be developed so that effects can be mitigated when possible. Clearly, survivors can benefit from guidelines established for the primary prevention of secondary cancers as well as continued surveillance.^{271,272}

Follow-Up Care for Late and Long-Term Effects

Optimal follow-up of survivors includes both ongoing monitoring and assessment of persistent and late effects of cancer treatment and the successful introduction of appropriate interventions to ameliorate these sequelae. The achievement of this goal is challenging, and inherent in that challenge is the recognition of the importance of preventing premature mortality from the disease and/or its treatment and the prevention or early detection of both the physiologic and psychologic sources of morbidity. The prevention of late effects, second cancers, and recurrences of the primary disease requires watchful follow up and optimal utilization of early detection screening techniques. Physical symptom management is as important in survivorship as it is during treatment, and effective symptom management during treatment may prevent or lessen lasting effects.

Regular monitoring of health status after cancer treatment is recommended, because this should (1) permit the timely diagnosis and treatment of long-term complications of cancer treatment; (2) provide the opportunity to institute preventive strategies such as diet modification, tobacco cessation, and other lifestyle changes; (3) facilitate screening for, and early detection of, a second cancer; (4) timely diagnosis and treatment of recurrent cancer; and (5) the detection of functional or physical or psychologic disability.

There has been no consensus on overall recommendations for routine follow-up after cancer therapy for *all* cancer survivors. A recent review by Kattlove and Winn can help guide oncologists in providing quality continuing care for their patients—care that spans a broad spectrum of medical areas ranging from surveillance to genetic susceptibility.²⁷³ Health promotion is a key concern of patients once acute management of their disease is complete. Increasingly, cancer survivors are looking to their oncology care providers for counsel and guidance with respect to lifestyle change that will improve their prospects of a healthier life and possibly a longer one as well. Although complete data regarding lifestyle change among cancer survivors have yet to be determined, and there remains an unmet need for behavioral interventions with proven efficacy in various cancer populations,²⁷⁴ the oncologist can nonetheless make use of extant data to inform practice and also should be attentive to new developments in the field.

Follow-up care and monitoring for late effects is usually done more systematically and rigorously for survivors of childhood cancer while they continue to be part of the program or clinic where they were treated. The monitoring of adult cancer sites for the development of late effects, particularly outside the oncology practice, is neither thorough nor systematic. It is important that survivors of both adult and childhood cancers be monitored for the late and long-term effects of treatment, as discussed in preceding sections, at regular intervals.

It is now recognized that cancer survivors may experience various late physical and psychologic sequelae of treatment and that many healthcare providers may be unaware of actual or potential survivor problems.²⁷⁵ Until recently, there were no clearly defined, easily accessible risk-based guidelines for cancer survivor follow-up care. Such clinical practice guidelines can serve as a guide for doctors, outline appropriate

methods of treatment and care, and address specific clinical situations (disease-oriented) or use of approved medical products, procedures, or tests (modality-oriented). In response to this growing mandate, the Children's Oncology Group has now developed and published its guidelines for long-term follow-up for Survivors of Childhood, Adolescent, and Young Adult Cancers.²⁷⁵ These risk-based, exposure-related clinical practice guidelines are intended to promote earlier detection of and intervention for complications that may potentially arise as a result of treatment for pediatric malignancies, and are both evidence based (utilizing established associations between therapeutic exposures and late effects to identify high-risk categories) and grounded in the collective clinical experience of experts (matching the magnitude of risk with the intensity of screening recommendations). Importantly, they are intended for use beginning 2 or more years following the completion of cancer therapy and are not intended to provide guidance for follow-up of the survivor's primary disease.

Of great significance to survivors of adult cancer, using the best available evidence, the American Society of Clinical Oncology (ASCO) expert panels have also identified and developed practice recommendations for posttreatment follow-up of specific cancer sites (breast and colorectal; source: www.asco.org). In addition, ASCO has also created an expert panel tasked with the development of follow-up care guidelines geared toward the prevention or early detection of late effects among survivors diagnosed and treated as adults.

To facilitate optimal follow-up during the posttreatment phase, the patient's age at diagnosis, side effects of treatment reported or observed during treatment, calculated cumulative doses of drugs or radiation, and an overview of late effects most likely for a given patient given the treatment history should be summarized and kept on file. A copy of this summary should be provided to the patient or to the parent of a child who has undergone treatment for cancer. The importance of conveying this detailed treatment history to primary care providers should be clearly communicated, especially if follow-up will occur in the primary/family care setting. Finally, screening tests that may help detect subclinical effects that could become clinically relevant in the future should be listed.

Recommendations for regular, ongoing follow-up of cancer survivors are summarized in Table 101.2. For the prevention or early detection of second malignant neoplasms occurring as a late effect of treatment, providers should remain ever vigilant for the possibility. A detailed history and physical examination is always appropriate, in conjunction with screening at age-appropriate intervals or as outlined by consensus panel recommendations.

Physicians, caregivers, and the family must be able to hear and observe what the patient is trying to communicate, reduce fear and anxiety, counter feelings of isolation, correct misconceptions, and obtain appropriate symptom relief. Practitioners inheriting care for child or adult survivors need to understand the effects of cytotoxic therapies on the growing child or the adult at varying stages/ages of life and be knowledgeable about interventions that may mitigate the effects of these treatments.

Patient education should guide lifestyle and choices for follow-up care, promote adaptation to the disease or relevant sequelae, and help the patient reach an optimal level of well-

ness and functioning, both physical and psychological, within the context of the disease and treatment effects.

Research Implications of Long-Term and Late Effects of Cancer

Cancer survivorship research continues to provide us with a growing body of evidence regarding the unique and uncharted consequences of cancer and its treatment among those diagnosed with this disease. It is becoming an acknowledged fact that most cancer treatment options available and in use today will affect the future health and life of those diagnosed with this disease. Adverse cancer treatment-related sequelae thus carry the potential to contribute to the ongoing burden of illness, health care costs, and decreased length and quality of survival.

Data and results from ongoing survivorship studies, examining outcomes among both adult and pediatric cancer survivors, are continuing to demonstrate that (a) there may be long latencies for potentially life-threatening late effects (e.g., cardiac failure secondary to the cardiotoxic effects of cancer treatment); (b) both late and chronic toxicities (e.g., fatigue, sexual dysfunction, cognitive impairment, neuropathies) are persistent, worsen over time, and carry significant potential to adversely affect the health and well being of survivors; (c) early interventions may hold the promise of reducing adverse outcomes; and (d) there may be a continued need for extended follow-up of survivors to prevent, detect early, control, or manage adverse sequelae of cancer or its treatment.

Among childhood cancer survivors, residual endocrine disorders have been shown to be as high as 40%.²⁷⁶ A recent study found the cumulative frequency of congestive heart failure to be 17.4% at 20 years after diagnosis^{277, (5)} and that risk factors such as female gender, higher cumulative doxorubicin doses, and lung and left abdominal irradiation increased the likelihood of heart failure in this population, variables that may affect practice in terms of initial cancer treatment, recommendations for posttreatment follow-up care, and interventions (behavioral, medical, or pharmacologic) to decrease future risk. Others have reported that there may be an increased risk of fetal malposition and premature labor among girls who received flank radiation therapy as part of their treatment for Wilm's tumor, and, among their offspring, an elevated risk for low birth weight, premature birth (less than 36 weeks gestation), and congenital malformations. These risks carry distinct implications for the obstetrical management of female survivors of Wilm's tumor.²⁷⁸ Finally, data continue to show that survivors of acute lymphoblastic leukemia are at significant risk of being overweight or obese when compared to sibling controls.¹²⁵ Because premature coronary artery disease has been reported in this population, these findings underscore the importance of lifestyle and health promotion interventions.

Studies have also begun to demonstrate the deleterious impact of cancer treatment among those diagnosed with this disease as adults. Even after adjustment for age, baseline functional health status, and multiple covariates, long-term breast

⁽⁵⁾Among survivors of Wilm's tumor treated with doxorubicin.

TABLE 101.2. Follow-up care and surveillance for late effects.

<i>Follow-up visit</i>	<i>Content of clinic visit</i>	<i>Suggested evaluative procedures and ancillary actions</i>
Chemotherapy treatment cessation visit	<ol style="list-style-type: none"> 1. Review complete treatment history 2. Calculate cumulative dosages of drugs 3. Document regimen(s) administered 4. Radiation ports, dosage, machine 5. Document patient age at diagnosis/treatment 6. Side effects during treatment 7. Identify likely late effects 8. Baseline "grading" of late effects (Garre or SPOG) 	<p>Develop late effect risk profile</p> <p>Summarize all information in previous column</p> <p>Provide copy to patient (or parent if minor child)</p> <p>Instruct that this summary should be provided to primary care or other healthcare providers</p> <p>Keep copy of summary in patient chart</p>
General measures at every visit	<ol style="list-style-type: none"> 1. Detailed history 2. Complete physical examination 3. Review systems 4. Meds, maintenance, prophylactic antibiotics 5. Education: GPA, school performance 6. Employment history 7. Menstrual status/cycle 8. Libido, sexual activity 9. Pregnancy and outcome 	<p>Evaluate symptomatology, patient reports of issues</p> <p>Review any intercurrent illnesses</p> <p>Evaluate for disease recurrence, second neoplasms</p> <p>Systematic evaluation of long-term (persistent) and late effects (see specific measures)</p> <p>Grade long-term and late effects: Garre or SPOG criteria</p> <p>CBC; urinalysis; other tests depending on exposure history and late effect risk profile</p>
Specific measures to evaluate late effects	Growth: includes issues such as short stature, scoliosis, hypoplasia	Monitor growth (growth curve); sitting height, parental heights, nutritional status/diet, evaluate scoliosis, bone age, growth hormone assays, thyroid function, endocrinologist consult; orthopedic consult
Relevance differs by:		
1. Age at diagnosis/treatment	Cardiac	EKG, echo, afterload reduction, cardiologist consult
2. Specific drugs, regimens		Counsel against isometric exercises if high risk, advise ob/gyn risk of cardiac failure in pregnancy
3. Combinations of treatment modalities	Neurocognitive	History and exam
4. Dosages administered		Communicate: school, family, special education
5. Expected toxicities (based on mechanics of action of cytotoxic drugs (cell-cycle-dependent; proliferation kinetics)		Compensatory remediation techniques
6. Exceptions occur to the theoretical assumption that least susceptible organs/tissues are those that replicate slowly or not at all (vinca, methotrexate, adriamycin)	Neuropathy	Neuropsychology consult; CT or MRI; CSF; basic myelin protein
		Written instructions, appointment cards
		History/exam: neurologic exam, sensory changes
		hands/feet, paresthesias, bladder, gait, vision, muscle strength
		Neurologist consult
	Gonadal toxicity	History for primary vs. secondary dysfunction, gonadal function (menstrual cycle, pubertal development/delay, libido); hormone therapy; interventions (bromocriptine)
7. Combinations of radiation/chemotherapy more often associated with late effects		Premature menopause: hormone replacement unless contraindicated; DXA scans for osteoporosis; calcium
		Endocrinologist consult
		Reproductive technologies
	Pulmonary	Chest X-ray; pulmonary function tests; pulmonologist consultation
	Urinary	Urinalysis; BUN/creatinine; urologist if hematuria
	Thyroid	Annual TSH; thyroid hormone replacement; endocrinologist
	Weight history	Evaluate dietary intake (food diary)/physical activity
		Nutritionist and/or endocrinologist consult
	Lymphedema	History/exam: swelling, sensations of heaviness/fullness
	Fatigue	Rule out hypothyroidism; anemia, cardiac/pulmonary sequelae; evaluate sleep habits
		Evaluate physical fitness and activity levels
		Regular physical activity unless contraindicated
	Surgical toxicity	Antibiotic prophylaxis (splenectomy)
	Gastrointestinal/hepatic	Liver function, hepatitis screen, gastroenterologist consult
Screening for second malignant neoplasms	Screening guidelines differ by age	Follow guidelines for age-appropriate cancer screening (mammogram, Pap smear, FOBT/flexible sigmoidoscopy)
	Oncologist consult	Mammogram at age 30 if history of mantle radiation for Hodgkins
		Screen for associated cancers in HNPCC family syndrome
		Screen for ovarian cancer if history of breast cancer and BRCAI II.
Assess/manage comorbidities	Osteoporosis; heart disease; arthritis, etc.	History/exam; be cognizant of risk; appropriate consult

Evaluations are suggestions only. Relevance will differ by treatment history and late effect risk profile.

Source: Data from Aziz (2002, 2003).^{2,6}

cancer survivors are more likely to experience persistent significant declines in *physical* health status when compared to cancer-free controls, with younger or socially isolated survivors faring worse than those middle-aged or older in both physical and psychosocial dimensions.²⁷⁹ These findings have been substantiated by another recent study where breast cancer survivors were found to be at significantly higher risk of physical declines in health status compared to age-matched controls.²⁸⁰

Outcomes of cancer and its treatment may be even more complex among medically underserved or ethnoculturally diverse populations. It has been reported that African-American survivors experience poorer functional health and consistently higher levels of comorbidities, decreased physical functioning, and general health vulnerability after cancer diagnosis and treatment compared to age-matched Caucasian patients.²⁸¹ From an economic standpoint, survivors working at the time of diagnosis may experience a significant reduction in annual market earnings,⁽⁶⁾ the adverse economic impact being worse among survivors with the greatest declines in health status.²⁸² Long reported as a late effect among pediatric survivors, the adverse neurocognitive impact of cancer treatment is now increasingly reported as a potentially devastating outcome among adult survivors. Breast and lymphoma survivors exposed to systemic chemotherapy are at increased risk for neurocognitive deficits affecting memory, concentration, and attention. Diffuse white and gray matter changes have been reported in magnetic resonance imaging studies, and early data indicate that APOEε4 may be a potential genetic marker for risk.^{283,284} Sexual dysfunction continues to be a persistent finding among both men and women years after cancer treatment.^{285,286} Finally, the extent to which women's daily living is affected by lymphedema is not recognized routinely by healthcare providers even today.²⁸⁷

There are promising findings from intervention studies among both adult and childhood cancer survivors. Daily consumption of aspirin may result in a significant reduction in relative risk of death from breast cancer.⁽⁷⁾ Dexrazoxane (DEXRA or Zinecard) administered during active treatment may prevent or reduce acute cardiac injury associated with doxorubicin therapy.^{288,289} Methylphenidate (Ritalin) may provide at least a short-term benefit in childhood cancer survivors who experience clinically significant learning problems and deficits in attention and memory.²⁹⁰

Home-based educational interventions can help to improve cancer knowledge, self-efficacy (coping), and awareness of resources among both white and African-American breast cancer survivors.²⁹¹

Self-reported depression burden may significantly influence the severity and number of side effects experienced by breast cancer survivors, and self-help interventions may reduce fatigue, pain, and nausea burden in women with breast cancer.²⁹² Last but not least, cognitive-behavioral stress management interventions may successfully reduce the prevalence of moderate depression and increase generalized optimism and positive reframing, lending support to the

importance of examining positive responses to traumatic events.²⁹³

Thus, research that examines the effects of cancer and its treatment among individuals diagnosed with the disease and their family members is critical if we are to help patients make decisions about treatment options that could affect their future. Cancer survivorship research carries the potential to enable providers of care to tailor therapies to maximize cure while minimizing adverse treatment-related effects. The development and dissemination of evidence-based interventions may help us to reduce cancer morbidity as well as mortality and facilitate adaptation among cancer survivors. Finally, knowledge gained from survivorship research could help improve quality of care, control costs, and equip the next generation of physicians, nurses, and other healthcare professionals to provide not just the science but also the art of comprehensive cancer medicine.

Conclusions

A large and growing community of cancer survivors is one of the major achievements of cancer research during the past three decades. Both length and quality of survival are important endpoints. Many cancer survivors are at risk for, and develop, physiologic late effects of cancer treatment that may lead to premature mortality and morbidity. As in the past when treatments were modified to decrease the chance of developing toxicities among survivors of childhood cancer, the goal of future research and treatment should also be to evaluate late effects systematically and further modify toxicities without diminishing cures. Interventions and treatments that can ameliorate or manage effectively both persistent and late physical effects of treatment should be developed and promoted for use in this population. Oncologists, primary care physicians, and ancillary providers should be educated and trained to effectively monitor, evaluate, and optimize the health and well-being of a patient who has been treated for cancer.

Additional research is needed to provide adequate knowledge about symptoms that persist following cancer treatment or those that arise as late effects. Prospective studies that collect data on late effects prospectively are needed as most of the literature on late effects is derived from cross-sectional studies in which it is not clear if the symptom began during treatment or immediately after treatment. Continued, systematic follow-up of survivors will provide information about the full spectrum of damage caused by cytotoxic or radiation therapy and possible interventions that may mitigate the effects. Interventions, therapeutic or lifestyle, that can treat or ameliorate these late effects need to be developed. Practice guidelines for follow-up care of cancer survivors and evaluation and management of late effects need to be developed so that effects can be mitigated when possible.

Our knowledge about the late effects of cancer treatment, in large part, comes from studies conducted among survivors of pediatric cancer. We need to explore further the impact cancer treatment on late effects in survivors diagnosed as adults. We also need to examine the role of comorbidities on the risk for, and development of, late effects of cancer treatment among these adult cancer survivors.

⁽⁶⁾Compared to age-matched cancer free controls.

⁽⁷⁾Holmes MA. Personal communication.

Although there has been considerable research on the late outcomes among survivors of cancer, future research must be directed toward identification of risks associated with more-recent treatment regimens, as well as the very late occurring outcomes resulting from treatment protocols utilized three or more decades ago. As treatment- and patient-related factors impact the subsequent risk of late-occurring adverse outcomes, clear delineation of those survivors who are at high risk of specific adverse outcomes is essential for the rational design of follow-up guidelines, prevention, and intervention strategies.

Each person with cancer has unique needs based on the extent of the disease, effects of treatment, prior health, functional level, coping skills, support systems, and many other influences. This complexity requires an interdisciplinary approach by all health professionals that is organized, systematic, and geared toward the provision of high-quality care. This ambience may facilitate the adaptation of cancer survivors to temporary or permanent sequelae of the disease and its treatment.

Medical and Psychosocial Issues in Childhood Cancer Survivors

Smita Bhatia, Wendy Landier,
Jacqueline Casillas, and Lonnie Zeltzer

More than 12,000 children and adolescents younger than 20 years are diagnosed with cancer each year in the United States.¹ With the use of risk-based therapies, the overall 5-year survival rate is approaching 80%, resulting in a growing population of childhood cancer survivors.¹ In 1997, there were an estimated 270,000 survivors of childhood cancer; over two-thirds of these were older than 20 years of age.² This figure translates into 1 in 810 individuals under the age of 20 and 1 in 640 individuals between the ages of 20 and 39 years having successfully survived childhood cancer (see Chapter 62).

Unlike an adult, the growing child tolerates the acute side effects of therapy relatively well. However, the use of cancer therapy at an early age can produce complications that may not become apparent until years later as the child matures. The resulting complications are related to the specific therapy employed and the age of the child at the time the therapy was administered. A *late effect* is defined as a late-occurring or chronic outcome—either physical or psychologic—that persists or develops beyond 5 years from the diagnosis of cancer. These late effects include complications such as cognitive impairment, cardiopulmonary compromise, endocrine dysfunction, renal impairment, chronic hepatitis, and subsequent malignancies. As many as two-thirds of survivors experience at least one late effect as a result of treatment for cancer during childhood.³⁻⁷ Therefore, ongoing evaluation of childhood cancer survivors is an essential component of follow-up. This chapter discusses the long-term complications that can occur among pediatric patients treated for cancer, along with recommendations for follow-up. Table 102.1 summarizes the data on the magnitude of risk and associated risk factors for select long-term outcomes.

Neurocognitive Sequelae

Neurocognitive sequelae of treatment for childhood cancer occur as a consequence of radiation to the whole brain and/or therapy with high-dose methotrexate, cytarabine, and/or

intrathecal methotrexate. Children with a history of brain tumors, acute lymphoblastic leukemia (ALL), or non-Hodgkin's lymphoma (NHL) are most likely to be affected. Risk factors include increasing radiation dose, young age at the time of treatment, therapy with both cranial radiation and systemic or intrathecal chemotherapy, and female sex.⁸ Severe deficits are most frequently noted in children with brain tumors, especially those who were treated with radiation therapy, and in children who were less than 5 years of age at the time of treatment.⁹

Neurocognitive deficits usually become evident within 1 to 2 years following radiation and are progressive in nature.¹⁰ Affected children may experience information-processing deficits, resulting in academic difficulties. These children are particularly prone to problems with receptive and expressive language, attention span, and visual and perceptual motor skills. They most often experience academic difficulties in the areas of reading, language, and mathematics. Children in the younger age groups and those treated for brain tumors may experience significant drops in intelligence quotient (IQ) scores, with irradiation- or chemotherapy-induced destruction in normal white matter partially explaining intellectual and academic achievement deficits.^{9,11-13}

Cardiovascular Function

Chronic cardiotoxicity usually manifests itself as cardiomyopathy, pericarditis, and congestive heart failure. The anthracyclines are well-known causes of cardiomyopathy.¹⁴⁻¹⁷ The incidence of cardiomyopathy is dose dependent and may exceed 30% among patients who received cumulative doses of anthracyclines in excess of 600 mg/m² (daunorubicin/doxorubicin equivalent).¹⁸ With a total dose of 500 to 600 mg/m², the incidence is 11%, falling to less than 1% for cumulative doses less than 500 mg/m².¹⁹ These data have formed the basis for the use of a threshold of 500 mg/m² as the cumulative dose for cardiotoxicity. However, Kremer et al.²⁰ reported that a cumulative dose of anthracyclines greater than 300 mg/m²

TABLE 102.1. Clinical characteristics and risk factors for select long-term sequelae after treatment for childhood cancer.

<i>Long-term sequelae</i>	<i>Cumulative probability</i>	<i>Risk factors</i>
Congestive heart failure	4%–17% at 20 years (risk increasing with increasing therapeutic exposures)	<ul style="list-style-type: none"> • Higher cumulative dose of anthracyclines • Female sex • Younger age at exposure to anthracyclines • Black race • Presence of trisomy 21 • Radiation therapy involving the heart • Exposure to cyclophosphamide, ifosfamide, or amsacrine
Myocardial infarction	21% at 20–25 years	<ul style="list-style-type: none"> • Radiation therapy to the mediastinum • Dose >30 Gy • Increasing time since irradiation • Younger age at irradiation (<20 years) • Hypertension/hypercholesterolemia/DM/smoking/obesity
Ischemic stroke	12% at 15 years (among patients exposed to neck radiation)	<ul style="list-style-type: none"> • Radiation therapy to the head and neck • Younger age at irradiation (<20 years) • Hypertension/hypercholesterolemia/DM/smoking
Subsequent malignant neoplasms	3% at 20 years	<ul style="list-style-type: none"> • HD, soft tissue sarcoma, hereditary retinoblastoma • Younger age at exposure to therapeutic agents • Female sex • Radiation therapy • Exposure to alkylating agents or topoisomerase • II inhibitors

DM, diabetes mellitus; HD, Hodgkin's disease.

was associated with an increased risk of clinical heart failure (relative risk, 11.8) compared with a cumulative dose lower than 300 mg/m². Thus, a lower cumulative dose of anthracyclines may place children at increased risk for cardiac compromise.²⁰

Cardiomyopathy can occur many years after completion of therapy, and the onset may be spontaneous or coincide with exertion or pregnancy. Risk factors known to be associated with anthracycline-related cardiac toxicity include mediastinal radiation,²¹ uncontrolled hypertension,^{17,18} exposure to other chemotherapeutic agents, especially cyclophosphamide,¹⁸ dactinomycin,²² mitomycin,¹⁸ decarbazine,²³ vincristine, bleomycin, and methotrexate;²⁴ female sex;²⁵ younger age;^{17,26,27} and electrolyte imbalance such as hypokalemia and hypomagnesemia.¹⁶

Chronic cardiac toxicity associated with radiation alone most commonly manifests as pericardial effusions or constrictive pericarditis, sometimes in association with pancarditis. Although 4,000 cGy of total heart radiation dose appears to be the usual threshold, pericarditis has been reported after as little as 1,500 cGy, even in the absence of radiomimetic chemotherapy.^{28,29} Symptomatic pericarditis, which usually develops 10 to 30 months after radiation, is found in 2% to 10% of patients.^{28–30} Subclinical pericardial and myocardial damage as well as valvular thickening may be common in this population,^{31,32} and symptomatic pericarditis may first appear as late as 45 years after therapy.^{33,34} Coronary artery disease has been reported following radiation to the mediastinum.³⁵

Prevention of cardiotoxicity is a primary focus of investigation. Liposomal anthracyclines are being explored to reduce cardiotoxicity. The anthracyclines chelate iron, and the anthracycline–iron complex catalyzes the formation of extremely hydroxyl radicals. Agents such as dexrazoxane that are able to remove iron from the anthracyclines have been investigated as cardioprotectants. Clinical trials of dexrazoxane have been conducted in children, with encouraging evidence of short-term cardioprotection.^{36,37} The long-term avoidance of cardiotoxicity with the use of this agent needs

to be determined.³⁸ Smaller doses and reduced port sizes of radiation therapy may also help in decreasing the incidence of carditis.

Pulmonary Function

Radiation-induced restrictive lung disease is seen in patients who received whole-lung radiation at a dose of 1,100 to 1,400 cGy and results primarily from a proportionate interference with the growth of both the lung and the chest wall.^{39–41} Children under 3 years of age at time of therapy appear to be more susceptible to chronic toxicity. Obstructive changes are also reported after conventional radiation therapy and have been reported after 1,000 cGy total-body irradiation for hematopoietic cell transplant (HCT).⁴² A cohort of 12,390 childhood cancer survivors participating in the Childhood Cancer Survivor Study (CCSS)⁴³ had a statistically significantly increased risk of lung fibrosis, recurrent pneumonia, chronic cough, pleurisy, use of supplemental oxygen, abnormal chest wall, exercise-induced shortness of breath, bronchitis, recurrent sinus infection, and tonsillitis when compared with sibling controls.⁴⁴ Statistically significant associations were identified for lung fibrosis and chest radiation, and for supplemental oxygen use and chest radiation, BCNU (carmustine), bleomycin, busulfan, CCNU (lomustine), and cyclophosphamide. Chest radiation was associated with a 3.5% cumulative incidence of lung fibrosis at 20 years after diagnosis.

Several chemotherapeutic agents have been associated with pulmonary disease in long-term survivors. Bleomycin toxicity is the prototype for chemotherapy-related lung injury. The chronic lung toxicity is dose dependent above a threshold cumulative dose of 400 units/m² and is exacerbated by previous or concurrent radiation therapy,⁴⁵ cyclophosphamide,⁴⁶ or subsequent oxygen therapy.⁴⁷ At doses exceeding 400 units/m², 10% of the patients experience fibrosis, and 35% to 55% suffer severe symptoms in the face of combina-

tions of other injuries.⁴⁸ Other chemotherapeutic agents associated with chronic lung injury include BCNU,⁴⁹ busulfan, and CCNU.

Symptoms of pulmonary dysfunction include chronic cough or dyspnea, and close evaluation should be performed during yearly follow-up. All patients must be educated about the risks of smoking. The best possible approach to chronic pulmonary toxicity of anticancer therapy is preventive and includes the following: careful monitoring of pulmonary function and chest radiographs before and during bleomycin and radiation; respecting cumulative dose restrictions on bleomycin administration; and limiting radiation dosage and port sizes.

Endocrine Function

Thyroid

Hypothyroidism is the most common nonmalignant late effect involving this gland and is almost always caused by radiation of the head and neck for a nonthyroid malignancy. Laboratory evidence of primary hypothyroidism is evident in 40% to 90% of patients receiving radiation doses in excess of 1,500 cGy.⁵⁰⁻⁵² The actuarial risk of clinical hypothyroidism for subjects treated with 4,500 Gy or more is 50% at 20 years from diagnosis. Childhood brain tumor survivors were compared with siblings as part of the CCSS study, and were found to be at a 14.3-fold-increased risk of developing hypothyroidisms.⁵³ Risk factors associated with the development of hypothyroidism include increasing dose of radiation (higher risk associated with conventionally fractionated radiotherapy as compared with hyperfractionated radiotherapy), thyroidectomy, use of iodide-containing contrast material as in lymphangiography, older age at irradiation, and female gender.^{54,55}

Hyperthyroidism has been reported in up to 5% of the survivors of Hodgkin's disease (HD) and is associated with radiation doses exceeding 3,500 cGy.⁵⁴ Thyroid nodules are observed among patients exposed to radiation. Female gender and radiation doses exceeding 2,500 cGy have been identified as risk factors.⁵⁴ The actuarial risk of female survivors of HD developing a thyroid nodule is 20% at 20 years from diagnosis. Patients with HD receiving radiation to the thyroid gland have been reported to be at an 18-fold-increased risk of developing thyroid cancer when compared with the general population.

Growth

Poor linear growth and short adult stature are common complications following successful treatment for childhood cancer.⁵⁶ Although in some children catch-up growth may occur, short stature may be permanent or even progressive. Severe growth retardation, defined as a standing height below the fifth percentile, has been observed in as many as 30% to 35% of survivors of childhood brain tumors⁵⁷⁻⁵⁹ and 10% to 15% of patients treated for leukemia.^{60,61} Whole-brain irradiation has been identified as the principal cause of short stature.⁶⁰ Compared with siblings, childhood brain tumor survivors participating in the CCSS study were at a 277.8-fold-

increased risk of developing growth hormone deficiency.⁵³ The effects of cranial irradiation appear to be related to age and sex, with children younger than 5 years at time of therapy and girls being more susceptible to the radiation effect.⁶²⁻⁶⁴ The effects of radiation are also dose dependent, with doses exceeding 3,000 cGy associated with growth retardation in 50% of the patients.^{58,59} The mechanism by which cranial irradiation induces short stature is not clear. Growth hormone deficiency and early onset of puberty in girls may contribute to loss of final height.⁶⁵ Direct inhibition of vertebral growth by spinal irradiation often contributes to short stature.

Body Mass Index

An increased prevalence of obesity has been reported among survivors of childhood ALL, with the prevalence increasing with increasing dose of cranial radiation. In a study conducted by Sklar et al.,⁶⁶ the percentage of subjects who were overweight at attainment of final height was 10.5%, 40%, and 38% for subjects treated with no cranial radiation, 18 Gy of cranial radiation, and 24 Gy of cranial radiation, respectively. This study documented that children with ALL given cranial radiation develop increases in their body mass index early on during their treatment and remain at significant risk for becoming overweight as young adults. A recent report has shown that the age- and race-adjusted odds ratio (OR) for being obese in ALL survivors treated with cranial radiation doses of 20 Gy or more in comparison with siblings was 2.6 for females and 1.9 for males.⁶⁷ Furthermore, the OR for obesity was greatest among girls diagnosed at 0 to 4 years of age and treated with radiation doses of 20 Gy or more. Thus, this study clearly demonstrated in a large cohort of ALL survivors that 20 Gy or more is associated with an increased prevalence of obesity, especially in females treated at a young age. It is therefore important for healthcare professionals to recognize this risk and to address it in the long-term follow-up of the survivors.

Gonadal Function

MALES

Male survivors of childhood cancer may experience germ cell depletion and abnormalities of gonadal endocrine function. These abnormalities may be secondary to radiation, chemotherapy, or surgery, with the effects of therapy varying depending on age at treatment. In patients who receive testicular radiation doses of 400 to 600 cGy, azoospermia may persist for 3 to 5 years, and at doses above 600 cGy, germinal loss with resulting increases in follicle-stimulating hormone (FSH) and decreases in testicular volume usually appears to be irreversible.^{68,69} Prepubertal testicular germ cells also appear to be radiosensitive, although tubular damage may be difficult to assess until the patient has progressed through puberty. Radiation therapy at doses of 2,000 cGy or higher is also toxic to Leydig cells, with resulting inadequate production of testosterone.⁷⁰

Chemotherapy can also interfere with testicular function. Alkylating agents decrease spermatogenesis in long-term survivors of cancer. The effects of cyclophosphamide and chlorambucil are dose dependent but are reversible in up to 70%

of patients after several years.⁷¹ Among pubertal boys treated for HD with six cycles of mechlorethamine, vincristine, prednisone, and procarbazine (MOPP), azoospermia is found in 80% to 100%, and is reversible in only 20% of cases.⁷² After adriamycin, bleomycin, vinblastine, and dacarbazine (ABVD), the incidence of azoospermia was 36%, with 100% recovery.⁷³ The effect of MOPP on Leydig cell function appears to be age related, with normal pubertal progression after therapy for patients treated before the onset of puberty, gynecomastia with low testosterone and increased luteinizing hormone (LH) in patients treated during adolescence, and compensated Leydig cell failure without gynecomastia in adults.⁷¹

FEMALES

Radiation therapy effects on the ovary are both age- and dose dependent. Amenorrhea develops in only 68% of prepubescent girls treated with higher doses of radiation (1,200–1,500 cGy).⁷⁴ Spinal irradiation for the treatment of ALL and brain tumors appears to result in clinically significant ovarian damage in some young women, although the majority of these women go on to experience normal puberty and menarche, generally at a slightly older age. Girls treated with whole abdominal and/or pelvic irradiation for HD or Wilm's tumor or other solid tumors are at a high risk of ovarian failure. Patients who receive HCT with total-body irradiation, both single-dose and fractionated, are at a high risk of developing permanent ovarian failure. Almost all patients who undergo HCT after the age of 10 years will develop premature ovarian failure, whereas only 50% of girls transplanted before the age of 10 years will.⁷⁵

Ovarian failure has also been observed after chemotherapy, in particular, with alkylating agents. Toxicity is, again, dose- and age dependent. Only 30% of women and girls younger than 35 years of age at exposure to MOPP chemotherapy develop temporary amenorrhea, with irreversible ovarian failure seen in a small minority.⁷⁶ Females who receive high-dose, myeloablative therapy with alkylating agents in the context of allogeneic or autologous HCT are at high risk of developing ovarian failure.⁷⁶

PREGNANCY OUTCOMES OF CHILDHOOD CANCER SURVIVORS

Radiation therapy and many of the chemotherapeutic agents used in the treatment of childhood cancer could potentially be mutagenic and have an adverse effect on the health of the offspring of the survivors. Green et al.⁷⁷ evaluated the health of the offspring of partners of male childhood cancer survivors participating in the CCSS and demonstrated that the proportion of pregnancies of the partners of male survivors that ended with a liveborn infant was significantly lower than for the partners of male siblings of the survivors who served as controls. This study of male survivors did not identify adverse pregnancy outcomes for the partners of male survivors treated with most chemotherapeutic agents. A similar study focusing on offspring of the female survivors failed to identify adverse pregnancy outcomes for female survivors treated with most chemotherapeutic agents. The offspring of women who received pelvic irradiation were at risk for low birth weight.⁷⁸

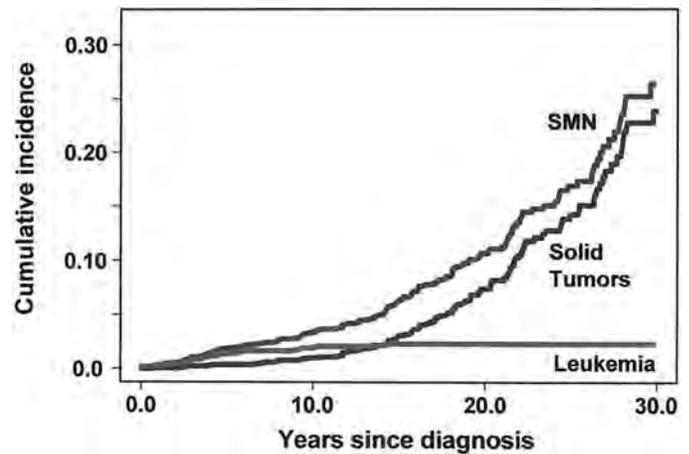

FIGURE 102.1. Cumulative incidence of subsequent malignant neoplasms after extended follow-up of Hodgkin's disease in childhood. (Adapted from Bhatia et al.,⁸¹ by permissions of *Journal of Clinical Oncology*.)

Second Malignant Neoplasms

Several studies following large cohorts of childhood cancer survivors have reported a threefold- to sixfold-increased risk of a second cancer, when compared with the general population, and this risk continues to increase as the cohort ages^{79–83} (Figure 102.1; see Chapter 111).

Late Mortality Among Childhood Cancer Survivors

Several investigators have shown a 10-fold excess in overall mortality among 5-year childhood cancer survivors when compared with the general population.^{84,85} The excess mortality was due to death from primary cancer, second cancer, cardiotoxicity, and noncancer death.

Psychosocial Issues of Childhood Cancer Survivors

There is a large body of scientific literature addressing the subject of psychosocial outcomes for childhood cancer survivors. Findings are varied in part as a result of differing definitions for psychosocial outcomes among the studies. For example, in some studies the outcomes are defined in terms of psychologic health (e.g., depression, anxiety, posttraumatic stress, posttraumatic growth, and somatization). In other studies, the outcomes are defined in terms of social health (e.g., employment, education, and marriage). In addition, many pediatric cancer survivorship studies focusing on psychosocial outcomes are limited because of small sample size and/or lack of a comparison group. Many of the studies are from the health-related quality of life (HRQOL) literature because assessment of psychosocial outcomes is often included as part of a global HRQOL assessment. Notwithstanding these differences in definitions of study outcomes and study designs, the scientific literature concerning psychosocial outcomes in childhood cancer survivors is summarized in the following sections.

Psychologic Health

An emerging body of literature indicates that childhood cancer survivors are experiencing good psychologic health years after completion of their cancer treatment. One of the earliest studies, done by Teta et al.,⁸⁶ assessed the prevalence of major depression in 450 long-term childhood cancer survivors and found no difference in depression between survivors, their siblings, and general population norms. Elkin et al.,⁸⁷ using a standardized self-report measure (the Symptom Checklist-90-Revised or SCL-90-R), assessed psychologic functioning in adolescent and young adult survivors who attended a long-term follow-up clinic for pediatric cancer survivors at a single institution. Results of this study indicated that the study population was significantly psychologically healthier than age- and gender-matched norms for the general population based on SCL-90 scores. For the small percentage of survivors who displayed some psychologic symptoms, three factors were associated with an increased risk of maladjustment: older patient age at follow-up, greater number of relapses, and presence of severe functional impairment (defined as requiring frequent assistance with activities of daily living). The findings from these earlier studies were confirmed in a recently reported study by Zebrack et al.⁸⁸ on psychological outcomes in survivors of childhood leukemia and lymphoma, using data from the Childhood Cancer Survivor Study (CCSS).

Systematic literature reviews of the smaller studies published on this topic have also reported psychological well-being following treatment for childhood cancer; however, there are subgroups of survivors who may be at risk for poorer psychosocial health outcomes.⁸⁹⁻⁹⁴ The largest and most recent of these studies to date was reported by Hudson et al.,⁹⁵ who analyzed data from the 9,535 adult survivors in the CCSS cohort compared with a randomly selected cohort of the survivors' siblings (*n* = 2,916). When compared with siblings, survivors in this study were significantly more likely to report adverse general health and moderate to severe impairment in mental health across all diagnostic groups. However, although general health was reported to be very good, with only 10.9 percent reporting fair or poor health, specific adverse effects were relatively common, as reflected by 43.6% of the cohort reporting impairment in one or more of the health domains evaluated in the study. Specifically, three

diagnostic groups (survivors of Hodgkin's disease, sarcomas, or bone tumors) were found to be at increased risk for continued cancer-related anxiety.⁹⁵ Furthermore, the authors emphasize that these three diagnoses are more common in the adolescent age group. Because adolescence is the developmental period during which abstract thinking develops, adolescents diagnosed with cancer may have a better understanding of the meaning of their diagnosis and the risks of treatment. The findings of this study confirmed the results of earlier studies⁹⁶⁻⁹⁸ (Table 102.2). Thus, these studies suggest that there are certain at-risk groups of survivors who may be experiencing negative psychosocial sequelae and therefore may benefit from targeted psychosocial support interventions during long-term follow-up care.

The childhood cancer survivorship literature also suggests that use of a posttraumatic stress model is helpful in elucidating the long-term psychosocial sequelae for certain subsets of childhood cancer survivors⁹⁹⁻¹⁰² (Table 102.3). Family members, friends, and caregivers are also affected by the survivorship experience and are therefore included in the definition of survivorship.² It is, therefore, not surprising that there are reports of family members being affected by posttraumatic stress disorder (PTSD). Kazak et al.⁹⁴ did not find an increased prevalence of PTSD in a cohort of 133 childhood leukemia survivors when compared with a control group, but did find more PTSD symptoms in their mothers and fathers. Barakat et al.⁹³ found that past perceived life threat and family social support resources contributed to PTSD symptoms in both parents and survivors. All these studies suggest that the childhood cancer experience is complex and extends beyond the survivor, even years after the completion of therapy.

Social Health

Review of the childhood cancer survivorship literature indicates that overall this population is doing well in terms of social and emotional adjustment. Differences in educational needs, behavioral adjustment, employment status, and marriage rate for certain populations of childhood cancer survivors do occur. A recent longitudinal study of the social functioning of childhood cancer survivors 2 years following completion of therapy was conducted by Reiter-Purtill et al.¹⁰³ Children who completed cancer treatment were compared

TABLE 102.2. Summary of additional studies demonstrating adverse psychologic outcomes in childhood cancer survivors.

<i>Study</i>	<i>Sample size</i>	<i>Primary disease</i>	<i>Comparison group</i>	<i>Adverse outcomes</i>	<i>Risk factors</i>
Zeltzer et al. ⁹⁶	500	ALL, treated on CCG protocols	Siblings	Depression, tension, anger, and confusion	Females, minorities, unemployed
Mulhern et al. ⁹⁷	183	Any pediatric malignancy	Normative data from the general population	Deficits in social competence and behavioral abnormalities	Presence of functional impairments, older age at evaluation, treatment with cranial irradiation, residence in a single-parent household
Glover et al. ⁹⁸	555	Leukemia	Siblings	Mood disturbance	Females, nonwhite males, females with a special education history, high school dropouts with a special education history, age younger than 12.5 years of age at diagnosis, survivors with negative perceptions of current health

ALL, acute lymphoblastic leukemia; CCG, Children's Cancer Group.

TABLE 102.3. Studies supporting the posttraumatic stress model in childhood cancer survivors.

Study	Sample size	Age range	Percent with posttraumatic stress symptoms or disorder	Risk factors
Stuber et al. ⁹⁹	64	7–19 years	13%	Symptoms of increased anxiety and reexperiencing traumatic incidents, which persisted many years after the end of treatment without evidence of decrement over time
Hobbie et al. ¹⁰¹	78	18–40 years	20.5%	Anxiety and other psychologic distress
Meeske et al. ¹⁰²	51	18–37 years	20%	Poorer QOL (as measured by the SF-36), increased psychologic distress

QOL, quality of life; SF-36, Short Form-36.

with children who were not chronically ill. The children's self-reports, as well as peer and teacher assessments of social functioning, were obtained while children were on therapy and then 2 years following completion of therapy. Findings of this study indicated minimal impact on the social functioning of the majority of childhood cancer survivors, but certain subpopulations were found to be vulnerable. Specifically, children who underwent high-intensity treatment were perceived by their peers as more "prosocial and less aggressive," although they had fewer nominations as "best friends." The authors hypothesized that this group of survivors may be less assertive about making and/or maintaining friendships or that their less-aggressive behavior may be due to fatigue. A study by Spirito et al.¹⁰⁴ reported similar findings when they compared 56 children (aged 5–12 years) to healthy controls using questionnaires assessing social adjustment, including the Self-Perception Profile. In this study, the only reported difference was of greater feelings of isolation in the childhood cancer survivors compared with the controls.

Conversely, reports of lower social competence were demonstrated by Mulhern et al.¹⁰⁵ In a cohort of survivors ($n = 183$) 2 or more years off-therapy, social competence and behavioral adjustment were assessed using a standardized questionnaire (The Child Behavior Checklist). Functional (but not cosmetic) impairments were found to increase the risk for academic and adjustment problems. Other risk factors for social and emotional problems included: older age at assessment (correlated with time since diagnosis and time since completion of therapy), treatment with cranial irradiation, and living in a single-parent household. Similarly, a

study by Pendley et al.¹⁰⁶ found that adolescent survivors who had been off treatment for longer periods of time reported more social anxiety as well as more-negative body image and lower self-worth.

Educational attainment as an outcome of social health has also been assessed in the leukemia survivor study¹⁰⁷ and in the CCSS^{108,109} (Table 102.4). The findings from these studies indicate that survivors are more likely to use special educational services, but overall are just as likely to graduate from high school when compared with their siblings.

Multiple studies have assessed the vocational status of childhood cancer survivors. One of the earliest studies assessing occupational status was completed by Meadows et al.¹¹⁰ The cohort of survivors demonstrated no differences in educational achievement or occupational status by diagnostic group, age at diagnosis, or treatment received. Nicholson et al.¹¹¹ compared osteosarcoma and Ewing sarcoma survivors with sibling controls and found that employment status and annual income were similar in the two groups despite the physical impairments following limb amputation for many of the sarcoma survivors. Hays et al.¹¹² reported similar employment findings in more than 200 childhood cancer survivors. Specifically, the employment status of the survivors was similar to individually matched controls. There were, however, findings of employment discrimination for entry into the military for survivors during the initial years following completion of therapy. The authors concluded that childhood cancer survivors who were treated in the era between 1945 and 1975 had few economic sequelae that extended beyond the first decades after treatment.

TABLE 102.4. Childhood Cancer Survivor Study (CCSS) studies assessing educational attainment as an outcome measure for social health.

Study	Sample size	Primary disease	Comparison group	Educational outcome assessed	Findings	Risk factors
Mitby et al. ¹⁰⁸	12,000	Any pediatric malignancy	3,000 siblings	Use of special education services	23% of survivors compared with 8% of siblings used special education services	Diagnosis <6 years of age; brain tumor, leukemia, and HD survivors; treatment variables of use of IT MTX and CXRT (with a positive dose-response relationship found)
Nagarajan et al. ¹⁰⁹	694	Osteosarcoma or Ewing's sarcoma	Age at diagnosis (≤ 12 years compared with >12 years), type of surgery (amputation vs. limb-sparing), and 2,667 siblings	Graduation from high school or college	No differences found between the different age or surgery groups.	More than 12 years/amputation group was less likely to graduate from high school and college compared with siblings, but there were still high rates of reports of graduation from high school in the survivors group (93%) and for those survivors older than 25 years of age, and 50% reported being a college graduate

HD, Hodgkin disease; IT MTX, intrathecal methotrexate; CXRT, cranial irradiation.

The literature regarding employment outcome for childhood cancer survivors yields mixed conclusions. For example, a study by Novakovic et al.¹¹³ found that although nearly 90 survivors of Ewing's sarcoma did not differ in educational achievement, they were less likely to be employed full time when compared with sibling controls. Conversely, Evans and Radford¹¹⁴ assessed educational achievement and employment in a small group of survivors and found that survivors were significantly less likely to complete higher education than their siblings, but had similar rates of employment and were earning similar salaries. The differences in the findings may represent the small sample sizes in the various studies.

Marital status has also been assessed as a measure of social well-being for survivors of childhood cancer. In one of the earlier studies, Makiperna¹¹⁵ interviewed 94 survivors of solid tumors diagnosed between 1960 and 1976. When the survivor population was compared with the general Finnish population, fewer female survivors were married. Green et al.¹¹⁶ found that the percentages of married male and female survivors were both significantly lower than the U.S. population norms. Byrne et al.¹¹⁷ studied a much larger population of childhood cancer survivors and found that both male and female survivors were less likely to be married when compared with a sibling control group. The study also demonstrated that survivors of central nervous system (CNS) malignancies accounted for the majority of unmarried survivors, with the males in this diagnostic group having the greatest relative risk. The findings of these two earlier studies were also confirmed more recently in a large CCSS cohort. Rauck et al.¹¹⁸ described the marital status of more than 10,000 childhood cancer survivors within the CCSS cohort and compared them to the U.S. population according to age-specific groups. Compared with the U.S. population, childhood cancer survivors, particularly females and Caucasians, were less likely to have ever been married. CNS tumor survivors as a subgroup, and particularly males within this group, were less likely to have ever been married and were more likely to divorce or separate when compared with childhood cancer survivors who had other diagnoses, as well as with the general U.S. population. Felder-Puig et al.¹¹⁹ also found a lower incidence of marriage in survivors of bone cancer. Interestingly, survivors in this study reported staying home longer after reaching adulthood than did the control group of a similar age. The investigators postulated that the survivors would, therefore, postpone marriage for a longer time than their peers. A study by Gray et al.¹²⁰ yields further insight regarding interpersonal relationships in survivors of childhood cancer. In this study, survivors reported higher intimacy motivation, but were more likely to express dissatisfaction with important relationships, when compared with a peer group. Nonetheless, despite differences in marriage rates, studies support the fact that, overall, survivors of pediatric malignancies are doing well in terms of psychosocial functioning and that only certain subgroups are at greatest risk for adverse psychosocial sequelae.

Special Populations

Two special populations of survivors (childhood acute lymphoblastic leukemia and brain tumors) warrant special attention due to their increased risk for adverse psychosocial

outcomes as a result of previous CNS treatment: Acute lymphoblastic leukemia (ALL) is the most commonly diagnosed pediatric malignancy, with an annual incidence of 3,250 children and adolescents diagnosed each year in the United States and a survival rate of approximately 85%.¹ Brain tumors are the second most commonly diagnosed pediatric malignancy, and the most common solid neoplasm. Approximately 2,200 children and adolescents under 20 years of age are diagnosed within the United States each year. The overall survival rate is approximately 68%.¹ Thus, there are rapidly growing numbers of survivors treated for both of the most commonly diagnosed pediatric malignancies.

ACUTE LYMPHOBLASTIC LEUKEMIA SURVIVORS

Improvement in the survival rates for ALL in the 1980s and 1990s has resulted in the emergence of studies focused on the neuropsychologic consequences in this population. Brown et al.¹²¹ followed a small cohort of ALL survivors who received prophylactic chemotherapy to the CNS. Survivors, when compared with their siblings, showed impairment in right hemispheric simultaneous processing when evaluated at the off-therapy time point. These differences were not found while the patient was actively undergoing treatment for ALL, a finding that illustrates the importance of continued long-term neuropsychologic evaluation for this group of survivors, as deficits may not be evident on initial assessments. Cetingul et al.¹²² studied a small sample of 5-year Turkish survivors of childhood ALL and compared them to their siblings. In this study, total IQ scores of survivors were significantly lower than the sibling control group, although small numbers limit the conclusions drawn from this study. Kingma et al.¹²³ also studied academic performance in a small sample of Dutch ALL survivors who were treated with cranial irradiation (18 or 25 Gy) and intrathecal methotrexate as CNS prophylaxis, and compared them to siblings. Survivors were more likely to be placed in special education programs than were siblings, although there was no effect of sex or irradiation dose. The investigators concluded that cranial irradiation and chemotherapy administered at a young age were associated with poorer academic career outcomes for survivors. Haupt et al.¹⁰⁷ completed a large multicenter retrospective trial of adult survivors of childhood ALL with sibling controls, assessing practical, easily understandable educational outcomes that included "enrollment in special programs, grades during high school, graduation from high school, college admission, and college graduation."¹⁰⁷ Similar to the findings of smaller studies, ALL survivors in this study were more likely to enter special education or learning-disabled programs when compared with siblings. Higher doses of cranial irradiation (24 Gy versus 18 Gy versus none) and young age (less than 6 years of age) at diagnosis were found to be the most important predictors for poor educational outcomes, defined as a lesser likelihood of entering college.

It should also be noted that craniospinal irradiation, used in early treatment regimens for ALL to prevent CNS leukemia, resulted in neurodevelopmental delays in children. In the early 1980s, Robison et al.¹²⁴ and Moss et al.¹²⁵ demonstrated that prophylactic treatment of the CNS with craniospinal irradiation was associated with decreased IQ scores. These early studies documenting the risk of neurocognitive late effects, coupled with the high cure rates, have led to the

elimination of prophylactic craniospinal irradiation from most current ALL treatment regimens. Therefore, the importance of assessing long-term psychosocial outcomes of childhood cancer treatment cannot be overemphasized, because there may be direct and practical applications for intervention and long-term follow-up care.

BRAIN TUMOR SURVIVORS

The second special population of childhood cancer survivors who warrant further discussion regarding psychosocial outcomes are those treated for pediatric brain tumors. Roman and Sperduto¹²⁶ reviewed the literature on the neuropsychologic effects of cranial radiation. Research on low-dose whole-brain radiation (such as that used for childhood ALL patients) was compared with studies on high-dose focal or whole-brain radiation used in the treatment of brain lesions. In this review, the investigators found that the low-dose whole-brain radiation (18–24 Gy) resulted in the mild decline of IQ and that subsequent learning disabilities may be the result of poor attention and memory instead of low intellectual level. Conversely, pediatric survivors who received higher-dose radiation for the treatment of brain tumors, particularly those who received whole-brain radiation, were found to be at risk for poorer cognitive outcomes. In a subsequent study by Anderson et al.,¹²⁷ higher-dose radiation used for treatment of brain tumors (when compared with that used for other malignancies) was more often found to be associated with late cognitive effects. Further research has shown that neurocognitive deficits occurring among brain tumor survivors most commonly involve the areas of memory, attention, and academic achievement.^{126,128} Whether cognitive deficits in these brain tumor survivors are primarily caused by disruption of “executive function” (ability to organize and prioritize activities to be functionally effective) is suspected but not yet proven. Data forthcoming from the CCSS will help to answer this question.

A study by Glaser et al.¹²⁹ evaluated school behavior in a small sample of brain tumor survivors compared with a control group of school-age siblings. The brain tumor survivors had good social reintegration but also had evidence of

impaired cognition, emotion, and lower self-esteem. Even though they worried more than the control group, the brain tumor survivors attended school willingly and interacted with their peers normally. Zebrack et al.⁸⁸ assessed psychologic outcomes in more than 1,000 adult long-term survivors of childhood brain tumors within the CCSS cohort and compared them with almost 3,000 sibling controls and normative data from the general population. The majority of survivors and siblings reported few symptoms of psychologic distress 5 or more years after the original cancer diagnosis. The prevalence of psychologic distress was similar to that found in the general population. Yet, when accounting for significant sociodemographic, socioeconomic, and health status variables, survivors of childhood brain cancer, in aggregate, appear to report significantly higher global distress and depression scores than do siblings. Factors associated with higher levels of psychologic distress for both survivors and siblings included female sex, low household income, lower educational attainment, being unmarried, having no employment in the past 12 months, and poor physical health status. There were no diagnostic- or treatment-related variables that were associated with an increase in distress symptoms for this group of childhood brain tumor survivors.

Providing Follow-Up Care for Childhood Cancer Survivors

Essential Elements of Follow-Up Care

General agreement exists that survivors of childhood cancer require ongoing lifelong follow-up to provide early intervention for, or prevention of, potential late effects of treatment.^{130–134} The Children’s Oncology Group (COG) has developed systematic evidence-based, exposure-related guidelines for ongoing follow-up of pediatric cancer survivors. These guidelines allow the clinician to determine a specific follow-up plan for each survivor, tailored to risk of late effects based on therapeutic exposures. A comprehensive treatment summary (Table 102.5) is also an essential tool for providing

TABLE 102.5. Components of a comprehensive treatment summary.

<i>Essential elements</i>	<i>Details</i>
Demographics	Treating institution, treatment team
Diagnosis	Date, site(s), stage
Relapse(s)	Date(s)
Subsequent malignant neoplasms	Date(s), types
Protocol(s)	Title(s)/number(s), dates initiated and completed
Completion of therapy	Date
Chemotherapy	Names and administration routes for all agents Cumulative doses (per m ²) for alkylators, anthracyclines, and bleomycin Determination of intermediate/high (≥1,000 mg/m ²) dose vs. standard dose for cytarabine and methotrexate
Radiation	Dates, type, fields, total dose, number of fractions/dose per fraction
Surgical procedures	Type(s), date(s)
Hematopoietic cell transplant	Type(s), date(s), GVHD prophylaxis/treatment
Major medical events	Events with potential for residual/late effects
Adverse drug reactions/allergies	Name of drug, type of reaction

GVHD, graft-versus-host disease.

comprehensive survivorship care. The Children's Oncology Group Long-Term Follow-Up Guidelines, accompanying health education materials (known as "Health Links"), and a model comprehensive treatment summary form are available to clinicians free of charge on the Children's Oncology Group website at www.survivorshipguidelines.org.

Models of Clinical Care Delivery

In 1997, the American Academy of Pediatrics mandated that children with cancer should be treated in specialized centers for pediatric oncology care¹³⁵; between 1989 and 1991, 94% of children diagnosed with cancer under the age of 15 in the United States were seen at an institution that was affiliated with the cooperative pediatric oncology clinical trials groups.¹³⁶ Specialized pediatric oncology centers that are members of the Children's Oncology Group are required to provide long-term follow-up services for survivors of pediatric cancer¹³⁷; this can be accomplished in a variety of ways.^{11,134,138-142}

SPECIALIZED LONG-TERM FOLLOW-UP CLINICS

In some pediatric oncology centers, the original treatment team, or a designated multidisciplinary long-term follow-up team at the treatment center, continue to provide life long follow-up to the childhood cancer survivor. Generally, the ongoing follow-up is limited to an annual comprehensive multidisciplinary health evaluation, and the survivor is encouraged to establish an ongoing relationship with a primary healthcare provider in their local community for routine healthcare needs. The long term follow-up care is often directed by a nurse practitioner specializing in healthcare for childhood cancer survivors. Benefits of this approach are that the patient remains in contact with a team that is knowledgeable and committed to long-term follow-up care, contact with the original treatment center is maintained, opportunities for research are optimized, and multidisciplinary referrals are usually available within the healthcare system (although referrals for patients who are beyond the pediatric age range may be limited in pediatric centers). Disadvantages of this approach include the unfamiliarity of the pediatric treatment team with the healthcare issues that arise as the survivor ages, reluctance of the older patient to return to a pediatric facility (especially if pediatric patients are present in the clinic/waiting room at the time of the long-term follow-up clinic), problems with reimbursement for specialized services not covered by insurance companies, and, often, problems of access due to long distances between the medical center and the survivor's residence. An example of successful implementation of this model is the Survivorship Clinic at the City of Hope National Medical Center in Duarte, California. As an NIH-designated Comprehensive Cancer Center, City of Hope provides specialized cancer-related care to patients throughout the lifespan, allowing ongoing long-term follow-up of patients with pediatric malignancies as they enter and progress through adulthood.

TRANSITION MODELS

Pediatric oncology centers, often as a result of institutional policies with an upper age limit for care, may require transition of young adult survivors to adult care providers. In some

instances, institutions have established formalized transition programs with specialized long-term follow-up programs for adult survivors of childhood cancer [e.g., Children's Medical Center of Dallas transitions its survivors to the ACE (After the Cancer Experience) Program for Young Adult Survivors at the University of Texas Southwestern, and Children's Memorial Hospital in Chicago transitions its survivors to the STAR (Survivors Taking Action and Responsibility) Program for Young Adult Survivors at Northwestern University]. Transition programs often use collaborative practice models, drawing on expertise from both oncology and primary care providers, and maintain many of the benefits of the specialized long-term follow-up clinics, with the added benefit of care providers with expertise in adult medicine. Affiliation of these programs with academic institutions usually provides access to multidisciplinary referrals; however, because the setting is academic and the focus is on survivorship care, ongoing primary care is often not accessible through these specialized programs, and distance to the center may remain problematic for some survivors.

ADULT ONCOLOGY DIRECTED CARE

In this model, when the survivor reaches adulthood, the pediatric provider makes a referral to an adult oncologist for ongoing follow-up. Advantages of this system include ongoing monitoring for disease recurrence in a system designed for adult medical care, and accessibility to care in the local community. Disadvantages include the unfamiliarity of most adult oncologists with the long-term follow-up evaluations indicated for childhood cancer survivors, and the likelihood of early discharge from specialty care once there is minimal risk of disease recurrence. However, with appropriate education and collaboration, this model has been used successfully to provide ongoing long-term follow-up care for childhood cancer survivors. An example of this model is the cooperative agreement between the Children's Hospital of Philadelphia and the oncology service of the University of Pennsylvania Medical Center.

COMMUNITY-BASED CARE

In this model, follow-up care is provided by an adult primary care provider (e.g., internist, family practitioner), who ideally is in ongoing communication with the original pediatric oncology treatment team or long-term follow-up center. Advantages of this system include seamless care for the patient, who can see their local primary care provider for most healthcare services and develop an ongoing relationship with a provider who is familiar with their specialized healthcare needs. Disadvantages include the primary care provider's lack of familiarity with the potential late effects for which the survivor is at risk, the considerable effort required for the primary care provider to determine appropriate follow-up care for the survivor, the survivor's potential lack of access to multidisciplinary specialty care providers, and the potential loss of contact with the survivor. The community-based system of care has been used successfully by St. Jude Children's Research Hospital (Memphis, TN) to provide care for survivors who are more than 10 years posttreatment. In this setting, potential disadvantages of this system have been addressed by providing a dedicated staff at St. Jude to track

the status of these survivors and to provide ongoing consultation with community healthcare providers as required.

Medical and Psychosocial Issues in Hodgkin's Disease Survivors

Jon Håvard Loge and Stein Kaasa

The first attempts to treat Hodgkin's disease by radiotherapy were conducted at the beginning of the last century. The prognosis for survival was poor but slowly improved by the use of radiotherapy and some chemotherapy until 1960. For example, in 1939 a 20-year survival rate of 17% was reported.¹

During the 1960s the prognosis for survival vastly improved, which was mainly related to the introduction of improved staging systems, better understanding of the spread and course of the disease, improved diagnostic methods, and refined therapy. The latter included improved radiotherapy and the introduction of chemotherapeutic regimens such as the MOPP (mechlorethamine, vincristine, procarbazine, prednisone) in 1967.² The therapeutic pessimism turned into optimism, and the clinicians dared to speak of a cure. Cure was defined as follows: "We can speak of a cure when in time, probably a decade or so after treatment, there remains a group of disease-free survivors whose progressive *death rate* from all causes is similar to that of a normal population of the same sex and age constitution"^{3,4} (see Chapter 67).

This chapter is about the price of cure in terms of medical late effects and psychosocial issues related to survivorship. To speak of a price of cure first became relevant when death no longer was the predominant outcome. The improved prognosis for survival achieved during the 1960s created an increasing number of survivors, and studies of possible late effects thereby became possible. For the clinician, a patient consulting for late effects, medical or psychosocial, probably has now become a more commonly encountered clinical problem than a patient presenting with Hodgkin's disease itself.

Late effects can mainly be divided into three categories. First, there are the late medical effects, which include secondary cancers or ill effects on one or more organ systems. Second, there are the late effects in subjective health, which include symptoms such as fatigue or pain as well as psychological phenomena such as anxiety and depression. Third, there are the late effects encountered as difficulties in returning to normal life such as resuming work or difficulties in partnership or in participation in leisure activities. The definition of a late effect is not commonly agreed upon, but it is reason-

able to separate late effects from acute effects by both duration and time of debut. Some late effects such as fatigue might be traced back to the period of active disease. Other late effects such as secondary cancers might present after a shorter or longer period without symptoms or signs of disease.

Challenges in Clinics and Research

The late effects represent several challenges for the researcher as well as for the clinician. In the investigation of late effects the researcher is challenged by the complexity of the late effects, but also by the effects of aging, environment, lifestyle, behavior, etc. upon health. Consequently, it may be difficult to find causal factors related to the outcomes observed. For the clinicians (as well as for the researcher) the challenge is to understand what the needs of the survivors are. An increased understanding of long-term effects of somatic, psychologic, and social nature will, it is hoped, help healthcare providers to better deliver follow-up programs and patients and family members to better understand their needs.

The low incidence of Hodgkin's disease generates relatively few survivors and consequently a relative scarcity of data. The social mobility in many Western countries is high, and many survivors are lost to follow-up or are even impossible to locate several years after treatment. Furthermore, the treatment regimens are under constant revision, and late effects caused by one regimen may not necessarily be caused by another type of treatment. Some late effects are relevant only for subgroups of survivors such as breast cancer affecting females irradiated by fields including their breast during their reproductive years. Such factors further add to the scarcity of data. Additionally, some late effects such as secondary cancers first become manifest several years after termination of treatment. A long latency period between active disease and debut of late effects might also generate findings, which are not necessarily related to Hodgkin's disease or its treatment. For example, is symptomatic coronary heart disease 30 years after termination of treatment to be looked upon as a late effect, as related to nutrition, smoking habits,

and physical exercise, after termination of treatment, or as a combination of all these factors? To answer such a question the researcher needs large samples (i.e., statistical power), advanced medical technology, and skilled experienced clinicians to evaluate the patients, and from a design point of view controlled groups are needed. The distinction between late effects and morbidity related to increasing age becomes increasingly blurred as the observation time increases. At present there is a scarcity of prospectively collected data, which limits the possibility of drawing valid conclusions about causality. Ideally, one should therefore have comparative data to identify the late effects of Hodgkin's disease. Lack of a comparison group is of particular concern regarding subjective outcomes such as fatigue, which is frequently found in a general population, and may be caused by a series of factors during a lifetime observation.⁵ The optimal study design is a prospective follow-up of the survivors from the time of diagnoses through the treatment and into the follow-up phase for many years. In such nonrandomized designs, valid control groups are needed, which should be age- and gender matched and generated by random draws from the general population. In cross-sectional designs, subjective health outcomes from the general population may serve as valid comparisons and will definitely strengthen the conclusions, while the validity of "ad hoc-generated comparisons groups" should be questioned. Volunteer bias is an example that may represent a serious threat to the internal validity of studies with ad hoc generated comparison groups such as relatives or hospital visitors.

The constitution of a survivor population might also be biased. For example, the patients treated at the Norwegian Radium Hospital (NRH) were assumed to be representative of the Norwegian population of Hodgkin's disease survivors. After survival of the NRH cohorts was investigated, it was concluded that patients with a better prognosis for survival were found in this sample, as compared with the national sample.⁶

The choice of outcome measures may also represent a challenge. For example, the current most commonly used measures for late effects such as psychologic distress and fatigue have limitations with regard to content, reliability, and validity. Another major limitation is the lack of standardization of outcome measures. Different outcome measures have been used to measure the same phenomenon such as fatigue and pain. On the other hand, prospective studies might *lock* the data collection to measurement techniques that become obsolete during the observation period.

Given an accumulating prevalence of late effects, content and organization of the follow-ups should be discussed and ideally investigated in research and in quality assurance programs, and an increasing emphasis on economic effects on the healthcare system should be questioned. Furthermore, it should be questioned: What part of the healthcare system is best suited for conducting surveillance, what is a reasonable price for a surveillance program, and should the optimal program be individualized? Finally, how are medical students and future oncologists/radiotherapists best trained to detect and treat late effects? In sum, these challenges also raise ethical dilemmas related to what to tell the patients about late effects and the possibility of creating lifelong patients under continuous observation for possible late effects that might never even occur.

Epidemiology

Incidence of Hodgkin's Disease

The incidence of Hodgkin's disease (HD) varies across countries but is at a comparable level (approximately 2 to 3 per 100,000) in the Western countries.⁷ Generally, more males than females are affected (M/F ratio, approximately 60:40). Incidence in the Western world was stable until 1980, slowly decreased during the period 1980-1990, and thereafter it has slightly increased.⁸ The decreased incidence was mostly due to a decreasing number of patients above 60 years of age with non-Hodgkin's lymphomas earlier being misclassified as Hodgkin's disease.^{6,8,9} More than 50% of the patients are 39 years of age or younger at time of diagnosis.⁷

Prevalence of Survivorship

A disease mainly affecting young adults combined with a good prognosis for survival (best among the younger patients) generates a population of survivors with a long life expectancy. In general, the 5-year survival for all patients with Hodgkin's disease exceeds 80%, and for patients 39 years of age or younger, more than 90% are expected to live for 5 years or more.^{10,11} Consequently, the prevalence of survivorship has steadily increased over the past three to four decades. The long life expectancy of the survivors permits long-term follow-up studies but also makes control for expected diseases necessary. As indicated earlier, it is therefore urgent to design prospective and large enough follow-up studies of Hodgkin's disease survivors. Without conducting such studies our follow-up programs may not only be burdensome to the healthcare system, but many patients may be offered invalid follow-up.

The latest Norwegian data illustrate this point clearly. Although the yearly incidence of Hodgkin's disease has been around 80 new cases per year (2/100,000) during the past two decades, the number of Norwegians alive and having had Hodgkin's disease has been steadily increasing and now exceeds 1,500.¹² In 1990 the prevalence of survivorship was 1,100 in a population of about 4.5 million.¹³

Advanced disease and B symptoms in addition to age predict incomplete remission, relapse, and shortened survival after first-line treatment.^{14,15} Age is at present the single most important predictor for survival. Advanced disease and relapse both increase the treatment burden. Some survivors have therefore received intensive treatment (chemotherapy and radiotherapy) in several cycles eventually supplemented with high-dose chemotherapy and bone marrow transplantation. In general, the most recent improvement in survival is therefore a consequence of more-intensive treatment. Potentially the more-intensive treatment may affect the prevalence of long-term medical and/or psychosocial effects. Subgroups of survivors might therefore be of special interest for future assessments of late effects. However, such groups must be considered relatively small, which affects whether proper follow-up studies can be performed, unless such studies are conducted as multicenter studies with a sufficient number of patients.

Medical Issues

About the Treatment

Treatment with radiotherapy has during the past decades been partly replaced and/or combined with chemotherapy. Radiotherapy as a single modality is today given only to a subgroup of patients with limited disease.

In the 1960s, fractionated large fields were irradiated with the consequence of a substantially increased survival rate. Continuous research on radiotherapy techniques has resulted in more individualized treatment, and today more often smaller fields are delivered as compared to the standard mantle fields used at the start of the radiotherapy era. To reduce radiotherapy-related acute and late toxicity, the total dose in many programs has been reduced from a standard total dose of 40 Gy treated in 3 Gy per fraction to a dose of 30 to 35 Gy with reduced single fraction to a proximately 1.75 Gy. Critical organs are sometimes included in the fields, such as lung, heart, thyroid, major blood vessel, and bone marrow, which may give long-term side effects.

Combination chemotherapy was introduced into the treatment plans of Hodgkin's disease in the mid-1960s with the so-called MOPP regimens (mechlorethamine, vincristine, procarbazine, prednisone) as the gold standard in most countries.² Other combinations of chemotherapy have been in use as well as various ways of escalating doses to improve survival and reduce acute toxicity and long-term morbidity.

Both treatment modalities, that is, radiotherapy and chemotherapy or combinations, can potentially give the patients medical (somatic) long-term side effects. Furthermore, the cancer itself may also have and will alter the biology of the host (i.e., the patient). So, consequently, either of these factors, separately or in combination, may result in late morbidity for HD survivors.

Long-Term Morbidity: General Considerations

The most frequent causes of death other than Hodgkin's disease itself are cardiac disease and secondary malignancy, while infertility, thyroid abnormalities, and pulmonary disease may cause serious late effects of various prevalences in Hodgkin's disease survivors.¹⁶ The most commonly encountered late medical effects are presented in Table 103.1. In a recent review it was concluded that secondary malignancies and ischemic heart disease are the two most frequent causes of death.¹⁷ However, it must be kept in mind that, in patients with good prognoses, the actual overall survival at 20 years is about 93%,¹¹ and that treatment-related mortality exceeds the mortality from Hodgkin's disease 12 to 15 years after the primary treatment.¹⁸

TABLE 103.1. Main medical late effects of Hodgkin's lymphoma and its treatment.

- Secondary cancers
- Cardiac disease
- Endocrine dysfunction
 - Hypothyroidism
 - Hypogonadism
- Lung damage
- Dental caries

Cardiac Late Effects

An increased incidence of coronary heart disease, specifically in patients less than 40 years of age, has been attributed to radiotherapy. The expected number of cardiovascular deaths in age- and sex-matched population was similar to the cardiovascular deaths in Hodgkin's disease populations.¹⁹ The history of myocardial infarction was no more frequent after mantle field irradiation than in HD patients who received chemotherapy,²⁰ whereas others have reported an increased risk of myocardial infarction after mediastinal irradiation.^{21,22} Up to a threefold increase in the relative risk of cardiac deaths has been reported.²³ In another retrospective review, coronary artery disease occurred in patients who were treated at the ages of 16, 21, 35, and 48 years with latency periods of 19, 12, 7, and 3 years, respectively.²⁴

The technology used to evaluate morbidity, such as valvular dysfunction, may have major impact on the findings. Before Doppler technology was used, valvular dysfunction was considered a rare finding in survivors of Hodgkin's disease. By using Doppler echo cardiography, aortic and/or mitral valvular regurgitation and valve thickness have been observed at rates of 24% to 40% of patients treated successfully for Hodgkin's disease.²⁵⁻²⁷ The clinical implications of these findings are at present unknown.

Endocrine Dysfunction

The prevalence of hypothyroidism varies substantially between studies. As for most of the other medical side effects as well as for the subjective ones, sample selection, definition of cases, etc. have a major influence on the results. The rate of hypothyroidism seems to be influenced by observation time, irradiation (field and amount), and the definition of hypothyroidism.²⁸⁻³⁰ In a sample from Norway where 221 patients were observed, 55% developed biochemical hypothyroidism 3 to 23 years after treatment.²⁰

In the Stanford study the actual risk of thyroid disease was 52% after 20 years and rose to 67% after a follow-up of 26 years.¹⁶ In this study, younger patients, women, combined-modality treatment, and time since radiation were associated with a high incidence of thyroid disease, whereas other studies from Europe have not confirmed these findings.^{20,31}

Although thyroid abnormality is prevalent in HD survivors, the early use of thyroid supplementation in patients with elevated thyroid-stimulating hormone (TSH) level has greatly reduced the risk of overt clinical hypothyroidism when compared with earlier studies.³² However, no consensus seems to have been reached with regard to when and on which indications to start hormonal substitution in patients with biochemical hypothyroidism.

Lung Damage

Dyspnea is a subjective phenomenon experienced by the patients as shortness of breath. Consequently it is recommended that dyspnea as well as other subjective symptoms should be assessed by the patients themselves by means of questionnaires or other subjective measures. Dyspnea is frequently reported in HD survivors in approximately 30% of the cases.²⁰ In the Norwegian study, dyspnea was not associated with sex, age, or chemotherapy.²⁰ Pulmonary complica-

tions after radiotherapy are first observed clinically as an acute radiation pneumonitis, followed by radiation fibrosis, which evolves over time and seems to reach a stable appearance after 9 to 12 months.³³ Pulmonary toxicity secondary to chemotherapy is rare; however, bleomycin may enhance pulmonary dysfunction when given in conjunction with radiotherapy.³⁴

In one study consisting of a selected cohort of 116 patients treated with mediastinal radiotherapy alone or in combination with chemotherapy, 30% of the patients had pulmonary dysfunction and associated reductions in total lung capacity, forced vital capacity, forced expiratory volume in 1 second, and gas transfer impairment.³⁵ The size of the radiation fields has been found to be related to the extent of fibrosis, and the most dramatic changes were observed in patients treated simultaneously with bleomycin and anthracyclines.³⁵ In single cases major interindividual variations have been found with respect to the sensitivity of the lung parenchyma to develop radiation fibrosis.

In conclusion, a consistent finding is that the severity of the fibrosis is related to the volume of irradiation, the presence of parenchymal involvement in the disease itself, and the use of bleomycin and anthracyclines.

Comments

Most studies assessing medical morbidity in HD survivors have either a retrospective design and/or a cross-sectional design. The studies are performed ad hoc, with few upfront hypotheses stated, and how to define the level of morbidity and which indicators to use to define morbidity varies considerably. Scientific discussions of possible confounding factors are rarely presented, and few studies have comparison groups. Based on the findings in one of the studies including a comparison group, it has been, for example, suggested that the incidence of cardiac death is not any higher than in the matched population.¹⁹ However, details on how these comparisons were performed were not given. A similar criticism can be raised for treatment of symptoms and biochemical findings of hypothyroidism. Most studies have an ad hoc retrospective design, and consequently it is difficult to draw valid conclusions with regard to treatment proposals.

Psychosocial Issues

Historical Perspective and General Points

The first descriptions of the psychosocial aspects of cancer survivorship were conflicting. Case observations led to the postulation of a Damocles syndrome in which the survivors lived their lives under the constant threat of a relapse.³⁶ The syndrome was characterized as a specific psychologic state with tension, emptiness, and lack of pleasure and direction of life. The other position, in general held by epidemiologists, stated that the cancer survivors lived well-adjusted lives and were as satisfied with their lives as the general population.³⁷ It is now obvious that the two concepts were equally wrong and that both positions were based on methodologic shortcomings. The epidemiologists based their statements on too-

general outcome measures and the psychologists based their postulation of a specific syndrome upon case observations without sufficient perspective on the generalizability of their observations.

From a psychiatric point of view, one can hypothesize that the psychologic burden of survivorship per se would be more of a posttraumatic stress disorder than depression. Being cured is difficult to characterize as a loss with subsequent potential for development of depression. However, reduced health status after cure, either objectively or subjectively, might represent a loss and thereby a potential for development of depression. Premorbid characteristics as well as social and psychologic support during and after the disease will always interact with the stressor (i.e., the disease and the treatment). No published studies have investigated these variables systematically.

Most published studies of psychosocial aspects of cancer survivorship have been descriptive and lacking a specific hypothesis. The study by Cella and Tross from 1986 is one exception, and three possible psychologic sequelae were proposed (anticipatory, residual, and current) and explored with generally negative findings.³⁸ Facing death and receiving burdensome treatment during a period of life when friends fulfill education and establish themselves in jobs and families may be regarded as a longlasting trauma, and the model of a posttraumatic stress disorder may apply for this population. Such a specific model for development of late psychosocial effects has not been tested, except for the study by Cella and Tross.³⁸ Generally, the studies of psychologic late effects have used self-report measures of psychologic distress as outcomes, and none has looked for specific psychiatric diagnoses. There have been several methodologic limitations, among which selection bias is probably the most serious and difficult to handle. It is reasonable to assume that late effects might increase the response rates, and this is of particular concern in cross-sectional studies relying on one single data collection. Still, it is reasonable to conclude that psychosocial late effects in survivors of Hodgkin's disease are the exception rather than the rule.

Quality of Life

Quality of life (QOL) reflects the definition of health as proposed by the World Health Organization in 1947 with emphasis on the subjective aspect of health and not only the absence of disease.³⁹ During the 1980s and 1990s, the concept of QOL became more directed toward health by the introduction of the term Health-Related Quality of Life. The latter operationalizes health as encompassing a social, a physical, and a mental dimension. It should be regarded as a narrowing of the concept QOL, and some therefore prefer the term subjective health. The distinction is not only of academic interest. Figure 103.1 demonstrates the responses from survivors of Hodgkin's disease and normal controls to a single question about satisfaction with life, which is close to the more global concept of QOL. More of the survivors reported being very satisfied with their lives than the normal controls, in spite of more health problems among the survivors. This is in line with findings reported by Cella and Tross.³⁸ In spite of the possible existential dimension of this finding, overall QOL does not seem to capture the health-related aspects of the survivors' quality of life (i.e., their subjective health status).

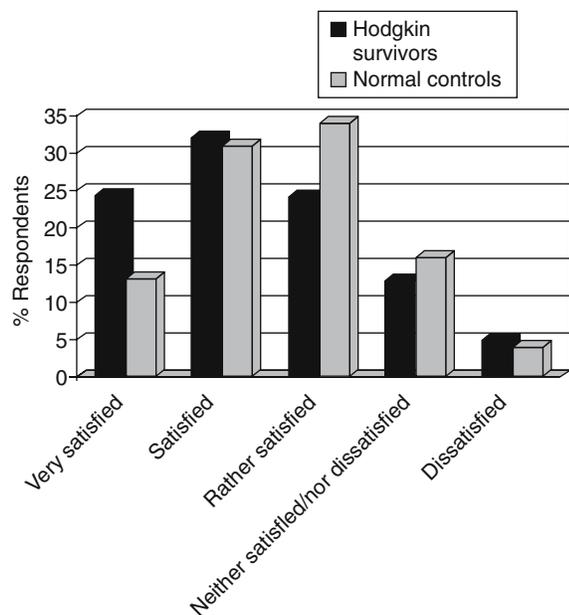

FIGURE 103.1. Satisfaction with life in Norwegian survivors of Hodgkin's disease ($n = 453$) and in normal control subjects ($n = 2323$). (Unpublished data from the authors.)

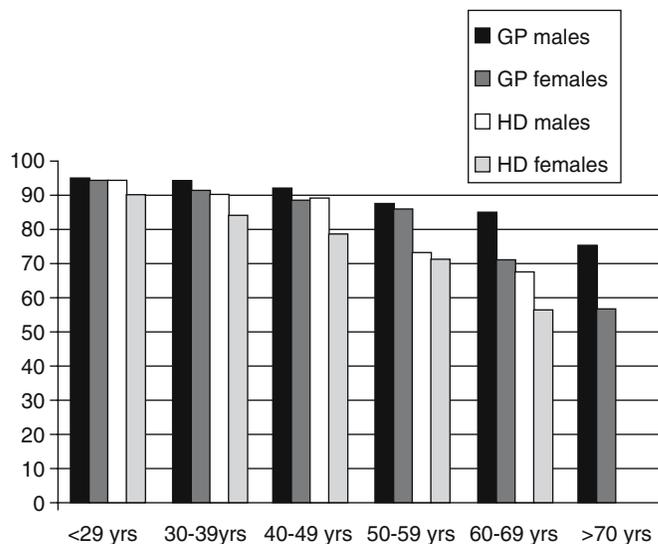

FIGURE 103.2. Physical functioning as measured by the Physical Functioning Scale of the SF-36 in the general Norwegian population (GP) (Norwegian norm data; $n = 2263$) and survivors of Hodgkin's disease (HD; $n = 459$). (Data from references 48, 49.)

Subjective Health Status: Early Findings

The first studies of subjective health status in survivors of Hodgkin's disease were published in 1986.^{38,40} As demonstrated in Table 103.2, the first studies included quite different sample sizes, and the findings were inconsistent, partly reflecting different measures of subjective health. Only two studies included comparison groups. In these studies, selected cohorts of U.S. patients from controlled clinical trials were included. A minority of all U.S. cancer patients are included in clinical trials, and the generalizability of the findings can therefore be questioned.

Subjective Health Status: Physical Health

Physical health is about physical symptoms such as pain, dyspnea, and nausea in addition to physical functioning, which generally includes different physical activities commonly performed during a day. Present subjective health status measures such as the SF-36, the European Organization for Research and Treatment of Cancer Core Quality of Life Questionnaire (EORTC QLQ C-30), and the Functional Assessment of Cancer Therapy-General (FACT-G) all put a great emphasis on physical functioning, which generally is affected by somatic health events and has low correlation with mental health.⁴⁵⁻⁴⁷ In the SF-36, 10 of 36 items are about

physical functioning.⁴⁷ However, the content of physical functioning scales varies among the instruments, and this hinders comparisons across the instruments. Physical functioning in the general population is related to age and gender (Figure 103.2).^{48,49} The decline by age reflects increasing morbidity with increasing age and needs to be controlled for in studies of cancer survivors.⁴⁸

The first studies of Hodgkin's disease survivors indicated problems with the survivors' physical health, but standardized measures were not applied.^{41,50,51} Three studies from the 1990s included both standardized measures of physical functioning (the EORTC QLQ C-30 and the SF-36) and comparison groups.^{42,44,49} The findings were surprisingly similar in that physical functioning was reduced by approximately 0.5 SD compared to the control groups.^{42,44,49} None of the studies demonstrated any robust associations between disease characteristics, treatment, and reduced physical functioning. Some later studies have failed to replicate this finding, but the design of these studies limits the possibility of drawing firm conclusions.^{52,53}

Clinicians report stiffness and pain from the musculoskeletal system as common among the survivors.²⁰ However, compared with healthy controls, no differences in pain level between survivors and controls have been detected.^{42,44,49} Another somatic symptom, dyspnea, is included in the cancer-specific instrument EORTC QLQ C30 but not in the generic instrument SF-36. Joly et al. compared

TABLE 103.2. Early studies of health-related quality of life among survivors of Hodgkin's disease.

Study	Year	Country	N	Origin of sample	Mean observation period (years)	Effect stage/treatment	Comparison group
Cella ³⁸	1986	USA	60	Hospital	Unknown	Yes	Yes
Fobair ⁴⁰	1986	USA	403	Clinical trials	9	Yes	No
Kornblith ⁴¹	1992	USA	273	Advanced disease/clinical trials	6	No	No
van Tulder ⁴²	1994	Netherlands	81	Hospital	14	No	Yes

Joly ⁴⁴	1996	France	93	Region	10	No	Yes

French survivors with randomly selected and matched controls and found nearly three times higher levels of dyspnea in the survivors than in the controls.⁴⁴ A Spanish study from 2003 also found higher levels of dyspnea in the survivors than in healthy controls.⁵⁴ Given the difficulties patient have in distinguishing dyspnea from fatigue and the association between fatigue and gas transfer impairment, a further elaboration on this point seems warranted.⁵⁵

The French study by Joly et al. found very low levels of nausea and vomiting as measured by the EORTC QLQ C30 and no difference between the survivors and the age- and gender-matched healthy controls.⁴⁴ Cameron et al. also reported low levels of nausea and vomiting but pointed to the possibility of classical conditioning as the mechanism underlying persisting symptoms such as distress in the survivors.⁵⁶ By exploring and confirming a specific mechanism, this study yielded knowledge that is directly applicable in the prevention and/or treatment of persisting symptoms by use of psychologic techniques.

There are some main limitations to our present knowledge on the physical health of the survivors. On a group level their physical health is lowered, and the reduction is of clinical significance.⁵⁷ Still, the majority enjoys a physical health similar to the general population of same age. The survivors with reduced physical health have not been clearly identified, and how the survivors' physical health is affected by time since termination of primary treatment is not documented. The mechanisms underlying the survivors' reduced physical health are unknown, and this lack hinders efforts to prevent and treat. The reduced physical health might reflect the total sum of negative health events such as gas transfer impairment, muscular waste, and hypothyrosis. Another explanation might be an association between reduced physical health and other subjective late effects such as fatigue.⁵⁸ However, none of the published studies on physical health has controlled for the level of fatigue.

Subjective Health Status: Fatigue

The first report on fatigue among Hodgkin's disease survivors was published by Fobair et al. in 1986, and fatigue was a major

problem as 37% had not regained their energy.⁴⁰ Patients with self-reported energy loss were more likely to be depressed.⁴⁰ Another early study demonstrated that Hodgkin's disease survivors were more fatigued than survivors of testicular cancer.⁵¹ A British study of lymphoma patients off treatment described mental and physical fatigue as major concerns.^{59,60} However, in all the earliest studies published before 1997 fatigue was measured by single questions (i.e., not validated and reliability tested questionnaires), and such single questions have disputable validity and reliability.⁶¹ Further, none of the early studies took into account the high prevalence of fatigue in the general population (11%–45%).^{61,62} The main studies on fatigue in the survivors are presented in Table 103.3.

Newer studies employing standardized measures and comparison groups have confirmed that fatigue is a major problem among the survivors compared to healthy subjects and more of a problem among survivors of Hodgkin's disease than among survivors of other cancer types.^{63–68} The prevalence of fatigue is clearly related to the measurement technique, and the exact magnitude of this problem is therefore not known.⁶¹

Attempts to relate persisting fatigue to disease and treatment characteristics have yielded conflicting results. The close connection between disease burden and type of treatment also hinders analyses of separate effects of the two. However, a recent prospective study demonstrated that combined treatment yielded higher levels of fatigue only during the first year as compared to radiation therapy.⁶³ Thereafter, the two groups reported similar levels of fatigue, which was significantly higher than in the general population (Figure 103.3).⁶³

A cross-sectional study reported an association between late pulmonary sequelae (in particular, gas transfer impairment) and fatigue.⁵⁵ A significant association between psychologic distress and fatigue has been demonstrated.^{40,69} However, a review strongly supported a differentiated view on fatigue and depression in cancer patients.⁷⁰ Some authors have proposed a common mechanism underlying the symptoms of cancer and cancer treatment, namely, cytokines, which induce sickness behavior in animal models including

TABLE 103.3. Fatigue in survivors of Hodgkin's disease: main studies.

Author	Year	Sample (N)	Main finding	Comparison group (N)	Type of measurement
Fobair ⁴⁰	1986	403	37% tired	—	Single item
Devlen ^{59,60}	1987	90/120 ^a	30%/42% tired	—	Single item
Bloom ⁵¹	1993	85	22% energy not returned	Testicular survivors	Single item
van Tulder ⁴²	1994	81	No significant difference	Healthy controls	SF-36

^aTwo studies, retrospective and prospective including Hodgkin's disease and non-Hodgkin lymphomas.

^bIdentical sample of Hodgkin's disease survivors.

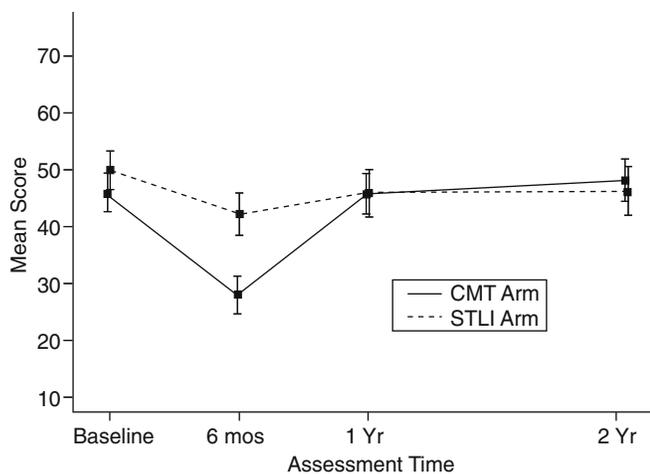

FIGURE 103.3. Average SF-36 Vitality Scale scores (mean with 95% CI) by assessment time and treatment arm. Lower scores reflect greater fatigue. *STLI*, subtotal lymphoid irradiation; *CMT*, combined-modality therapy. For healthy men aged 35 to 44 years, the mean Vitality Scale score is 65.5. For women aged 35 to 44 years, it is 59.4. (From Ganz et al.,⁶³ by permission of *Journal of Clinical Oncology*.)

fatigued behavior.⁷¹ However, attempts to correlate some of the relevant cytokines to fatigue have failed.⁷²

Except for the study by Ganz, all studies on fatigue in Hodgkin's disease survivors were cross-sectional, which limits the possibility of inferences about causality. No prospective longitudinal studies to investigate the course of fatigue among Hodgkin's disease survivors have been published. This lack of knowledge limits the clinician's ability to give valid and reliable information to individual patients on the expected course of their fatigue.

At present we can therefore only hypothesize about the mechanisms underlying fatigue in the survivors. In some, as in the general population, fatigue is probably part of being psychologically distressed.⁷³ However, as compared to sufferers of the chronic fatigue syndrome, the survivors have significantly lower levels of psychologic distress as measured by the Hospital Anxiety and Depression Scale.^{69,73} Second, fatigue might reflect the combined burden of the late complications after having had Hodgkin's disease. Fatigue is by many considered a final common endpoint that is associated with most diseases; this indicates that fatigue is an "unclean" endpoint affected by most altered health states. Third, fatigue might be a specific late effect after Hodgkin's disease and related to some specific mechanisms characteristic of this disease; this might include the cytokines, which is supported by the altered immunity found in many of the survivors. At present, none of these seems more strongly supported than the others, and given the complexity of fatigue all might be correct in subgroups of fatigued survivors.

Subjective Health Status: Mental Health

Some of the earliest studies indicated rather great psychologic problems among the survivors. For example, Kornblith et al. reported in 1992 psychologic distress one SD above that of healthy subjects, and 22% met the criterion suggested for a psychiatric diagnosis.⁴¹ Later studies from the 1990s did not confirm this finding. Three studies used health-related

quality of life (HRQOL) measures and different comparison groups, and none reported any deviations in mental health (SF-36) or emotional functioning (EORTC QLQ C-30) between the survivors and the controls.^{42,44,49} The first comparative study between Hodgkin's disease survivors and testicular cancer survivors did not find any significant difference in psychologic outcomes between the two groups of survivors.⁵¹

One study from the last part of the 1990s identified as many as 27% of the survivors as probable anxiety and depression cases, but no comparison group was included.⁷⁴ Previous psychiatric problems, psychiatric problems during the treatment phase, and low education were identified as risk factors. The most intensive treatment regimen was associated with increased risk for probable anxiety.⁷⁴ This study employed the Hospital Anxiety and Depression Scale (the HADS), which generally tends to produce high levels of anxiety and higher prevalences of anxiety cases than depression cases.⁷⁵ This finding was confirmed by the most recent study, which found no differences in the level of depression between Hodgkin's disease survivors, testicular cancer survivors, and the general Norwegian population.⁶⁸ The levels of anxiety in both groups of survivors (4.7 in testicular cancer survivors and 4.6 in Hodgkin's disease survivors) were slightly elevated as compared to the general population (3.9).⁶⁸ In sum, these studies indicate that the level of depressive symptoms is not elevated in the survivors, that anxiety symptoms are just slightly elevated, and that we do not know whether these symptoms are part of a specific psychiatric condition.

Some other psychologic symptoms have been assessed and reported as more prevalent than expected. Cella et al. in 1986 reported no elevated level of psychologic distress, but indication of psychosocial dysfunction in areas such as intimacy motivation, increased avoidant thinking about disease, and illness-related concerns.³⁸ These findings may be of clinical relevance, for example, as effectors on partnership and illness behavior but have to our knowledge not been addressed in later studies.

Social Functioning

Three aspects of social functioning have received special attention in the literature: divorce rate, difficulties in returning to ordinary work, and difficulties in getting health insurance/borrowing from banks. Additional aspects of social life such as participation in leisure activities, sexual activity, sexual interest, and reproduction have also been included in some studies.

In general it is reasonable to state that the social consequences of survivorship from cancer are influenced by social mechanisms that may vary considerably across culturally relatively comparable nations, as is in accordance with the handicap model as proposed by the WHO.⁷⁶ For example, in the Scandinavian countries health insurance is public and granted to every citizen. Life insurance is partly private and partly public, and in sum insurance is probably of lesser relevance in these countries than in the United States. An early U.S. study demonstrated difficulties in getting health insurance.⁴¹ The lack of a comparison group hinders estimation of the clinical significance of this possible late effect.

In general, the relationship between cancer, cancer treatment, late medical or late subjective health effects, and social consequences is complex and relatively poorly understood.

Type of treatment seems to be of lesser relevance, while subjective late effects was associated with poorer social functioning.^{63,77}

Difficulties returning to an ordinary job are also affected by country-specific variables in addition to the labor market in general. The earliest U.S. studies indicated various work-related problems such as getting a job or working at a former pace.^{38,40,41} The Norwegian data demonstrated that the majority of the survivors with a mean follow-up time of 12 years were in full-time work at follow-up.⁷⁷ However, about 20% were permanently disabled, compared with 10% of the general Norwegian population of similar age at the time of the follow-up study.⁷⁷ Predictors of disablement were increasing age, low education, combined-treatment modality, and high levels of anxiety, depression, and fatigue.⁷⁷ The French study by Joly et al. did not demonstrate lower proportions of survivors at work, but they had less ambitious professional plans.⁴⁴ The latter finding was replicated by the Norwegian study.⁷⁷

Divorce is generally a common event in most Western countries. The earliest studies found divorce rates up to 32% among the survivors.⁴⁰ Among the French survivors studied by Joly et al., the divorce rate was lower among the survivors than among the controls but length of the marriage was not controlled for.⁴⁴ Generally, several methodologic aspects hinder interpretation of whether the divorce rate deviates from the general population. The age of the survivors and controls at time of data collection, the different divorce rates across different age groups, and the effect of marriage duration upon divorce rate all add to the uncertainty of the published data on divorce rates. Additionally, one could also hypothesize different mechanisms for divorce between spouses being married during the treatment phase and between spouses who marry after termination of treatment. A couple living through the treatment of Hodgkin's disease faces serious and long-lasting stressors. Generally such strain may strengthen bonds in some couples but also represent tensions that subsequently end up in divorce in others. The modern tendency to involve the family including the children during the treatment phase may have positive effects for the family as a whole, but this has not been addressed in published studies until now. On the other hand, one may also speculate that such a practice increases the total burden on the family and particularly on the healthy spouse. No studies until now have addressed the burden of disease and treatment on the family, but one might speculate that the stress on the family is affected by the quality of care which the family receives during and after the treatment phase. For example, a recent study has demonstrated much less psychologic distress among the relatives of patients included in a palliative program as compared to the relatives of patients receiving standard care.⁷⁸

The prevalence of sexual problems among Hodgkin's disease survivors has been reported to be between 12% and 20%, whereas infertility among women and men has been reported to be less than 10% and less than 20%, respectively.^{40,41,44,64,77} In the Norwegian sample, the great majority of the men reporting infertility had received treatment known to reduce fertility (chemotherapy containing an alkylating agent and procarbazine). One single study reported difficulties in participation in leisure activities, and this was related to fatigue.³⁷

Treatment

Medical Late Effects

Treatment of late medical effects after curative treatment of Hodgkin's disease has, to our knowledge, not been systematically investigated. For patients with symptoms from heart, lung, and/or thyroid gland, general guidelines on how to treat or relieve symptoms have been followed. For patients with hypothyroidism, general international accepted treatment guidelines seem advisable to follow. Similar approaches have also been used by cardiologists and lung physicians. However, it is reasonable to assume that the pathophysiology for these conditions in many cases is different in Hodgkin's disease survivors than in other groups of patients. If these assumptions are correct, one may argue that at least patients need to be followed systematically and prospectively after treatment is initiated to evaluate both immediate and long-term effects of the intervention. Furthermore, one may also expect that the condition itself, for example, cardiac sequelae after radiotherapy, may have a different "natural cause" than what is expected in patients with the same condition, but with other causes. Additionally, one may also expect that in many patients with Hodgkin's disease a combination of factors may cause the condition itself.

For patients with no symptoms, but with pathologic blood markers, X-rays, or physiologic tests, no clear treatment guidelines are established to our knowledge. For these patients one may possibly overtreat some patients who are nonsymptomatic if the treatment itself does not prevent the development of the disease or undertreat patients if the treatment itself is effective to prevent the development of symptoms.

Taking all these uncertainties under consideration, we therefore argue that multicenter treatment studies are needed to establish sufficient knowledge so it may become possible to establish international guidelines, not only on the diagnostic level in this cohort of patients, but also on the treatment level.

Subjective Late Effects

Generally, specific treatment studies of subjective late effects have not been published and the clinician must therefore rely on general knowledge from other fields of medicine. An open pilot study on the effects of physical exercise upon fatigue in survivors supported the findings of a meta-analysis on the treatment of the chronic fatigue syndrome (CFS).^{79,80} The fatigue level was reduced by 50% after an intervention of 12 weeks duration.⁷⁹ CFS differs from chronic fatigue in the survivors on several variables, including level of psychologic distress,⁶⁹ but physical exercise has multiple effects including lowered anxiety, depression, and fatigue levels. The exact mechanism for this effect in the survivors and in other patient groups is not known. The other type of therapy with effect on CFS, cognitive behavioral therapy, has not been tested on survivors specifically. However, it is reasonable to assume that physical exercise also has cognitive effects, that is, the subjects gain other cognitions about their physical capacity during such a training period. Oldervoll et al. also demonstrated that aerobic exercise improved subjective physical functioning and aerobic capacity.⁷⁹

The high prevalence of hypothyroidism among the survivors and the tendency to substitute with thyroxin yield many survivors on thyroxin substitution therapy for long periods. It is reasonable to assume that fatigue is a central symptom when substitution is started. However, the clinical effect of such substitution is questionable, at least in terms of reduced fatigue-level. Knobel et al. demonstrated a significant higher level of fatigue among patients receiving thyroxin substitution than among unsubstituted patients with biochemical hypothyroidism.⁵⁵

Anecdotally, fatigued survivors are offered antidepressants. In sufferers of the CFS, antidepressants have no effect unless fatigue is part of a depressive disorder.⁸⁰ A recent study of the effects of an antidepressant upon fatigue and depression in cancer patients demonstrated that fatigue was not improved (i.e., serotonin was not the mediator of fatigue in cancer patients) while depressive symptoms improved.⁸¹ In sum, these findings indicate that fatigue in the survivors should not be treated with antidepressants unless fatigue is part of a depressive condition characterized by lowered mood and other depressive symptoms.

Treatment of psychologic symptoms should be based on a psychiatric diagnosis. Conditioned responses are best treated by unconditioning if the symptoms need to be treated. Whether to treat such symptoms depends on the subjects' wishes and the symptom burden. Conditioned responses only experienced at the sight of the hospital are probably less burdensome than responses triggered by food or beverages.⁵⁶ Anxiety may reflect quite different disorders: posttraumatic stress disorder (PTSD), panic disorder, or generalized anxiety disorder. Both pharmacologic and psychotherapeutic interventions differ among the three, and treatment must follow the general outlines for treatment of these conditions. For example, PTSD can be treated with exposure therapy, cognitive therapy, selective serotonin reuptake inhibitors (SSRIs), or combinations of the three.⁸² Treatment of depression in somatically ill patients principally equals treatment of depression in "pure" psychiatric patients, although the presence of other somatic symptoms such as nausea can be of importance for the patients' compliance with the treatment.⁸³

Conclusions

Present Level of Knowledge

Our present level of knowledge on late medical effects is characterized by uncertainties regarding prevalence and clinical significance of reported findings. The distinction between late effects and age- and lifestyle-related morbidity is unclear and generally is not properly controlled for. However, there is an increased risk for secondary cancers and particularly breast cancer in women irradiated by fields involving their breast during their reproductive years. Fatigue seem to be the most consistently reported subjective late effect, and survivors of Hodgkin's disease seem to be at particular risk for this late effect compared to other cancer survivors.

Treatment of late effects generally follows the general guidelines for treatment of the specific condition at stake, and the need for specific treatment studies may seem disputable. Some special considerations regarding volume of irradiation might indicate a need for specialized studies of optimal adju-

vant treatment of breast cancer, for example. Given the prevalence of persisting fatigue and the uncertainty related to the treatment of fatigue, there seems to be a need for controlled trials on the treatment of this symptom.

Future

Future research on late effects should ideally be based upon larger data sets collected prospectively as part of multicenter studies, and the data collection should ideally start when treatment starts. Smaller or medium-sized cross-sectionally designed studies with retrospective data collection without specified hypotheses have been dominating until now, and such studies will probably be of lesser relevance in the future. There is also a need for representative comparison groups that make it possible to specifically estimate if there is an increase in specific disorders and symptoms. At present the cancer registers have this function regarding the secondary cancers, and this advantage has made the prevalence estimates of secondary cancers the most reliable among the reported late medical effects. An optimal strategy can be establishment of surveillance programs for the most prevalent and/or disabling late effects. There is also a definite need for improvement of measurement techniques for subjective late effects, but this is not a challenge for studies of cancer survivors in particular but rather a general challenge for the assessment of subjective health status. A better understanding of biologic mechanisms related to late subjective effects and particularly fatigue is warranted. Such knowledge can improve prevention as well as therapy.

In sum, the ideal goal should be to have sufficient knowledge to identify which patients are at risk for developing which late effects so that preventive measures can be taken at the earliest possible time or that optimal treatment can be offered before the late effects become a health problem of significant magnitude.

Medical and Psychosocial Issues in Testicular Cancer Survivors

Sophie D. Fosså, Lois B. Travis, and Alvin A. Dahl

Testicular cancer (TC) is the most frequent malignancy in men between 20 and 40 years of age, and the annual incidence rates are continuously increasing in the Western world.¹ Since the introduction of cisplatin-based chemotherapy, at least 90% of the patients are cured,² and testicular cancer survivors (TCSs) currently have a life expectancy similar to that of age-matched normal men, with posttreatment life spans of 30 to 50 years. Thus, an increasing number of TCSs experience survivorship problems related to the malignancy, its treatment, or both.

Treatment

Unilateral orchiectomy is the primary treatment of TC and yields the histologic diagnosis of seminoma and nonseminoma with equal frequency (see Chapter 49). Modern post-orchiectomy therapy of TC is based on the histologic type and the extent of disease. Risk-adapted treatment is based on a balance between malignancy-related risk factors, expected side effects, the likelihood of regular follow-up, and, not least, the patient's preference. As effective chemotherapy is available to salvage most of the patients who relapse, today's clinicians tend to administer the least toxic treatment schedule to both low-risk patients without metastases and to the good prognosis metastatic group.³

In patients with nonmetastatic seminoma, the standard adjuvant radiotherapy field currently comprises the intradiaphragmatic paraaortic lymph nodes,⁴ which are irradiated to 20Gy.⁵ Surveillance⁶ is a valid alternative, or the use of one cycle of chemotherapy.⁷ *Surveillance* is also the standard policy in patients with nonmetastatic, nonseminomatous germ cell tumors,⁸ with nerve-sparing retroperitoneal lymph node dissection (RPLND), or two cycles of chemotherapy as alternatives in selected patients.^{9,10} In patients with metastatic disease, the standard *chemotherapy* regimen is cisplatin based, most often containing etoposide and bleomycin,^{11,12} eventually modified by ifosfamide¹³ or taxol in high-risk patients or used as salvage chemotherapy.¹⁴ In patients with metastatic disease, induction chemotherapy is frequently followed by surgical resection of residual masses.¹⁵

Each of the foregoing principal therapeutic modalities (surgery, radiotherapy, chemotherapy) leads to transient short-term (less than 1 year) and long-term (1 year or more) side effects, and their severity often increases with combined treatment. Previous cross-sectional studies on long-term side effects in TCSs have predominantly examined the side effects within the first 5 years posttreatment. Relatively few studies have follow-up times beyond 5 years.

Not all long-term sequelae in TCSs are caused by treatment. Impaired posttreatment endocrine and exocrine gonadal function, for example, is related both to the germ cell malignancy itself and to its treatment. The development of a contralateral testicular tumor is treatment independent and represents primary germ cell carcinogenesis at another site. The diagnosis of a second, possibly treatment-related, malignancy must be clearly separated from a late relapse with non-germ cell differentiation. Leukemia in patients with mediastinal germ cell tumor may thus be treatment related or may arise on the background of the extragonadal germ cell malignancy,¹⁶ recognizable by modern molecular biologic techniques.¹⁷

Second Malignancies

Solid Tumors

The most serious late toxicity of therapy for TC is the development of a non-germ cell malignancy, for simplicity referred to as second cancer. Although several investigations^{18,19} have evaluated the risk of second cancers among patients with TC, few studies have estimated long-term risks among large numbers of TCSs, taking into consideration both histology and initial treatment. The largest study to date comprised more than 28,000 1-year TCSs (1935–1993) reported to population-based cancer registries in North America and Europe.¹⁸ Second cancers were diagnosed in 1,406 patients [observed to expected ratio (O/E), 1.43; 95% confidence interval (CI), 1.36–1.51; absolute excess risk, 16 excess cancers per 10,000 men per year]. Second cancer risk was similar following seminomas (O/E, 1.4) and nonseminomatous tumors (O/E, 1.5).

TABLE 104.1. Relative risk of second malignancies following treatment of testicular cancer.

	No. of second cancers	Relative risk		
		All	Seminoma	Nonseminoma
All second cancers	1,406	1.43	1.42	1.50
All solid tumours	1,251	1.35	1.35	1.36
Stomach	93	1.95	1.73	2.95
Small intestine	12	3.18	4.35	—
Colon	105	1.27	1.30	1.32*
Rectum	77	1.41	1.58	0.92*
Pancreas	66	2.21	2.35	1.85*
Kidney	55	1.50	1.50	1.41*
Bladder	154	2.02	2.12	1.85
Melanoma	58	1.69	1.57	1.74
Thyroid	19	2.92	2.61	3.82
Connective tissue	22	3.16	3.46	2.40*
Non-Hodgkin's lymphoma	68	1.88	1.83	2.09
All leukemias**	64	2.13	1.92	2.78

*Nonsignificant.

**Statistical significance restricted to acute leukemia.

Source: Modified from Travis et al.,¹⁸ by permission of *Journal of the National Cancer Institute*, with emphasis on statistically significant ($P < 0.05$) observations.

Among all TCSs, significantly increased risks were observed for all malignancies taken together: malignant melanoma, acute lymphoblastic leukemia, acute nonlymphocytic leukemia, non-Hodgkin's lymphoma, and cancers of the stomach, colon, rectum, pancreas, kidney, bladder, thyroid, and connective tissue (Table 104.1). The risk of solid tumors increased with follow-up time since the diagnosis of TC and reached 1.5 after two decades (P trend, 0.00002). Twenty-year survivors of TC remained at significantly increased risk for cancers of stomach (O/E, 2.3), colon (O/E, 1.7), pancreas (O/E, 3.2), kidney (O/E, 2.3), bladder (O/E, 2.8), and connective tissue (O/E, 4.7). The cumulative risk of any second cancer 25 years after TC diagnosis was 15.7% (Figure 104.1, Table 104.2). The larger risk for seminoma patients (18.2%; 95% CI,

16.8–19.6) than for those with nonseminomatous tumors (11.1%; 95% CI, 9.3–12.9) most likely reflects the older mean age of the former group (39.2 years versus 29.8 years), given the similarity in the excess cumulative risks. The temporal distribution of increased risks and apportionment between treatment groups were consistent with the late sequelae of radiation for cancers of stomach, bladder, and possibly pancreas. These findings were thus consistent with the location of these organs in the infradiaphragmatic radiotherapy fields administered for TC. Although information on radiotherapy fields and dose are not registered in cancer registry records, Travis et al.¹⁸ provided estimates of the average radiation doses received by stomach (mean, 13–26 Gy), bladder (mean, 22.4–45 Gy), and pancreas (mean, 16.7–33.8 Gy) at treatment doses of 25 and 50 Gy for seminomas and nonseminomatous germ cell cancer, respectively, using standard anteroposterior (AP)/posteroanterior paraaortic or inguinal iliac fields.⁴

Previous clinical series have found significantly eightfold-increased risks of stomach cancer ($n = 2$) following infra- and supradiaphragmatic irradiation for testicular tumors²⁰ and a four- to fivefold risk with abdominal radiotherapy ($n = 10$).²¹ There are few data, however, that quantify the relationship between radiation dose and the risk of gastric cancer.²² In particular, the precise impact of radiation field size and/or dose is not clearly defined for current infradiaphragmatic adjuvant

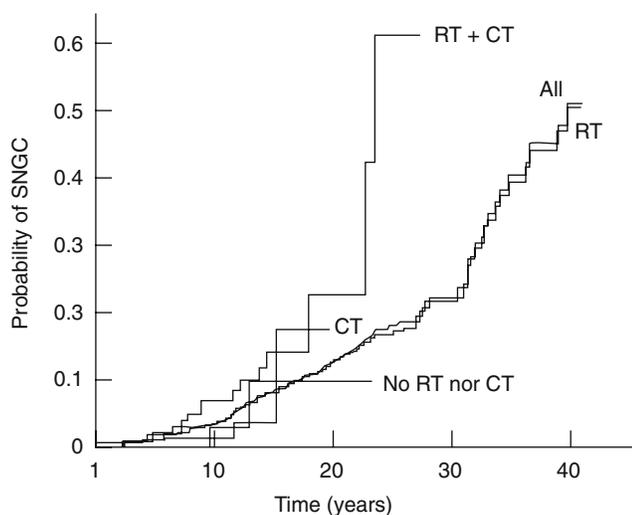

FIGURE 104.1. Cumulative risk of any second non-germ cell cancer by time from primary diagnosis for different treatment groups. (See Table 104.2.) RT, radiotherapy; CT, chemotherapy. (From Hoff Wanderas et al.,²³ by permission of *European Journal of Cancer*.)

TABLE 104.2. Patients at risk at start of interval.^a

Time from diagnosis (years)	Treatment category (n)				
	RT	CT	RT + CT	No RT or CT	All
1–9	1,194	346	277	189	2,006
10–19	827	112	83	59	1,081
20–29	365	2	7	5	379
30–39	92	—	—	—	92

radiotherapy. Therefore, the NCRI (National Cancer Research Institute, UK) Testis Cancer Clinical Studies Group has initiated a long-term follow-up study of 2,500 patients with stage I TC treated between 1962 and 1994 with infra-diaphragmatic radiotherapy, recording the individual target fields and doses, and any salvage treatment as predictors of development of second cancer.

Before the use of cisplatin in TC therapy, few patients treated with chemotherapy only lived long enough to develop a secondary malignancy. To date, modern chemotherapy alone (e.g., bleomycin, etoposide, and cisplatin, or BEP) has not, to our knowledge, been associated with an increased risk of secondary solid tumors. The number of patients observed for more than 10 years after cisplatin-based chemotherapy is limited, however, and further follow-up will be required.

There is also little information on whether TC patients treated with both radiotherapy and chemotherapy are at greater risk of solid tumors than those who received radiation alone. Van Leeuwen et al.²¹ found that the risk of all gastrointestinal cancers following radiotherapy alone (O/E, 2.9; 95% CI, 1.8–4.4; observed, 22) did not differ significantly from the risk (O/E, 5.5; 95% CI 1.1–15.9; observed, 3) in patients given both radiotherapy and chemotherapy, but low numbers in the latter group limit the statistical power to detect any difference.

Hoff Wanderas et al.²³ showed that the risk of all second non-germ cell cancers following radiotherapy alone (O/E, 1.58; 95% CI, 1.3–1.9; observed, 130) was significantly larger than the risk (O/E, 3.54; 95% CI, 2.0–5.8; observed, 15) after radiotherapy plus chemotherapy, but also pointed out that patients in the latter group frequently received multiple irradiation fields and larger doses. Further, many patients who received combined-modality therapy also received chemotherapy regimens that included doxorubicin.²³ Breslow and colleagues²⁴ reported that children ($n = 234$) given doxorubicin and more than 35 Gy of abdominal radiation for Wilm's tumor were at 36-fold risk (95% CI, 16–72; observed, 8) of second solid tumors, compared with no second tumors observed among children ($n = 291$) given doxorubicin alone.²⁴ These investigators²⁴ hypothesized that doxorubicin might inhibit the repair of radiation-induced damage, perhaps through its effects on topo-isomerase II. Evidence with regard to the human carcinogenicity of doxorubicin itself remains conflicting.²⁰

Leukemias

TCS patients are at increased risk of leukemia^{18,21,25–29}; however, there are few analytical studies that characterize in detail the contribution of both radiotherapy and chemotherapy to these cancers. Travis and colleagues¹⁶ conducted an international case-control investigation of secondary myelodysplastic syndrome or leukemia within a cohort of 18,567 1-year TCSs survivors of TC diagnosed between 1970 and 1993 and reported to eight population-based cancer registries in North America and Europe. For all patients (36 cases, 106 controls), detailed information on all treatment was gathered for chemotherapy drugs including cumulative dose and duration of chemotherapy. External-beam radiotherapy, usually to paraaortic and pelvic regions, was administered to 101 patients. Radiotherapy for 17 patients (restricted to 1970–1980) included mediastinal irradiation

(mean dose, 35.0 Gy), in addition to abdominal and pelvic fields; 3 additional patients were given extended-field (abdomen/pelvis/chest) radiotherapy and alkylating agent chemotherapy. For patients who received radiation limited to abdomen and pelvis without alkylating agents, larger mean treatment doses were used for nonseminomatous tumors (35.4 Gy) than for seminomas (30.7 Gy). Daily radiotherapy logs for each patient were used to calculate an average dose to the active bone marrow.

For all TC patients, leukemia risk increased with increasing radiation dose to active bone marrow ($P = 0.02$), with patients given chest radiotherapy in addition to abdominal/pelvic fields accounting for much of the risk at higher doses.¹⁶ A nonsignificant 3-fold-increased relative risk of leukemia was demonstrated after pelvic-abdominal radiotherapy (mean dose to bone marrow, 10.9 Gy) without alkylating agent chemotherapy; for patients who received additional supradiaphragmatic irradiation (mean dose to bone marrow 19.5 Gy), a significantly increased 11-fold risk was apparent. For patients given radiotherapy limited to abdomen and pelvis, the estimated relative risk (RR) of leukemia associated with a treatment dose of 25, 30, and 35 Gy was 2.2, 2.5, and 2.9, respectively; none of these estimates was statistically significant.

Radiation dose to active bone marrow and cumulative dose of cisplatin to treat TC were both predictive of elevated risks of leukemia ($P = 0.001$) in a statistical model that took into account all treatment parameters.¹⁶ The highly significant dose-response relationship observed for total amount of cisplatin and leukemia risk was in accord with results in a study of women treated with platinum-based chemotherapy for ovarian cancer.³⁰

Although the cumulative dose of etoposide used to treat TC did not contribute to leukemia risk when doses of cisplatin and radiation were taken into account, patients given etoposide also received larger amounts of cisplatin, making it difficult to tease apart any individual contributions to leukemia risk.¹⁶ The predicted risk of leukemia associated with a cumulative cisplatin dose of 650 mg was 3.2 (95% CI, 1.5–8.4); larger cumulative doses (1,000 mg cisplatin) were associated with significantly increased sixfold risks. In terms of absolute risk, Travis et al.¹⁶ estimated that of 10,000 testicular cancer patients treated with cisplatin-based chemotherapy with a cumulative cisplatin dose of about 650 mg and followed for 15 years, 16 excess leukemias might result.

Based on small numbers, prior studies have linked etoposide and cisplatin for TC with excess leukemias,^{26–29} usually at high cumulative doses of etoposide (3,000 mg/m²)²⁶ in contrast to the lower total doses administered in the study by Travis et al.,³⁰ which are similar to the dose of less than 2,000 mg/m² (33) used today. Smith et al.³¹ reported that the 6-year cumulative risk of secondary leukemia among patients who received 1,500 to 2,999 mg/m² etoposide was small (0.7%), based on a survey of clinical trials. In a recent review of the literature, Kollmannsberger et al.³² concluded that the cumulative incidence of leukemia for TC patients given etoposide at cumulative doses of less than 2,000 mg/m² and more than 2,000 mg/m² was 0.5% and 2% at a median of 5 years follow-up.

Whether combined radiochemotherapy for TC results in a larger risk of leukemia than chemotherapy alone has not

been well-studied. Van Leeuwen et al.²¹ found no significant difference between the risk of leukemia following chemotherapy alone (one case) and combined modality therapy (two cases), but the small numbers precluded any opportunity to detect a difference. Similarly, in the case-control study by Travis et al.,¹⁶ only a small number of patients were given combined-modality therapy (two cases and four controls), and the risk of leukemia (fivefold) was nearly identical for all investigated patients.

Contralateral TC

Three percent to 5% of the patients with unilateral TC develop a germ cell malignancy of the contralateral testicle.³³ The increased risk of contralateral TC in men with TC has generally been thought to reflect shared etiologic influences.³⁴ Few large studies,^{33,35} however, have provided estimates of the risk for contralateral TC. The largest investigation³⁵ to date, based on 60 cases occurring in 2,201 men diagnosed with a first primary germ cell cancer (1953–1990), reported that the cumulative risk of a contralateral testicular cancer at 15 years of follow-up was 3.9% (95% CI, 2.8%–5.0%). The investigators also concluded that the risk was not significantly altered by treatment of the first cancer. Patients with a contralateral testicular cancer usually undergo a second orchiectomy with the subsequent need of lifelong androgen substitution.

Patients with extragonadal germ cell tumors (EGCT) are at a significantly elevated risk for subsequently developing TC, most probably based on the existence of carcinoma in situ in one or both testicles.^{36,37} In a large, international study of 635 patients with EGCT conducted by Hartmann and colleagues,³⁶ the cumulative risk of developing a metachronous TC was 10.3% at 10 years. The treatment follows the risk-adapted strategies as for TC with principally the same long-term sequelae.

Based on the increased risk of developing a new gonadal germ cell tumor, TCSs and patients with a cured extragonadal tumor are recommended to perform regular testicular self-examination.

Gonadal Toxicity

Spermatogenesis and Leydig Cell Function

According to today's most relevant hypothesis, germ cell carcinogenesis starts in the primordial cells during the 8th week of embryonic life.³⁸ Deleterious environmental influences may result in aberrant gonadal development that subsequently manifests as testicular maldescent, testicular atrophy, reduced Leydig cell function, impaired spermatogenesis, or even germ cell malignancy. These etiologic factors together with tumor-related influences are the reasons why about 60% of unilaterally orchiectomized patients with newly diagnosed TC have impaired spermatogenesis before any additional treatment.^{39–43} Impaired Leydig cell function and reduced sperm cell production may be found even in patients with TC before orchiectomy of the affected testicle.^{41–43} Further, this etiologic hypothesis also explains why 10% to 15% of TCSs have permanently reduced exocrine and endocrine gonadal function even without having received chemotherapy or radiotherapy.^{44,45}

The exocrine long-term gonadal function in TCSs has been extensively studied, although the available investigations do not clearly differentiate between cisplatin-based chemotherapy containing vinblastine from those containing etoposide or ifosfamide. Carboplatin seems to be less gonadotoxic than cisplatin.⁴⁶ Standard cisplatin-based chemotherapy (four cycles) and infradiaphragmatic radiotherapy (36 Gy or less) transiently reduces or abolishes spermatogenesis (low sperm counts; high serum follicle-stimulating hormone, FSH) with recovery starting 6 to 8 months after treatment discontinuation. These effects are dependent on the type of the radiation target field as well as types of cytotoxic drugs, number of cycles, and cumulative doses^{4,39,40,42,47–59} (Figure 104.2, Table 104.3). Age above 35 years and reduced pretreatment gonadal function reduce the ability for such recovery.⁵²

The Leydig cell function is affected by radiotherapy or chemotherapy at a lesser degree than spermatogenesis, but Nord et al.⁴⁵ demonstrated an increasing number of hypogonadal long-term TCSs in relation to treatment type and treatment intensity. According to this study 16% of the long-term TCSs are hypogonadal, most often subclinically, but 25% of these TCSs need androgen substitution.

There is no effective treatment available for TCSs who have become oligo- or azospermic as a result of cytotoxic treatment. Moreover, treatment with luteinizing hormone-releasing hormone (LH-RH) analogues together with chemotherapy has not shown sufficient gonadal protection either.⁶⁰ Pretreatment cryopreservation of sperm cells⁶¹ and exogenous androgen substitution⁶² thus remain the only means to ameliorate gonadotoxic long-term sequelae.

Somatic Aspects of Fertility

Posttreatment fertility is threatened by ejaculatory dysfunction, permanent azospermia, or high-grade oligospermia, and psychosocial distress.

After bilateral radical template RPLND^{63,64} almost all TCSs have to face infertility problems as a result of postoperative "dry ejaculation." The introduction of unilateral and/or nerve-sparing procedures¹⁰ has reduced this proportion to 10% to 15% even when the operation is performed following chemotherapy.⁶⁵ However, even though statistical analyses have proven that fertility-saving strategies have been successful in groups of patients prediction of posttreatment fertility is difficult in the *individual patient*. It is, therefore,

recommended that sperm banking⁶¹ with the possibility of assisted fertilization⁶⁶ is offered to all patients with newly diagnosed TC who do not explicitly exclude future fatherhood. (See also Chapter 90).

Gonadal Long-Term Effects of Treatment for Bilateral TC

Testicular radiotherapy (18–20 Gy) usually prevents the development of an invasive cancer in TCSs with cancer in situ in the contralateral testicle,⁶⁷ although with an increased risk of hypogonadism. Surgical testicle-saving strategies are recommended in case of small tumors.⁶⁸

Neurologic Morbidity

Peripheral Neurotoxicity

Cisplatin-based chemotherapy leads to dose-dependent peripheral sensory neuropathy (paraesthesiae, pain) with a peak occurrence about 6 months after treatment initiation and a slight decrease thereafter.^{53,69–73} Vinblastine displays an at least additive effect, whereas VP-16 is less neurotoxic.¹¹ About 20% of TCSs report peripheral sensory neuropathy

(“quite a bit,” “very much”) 2 years after three or four cycles of BEP chemotherapy,⁷³ although objective measurements reveal persistent peripheral neuropathy in 70% to 80% of the patients.⁷⁴ The long-term peripheral sensory neuropathy is, however, only rarely handicapping, and most TCSs have “become used” to this problem at long-term follow-up.

Ototoxicity

Ototoxicity represents a specific long-term sequela in TCSs after cisplatin-containing chemotherapy,^{53,57,69,73,75,76} with tinnitus and hearing loss in about 25% and 20% of the patients, respectively.^{53,69,73} Audiograms indicate that cisplatin mostly decreases the auditory acuity above 4,000 Hz.⁵⁷ To decrease long-term ototoxicity, each cycle of standard chemotherapy (BEP) should be given during 5 days, in particular if more than three cycles are planned.⁷³

Autonomic Neuropathy

The resection of sympathetic nerve fibers may lead to considerable persistent disturbance of blood flow and temperature sense in the legs.⁷⁷ The possibility exists that chemotherapy-induced long-term autonomic neurotoxicity contributes to vascular dysfunction.^{78,79}

Because no effective treatment exists for cisplatin-induced peripheral neuropathy or ototoxicity, prevention of these late effects is essential by adequate hydration during drug administration and possibly by the supportive use of amifosfine.⁸⁰

Nephrotoxicity

Cisplatin is highly nephrotoxic if sufficient hydration and diuresis are not provided during the drug's administration. Even then, four cycles of standard BEP may lead to chronic dose-dependent, though often subclinical, decrease of the glomerular function.⁸¹

Several authors have described persistent low serum magnesium and/or low phosphate levels after standard chemotherapy,^{53,69} although not all investigators have been able to confirm these findings.^{81,82} Carboplatin is less nephrotoxic than cisplatin, but doses of 1,500 mg/m² or more given over 3 days have a comparable effect as cisplatin 50 mg/m² applied on 1 day.⁸³

Radiation target fields always include parts of the renal arteries, with the risk of postradiation subintimal fibrosis and reduction of the arterial flow. Fosså et al.⁸¹ showed that infra-diaphragmatic radiotherapy (30–40 Gy) leads to subclinical nephrotoxicity after a mean observation time of 11 years, in particular if combined with chemotherapy.

Cardiovascular Toxicity

Raynaud's Phenomenon

About 20% to 30% of TCSs report the development of Raynaud-like phenomenon after standard BEP chemotherapy

that peak at 6 months after chemotherapy and subsequently slightly decrease to a persistent pathologic level.^{53,56,73,76,84} These side effects are related to disturbance of autonomous innervation as well as thickening of the intima in small arteries with reduction of the blood vessel volume. Most studies point to bleomycin as an important etiological agent.⁶⁹ Interestingly, TCSs complaining of postchemotherapy Raynaud's phenomenon display an increased risk for erectile dysfunction.⁷⁸

Cardiovascular Risk Factors and Major Events

Increased risk of postchemotherapy cardiovascular morbidity in TCSs as compared with TCSs on surveillance or men from the general population is evidenced in several studies^{53,85–87} (Tables 104.4, 104.5). Today's chemotherapy for TC may even represent a high-risk factor for the development of a "metabolic syndrome" (diabetes mellitus, hypertension, hypercholesterolemia, obesity) and myocardial infarction.^{86,88}

Huddart et al.⁸² point out the possibility that partial heart irradiation during adjuvant radiotherapy may increase the risk of life-threatening cardiac events, as portions of the heart receive radiation doses of 30 to 90 cGy during current routine radiotherapy. TCSs having received former times mediastinal radiotherapy (30–40 Gy) for stage II or III TC represent a high-risk group for cardiac events and should be monitored accordingly.⁸⁹ These observations are in line with the findings of Fosså et al.⁹⁰ of an increased relative risk of cardiovascular mortality in TCSs treated from 1962 to 1993, most of them having received radiotherapy.

Gastrointestinal Toxicity

With the target doses and target fields administered today,^{4,91} the prevalence of slight gastrointestinal (GI) symptoms among TCSs^{70,91,92} is only marginally above the proportion reported by the general population.⁹³ Major long-term GI problems such as peptic ulcer are observed in only 3% to 5% of the TCSs.^{94,95} Target doses of 36 Gy or more or the combination of radiotherapy with radiosensitizing cytostatic drugs (adriamycin, cisplatin) increase the risk of persistent diarrhea and malabsorption.^{70,96} Increased retroperitoneal fibrosis has occasionally been observed causing ureteric or biliary stenosis⁹⁷ or mimicking pancreatic cancer.⁹⁸

Other Long-Term Toxicities

The typical acute toxicities of bleomycin of the skin and the lungs do not, in general, remain as long-term morbidities, whereas corticosteroid-related aseptic osteonecrosis represents a rare long-term complication in TCSs.⁹⁹

Psychosocial and Quality of Life Issues

Introduction

Psychologic distress, health-related quality of life, as well as sexual dysfunctions and paternity distress, have all been the focus for several quantitative and a few qualitative investigations in TCSs. Hardly any of these studies have randomized controlled designs.

TC involves an organ intrinsically associated with reproduction, sexuality, and masculine self-image, issues of importance to ill and healthy men alike. Global health-related quality of life (HRQoL) as assessed by available instruments does not cover these functions. The only

available TC module¹⁰⁰ has not been completely validated. Paternity issues are regularly rated with unvalidated questions, whereas mental health and issues of sexuality have been studied by psychometrically validated and nonvalidated forms.

TCSs, similar to men in the general population, may have significant pretreatment problems such as unemployment, economical worries, mental disorders, relational problems, and other physical illnesses. The influence of such pretreatment issues on posttreatment adaptation is not well known because of the lack of prospective studies with sufficient sample sizes. Sociocultural differences in relationship to masculinity, sexuality, fertility, and employment should also be kept in mind when findings are compared across studies. Long-term TCSs also have problems in common with cancer patients in general, such as fear of recurrence and death. Coping ability has not been studied in either short- or long-term TCSs.

The overall conclusion so far is that long-term TCSs in general show good psychosocial adaptation; the mean HRQoL is at the level of the general male population. However, TCSs show a higher prevalence of anxiety disorders and some sexual dysfunctions.

Partnered Relationship in TCSs

In most studies, the majority of TCSs (70% to 90%) were in partnered relationships when TC was diagnosed. The rate of divorce and broken relationships for TCSs is 5% to 10% in most follow-up studies. Those couples that did separate saw the cancer as a significant factor in their breakup.^{101,102}

Few wives found their husbands less attractive or masculine as TCSs, and in the few studies of wives, the majority found their sexual satisfaction unchanged.¹⁰³ The main concern of the wives was to have children, particularly if the couple had not achieved parenthood before the TC was diagnosed. Moynihan¹⁰⁴ found that 22% of partners had psychiatric morbidity, mainly anxiety and fertility worries.

Changes in Body Image

The studies published so far do not confirm any devastating effects on body image or feelings of masculinity as suggested by van Basten et al.¹⁰⁵ However, Gritz et al.¹⁰³ reported that 23% of patients perceived a permanent decrease in overall attractiveness. Rudberg et al.⁸⁴ reported that 15% of Swedish TCSs felt less attractive, whereas 33% was found in a sample from Japan.¹⁰⁶ No negative impact of orchidectomy was reported in a Scottish¹⁰⁷ and in an Italian sample.¹⁰⁸ These differences could reflect different cultural attitudes toward orchidectomy.

Health-Related Quality of Life

Posttreatment HRQoL is not identical to therapy-related psychologic or somatic morbidity, but relates to the patient's overall perception of physical and psychosocial well-being, including family life, leisure activity, and occupational situation. Older studies found that TCSs generally were strong, fit, and satisfied compared with controls.^{103,109-111} Newer studies with validated instruments have confirmed that HRQoL generally is as good in TCSs as in the general male population.^{112,113} Data from Norwegian TCSs ($n = 1,409$) with a mean follow-up age of 11 years show minimal differences on the eight dimensions of Short Form 36 (SF-36) compared with the general male population ($n = 2673$)¹¹⁴ (Figure 104.3).

The influence of treatment modalities on HRQoL is still unsettled, mostly due to small samples with lack of statistical power. Joly et al.¹¹³ found no differences ($n = 71$), while Rudberg et al.¹¹² ($n = 277$) found that those treated with intensive chemotherapy scored less favorably concerning HRQoL. In initially metastatic patients postchemotherapy RPLND did not worsen HRQoL as compared with chemotherapy alone.¹¹⁵ Recently, Fosså et al.⁷³ reported that 2 years after chemotherapy, 36% of TCSs displayed improved and 13% deteriorated HRQoL, compared with baseline.

Mental Health

Most studies report a higher level of anxiety symptoms and higher prevalence of anxiety disorders among TCSs (20%)

compared with controls and in the general population.^{104,116,117} There is indication that a considerable proportion of TCSs live with a low feeling of safety.¹¹⁷ It is unclear if there is more mental morbidity associated with the more-intensive treatment regimens. If the prevalence of depression is increased, it is also unsettled due to considerable overlap between depression and fatigue. The level of fatigue, but not of depression, was reported to be higher than in the general population, but lower than among male patients with Hodgkin's disease.¹¹⁷ Fatigue was considered a major problem by many TCSs.¹¹⁸

During recent years, increasing attention has been paid to postchemotherapy cognitive mental disturbances in cancer patients.^{119,120} In the European experience about 20% of the TCSs report decreased cognitive functions 2 years after four cycles of BEP.⁷³ In the future, prospective studies are highly needed to assess changes of cognitive functions in TCSs.

Social Functioning

The continuation of planned education and professional life after treatment obviously is of great importance for TCSs, but only few reports have dealt with this issue. Studies indicate that most TCSs continue in work.^{105,108} Kaasa et al.¹¹⁶ reported even greater work satisfaction in TCSs in general than in an age-matched population sample. There appears to be little change in relation to friends and social contacts.¹¹²

Obtaining bank loans and life insurance is a common problem for TCSs,¹¹³ although national policies vary considerably.

Sexual Dysfunctions

Two systematic reviews of sexual functioning in TCSs^{121,122} emphasize the considerable methodologic problems in the field. TC treatment can result in both physiologic changes in sexual functioning and trigger emotional reactions (e.g., sexual performance anxiety, fear of loss of control, uncertainty about the future). Fatigue and general malaise can have profound effect on libido, as can hair loss and weight loss. Emotional factors such as uncertainty about the future, anxiety, and loss of control may also inhibit libido. Generally,

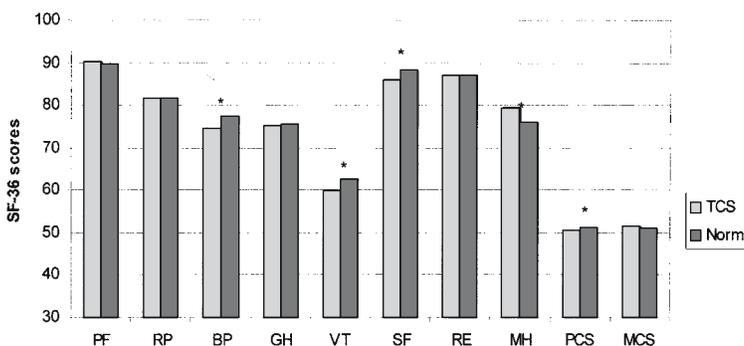

FIGURE 104.3. Health-related quality of life (SF-36) in testicular cancer survivors (TCSs) versus age-matched men from the general population. there seems to be a high correlation between sexual functioning before and after treatment for TC, whereas the relation to treatment modality is less clear.^{123–125} Findings must be considered in relation to age¹²³ and to the prevalence in the general population.¹²⁶ Erectile dysfunction is, for example, reported at the same level as in the general population (approximately 10%).¹²⁷

Thirty per cent to 50% of TCSs report a decrease in sexual functioning compared with before treatment for TC.^{112,123–125,127} Two-thirds reported decreased sexual activity, and one-third was dissatisfied with their sexual functioning.¹²⁷

Psychologic and behavioral features such as desire, orgasmic pleasure, sexual activity, and satisfaction are affected by all treatment modalities, even surveillance. Reduction or loss of orgasm, loss of desire, and sexual dissatisfaction all show a prevalence of approximately 20%, which is significantly higher than in the general population.¹²⁷ Even in the surveillance group, 25% of TCSs report negative changes, which is the same proportion as in the radiation group, whereas those with chemotherapy reported more dysfunctions.¹²² Psychologic functions play a strong role for these sexual dysfunctions.^{128,129}

Fertility Issues

Biologic inability to father a child presents a serious challenge to a man's perception of his masculinity, to his self-esteem, and to his intimate relations, although the inability to achieve paternity evokes different responses at various points in a man's life.

Rieker et al.¹³⁰ found that fertility distress was common, but was a major problem only among those childless and those with ejaculatory dysfunction. No significant relationship was, however, found between TC-related infertility and marital separation.^{101,104}

Psychologic Interventions

A randomized controlled trial of psychologic support in relation to primary treatment of TC showed an effectiveness that hardly differed from that of nonintervention.¹³¹ Treatment for sexual dysfunctions in TCSs has been scarcely described, but seems to follow general principles for such dysfunctions.

Summary and Future Directions

The introduction of cisplatin-based chemotherapy into the treatment of testicular cancer has been one of the largest successes during the past three decades in oncology. Both oncologists and TCSs, however, must accept that long-term toxicity cannot completely be avoided: 10% to 20% of TCSs develop long-term health problems, most of them only slightly interfering with the patients' quality of life.

To minimize treatment-induced side effects, oncologists should follow evidence-based risk-adapted therapeutic guidelines, thus avoiding over- and undertreatment (Table 104.6). Furthermore, TCSs must be educated about the importance of adopting a healthy lifestyle (smoking cessation, weight control, physical activity) to minimize life-threatening side effects such as cardiovascular toxicity. They should be offered long-term follow-up in specialized multidisciplinary cancer survivor clinics that follow structured clinical and research programs with the aim at an early phase to recognize side effects and, if possible, to intervene (for example, testosterone substitution in hypogonadal TCSs). Such long-term follow-up of TCSs and other cancer survivors will enable large-scale comparative epidemiologic investigations. Avoiding unnecessary anxiety, a former TC patient should also be made aware of his increased risk of tumor development in the contralateral testicle, warranting regular self-examination. Only rarely the oncologist will have to discuss the excess risk of subsequent non-germ cell cancer, although this risk should always be considered by healthcare professionals seeing TCSs with "unusual" symptoms.

Many of the reports on TCSs' long-term toxicity rely on the patients' responses to questionnaires. However, during recent years clinical investigators increasingly have validated these responses by objective measures, such as clinical examinations and organ-specific functional tests.^{45,79,82,86} Interestingly, such studies have demonstrated that, for example, cisplatin or cisplatin adducts are retained in the human body (plasma, liver, muscle) for at least 20 years.^{132,133} Whether an association exists between such cisplatin retention and long-term toxicity should be studied in future analyses, which should also take into account pharmacogenetic and molecular biologic parameters. The results of such investigations will increase our understanding of the considerable variability of physical and psychosocial long-term toxicity and will assist the identification of risk groups.

So far, the medical literature on long-term survivorship in TC patients almost exclusively contains cross-sectional studies. Prospective investigations are needed to identify pre-morbid risk factors of physical and psychosocial long-term toxicity.

Medical and Psychosocial Issues in Gynecologic Cancer Survivors

Karen Basen-Engquist and Diane C. Bodurka

An emerging body of research has documented the quality of life of women with gynecologic cancer around the time of diagnosis and during treatment. However, we know much less about the quality of life and psychosocial and medical needs of gynecologic cancer survivors after treatment.^{1,2} In particular, there are very few studies documenting the risk of possible late medical effects of gynecologic cancer treatment such as osteoporosis and second primary cancers. More is known about self-reported symptoms and psychosocial sequelae, such as sexual functioning and psychologic distress, but even these studies rarely focus on survivors more than 5 years after diagnosis. Additionally, much of the extant research has limitations such as small sample sizes, nonstandardized measures, and cross-sectional designs, often without appropriate comparison groups. Finally, there is a dearth of research testing interventions to ameliorate problems experienced by gynecologic cancer survivors. While in some areas additional research is needed to better describe the sequelae and determine who is at risk for adverse late effects, in others areas (e.g., sexual functioning), adequate data describing the problem are available, and a stronger focus on treatment interventions is needed. (See also Chapter 90, Reproductive Complications and Sexual Dysfunction in the Cancer Patient.)

The shortage of research contributes to several clinical challenges in the health care of gynecologic cancer survivors. Without adequate research on the long-term late effects of gynecologic cancer, appropriate follow-up care is difficult to establish. For example, should screening tests for other cancers or for conditions such as osteoporosis be started at an earlier age or done on a different schedule? The lack of an evidence base from which to make such decisions hampers effective health care for long-term survivors. We also have limited data on potential interventions for ameliorating certain late effects. For example, the data to support clinician and patient decision making about hormone replacement therapy for gynecologic cancer survivors do not exist, particularly for those who are premenopausal at diagnosis. This situation forces providers and survivors to extrapolate data on the risks and benefits of hormone replacement in healthy post-

menopausal women to women who experience premature menopause as a result of cancer treatment.

A further challenge in the care of long-term survivors of gynecologic cancer is to identify not only what the healthcare system can provide to help survivors maintain their health but what they themselves can do. Research on improving health behaviors in cancer survivors, for example, increasing physical activity, is in its infancy. Early studies show that exercise benefits quality of life and functional capacity in breast cancer survivors^{3,4} and decreases fatigue in prostate cancer survivors.⁵ There have been no trials in the gynecologic cancer survivor population to test the effects of changes in health behaviors such as diet, exercise, and smoking cessation on potential late effects such as chronic fatigue, osteoporosis, second primary cancers, or recurrence. Such interventions could also benefit women with comorbid conditions that are either coincidental to their cancer or risk factors for the development of gynecologic cancer, such as the obesity, hypertension, and diabetes that are prevalent among endometrial cancer survivors.⁶⁻⁸

Characteristics of Gynecologic Cancer Survivors

The three major gynecologic cancers (endometrial, cervical, ovarian) differ in terms of their risk factors, median age at diagnosis, ethnic distribution, type of treatment, and survival probability. The characteristics of survivors, therefore, vary as a function of these factors as well. Table 105.1 provides information about the three diseases that impact the characteristics of the survivor population.

Endometrial cancer is the most common gynecologic cancer in the United States, followed by ovarian and cervical.^{9,10} By contrast, however, cervical cancer is more common in developing countries; worldwide it is the second most common cancer among women.¹¹ Despite the fact that ovarian cancer is a more common diagnosis in the United States than cervical cancer, there are more cervical cancer survivors because ovarian cancer has a relatively low overall

TABLE 105.1. Variables related to gynecologic cancers that influence the characteristics of the survivor population.

	<i>Endometrial</i>	<i>Ovarian</i>	<i>Cervical</i>
Projected number of cases in U.S. in 2004 ⁹	40,320	25,580	10,520
Percentage diagnosed with localized disease ¹⁰	73%	29%	54%
Average 5-year survival ¹⁰	84%	53%	71%
Median age at diagnosis ¹⁰	65	59	47
Number of survivors in U.S. ¹⁰	556,640	202,949	231,064
Percentage of survivors within 10 years of diagnosis ¹⁰	44%	55%	37%
Ethnic distribution of survivors within 10 years of diagnosis ^{a10}			
• White	92%	89%	77%
• African-American	5%	7%	14%
• Asian/Pacific Islander	2%	3%	4%
• Hispanic ^b	4%	6%	16%
Risk factors ^{6-8,13-17,63-65}	Obesity Diabetes (among obese women) Hypertension Nulliparity	Family history Nulliparity Use of talc Oral Contraceptives (protective) Tubal ligation and hysterectomy (protective)	Early initiation of sexual intercourse More than four sexual partners Smoking

^aInformation on ethnicity of survivors is available only for those diagnosed in past 10 years.

^bPercentages total to more than 100 because the ethnic group Hispanic is not mutually exclusive of the other racial/ethnic categories.

survival. On average, cervical cancer is diagnosed at a younger age than ovarian and endometrial cancer, so survivors of cervical cancer are more likely to be dealing with family and work responsibilities in addition to cancer survivorship issues.

The ethnic distribution of each survivorship group also varies, with endometrial and ovarian cancer survivors being predominantly white. Among cervical cancer survivors, the proportion of minority ethnicity women is higher.¹⁰ Because many cases of invasive cervical cancer are prevented by screening and treatment of preinvasive lesions, a number of invasive cervical cancers arise in women who have not had adequate screening,¹² either by choice or because of lack of access. Thus, women of lower socioeconomic status, who have poorer access to health care, may be overrepresented among cervical cancer patients and survivors.

The behavioral risk factors for the gynecologic cancer differ, and many of these behaviors may be continued after diagnosis and treatment, putting survivors at additional risk of second primaries or other comorbid conditions. Smoking, for example, is a risk factor for cervical cancer,¹³⁻¹⁵ and one study has found that few cervical cancer survivors quit smoking after diagnosis.¹⁶ Obesity is a risk factor for endometrial cancer,^{6,7,17} indicating relatively low levels of physical activity relative to calorie consumption before diagnosis. Data are emerging that indicate endometrial cancer survivors also have low levels of physical activity.^{18,19}

Medical Issues

Survivors of gynecologic cancer report lingering symptoms and treatment side effects even after treatment has concluded. Most studies of medical sequelae are limited to sur-

vivor self-report of symptoms, rather than medical evaluations. Although the self-report data are valuable, more data are needed on conditions that may not cause immediately observable symptoms, such as osteoporosis, second cancers, and cardiovascular disease.

Gastrointestinal Symptoms

Gynecologic cancer survivors, particularly those who are treated with pelvic radiation, report more gastrointestinal symptoms than women from the general population, even several years after treatment. Li et al.¹⁸ studied 61 five-year endometrial cancer survivors (47% of whom received radiation therapy) and found that they reported more gastrointestinal symptoms (stomach ache, diarrhea, and nausea) than a comparison group of women of comparable age. A similar study of 46 cervical cancer survivors (who had not received radiation) found that they reported a similar degree of gastrointestinal distress to the same comparison group.²⁰ Klee and Machin also found that endometrial²¹ and cervical²² cancer survivors treated with radiation therapy reported more diarrhea than population-based controls matched for age and partner status; the group differences in diarrhea were present out to the final evaluation point, 24 months from diagnosis, although levels of diarrhea were low (average score between "not at all" and "a little"). Bye studied 79 survivors of endometrial and cervical cancer who were 3 to 4 years from their radiation treatment and found that diarrhea was their most common symptom. They reported more diarrhea than the general population, and experiencing frequent diarrhea was associated with higher fatigue and poorer social functioning.²³ Acute bowel toxicity during radiation treatment increases the probability of late bowel toxicity,²⁴ indicating that effective interventions to reduce bowel toxicity may have beneficial long-term effects as well.²³

Neurotoxicity

Women with advanced cervical and endometrial cancer and most ovarian cancer patients receive neurotoxic chemotherapy regimens.²⁵ Although in many cases neurotoxicity remits after the conclusion of treatment, some survivors continue to experience neurotoxic effects. A study of 49 early-stage ovarian cancer survivors who were between 5 and 10 years from diagnosis found that a significant proportion still reported symptoms of neurotoxicity: numbness in the hands was reported by 10%; trouble walking, 16%, discomfort in hands, 23%; ringing in ears, 29%, discomfort in feet, 29%; trouble hearing, 35%; and muscle cramps, 39%.²⁶ Neurotoxicity symptoms were associated with poor physical and psychologic well-being, depression, sexual discomfort, and low confidence for managing cancer.

Pain

Approximately half of the 200 ovarian cancer survivors (no evidence of disease, 2 or more years from diagnosis) in one study reported pain or discomfort that they attributed to ovarian cancer or its treatment. Pain was located mainly in the bowel, pelvis, bladder, or groin. Of those who reported pain, 46% rated it as mild, 21.1% as severe. Approximately half of those with pain reported that it had a low impact on their lives.²⁷ Various somatic pains (e.g., headache, leg and back pain) were reported by 30% to 50% of cervical cancer survivors²⁰; however, several studies found that pain levels of endometrial and cervical cancer survivors are similar to, or even lower than, those of controls.^{18,20–23} Continued pain naturally has an impact on overall quality of life; Bye et al.²³ found that pain in endometrial cancer survivors 3 to 4 years after treatment was associated with lower quality of life and higher fatigue.

Menopausal Symptoms

Women who are premenopausal when diagnosed with gynecologic cancer often suffer a loss of ovarian function and experience premature menopause. Andersen's study of gynecologic cancer survivors in the year after diagnosis indicates that menopausal symptoms among the survivors remain higher than those of healthy controls up to 12 months from diagnosis.²⁸ Other studies of endometrial and cervical cancer survivors have also noted significant problems with menopausal symptoms (e.g., hot flashes, vaginal dryness/irritation^{18,20,21}). However, two studies of cervical cancer survivors did not find the prevalence of hot flashes to be higher than that of a comparison group, possibly because of the use of hormone replacement therapy.^{20,22} Among endometrial survivors, younger women report more hot flashes and other menopausal symptoms than older survivors.¹⁸ In a study of ovarian cancer survivors, Carmack Taylor et al.²⁹ found that those who were off treatment reported less vaginal dryness and pain during intercourse than patients receiving treatment, but more than breast cancer survivors or women who had not had cancer.

Another implication of early ovarian failure, especially for younger survivors, is the increased risk of osteoporosis. This problem has not been well studied in gynecologic cancer patients, to determine either the prevalence of the problem

or effective strategies to treat and/or prevent osteoporosis. One pilot study of 27 breast cancer survivors found that those who became permanently amenorrheic after chemotherapy had a 14% lower bone mineral density than breast cancer survivors who maintained or resumed menses.³⁰ Although this is a potentially serious problem, particularly for those survivors who have their ovaries removed or experience ovarian failure at a young age, many healthcare providers do not routinely recommend screening for osteoporosis in this population. A survey of outpatient oncology nurses indicated that bone mineral density testing is one of the least frequently performed screening tests for cancer survivors.³¹

Fatigue

Fatigue is a significant problem for many cancer patients during treatment, and it can last beyond the acute treatment phase.³² In a longitudinal study of gynecologic patients in the year after diagnosis, Lutgendorf et al.³³ found that most aspects of survivors' mood were similar to healthy individuals, but that fatigue was elevated above norms for survivors of both early-stage and advanced disease. The study by Ersek and colleagues³² of ovarian cancer survivors found that fatigue was the most severe physical symptom experienced by the sample. Qualitative data indicated that fatigue interfered with general activities, employment, relationships, and ability to enjoy life. Li et al.¹⁸ found that their sample of 5-year endometrial cancer survivors reported less energy, poorer memory, and less patience than age-matched population controls, whereas Klee and Machin^{21,22} found no differences in the level of tiredness between controls and survivors of endometrial and cervical cancer, and Bye et al.²³ found higher levels of fatigue in controls than survivors.

Psychosocial Issues

Despite losses inherent in gynecologic cancer and treatment, reports of overall quality of life are good.³⁴ The psychosocial issues that have been most frequently studied in gynecologic cancer survivors are psychological distress and sexuality.

Psychologic Distress

Although the reported prevalence of psychologic distress among gynecologic cancer survivors varies depending on the population and the measure used, several studies have followed survivors longitudinally from diagnosis and have found that the distress experienced by gynecologic cancer survivors after diagnosis and during treatment abates over time.^{21,33,35–37} A study that followed women with gynecologic cancer for 1 year after diagnosis found that their mood disturbance was not significantly different from that of women receiving surgical intervention for benign gynecologic conditions or healthy women 8 and 12 months posttreatment.³⁵ The majority of cross-sectional studies have found that long-term survivors report levels of psychologic distress that are comparable to women who have not had cancer,^{26,33,38–41} although one study reported elevated levels of distress for survivors.⁴² Wenzel's study of long-term survivors of early-stage ovarian cancer found that only 6% scored above the cutpoint for the Center for Epidemiologic Studies—Depression (CESD)

Scale.²⁶ Bodurka-Bevers et al.³⁸ found that 15% of posttreatment survivors were above the CESD cutpoint (compared to 15%–19%) for the healthy population^{43,44} and that only 22% were above the 75th percentile for anxiety.⁴⁵ Congruent with findings of lower psychologic distress for long-term survivors, they also appear to be less interested in psychologic services, particularly individual counseling.⁴⁶ One study indicated that anxiety may be a bigger problem for gynecology cancer survivors than depression. Paraskevidis et al.⁴⁷ found, in a sample of gynecologic cancer survivors (median time since diagnosis, 25 months), that 21% had clinically significant anxiety while 4% reported high levels of depression.

Psychologic concerns can persist for gynecologic cancer survivors, however, particularly those who are at high risk for recurrence or suffer lingering physical problems as a result of the cancer or its treatment. While not reporting a high prevalence of major psychiatric disorder, survivors do describe continued distress related to fears of second cancers, recurrence, and diagnostic tests.^{2,26,32,39,42} This distress has been labeled the Damocles syndrome, referring to the story of Damocles, first told by Cicero, who must enjoy a grand banquet with a sword hanging by a single horsehair over his head. Cancer survivors, particularly those who have survived advanced disease, often report feeling that they have the 'sword' of recurrence hanging above them. Survivors who are at increased risk of recurrent or persistent disease, such as those with advanced gynecologic cancer, have been reported to experience higher levels of anxiety and depression.³³ Ovarian cancer, in particular, has a high risk of recurrence, and the diagnosis of persistent disease after conventional treatment appears to be more stressful than the initial diagnosis.⁴⁸

Some studies report that younger survivors experience more severe psychologic symptoms than those who are older.^{20,38} One study of long-term cervical cancer survivors of childbearing age found that while their overall quality of life was good, they were more likely to be in the lowest quartile on general health, vitality, and mental health subscales than expected based on normative data. They reported more problems with social and emotional well-being, sexual discomfort, and gynecologic symptoms compared to women who have had gestational trophoblastic disease or lymphoma.⁴⁹

Sexual Functioning

Gynecologic cancer and its treatment often has serious, long-term effects on the sexual functioning of survivors. In 1962, Decker and Schwartzman noted that "The deprivation of sexual function may have serious sequelae . . . it appears that little attention has been given to the problem of sexual function following treatment for cervical carcinoma".⁵⁰ These authors studied 78 patients at one point in time 6 to 10 years after treatment and noted that 31% experienced partial or complete loss of sexual function. In one study that prospectively assessed sexual functioning in women with gynecologic cancer, women having surgery for benign gynecologic conditions, and healthy women, Andersen et al.²⁸ found numerous sexual difficulties among gynecologic cancer survivors in the year after diagnosis. Cancer survivors reported

greater difficulty with sexual desire, excitement, orgasm, and resolution. Although the women who received surgery for benign conditions also reported some sexual functioning problems, they were less severe than those reported by the cancer survivors.

Carmack Taylor and colleagues²⁹ found lower levels of sexual activity and sexual pleasure, and higher sexual discomfort, among 248 ovarian cancer patients and survivors as compared to data from samples of healthy women and breast cancer survivors reported in other studies using the same questionnaire. Ovarian cancer survivors were also less likely to be sexually active than healthy women, regardless of whether the healthy women were pre- or postmenopausal, or on hormone replacement therapy. Patients and survivors were more likely to be sexually active if they were married, happy with their body's appearance, younger, and not on active treatment. In two additional cross-sectional studies of long-term ovarian cancer survivors, problems in sexual functioning emerged as a major concern. In a study of long-term survivors of early-stage ovarian cancer, respondents reported difficulties with decreased libido (37%) and arousal (28%), problems with orgasm (13%), and difficulty with intercourse as a result of treatment (20%). Only 12 of 49 survivors were sexually active (25%), although 51% were married.²⁶ Stewart and colleagues²⁷ reported that a significant number of the 200 ovarian cancer survivors who responded to their survey had problems with sexuality; these reports were highest among women who were treated with radiation therapy. Over half of the survivors reported that their sex lives had been negatively affected by cancer and/or its treatment. Although 64% reported that their sex lives were average to excellent before diagnosis, only 25% reported average to excellent sex lives currently. Before cancer, 36% reported their sex lives were poor to adequate, whereas now 75% rated their sex lives as poor to adequate. However, only about 20% of the sample reported a moderate to great sense of loss associated with the decline in their sexual functioning.

Survivors of cervical and endometrial cancer also experience declines in sexual functioning, and those who receive radiation therapy report more sexual difficulties.^{51,52} A study of 221 indigent women treated with radiation therapy for invasive cervix cancer reported an 88% incidence of vaginal stenosis; however, sexual functioning was not evaluated in this study.⁵³ A decrease in sexual function in irradiated patients was reported by Seibel et al., who compared 22 patients radiated for cervical cancer versus 20 patients undergoing hysterectomy for preinvasive disease 1 year posttreatment.⁵⁴

Schover et al.⁵² conducted the first prospective evaluation of sexual function, frequency, and behavior, as well as marital happiness and psychologic distress, in 61 patients treated for early-stage cervical cancer in the United States. Although the surgical and radiation treatment groups appeared similar posttreatment and at 6-month follow-up, by 1-year women treated with radiation had more dyspareunia and problems with sexual desire and arousal than women who underwent radical hysterectomy. Pelvic examinations were performed, and a rating scale used to assess vaginal atrophy correlated with women's reports of dyspareunia, but no specific vaginal measurements were obtained. This study remains one of the few to compare the specific sexual impact of surgery versus radiation therapy.

Bruner et al. evaluated vaginal stenosis, sexual activity, and satisfaction in 90 patients treated with intracavitary radiation for endometrial or cervical cancer.⁵⁵ The authors noted a correlation between decrease in vaginal length and decrease in sexual satisfaction, but a cause-and-effect relationship was not demonstrated. Most recently, Bergmark and colleagues studied vaginal changes and sexuality in Swedish women 4 or more years after completion of treatment for cervical cancer. When compared to controls, patients with a history of cervical cancer noted similar frequency of sexual intercourse, but reported decreased vaginal lubrication and a reduction in perceived vaginal length and elasticity during intercourse. A large proportion of these women also reported that they were distressed by these changes and their effects on sexual function.⁵⁶ Although this study was described as one focusing on the impact of radical hysterectomy, the majority of women had also had radiation therapy, a likely confounding variable.

Women treated for vulvar cancer may have the most severe sexual functioning problems because of the radical surgery they often receive. A cross-sectional study of 105 survivors of vulvar and cervical cancer (average of 28 months from diagnosis)³⁹ found that most women who were sexually active before cancer diagnosis had resumed sexual intercourse, with the exception of older women who had received radical vulvectomies and the 3 women who received pelvic exenterations. Frequency of sexual intercourse was reduced, however. Approximately three-fourths of the women experienced sexual problems during the year following diagnosis, and 66% reported continued problems. In a study of 42 women treated for in situ vulvar cancer, Andersen and colleagues found that these women experienced more disruption in sexual functioning compared to healthy women, and that these disruptions increased over time. In addition, increasing numbers of survivors discontinued sexual activity over time. Degree of sexual dysfunction was related to the extensiveness of the treatment.⁵⁷

Interventions

The literature includes no published trials of interventions to address late psychosocial or medical effects of gynecology cancer and its treatment. There is a small number of studies testing interventions delivered during cancer treatment that may influence long-term sequelae in survivors. These studies are reviewed here to provide information regarding what interventions might benefit gynecologic cancer survivors. Several of the studies assess outcomes 12 months or more from diagnosis. We focus on these longer-term outcomes where available (Table 105.2).

Psychosocial Issues

Four studies were identified that evaluated interventions to improve psychosocial functioning of gynecologic cancer survivors. Three of these focused primarily on sexuality⁵⁸⁻⁶⁰ and one was concerned with a broader range of psychosocial issues.⁶¹ All four programs used fairly standard psychoeducational approaches, providing information and opportunities for emotional expression and problem solving. Two of the studies used group interventions.^{60,61} The treatments focusing

on sexuality appear to have some positive effects on sexual functioning, including resuming sexual activity,⁵⁸ returning to usual frequency of sexual activity,⁵⁹ decreasing sexual fears,⁶⁰ and increasing dilator use (among younger women).⁶⁰ The intervention with the broader psychosocial focus decreased psychologic distress and improved adjustment to cancer.⁶¹ These results indicate that psychoeducational interventions can be helpful to gynecologic cancer survivors up to a year from diagnosis and may provide benefits beyond that point. Studies by Wenzel and colleagues^{26,49} indicated that a high percentage of long-term (greater than 5 years) ovarian (43%) and cervical (60%) cancer survivors would be interested in participating in programs offering psychosocial support. Given that sexual dysfunction seems to be a very prevalent problem for long-term gynecologic cancer survivors, interventions that focus on sexuality are particularly appropriate. More research is needed to refine interventions such as those tested in these studies to produce programs that can be disseminated and implemented by physician extenders and/or survivor organizations.

Medical Issues

Only one study was identified that tested an intervention for its ability to reduce late medical effects of gynecologic cancer. Bye et al.^{23,62} tested a dietary intervention to reduce diarrhea in cervical and endometrial cancer patients receiving radiation therapy. The intervention (recommendation of a low-fat, low-lactose diet during radiation therapy and for 6 weeks after treatment) was effective during treatment⁶²; 3 to 4 years after treatment some positive effects were still present.²³ While these results are intriguing, more research is needed to replicate this finding.

Emerging Areas

It is critical that the study of cancer survivorship in gynecology advance beyond small descriptive studies of the sequelae of gynecologic cancer. The field needs more carefully controlled longitudinal studies of late effects, using standardized measures, triangulation of self-report measures with clinical evaluation, and adequate sample sizes. Additionally, input from survivors themselves is needed to determine what sequelae and late effects of cancer are salient to them. For example, although the prevalence of clinically significant psychologic distress appears to be fairly low in gynecologic cancer survivors, some studies indicate that long-term survivors feel they would benefit from additional psychosocial services.^{26,49}

Additional research data would guide clinical care of long-term cancer survivors and would identify areas in which interventions are needed. The existing research base indicates that treatment to address menopausal symptoms, sexual functioning, anxiety about recurrence and follow-up visits, fatigue, pain, gastrointestinal symptoms, and health behaviors such as physical activity and smoking cessation would be helpful to gynecologic cancer survivors. More careful longitudinal research would identify which survivors need intervention and elucidate optimal timing for providing assistance in these areas.

TABLE 105.2. Studies evaluating interventions for gynecologic cancer survivors.

Author	Year	Intervention focus	Type of trial	No. of participants	Type of participants	Type of treatment	Length of follow-up	Results
Lamont et al. ⁵⁸	1978	Psychosexual rehabilitation after pelvic exenteration	Case series	12	Gynecologic cancer patients receiving pelvic exenteration	Team approach to treatment including sex therapist meetings with patient and partner before surgery, in hospital, and after discharge as needed Provides information and counseling	6 months	Of the 12 women receiving treatment with the team approach, 8 were thought to have good adjustment before surgery. Seven of these women resumed sexual activity. Six were having orgasms within 6 months; the 7th was still recovering from surgery at the time of article publication. Decreased sexual desire and difficulty using dilators was a common concern.
Capone et al. ⁵⁹	1980	Psychosocial rehabilitation and sexuality (for sexually active patients)	Quasi-experimental	97	Gynecologic cancer patients	Counseling by psychologist during initial hospitalization, minimum of four sessions	12 months	Women in experimental group more likely to have returned to usual frequency of sexual activity at 12 months than women in control group. Experimental group twice as likely to have returned to work at 12 months, but differences not significant. No significant differences between groups in emotional functioning at 12 months.
Cain et al. ⁶¹	1986	Individual and group counseling	Randomized	80 (60 with 1-year follow-up)	Gynecologic cancer patients	Patients randomized to group or individual counseling, or standard care Counseling consisted of eight weekly sessions focusing on predetermined themes Techniques included providing information, emotional expression, problem-solving, and relaxation	12 months	Survivors in both the individual and group counseling conditions had less anxiety and depression and better adjustment to their illness than the standard care group at the final (12-month) assessment.
Robinson et al. ⁶⁰	1999	Sexuality and use of vaginal dilators	Randomized	32	Cervix and endometrial cancer patients receiving radiotherapy	Two 1.5-hour group sessions presented information about sexuality and cancer, promoted the idea that sex is pleasurable, and taught behavioral skills in communication about sexuality, using dilators and lubricants, and performing Kegel exercises	12 months	No impact on Sexual History Form scores (overall sexual functioning); intervention group had significantly lower scores on scale measuring sexual fears, intervention improved knowledge in older group but not younger group. Intervention increased dilator use in younger group but not older group.
Bye et al. ²³	2000	Diet to reduce diarrhea during radiation treatment	Randomized	143 in initial trial, 79 (43 intervention, 36 control) in 3- to 4-year follow-up	Cervix and endometrial cancer patients receiving radiation therapy	Low-fat, low-lactose diet during radiation therapy and for 6 weeks after the end of treatment	3-4 years	7% of the intervention group and 22% of the control group reported diarrhea at follow-up ($P = 0.05$), although difference in diarrhea score was not statistically significant (Intervention group, $M = 19.4$; Control group, $M = 29.6$; $P = 0.09$). In original study, 23% of intervention group and 48% of control group reported diarrhea during radiation therapy. Diarrhea during radiation was associated with diarrhea at follow-up for the control group only. There were no differences at follow-up in quality of life.

Medical, Psychosocial, and Health-Related Quality of Life Issues in Breast Cancer Survivors

Julie Lemieux, Louise J. Bordeleau, and
Pamela J. Goodwin

Women with breast cancer account for the largest group of female cancer survivors. It is estimated that there are currently 8.9 million cancer survivors in the United States; 41% of the female subjects are breast cancer survivors.¹ The growing number of breast cancer survivors reflects increasing incidence of the disease, diagnosis at earlier stages when outcome is better, and widespread adoption of effective adjuvant treatment (see Chapter 28 and Chapter 54).

Methodologic Issues in Survivorship Research

The Office of Cancer Survivorship of the National Cancer Institute (U.S.) defines a survivor as follows: "An individual is considered a cancer survivor from the time of cancer diagnosis, through the balance of his or her life. Family members, friends and caregivers are also impacted by the survivorship experience and are therefore included in this definition."¹ This is a very broad definition; most survivorship research in breast cancer focuses on the experience of individuals with cancer after they have completed their primary therapy, usually while they are free of recurrent disease. Some studies have focused on women who are 1, 3, 5, or more years post-diagnosis. In breast cancer, where long-term survival is becoming increasingly common, this variable definition may account for some of the inconsistencies in the literature. In this chapter, we have not adopted a single definition of survivorship but have tried to relate results to the definition used in each study.

Definition, recruitment, and identification of study populations are among the most challenging aspects of breast cancer survivorship research. Ideally, if the objective is to examine long-term outcomes, an inception cohort identified at a uniform time early in the course of the disease should be

assembled (e.g., women with locoregional breast cancer in the immediate postoperative period, before adjuvant therapy). Prospective recruitment of a sample such as this is costly and time consuming. An alternative approach involves the use of administrative databases (including tumor registries) that retrospectively identify women diagnosed years earlier; however, careful attention must be paid to refusers and non-responders, who may differ in important ways from responders. Investigators often conducted cross-sectional surveys of breast cancer patients attending follow-up clinics, or in a community. The populations thus assembled may not be representative of all breast cancer survivors, particularly when response rates are low, or well women have been discharged from follow-up clinics. Convenience samples, drawn from breast cancer advocacy groups or other sources, were recruited in some studies. This approach may lead to systematic overestimation or underestimation of the long-term impact of breast cancer and its treatment, because participation of women in these groups may be related to their survivorship experience.

Inclusion of a control population without cancer should be considered in breast cancer survivorship research. This condition allows the effects of aging and comorbid conditions to be differentiated from those of prior breast cancer and its treatment, important for many of the medical concerns of breast cancer survivors (e.g., menopause, osteoporosis, heart disease). Although inclusion of a noncancer control group is often desirable, it increases costs and complexity of research. Instead, investigators may opt to use measurement instruments for which population-based norms are available, comparing the results obtained in the breast cancer survivors with published results in age-matched controls.

Breast cancer survivorship studies often examine a broad variety of attributes: medical status, psychosocial issues, health-related quality of life (HRQOL), and sexuality, for

example. Some of these attributes are readily measurable (e.g., bone density after chemotherapy-induced early menopause) while others are not (e.g., the social impact of breast cancer diagnosis). It is important that measurement instruments be valid and reliable and that they measure key areas of interest. A wide variety of standardized, validated instruments are available to measure many of the important psychosocial issues and health-related quality of life (HRQOL) in breast cancer survivors. When valid instruments are not available for key attributes, such as body image postmastectomy, investigators may need to develop new instruments and validate these instruments during the course of the research. In selecting questionnaires, investigators should avoid overburdening respondents.

It is likely that not all salient issues in breast cancer survivors have been identified. Recent evidence that cognitive dysfunction may occur in women receiving adjuvant chemotherapy is a prime example. Investigators should be aware of new and ongoing research and be prepared to examine newly emerging concepts.

Statistical analysis should include the use of appropriate statistical tests, with adjustment for the effects of age because it could be an important confounder. The use of baseline information, which allows evaluation of change over time, can provide valuable insights into the breast cancer survivorship process. As noted previously, comparison of study data with population-based norms also provides insight into the impact of aging versus the impact of prior breast cancer diagnosis.

In the remainder of this chapter, we review the survivorship literature in breast cancer, first as it relates to medical status and then as it relates to psychosocial status and HRQOL. This separation is somewhat artificial; there is overlap between the sections. Because most studies are observational, grading of evidence regarding efficacy of interventions is usually not possible.

Medical Status

Arm Symptoms/Upper Body Function

Treatment for breast cancer can be associated with a number of localized physical sequelae including arm edema (AE), impaired shoulder mobility, pain, neurologic deficits, and reduced upper body function. The literature assessing arm symptoms and limitations is summarized in Table 106.1.

There are three approaches to arm measurement: (1) circumference at various points (with bony landmarks as references), (2) volumetric measurements using limb submersion in water, and (3) skin and soft tissue tonometry.² Tape-measured circumference (10 cm above and below the olecranon or the lateral epicondyle) has been the traditional method but can be imprecise. Volumetric measurements are more accurate but have limited availability. Tonometry is not used clinically.

The occurrence of, and risk factors for, AE have been reviewed by Erickson et al.³ The reported incidence of AE has ranged from 0% after partial or total mastectomy with sentinel node biopsy to 56% after modified radical mastectomy (MRM) or breast-conserving surgery (BCS) with both axillary lymph node dissection (ALND) and axillary radiation therapy

(XRT).^{4,5} Werner et al.⁶ reported that the median time to development of AE in patients treated with BCS, ALND (almost one-third had level 3 ALND), and breast XRT (with or without axillary XRT) was 14 months (range, 2–92 months); 97% of those who developed AE did so by 4 years.

The association between the extent of breast surgery and AE is less clear. Tasmuth et al. reported AE to be significantly more frequent in a prospective cohort study of 93 women treated with MRM versus BCS; however, women undergoing MRM had axillary XRT (also associated with AE) more commonly than those undergoing BCS.⁷ Paci et al.⁸ reported the odds ratio of chronic AE to be slightly, but not significantly, higher after MRM [odds ratio (OR), 1.62; 95% confidence interval (CI), 0.91–2.88] than after BCS (XRT was not examined). In a randomized trial comparing MRM to BCS with XRT to the breast and internal mammary and supraclavicular nodes, Gerber et al. reported the rate of AE did not differ between the two groups; however, axillary XRT (given if the dissection was inadequate or there was extracapsular extension) was not considered in the analysis.⁵

The risk of AE increases with the extent of axillary dissection. Yeoh et al.⁹ reported frequency of AE to be 25% with no axillary surgery, 50% after axillary sampling, and 84% after ALND. The risk of AE was higher with an increasing number of axillary lymph nodes resected (more than 15 nodes¹⁰; more than 40 nodes¹¹) in two studies. Schrenk et al. reported AE did not occur in a small cohort of patients undergoing sentinel lymph node dissection.⁴ In a prospective randomized trial of sector resection and ALND with or without breast XRT, young age [relative risk (RR), 0.93 per year of increasing age; 95% CI, 0.91–0.97] and number of lymph nodes resected (RR, 1.11 per lymph node resected; 95% CI, 1.05–1.18) were significantly associated with any arm symptoms (not necessarily AE).¹²

Axillary XRT has been associated with AE. Senofsky et al., in a cohort of 264 patients treated with total ALND, found AE to occur in 6% of those not treated with XRT, 14.7% of those receiving XRT to the breast only, and 29.6% of those receiving XRT to the breast and regional nodes.¹³ Furthermore, Keramopoulos et al. reported AE to be significantly more frequent when XRT was delayed (6 months postoperatively) than when it was given immediately postoperatively (4% versus 27%).¹¹

The combination of XRT and ALND further increases the risk of AE. Kissin et al.¹⁴ reported AE in 8.3% of women treated with breast surgery and axillary XRT, 9.1% undergoing axillary sampling and XRT, and 7.4% undergoing ALND only (7.4%). However, AE occurred in 38.3% of women undergoing both ALND and axillary XRT. In a randomized trial comparing ALND to axillary sampling, a significant increase in arm volume was experienced in 14 (12 of whom received axillary XRT) of 47 (29.8%) patients treated with ALND.¹⁵ None of the 48 patients undergoing axillary sampling experienced AE (regardless of XRT).

The occurrence of other reduced upper body function, pain, neurologic deficits, and restricted shoulder mobility has also been evaluated. In a prospective cohort study, decline in upper body function was substantially higher during the first year after MRM or BCS with or without XRT than in the subsequent 4 years.¹⁶ Cardiopulmonary comorbidity significantly increased the risk of decline in upper body function at 5 months (OR, 2.8; 95% CI, 1.3–5.7). Cardiopulmonary

TABLE 106.1. Arm symptoms in treatment for breast cancer.

Reference	Primary objective(s)	Study population and follow-up (years)	No. of patients	Type of local treatment	Instruments	Response rate	Results and conclusions
Kissin et al. 1986 ¹⁴	Compare the incidence of AE by subjective and objective methods; identify independent risk for late AE; compare the incidence of AE after different treatments	Cohort (clinic) diagnosed at least 1 year prior	200 patients	BCS or MRM with no axillary surgery, sampling or ALND	<ul style="list-style-type: none"> Subjective: graded as no difference, moderate AE, or severe AE (patient + observer) Objective: (1) arm circumference measured 15 cm above and 10 cm below the lateral epicondyle, (2) volume measured by water immersion 		Objective AE more frequent (25.5%) than subjective AE (14%). Subjective AE was significantly more common after ALND with XRT (38.3%), axillary XRT alone (8.3%), axillary sampling with XRT (9.1%), and ALND alone (7.4%).
Yeoh et al. 1986 ⁹	Assess the complications following surgery and postoperative XRT	Cohort assessed median F/U of 1.7–3.24 years	187 patients	Surgical management of the axilla: none, sampling, or ALND with three different XRT dose fractionation	<ul style="list-style-type: none"> Physical exam: (1) arm circumference measured 7.5 cm above the olecranon process, (2) shoulder movement and degree of restriction 		Complication rates similar with three different XRT schedules. AE ± restriction of shoulder movements were different at 30 months with no surgery (25%), sampling (50%), and ALND (84%).
Bonup Christensen et al. 1989 ¹⁵	Compare the sequelae of ALND vs. axillary sampling ± XRT	Prospective randomized trial with assessment at 14 days, 3, 6, and 12 months postoperative	100 patients	BCS or MRM ± XRT, randomization to ALND vs. axillary sampling	<ul style="list-style-type: none"> Physical exam: (1) arm volume (measured by water displacement and corrected for changes in body weight), (2) shoulder mobility using 360 scale Questionnaire re: arm swelling, shoulder mobility, and loss of sensibility. 		AE (≥10% volume increase) in 14 pts (all with ALND), 12 received XRT. Impairment of shoulder mobility was more frequent after axillary XRT ($P = 0.07$).

Satariano et al. 1990 ³⁸	Assess physical functioning	Case control (3 and 12 months post diagnosis) (Metropolitan Detroit Cancer Surveillance System)	571 cases (breast cancer) 647 controls (no breast cancer)	Not mentioned	<ul style="list-style-type: none"> Structured interview with items from (1) Massachusetts Health Care Panel Study, (2) Framingham Disability Study, and (3) the National Institute on Aging EPESE 	<p>Cases: 81.1% 3 months, 95.1% 12 months Controls: 83.3% 3 months, 90.9% 12 months</p>	At 3 months, cases age 55–74 had greater difficulty completing tasks requiring upper body strength. At 12 months, upper body strength remained diminished in cases aged 65–74, more so than cases aged 55–64.
Senofsky G.M. et al. 1991 ¹³	Assess the effects of TAL	Prospective cohort, median follow-up of 41 months	264 patients	BSC or MRM + TAL ± XRT	<ul style="list-style-type: none"> Medical records review Clinical examination: AE graded I–IV (method of measurement not stated). 	AE in 9.4% of patients. Breast and nodal XRT significantly associated with AE. Breast edema associated with XRT.	
Segerstrom et al. 1991 ¹⁸	Study the natural history of pain and functional impairment after surgery and XRT	Prospective cohort assessed at 1–23 months and 1 week–24 months after exam 1	100 patients	MRM + ALND + high-dose XRT (±XRT to axilla)	<ul style="list-style-type: none"> Questionnaire Physical exam: (1) arm edema (water displacement method), (2) ROM (inspection) 	93 patients (93%)	AE observed in 43% of patients; AE disappeared in 8 patients at follow-up (all had slight to moderate edema). Stiffness and edema good predictors of subjective functional impairment.
Werner et al. 1991 ⁶	Assess predictors of AE	Cohort of patients receiving XRT; median F/U of 37 months	282 patients	BCS + ALND (30.5% had level I, II, and III dissected) + XRT	<ul style="list-style-type: none"> Arm circumference measured 13 cm above and 10 cm below the olecranon on both arms 	Transient AE in 7.4%, chronic arm edema in 12.1%. Persistent AE at 5 years in 16%. Body mass index strongly associated with AE.	
Sneeuw et al. 1992 ³⁹	Assess the cosmetic and functional outcomes of BCS and relationship to psychosocial functioning	Cohort, mean 4 years (2–11 years)	160 patients eligible	BCS + XRT; most patients had ALND	<ul style="list-style-type: none"> In-home interview: GHQ, QOL Physical exam 	76 (47.5%) patients	High levels of psychologic distress, disturbance of body image, and decreased sexual functioning ~25%. Patient ratings of overall cosmesis and AE significantly associated with body image.
Gerber et al. 1992 ⁵	To compare pain, motion, and edema after MRM vs. BCS with ALND and XRT	Prospective randomized trial, annual evaluation	247 patients	MRM vs. BCS + XRT with ALND	<ul style="list-style-type: none"> Physical exam: (1) functional ROM (goniometry), (2) chest wall tenderness, (3) arm circumference at ulnar styloid, olecranon, and 35 cm proximal to the ulnar styloid, (4) cosmetic outcome 	165 patients (66.8%) had pre-op and post-op ROM, 131 (53%) patients had pre-op and 1 yr post-op arm circumference	Greater chest wall tenderness post-XRT. Slower recovery of pre-operative ROM post MRM. No difference in arm circumference.

TABLE 106.1. Arm symptoms in treatment for breast cancer. (continued)

Reference	Primary objective(s)	Study population and follow-up (years)	No. of patients	Type of local treatment	Instruments	Response rate	Results and conclusions
Lin et al. 1993 ¹⁹	Assess impact of ALND	Retrospective review	283 patients	BCS or MRM + ALND	<ul style="list-style-type: none"> • Chart review • Physical examination 1 year: arm circumference, ROM, numbness, and pain. 		Arm swelling (≥ 2 cm) in 16% of women, ≥ 15 degrees of restriction in 17%, numbness in the distribution of the intercostals brachial nerve in 78%, and numbness and pain in 22%.
Keramopoulos et al. 1993 ¹¹	Assess arm morbidity following treatment	Clinic population over a 6-month window	104 patients	BCS or MRM with ALND	<ul style="list-style-type: none"> • Interview • Physical examination: arm circumference measured at 15 cm above and 10 cm below the lateral epicondyles in both hands. 		Late AE (> 3 months postsurgery) occurred in 17%; more frequent when XRT < 6 months postoperative or > 40 LN resected. Limb pain was more frequent > 60 years old or after MRM.
Kiel et al. 1996 ¹⁰	Incidence of AE after BCS and XRT	Cohort q 6 mo for up to 3 years	402 women	BCS + XRT (\pm ALND)	<ul style="list-style-type: none"> • Physical examination: arm circumference measured 15 cm above and 10 cm below the olecranon process. 	183 included in the study	Axillary dissection (> 15 LN) and age (> 55 years) are predictors of AE.
Paci et al. 1996 ⁸	Assess long-term sequelae of breast cancer surgery	Cohort of 5-year survivors	346 survivors	BCS or MRM	<ul style="list-style-type: none"> • Interview • Physical exam: arm circumference measured at six points 	238 women (68.8%)	30.2% had a chronic lymphedema and 18.9% a shoulder deficit. Chronic lymphedema greater after MRM vs. BCS. Early lymphedema more frequent after BCS.
Tasmuth et al. 1996 ⁷	Assess physical symptoms and anxiety/depression	Prospective cohort day—1, 1 month, 6 months, and 1 year after surgery	105 women	MRM vs. BCS with ALND \pm XRT	<ul style="list-style-type: none"> • Interview • Neurologic examination • Grip strength • Arm circumference • STAI + 2 additional questions re depression 	93 women (89%)	Incidence of chronic posttreatment pain higher after BCS vs. MRM. Phantom sensations in 25%. Psychologic morbidity highest before surgery and decreased with time.

Liljegren et al. 1997 ¹²	Assess arm morbidity after sector resection and ALND ± XRT	Prospective randomized trial 3, 12, 24, and 36 months after surgery	381 women	Sector resection and ALND ± XRT	<ul style="list-style-type: none"> • Arm circumference 10 cm above and below the elbow on both arms • Subjective arm symptoms (graded as none, moderate, or severe) 	<p>Arm circumference: 273 pts at 3–12 mo., 270 pts at 13–36 mo., <50 pts at >36 mo.</p> <p>Arm symptoms: 368 pts at 3–12 mo., 335 pts at 13–36 mo., 115 pts >36 mo.</p>	Extent of surgical procedure and young age are determinants of arm morbidity. Arm symptoms are most common during the first year.
Silliman et al. 1999 ¹⁷	To identify risk factors for decline in upper body function	Cross-sectional observational study 3–5 months postoperative	300 women	BCS or MRM ± XRT	<ul style="list-style-type: none"> • Review of medical records • Telephone interview 	213 women (71%)	Extent and type of primary therapy and cardiopulmonary comorbidity associated with a decline in upper body function.
Schrenk et al. 2000 ⁴	Assess postoperative morbidity of the operated arm	Prospective cohort 15–17 months F/U	35 women	BCS or MRM ± XRT with ALND or SN dissection	<ul style="list-style-type: none"> • Physical exam: arm circumference (15 cm above and 10 cm below the lateral epicondyle), numbness, mobility, strength, stiffness • Interview 	35 patients (100%)	SN associated with negligible morbidity compared with ALND.
Lash et al. 2000 ¹⁶	Assess the effect of patient characteristics and therapy on self-reported upper-body function and discomfort	Prospective cohort 5 and 21 months postoperative	388 invited, 303 interviewed	MRM or BCS ± XRT	<ul style="list-style-type: none"> • Review of medical records • Computer-assisted telephone interviews 	Cardiopulmonary comorbidity associated with decline at 5-month interview [OR 2.8, 95% CI 1.3–5.7]. ALND associated with axillary numbness, pain.	
Lash et al. 2002 ¹⁴⁰	Characterize the incidence and predictors of upper body function decline and recovery	Cohort for 5 years	303 women	BCS ± XRT or MRM	<ul style="list-style-type: none"> • Review of medical records • Telephone interviews • SF-36 	82 met case definition for upper-body function decline. 32 met the definition for recovery.	The incidence of decline in the first year was substantially higher than in the subsequent 4 years. Women with less than a high school education had an increased risk of decline (HR 2.3). Recovery was higher for women followed by breast cancer specialist.

BCS, breast-conserving surgery; XRT, radiation therapy; HR, hazard ratio; OR, odds ratio; ALND, axillary lymph node dissection; SN, sentinel node dissection; AE, arm edema; F/U, follow-up; TAL, total axillary lymphadenectomy; EPESE, Established Populations for the Epidemiological Study of the Elderly; GHQ, General Health Questionnaire; STAI, State Trait Anxiety Inventory; SF-36, Medical Outcomes Study Short Form—36 Items.

morbidity was an independent predictor of upper body function decline ($P = 0.006$) in a second study¹⁷; mastectomy and XRT were also associated with significant declines in upper body function. Women treated with an ALND were more likely to report numbness or pain in the axilla (OR, 6.4; 95% CI, 0.2–33).¹⁶

In a prospective cohort study, Segerstrom et al.¹⁸ reported 35 of 93 (37.6%) patients had restricted shoulder range of motion during the first 2 years after surgery; this increased to 49.5% up to 2 years later. Paci et al.⁸ reported that 18.9% of patients experienced shoulder deficit as assessed by physical examination performed 5 or more years after diagnosis. Lin et al.¹⁹ reported 15° or greater loss of ROM in 17% of the patients and 30° or more loss in 4% at 1 or more years after ALND. In contrast, Gerber et al.⁵ found no significant loss in functional ROM (assessed using goniometry) 1 year postoperatively; however, patients undergoing MRM reached their preoperative ROM more slowly than those undergoing BCS.⁵ Pain and chest wall tenderness have been reported following breast surgery.^{5,7,11} Pain was more frequent after BCS in one study⁷ and after mastectomy in another.¹¹

Arm symptoms have been associated with psychologic, social, sexual, and functional morbidity.²⁰ In two case-control studies, women experiencing AE after treatment for breast cancer showed greater psychologic morbidity and greater impact of illness measured using the Psychosocial Adjustment to Illness Scale (PAIS), effects that remained stable over a 6-month period, even if AE was being treated.^{21,22} Maunsell et al. also reported the proportion of women experiencing psychological distress as measured by the Psychiatric Symptom Index (PSI) increased significantly with an increased number of problems in the affected arm.²³

In summary, significant physical and functional sequelae in the arm and upper body may occur as a result of local therapy, especially ALND and axillary XRT. Prospective, population-based studies that include an assessment of patient demographics, risk factors, stage, and treatment coupled with outcome evaluation that involves standardized, blinded assessment of arm symptoms and function preoperatively and during long-term follow-up would expand available information; intervention research to identify effective management approaches is urgently needed.

Menopause

Women with breast cancer may experience early menopause as a result of their treatment. They report a higher frequency of menopausal symptoms than women in the general population.²⁴ The high frequency of menopausal symptoms in breast cancer survivors is caused by several factors²⁵: (1) age at diagnosis (frequently over 50 years), (2) abrupt discontinuation of hormone replacement therapy (HRT) at the time of breast cancer diagnosis, (3) induction of premature menopause by therapy (i.e., chemotherapy and ovarian ablation), and (4) induction of estrogen deficiency symptoms by therapy (e.g., tamoxifen and aromatase inhibitors) (Table 106.2). Chemotherapy is frequently associated with either temporary or permanent amenorrhea. The incidence of amenorrhea is related to the type of chemotherapy regimen, the cumulative dose (particularly cyclophosphamide), and the age of the patient.^{26,27} Surgically induced menopause and premature menopause have been associated with more severe symp-

tom than natural menopause.^{28,29} The health consequences of menopause can be divided into four categories: vasomotor symptoms, genitourinary signs and symptoms, skeletal effects, and cardiovascular effects.³⁰ In a survey of 190 breast cancer survivors, the most common symptoms experienced were hot flashes (65%), night sweats (44%), vaginal dryness (44%), difficulty sleeping (44%), depression (44%), and dyspareunia (26%).³¹ Hot flashes (HF) are more frequent, severe, distressing, and of greater duration in breast cancer survivors compared with controls without breast cancer.³²

Before 2002, HRT was frequently prescribed to healthy women for the control of menopausal symptoms and primary prevention of disease (i.e., cardiovascular disease and osteoporosis). In 2002, the Women's Health Initiative (WHI), a large randomized trial of HRT versus placebo in healthy women, was stopped early because overall health risks of combined estrogen plus progesterone exceeded benefits at an average 5.2-year follow-up.³³ Risks of coronary heart disease, stroke, pulmonary embolism, and invasive breast cancer were increased, whereas risks of colon cancer and hip fracture were minimally decreased. Results for estrogen alone versus placebo are pending.

The use of HRT in breast cancer survivors has been controversial.^{34,35} Four case series,^{36–39} three case-control studies,^{40–43} and one cohort study⁴⁴ failed to identify an increased risk in women who chose to take HRT; two additional studies reported a lower risk of recurrence and death when HRT was used.^{42,43} The studies are susceptible to selection bias, particularly in view of the reluctance of many breast cancer survivors to accept HRT.^{45,46} One randomized clinical trial of HRT in 434 breast cancer survivors was recently stopped for safety reasons because of an unacceptably high risk of breast cancer events [hazard ratio (HR), 3.5; 95% CI, 1.5–8.1] in women receiving HRT.⁴⁷ Women on HRT were advised to discontinue the treatment. Current guidelines^{34,48} that recommend postmenopausal breast cancer survivors be encouraged to consider alternatives to HRT but state that minimal HRT use may be considered in a well-informed patient with severe symptoms will likely be modified in view of these results, with a greater focus on recommending non-hormonal approaches to symptom management.

Vasomotor symptoms are the most common complaint of perimenopausal and postmenopausal women. More than 60% of postmenopausal women experience hot flashes, and one-third of those find them nearly intolerable.⁴⁹ HRT relieves HF in 80% to 90% of women who initiate treatment.^{50–52}

Progestational agents (e.g., megestrol acetate, medroxyprogesterone acetate, and depo-Provera) decrease HF by 85%.^{53–57} Herbal remedies, including soy products and black cohosh, have been reported to minimally decrease HF or have no effect. Vitamin E (800 IU/day) minimally decreases HF (i.e., one fewer HF/day). Clonidine is modestly active in reducing hot flashes. Selective serotonin reuptake inhibitors (SSRIs) such as venlafaxine and paroxetine have also been shown to significantly reduce HF. Possible interactions between SSRIs and selective estrogen receptor modulators (SERMS) are being evaluated. Gabapentin (widely used in neurologic disorders) has been recently reported to reduce HF scores.⁵⁸ Most of these trials have evaluated the short-term effect (e.g., 4–12 weeks); long-term effects have not been addressed.

Severe symptoms of urogenital atrophy occur in nearly half of postmenopausal women surviving breast cancer.

Lubricants and moisturizers have been shown to be helpful but do not completely relieve symptoms. Very low dose vaginal estrogen creams can reverse atrophy but systemic absorption of estrogen may occur. Newer methods of estrogen delivery include a ring device (Estring; Pfizer, New York, NY). This device provides almost complete relief of symptoms and minimal systemic absorption⁴⁸; however, recent evidence that lipid levels may be altered⁵⁹ raises concerns about its use.

One randomized trial⁶⁰ evaluated the use of a comprehensive menopause assessment program in breast cancer survivors; the intervention (which did not involve use of estrogen but permitted megestrol acetate and nonhormonal agents such as clonidine) reduced menopausal symptoms and improved sexual functioning when compared with a control arm.

Bone loss occurs at a rate of 1% to 5% per year and is greatest during the first 5 years after natural menopause.⁶¹ Chemotherapy-induced ovarian failure causes more rapid and significant bone loss.⁶² Tamoxifen in premenopausal, but not postmenopausal, women and aromatase inhibitors have also been associated with increased bone loss. Bone density should be monitored in survivors.⁶³ Preventive measures such as proper intake of vitamin D and calcium, regular exercise, and counseling about the relationship between cigarette smoking, alcohol, and bone loss should be initiated in all patients. Pharmacologic approaches currently recommended for survivors include (1) bisphosphonates (alendronate, risedronate), (2) SERMs (raloxifene), and (3) calcitonin.

The risk of coronary heart disease increases with increasing age.^{64,65} HRT in the primary and secondary prevention of coronary heart disease has not been shown to reduce cardiac events in four large randomized clinical trials.^{33,66,67} Management of known risk factors and encouragement of lifestyle modification are warranted.⁶⁸

Pregnancy

Limited data exist on the effect of pregnancy on breast cancer outcome. Based on the experience at major institutions⁶⁸⁻⁷¹ and population-based registries,^{68,72,73} women who become pregnant after a diagnosis of breast cancer appear to have similar breast cancer outcomes to those who do not. Selection biases may be responsible for these results. Prior chemotherapy does not appear to have teratogenic effects in future pregnancies^{74,75}; however, local breast cancer treatment (i.e., surgery and XRT) may affect the ability to lactate after BCS.^{68,76,77} Breast cancer and pregnancy have been recently reviewed (see Chapter 99).^{78,79}

Fatigue

Fatigue is often experienced during, and shortly after, cancer treatment. The level of fatigue in a large survey of breast cancer survivors (1-5 years after initial diagnosis) was comparable with that of age-matched controls using the RAND-36 questionnaire.^{80,81} However, severe and persistent fatigue was experienced in a subgroup of survivors and was related to depression and pain. In a second smaller cohort study, fatigue (measured using a number of fatigue questionnaires including the RAND-36) was more common in breast cancer survivors than in age-matched controls.^{81,82}

Second Malignancies

Second malignancies (e.g., angiosarcoma, sarcoma, and skin cancer) at the site of previous local treatment for breast cancer occur in less than 1% of survivors (see Chapter 111).⁶⁸

Cardiac Toxicity

The most common form of anthracycline-induced cardiotoxicity is chronic cardiomyopathy.⁸³ The risk of cardiomyopathy is principally dependent on the cumulative anthracycline dose and may occur years after therapy.⁸⁴ Prospective monitoring of signs and symptoms of congestive heart failure (CHF) revealed a 9% risk of CHF after 450 mg/m² doxorubicin and 25% after 500 mg/m²⁸⁵; this risk may be higher when doxorubicin is used in combination with paclitaxel.⁸⁶ Prospective cardiac monitoring using MUGA scans has been included in more recent clinical trials of breast cancer treatment including anthracyclines, taxanes, and herceptin. Based on a recent randomized trial,⁸⁷ cardiotoxicity is particularly pronounced when herceptin is combined with either adriamycin or epirubicin plus cyclophosphamide (any cardiotoxicity = 27%, grade 3-4 cardiotoxicity = 10%). Bradycardia has been reported with the use of paclitaxel alone.

Surveillance

Evidence-based surveillance strategies for breast cancer survivors have been established.⁶³ There are sufficient data to recommend monthly breast self-examination, annual mammography of the preserved and contralateral breast, as well as a careful history and physical examination every 3 to 6 months for 3 years, then every 6 to 12 months for 2 years, then annually. Data are not sufficient to recommend routine radiologic investigations or blood work (including tumor markers). Primary care of breast cancer survivors has also been reviewed.⁶⁸ Grunfeld et al.⁸⁸ conducted a large randomized trial of specialist versus general practitioner care in Great Britain; patients were more satisfied with care provided by the latter, with no differences in medical outcomes being observed, although only a small number of medical events were reported.

Psychosocial Status and HRQOL

Breast cancer is a stressful event that can perturb psychologic equilibrium and reduce HRQOL in the short-term⁸⁹⁻⁹²; recent survivorship research has evaluated long-term sequelae. Early studies involved mainly small convenience samples (maximum, 61 survivors), descriptive designs, and interview-based measurements.⁹³⁻⁹⁷ Key results of these studies include observations that the majority of survivors are fairly to very satisfied with their lives 8 years after diagnosis despite thoughts of recurrence reported by 50%⁹³; that survivors have a positive perception of life and attach less importance to trivial stressors even though fear of recurrence is a major concern⁹⁴; and that the majority of survivors thrive despite experiencing problems related to breast cancer and its treatment.⁹⁵ Several ongoing issues were identified in a focus group of 10-year survivors: integration of disease into current life, change in relationship with others, restructuring life perspective, and unresolved issues.⁹⁶

TABLE 106.2. Menopause in breast cancer survivors.

Reference	Primary objective(s)	Study population and follow-up (years)	No. of patients	Instruments	Response rate	Results and conclusions
Guidozzi et al. 1999 ¹⁴¹	Determine whether ERT adversely affects outcome of survivors	Prospective descriptive study of women 8–91 months postdiagnosis treated with oral continuous opposed ERT observed for 24–44 months	24	<ul style="list-style-type: none"> History and physical exam 3×/year Mammogram yearly. BSE taught to the patient. Appointment with surgeon annually. 		No recurrences.
Brewster et al. 1999 ¹⁴²	Evaluate the outcome of patients who elected ERT	Convenience sample treated with oral continuous ERT for at least 3 months starting 41 months (range 0–401 months) postdiagnosis; median F/U 30 months	145	<ul style="list-style-type: none"> Routine surveillance by an oncologist 	145/168	13 recurrences (9%).

QOL was compared for 3 groups based on the time since diagnosis: <4 years, 4-8 years and >8 years	123	Questionnaires including: <ul style="list-style-type: none"> Demographic data QOL Breast Cancer version Questionnaire QOL Self Evaluation Questionnaire 	No significant difference between users and nonusers. Near-normal QOL after a 4-year adjustment period.
Carpenter et al. 2002 ³²	Compare the HF symptom experience and related outcomes between survivors and healthy women	Descriptive, cross-sectional, comparative study of survivors (mean of 39 months postdiagnosis) and age-matched healthy female volunteers	69 survivors/ 63 age-matched	Questionnaires: <ul style="list-style-type: none"> Demographic and disease/treatment information Gynecologic and reproductive history form Hot flash questionnaire and diary POMS-SF PANAS HFRDIS 	Hot flashes are a significant problem for survivors. Survivors with severe hot flashes reported significantly greater mood disturbance, higher negative affect, more interference with daily activities (sleep, concentration, and sexuality), and decreased QOL.
Biglia et al. 2003 ⁴⁶	Determine the prevalence of menopausal symptoms, explore attitudes toward HRT or other treatments and the willingness to take estrogen	Convenience sample (early breast cancer) Mean F/U not stated	250	<ul style="list-style-type: none"> 35-item questionnaire formulated for this study 	Survivors are interested in treatments that may improve their QOL, but fear of HRT persists among survivors and their doctors.
Holmberg 2004 ⁴⁷	To examine impact of HRT on events in survivors	RCT of HRT vs. no therapy in survivors	434	<ul style="list-style-type: none"> Clinical examination, mammography 	RCT stopped early because of excess events in survivors treated with HRT (relative hazard 3.5, 95% CI 1.5-8.1).

HRT, hormone replacement therapy; ER, estrogen replacement therapy; RCT, randomized clinical trial; F/U, follow-up; POMS-SF, Profile of Mood States-Short Form; PANAS, Positive and Negative Affect Scale; HFRDIS, Hot Flash-Related Daily Interference Scale; BSE, breast self-examination; QOL, quality of life.

Second-generation studies used stronger designs, more standardized measurement approaches, and larger sample sizes. They were more often population based and/or used control groups of women without breast cancer. They frequently used generic instruments (applicable to healthy and medically ill individuals) for which normative data are available. One generic instrument that has been widely used in survivorship research is the Medical Outcomes Study Short Form—36 (MOS SF-36), a reliable and valid measure of HRQOL. It has 36 items rated on a 5-point Likert scale. There are eight subscales grouped in two composite scales: Physical Component Summary (PCS) and Mental Component Summary (MCS). Cancer-specific instruments, which measure attributes that are specific or unique to cancer patients, were also used in a large number of studies. Due to their nature, normative data for the general population are not available for these instruments. Nonetheless, they provide data that can be used to describe groups of survivors, evaluate change in their status over time, or compare different groups of survivors. Specific examples of these instruments are discussed.

Psychologic Status and Overall HRQOL

Many studies have examined psychosocial status and HRQOL in breast cancer survivors as a single group. Results of these studies are reviewed first, followed by a discussion of the status of defined subgroups of survivors.

Several cross-sectional, case-control, and cohort studies using the MOS SF-36 have reported scores on the Mental Component Summary scale or one of its subscales in breast cancer survivors 2 to 8 years postdiagnosis to be comparable with, or better than, scores obtained from either the general population or individuals with other chronic illnesses^{80,98–102} (Table 106.3). Dorval et al.¹⁰³ used the Psychiatric Symptom Index (PSI), another generic instrument that measures the presence and intensity of four psychologic dimensions (depression, anxiety, cognitive impairment, and irritability) in a case-control study; no difference was found between 8-year survivors and controls randomly matched for age and residence. Studies using the generic measure of mood, the Profile of Mood States (POMS), reported women with breast cancer who were 2 years postdiagnosis to have scores comparable to published norms⁸⁰ or to a control group.¹⁰⁴ Taken together, these observations using generic instruments provide little evidence of impaired long-term HRQOL or psychologic status in breast cancer survivors compared to the general population.

A cancer-specific instrument, the QOL Cancer Survivors Tool (QOL-CS), yielded psychologic subscale scores that were worse than those for the social, spiritual well-being, and physical subscales 5.7 years postdiagnosis.¹⁰⁵ The inclusion of specific questions related to fear of recurrence of the cancer, which are not explicitly evaluated in generic questionnaires, and the specific population studied (members of the National Coalition for Cancer Survivorship) may have contributed to this result. Mosconi et al.¹⁰² used the European Organization for Research and Treatment of Cancer Quality of Life Questionnaire Core-30 (EORTC QLQ-C30), a multidimensional cancer-specific questionnaire, to study Italian breast and colon cancer survivors. Overall HRQOL was reported to be

good, and scores for emotional functioning did not differ between the two groups of survivors.

Physical Functioning

Earlier, we discussed specific physical symptoms in breast cancer survivors. The MOS SF-36 has been employed to measure general physical functioning. Physical functioning scores in survivors have been reported to be similar to,¹⁰² or better than, published norms for individuals with other chronic illnesses^{80,106} or the general population.¹⁰⁶ However, some studies^{98,99,101} reported physical functioning scores in survivors that were lower than norms for the general population. A modest decline in physical functioning over time (mean, 6.3 years) has been reported by Ganz et al.⁹⁹; the magnitude of the decline was small and was thought to be related to aging. Dow et al.¹⁰⁵ studied members of the National Coalition for Cancer Survivorship, a group that may not be representative of all cancer survivors. Overall physical well-being scores were good compared with other domains (e.g. psychologic); however, problems with components of physical well-being (i.e., pain, energy) were identified.

Thus, evaluation of general physical functioning in breast cancer survivors has yielded inconsistent results in comparison with published norms for the general population. However, differences from general population norms are small and may be due to effects of age.

Sexual Functioning

Breast cancer diagnosis and treatment can adversely affect sexuality. Surgical treatment of the primary tumor can affect body image, while systemic therapy can cause premature menopause or vaginal dryness. Measurement of the impact of breast cancer and its treatment on sexual functioning is challenging because few instruments specifically address this aspect of HRQOL. These measurement challenges may be compounded by a reporting bias if survivors are reluctant to respond to questions about sexual functioning. The use of specific questionnaires (e.g., the Sexual Activity Questionnaire, SAQ) in recent studies permits a more detailed assessment than is possible using more general multidimensional questionnaires.

Matthews et al.⁹⁸ administered the Satisfaction with Life Domains Scale for Cancer (SLDS-C) to breast cancer survivors (American Cancer Society Reach to Recovery volunteers) a mean of 8.6 years postdiagnosis. Scores for sexual functioning were worse than for other aspects of functioning. Dow et al.¹⁰⁵ also reported that satisfaction with sex life was the worst of all domains on the Functional Assessment of Cancer Therapy—General (FACT-G) in 294 survivors taking part in a peer-support group 5.7 years postdiagnosis. In contrast, Kurtz et al.¹⁰⁷ reported 5- to 10-year breast cancer survivors had high levels of sexual satisfaction on the Long Term Quality of Life Instrument.

Ganz et al.^{99,106} used questionnaires that specifically address sexual functioning in two recent studies. In a cross-sectional study of 864 women,¹⁰⁶ use of the Watts Sexual Functioning Questionnaire identified modest increases in sexual dysfunction with aging but use of the Cancer

Rehabilitation Evaluation System (CARES) identified no impairment in sexual satisfaction. Sexual functioning was significantly worse in those who received chemotherapy (but not tamoxifen), particularly in women who were menopausal (either naturally or secondary to treatment) and in women under 50 years of age. Using the SAQ in their cohort study of 763 long-term breast cancer survivors, this group also reported sexual discomfort to be greatest in women who received chemotherapy but identified no differences in sexual pleasure or sexual habits.⁹⁹ In summary, sexual functioning appears to be adversely impacted in breast cancer survivors, particularly in younger women who receive adjuvant chemotherapy.

Social Functioning and Marital Status

Studies evaluating social functioning in breast cancer survivors have usually shown little evidence of impairment. The social functioning subscale of the MOS SF-36 has yielded similar scores in breast cancer survivors and in the general population in the majority of studies.^{80,98-102} Use of the EORTC QLQ-C30 has also demonstrated high level of social functioning in breast cancer survivors.¹⁰² Use of the MOS Social Support Measure also showed no difference between breast cancer patients with a control population^{99,103} and no change according to time elapsed since diagnosis.⁹⁹

In a cohort of 763 survivors, there was no significant change in marital status over 5 years of follow-up.⁹⁹ In another cohort followed for 8 years, no difference in divorce or separation rates at 12 months, 18 months, and 8 years after diagnosis was identified in survivors compared to age-/residence-matched women.¹⁰⁸ In survivors, low marital satisfaction at 3 months predicted future marital difficulties (16.7% divorced at 1 year versus 2.1% in those with high marital satisfaction; $P = 0.02$). Women not in a partnered relationship expressed concerns about dating, telling about cancer, and fear of initiating sexual relationship.^{80,106}

Finally, in their follow-up of 817 long-term breast cancer survivors, Ganz et al. reported more than two-thirds had stable household income and 20% had increased income (versus 12% who had decreased income) since diagnosis.⁹⁹ Eighty percent reported no change in employment status; a minority moved from full- to part-time work or retired. Marital status did not change. In a separate study, this group reported that 90% of survivors had health insurance 2 or 3 years postdiagnosis, although some had their premiums increased or had switched to a spouse's plan.⁸⁰ Most (65%) were working or doing volunteer work.

Thus, there is little evidence that social or marital functioning or employment is adversely affected in survivors. Specific concerns about dating have been reported, especially in young, unpartnered women.

Cognitive Functioning

In 1995, Wieneke and Dienst¹⁰⁹ published the first report of cognitive dysfunction in women with breast cancer (Table 106.4). To date, four reports have evaluated cognitive functioning during and within the first 2 years postchemotherapy using a battery of neuropsychologic tests¹⁰⁹⁻¹¹¹ or the High

Sensitivity Cognitive Screen,¹⁰⁴ a valid reliable instrument that predicts overall qualitative results of formal neuropsychologic testing. All four studies identified significantly lower cognitive functioning in women receiving adjuvant chemotherapy (with or without anthracyclines) compared with those not receiving chemotherapy or to a control group without breast cancer. Cognitive dysfunction was more prevalent in women who received high-dose chemotherapy in one study.¹¹¹ Interestingly, there appears to be little correlation between cognitive functioning as assessed by the test battery and self-reported by the patient.^{110,111}

Studies evaluating cognitive dysfunction beyond 2 years have yielded conflicting results. Schagen et al.¹¹² reported improvement in performance in all chemotherapy groups between 2 and 4 years posttreatment. Ahles et al.¹¹³ reported patients who had been diagnosed at least 5 years earlier had greater cognitive impairment on a battery of neuropsychologic tests and were more likely to report memory problems on the Squire Memory Self-Rating Questionnaire if they had received adjuvant chemotherapy.

Cognitive dysfunction in women receiving adjuvant chemotherapy is an emerging area of interest in survivorship research. Future research should identify risk factors for this complication and evaluate potential interventions to minimize its impact.

Spirituality

Spirituality is often poorly addressed in multidimensional questionnaires. Based on the holistic Ferrell¹¹⁴ model of QOL in breast cancer survivors (physical, psychologic, social, spiritual), Wyatt et al. developed the Long-Term Quality of Life (LTQL) instrument, which includes a philosophical/spiritual view dimension.¹¹⁵ Kurtz et al.,¹⁰⁷ using this instrument in long-term (more than 5 years) survivors, reported a positive spiritual outlook to be associated with good health habits and an increased likelihood of being supportive of others. In their cohort of long-term survivors (6.3 years), Ganz et al.⁹⁹ reported a positive impact of breast cancer on religious beliefs and activities, an effect that tended to be more pronounced in young survivors. Dow et al.¹⁰⁵ used the QOL-CS to evaluate spiritual well-being in members of the National Coalition for Cancer Survivorship. Although fears about future cancer and uncertainty about the future were identified as important concerns, beneficial spiritual outcomes including hopefulness and having a purpose in life as well as positive and spiritual change were also reported. Further research is needed to confirm these early observations, using population-based controls as a comparison group.

Diet and Complementary and Alternative Medicine

Maunsell et al.¹¹⁶ evaluated diet during the first year after breast cancer diagnosis in a group of 250 women who were surveyed with a standardized interview about diet changes. Forty-one percent of women reported a change in their diet; these changes were positive (i.e., healthy) in over 90%. Women under 50 years and those who were more distressed

CMF, cyclophosphamide, methotrexate, 5-fluorouracil; Chemo, chemotherapy; RCT, randomized controlled trial; FEC, 5-fluorouracil, epirubicin, cyclophosphamide; BC, breast cancer; neuropsychologic tests, a battery of tests were used; Cf., see reference for more details; EORTC-QLQC-30, European Organization for Research and Treatment of Cancer–Quality of Life Questionnaire C-30^{*}; HSCL, Hopkins Symptom Checklist-25; HSCS, High Sensitivity Cognitive Screen^{*}; POMS, Profile of Mood States^{*}; SMSRQ, Squire Memory Self-Rating Questionnaire; CES-D, Center for Epidemiological Study-Depression^{*}; STAI, State-Trait Anxiety Inventory^{*}; FSI, Fatigue Symptom Inventory^{*}.

at diagnosis were most likely to change their diets ($P = 0.0001$).

Burstein et al.¹¹⁷ evaluated complementary and alternative medicine (CAM) use during the first 12 months after breast cancer diagnosis (see Chapter 15). Twenty-eight percent of 480 women began an alternative therapy after diagnosis; these women tended to be younger and more educated. Ganz et al.⁹⁹ reported vitamins and herbal preparations were used by 86.6% and 49.3% of breast cancer survivors, respectively. More than half (60.7%) altered diet or used dietary supplements. Few women were using psychosocial or counseling therapies (13%) or attending a cancer support group (5.5%). More than one-third reported enhanced physical activity postdiagnosis. Lee et al.¹¹⁸ conducted telephone interviews in 379 women (black, Chinese, Latino, white) 3 to 6 years after breast cancer diagnosis. At least one alternative therapy was used by 48.3%. Most common approaches therapies were dietary change (26.6%), herbal/homeopathic medication (13.5%), psychologic or spiritual healing (30.1%), and physical approaches such as yoga or acupuncture (14.2%). Therapies were used for brief periods, usually for 3 to 6 months. Women who used alternative therapies were younger and more educated.

Thus, more than one-third of breast cancer survivors use at least one kind of alternative therapy. Nonpharmacologic supplements appear to be most commonly used. Further research is needed to evaluate duration of use and changes over time in use of CAMS, comparing survivors to healthy controls.

Psychosocial Status and HRQOL in Defined Subgroups

Consideration of breast cancer survivors as a group may mask important differences in subgroups and over time. In this section we summarize research examining subgroups defined by age, ethnicity, and treatment (surgery, adjuvant therapy) and according to time elapsed since diagnosis.

Age at Diagnosis

Age at diagnosis appears to be an important determinant of survivorship. This may be due, in part, to treatment: women who receive chemotherapy, many of whom are younger, experience greater long-term physical and sexual sequelae (see following discussion); psychosocial effects of mastectomy may also differ with age, especially in the short term.¹¹⁹ However, Ganz et al.¹⁰⁶ reported poorer sexual functioning in younger survivors who became menopausal, regardless of whether they received chemotherapy. Vinokur et al.¹²⁰ compared survivors (50% of whom were followed more than 5 years) to controls participating in a breast cancer screening program; younger survivors had more problems in psychosocial adjustment while older survivors had more physical difficulties. Cimprich et al.¹²¹ reported similar findings in 105 survivors using the QOL-CS. Women over 65 at diagnosis had worse scores in the physical domain while those diagnosed before 44 years of age had poorer scores in the social domain. Women diagnosed between 45 and 65 years of age had the best overall HRQOL. Two pivotal studies examining survivorship issues in younger¹²² and older women¹²³ have been reported recently.

In the first of these, a cohort of 577 patients diagnosed at age 50 or younger was assembled for the Cancer and Menopause Study a mean of 5.9 years postdiagnosis.¹²² Most had received adjuvant chemotherapy. Physical functioning was good. The youngest women reported poor mental health, less vitality, and poorer social and emotional functioning (MOS SF36). In the second study, 691 women aged 65 years of age or more at diagnosis were evaluated 3, 6, and 15 months after surgery.¹²³ Physical and mental functioning (MOS SF-36) showed significant declines during the year of follow-up. Declines in the former were associated with greater comorbidity and receipt of adjuvant chemotherapy. In contrast, the CARES Psychosocial Summary and Medical Interaction Scales showed significant improvement over time. Social support was lowest in women over 75 years. The discrepant results obtained with the MOS SF-36 Mental Health Inventory and the CARES Psychosocial Summary Scale were explored: the former appeared to be influenced to a greater extent by declines in physical functioning and the latter appeared to reflect adaptation and adjustment to cancer-specific concerns. In summary, younger age is associated with lower mental and emotional well-being. Older women experience more physical problems, partly the result of aging.

Ethnicity

The impact of ethnicity on survivorship has been poorly studied. Ashing-Giwa et al.¹²⁴ investigated HRQOL in white and African-American survivors. Response rate among African-Americans was significantly lower than among whites (44% versus 65%). The former were more often single, had a lower income, and lower HRQOL. Multivariate analyses revealed that 45% of the variance in HRQOL was accounted for by general health perception, life stress, partnership status, and income; ethnicity was not a significant contributor. The authors concluded that African-American and white report favorable overall QOL; differences are secondary to life burden and socioeconomic factors but not to ethnicity per se.

Primary Surgical Procedure

The primary surgical procedure performed also appears to impact survivorship (Table 106.5). Maunsell et al.¹¹⁹ reported that psychologic distress (measured using the PSI) at 3 months was worse in women undergoing BCS; this difference was not present at 18 months. Age modified this effect; the greater psychologic distress at 3 months was not present in women under 40 years. Follow-up 8 years after diagnosis found that psychologic distress declined over time and was similar to that in the general population.¹²⁵ Ganz et al.,¹²⁶ using a battery of general questionnaires, reported few differences in HRQOL with respect to type of surgery; however, women undergoing mastectomy had more problems with clothing and body image than those undergoing BCS. Mosconi et al.¹⁰² found none of the EORTC QLQ C-30 domains to be affected by the type of surgery. Janni et al.¹²⁷ studied 76 pairs of patients who had undergone either a mastectomy or BCS a mean of 3.8 years earlier; women undergoing mastectomy were significantly less satisfied with their cosmetic result and change in appearance and were twice as likely to be stressed by their physical appearance secondary to the surgery. No

differences were seen in EORTC QLQ-C30 scores. Psychosocial adjustment measured using the Social Adjustment Scale was similar in the mastectomy and BCS treatment groups; however, women undergoing mastectomy felt mutilated and less attractive.¹²⁸ A companion study to EORTC trial 10801 comparing mastectomy to BCS and radiotherapy surveyed 278 patients 2 years after treatment.¹²⁹ Body image and satisfaction with treatment were better in the BCS. There was no difference in fear of recurrence. Patients considered their cosmetic results to be more acceptable than the surgeon did at several time points. Other studies have reported beneficial effects of BCS on body image.^{130,131} In summary, BCS leads to enhanced body image and, in younger women (less than 40), it may protect against psychologic distress. No differences in depression were identified in one study of spouses of women undergoing mastectomy or BCS.¹³²

Breast Reconstruction

Breast reconstruction is offered to reduce the adverse impact of mastectomy. Rowland et al.¹³³ studied a cohort of 1,957 long-term (1 to 5 years) survivors in Los Angeles and Washington. Women undergoing mastectomy had more physical symptoms related to the surgery regardless of whether they had reconstruction. No differences in overall HRQOL or worry about cancer returning were identified in women undergoing BCS, mastectomy alone, or mastectomy with reconstruction. Body image and feelings of sexual attractiveness were significantly better after BCS compared with mastectomy with or without reconstruction. Women who had reconstruction were younger and better educated than those in the other two groups. They also expressed greater concern that their cancer had a negative impact on their sex life. Nissen et al.¹³⁴ reported that women who had a mastectomy with reconstruction had greater mood disturbance and poorer well-being 18 months after surgery compared with those who did not undergo reconstruction.

Adjuvant Therapy

There is growing evidence that adjuvant therapy adversely affects survivors' HRQOL. In a cross-sectional survey, Ganz et al.¹⁰⁰ reported global HRQOL (measured using the Ladder of Life and the MOS SF-36) to be similar 1 to 5 years postdiagnosis in women who received chemotherapy and/or tamoxifen compared with those who received no adjuvant therapy. However, physical and sexual functioning were worse in women receiving adjuvant therapy. A mean of 6.3 years postdiagnosis, the no-adjuvant treatment group reported more favorable scores for global HRQOL (Ladder of Life) and most domains of the MOS SF-36 than those who received adjuvant therapy.⁹⁹ There were no differences in emotional functioning (MOS SF-36, Center for Epidemiology Study—Depression). The sexual discomfort scale (SAQ) and sexual functioning (CARES) were significantly worse in women who received adjuvant chemotherapy compared to those who received either tamoxifen or no therapy. Mosconi et al.¹⁰² reported slightly better HRQOL (EORTC QLQ-C30) in women treated with tamoxifen versus those who received either chemotherapy or no adjuvant therapy. In contrast, participants of an adjuvant trial of chemotherapy versus no treatment who were 9.6 years postdiagnosis reported no

differences in sexual functioning/enjoyment according to treatment arm.¹³⁵ Small sample size (119 patients) and the long interval after diagnosis may account for these results. In summary, the majority of studies have identified long-term adverse effects of adjuvant therapy, notably chemotherapy.

Time Elapsed Since Diagnosis

The status of survivors also varies according to time elapsed since diagnosis. Ganz et al.⁹⁹ re-evaluated a cross-sectional sample of survivors who had been recruited 1 to 5 years postdiagnosis when they were a mean of 6.3 (minimum, 5) years postdiagnosis. Small decreases in physical functioning, role functioning-physical, bodily pain, and general health (MOS SF-36) over time were thought to be related to aging. Sexual activity with a partner declined significantly and specific symptoms persisted, especially in women receiving chemotherapy. In an earlier cohort study, Ganz et al.⁸⁰ compared HRQOL measured using the POMS and Functional Living Index for Cancer at 2 and 3 years after surgery to that between 1 month and 1 year after surgery. Most scores improved between 1 month and 1 year,¹²⁶ but there was no subsequent improvement. This might reflect ongoing rehabilitation problems, as most CARES scores worsened between 1 and 3 years postdiagnosis. Holzner et al.¹³⁶ evaluated 87 breast cancer survivors using two cancer-specific questionnaires. Women who were more than 5 years postdiagnosis had significantly worse global QOL, role functioning, sexual functioning, and enjoyment than those 1 to 2 or 2 to 5 years postdiagnosis. However, women more than 5 years postdiagnosis were slightly older than those 1 to 2 and 2 to 5 years postdiagnosis (55.1 years old versus 52.9 and 52.5 years old, respectively). Women 2 to 5 years postdiagnosis had less impairment in emotional and social functioning than those diagnosed earlier or later. In contrast, Kessler et al.,¹³⁷ studying a convenience sample of 148 breast cancer survivors 0.3 to 19 years postdiagnosis, reported that overall QOL and life satisfaction were high and that greater time since diagnosis and lesser extent of disease were associated with improved global QOL. Thus, HRQOL and most aspects of physical and psychosocial functioning improve during the first few years after breast cancer diagnosis. However, specific treatment-related problems and symptoms persist long term, and there is some evidence of HRQOL decline 2 to 5 years after diagnosis, possibly related to aging.

Conclusions

Long-term survivors have a high level of functioning and good HRQOL, often comparable to that of the general population. However, many survivors experience physical symptoms (notably arm symptoms and early menopause) and reduced sexual functioning related to their diagnosis and treatment. Young women, those receiving chemotherapy, and those with comorbidity may be at greatest risk. Younger women experience greater psychologic distress. Cognitive dysfunction has recently been identified in women receiving adjuvant chemotherapy. BCS leads to enhanced body image; however, reconstruction does not add a major benefit in terms of QOL. Quality of survivorship in different ethnic groups has been inadequately investigated.

A considerable body of observational research has been conducted in breast cancer survivors. Although there are knowledge gaps that should be addressed in further observational research, there is also a need for research to develop and evaluate interventions that will reduce the adverse impact of breast cancer diagnosis and treatment which has been identified in research to date. Primary areas for intervention research include psychologic distress and sexual dysfunction in younger women; cognitive dysfunction, sexual dysfunction, and fatigue in women receiving chemotherapy; and body image in women undergoing mastectomy with or without reconstruction.

Medical and Psychosocial Issues in Prostate Cancer Survivors

Tracey L. Krupski and
Mark S. Litwin

Of the more than 200,000 men diagnosed each year with prostate cancer in the United States,¹ most live with their disease or the effects of treatment for many years.² Although many men remain asymptomatic throughout their lives, others face a multitude of physical and psychosocial challenges. Because the duration of survival is typically long, patients and their families are particularly interested in optimizing their quality of life. At the generic level, health-related quality of life (HRQOL) encompasses an individual's perceptions of his or her own health and ability to function in the physical, emotional, and social domains.^{3,4} In prostate cancer survivors, the medical outcomes of urinary, bowel, and sexual impairments that result from treatment will influence the rest of the patient's life. The psychosocial aspects of HRQOL are impacted by the intimate nature of these medical side effects. Urinary leakage and erectile dysfunction may cause both private and public social embarrassment. In addition, such treatment-related complications may be compounded by the additional stressors associated with aging, such as retirement or death of peers.⁵ Nearly one-third of men diagnosed with prostate cancer in a genitourinary clinic had levels of psychologic distress that met criteria for anxiety disorder.⁶

This chapter examines the medical and psychosocial issues impacting men with early- and late-stage prostate cancer. Late-stage patients are included because the course of prostate cancer recurrence is often indolent. Therefore, men with prostate cancer typically "survive" to require secondary treatments that compound existing medical problems. For men with early-stage tumors, the focus is on the repercussions of treatment decision on medical outcomes, the partner, decisional regret, and fear of recurrence. For men with advanced disease, the focus is on these issues with the addition of end-of-life decisions. The chapter concludes with emerging research challenges.

Early-Stage Medical Issues

Survivor Demographics

The strongest risk factors for prostate cancer are age and positive family history.^{7,8} When survival rates are compared without controlling for stage, Caucasian men have improved survival rate compared to African-American, Hispanic, and American Indian men.⁹⁻¹¹ Survival rates are favorably influenced by higher socioeconomic status and the presence of a spouse or partner.^{12,13} African American and Hispanic men bear a disproportionately high prostate cancer burden when compared to Caucasians.¹⁴ Numerous studies have confirmed that both African-American and Hispanic men present with more-advanced [higher initial prostate-specific antigen (PSA) and T stage] prostate cancer than do non-Hispanic white men.^{1,10,15-17} Debate exists as to whether this is a function of underlying differences in biology or disparities in access to health care. Ross et al.¹⁸ found African-American men to have testosterone levels that were 15% higher than white men, suggesting a possible endocrine explanation for their increased risk. Because access to the healthcare system is influenced by socioeconomic parameters such as income and insurance status, African-American and Hispanic men often lack consistent high-quality medical care.^{19,20}

Treatment Decision Making and the Effect on Survivorship

The impact of treatment effects on HRQOL is the major issue affecting posttreatment psychosocial quality of survivorship. Since the advent of prostate-specific antigen (PSA) screening in the early 1990s, most men present with early-stage disease, leading them to consider a variety of issues related to treatment. Those diagnosed with early-stage prostate cancer are

challenged to choose among several treatment options (radical prostatectomy, radiation therapy, or watchful waiting) because studies have not yet proven an overall survival benefit of one treatment option over another.^{21,22} The cure rates, defined as no evidence of biochemical (PSA) recurrence, for early-stage disease following radiation therapy or surgery range from 70% to 94%.²³⁻²⁶ However, the medical outcomes do differ among these treatment options.

Medical Outcomes

Prostate cancer survivors face three long-term medical problems following primary treatment: incontinence, erectile dysfunction, and recurrence. The likelihood of these side effects will vary depending on the primary treatment chosen, stage of disease, and need for additional treatments. However, to date, no randomized controlled trials evaluating brachytherapy versus prostatectomy have been performed. The American College of Surgeons Oncology Group initiated such a trial but it was closed in 2004 for lack of enrollment. Cancer control outcomes and complication rates are inferred from predominantly retrospective, single-institution studies using different endpoints.

POSTSURGICAL INCONTINENCE

Even with improved surgical technique, urinary leakage after operative intervention persists (Table 107.1). Centers of excellence often report high rates of continence and potency whereas community-based outcomes may be different.²⁷⁻³⁰ Causative factors for disparate outcomes include differences in patient selection, surgical volume, surgical skill, and definitions used for particular outcomes.³⁰⁻³⁴ Further, the reporting of symptoms has been shown to be most accurate when elicited with written, confidential surveys that are self-administered and submitted to third parties, rather than by physician assessment.^{35,36}

Time to recovery varies for each condition and may continue for at least 2 years after therapy.³⁷⁻³⁹ Talcott et al.⁴⁰⁻⁴² reported that 12 months after prostatectomy 35% of patients were wearing pads, whereas Walsh et al.⁴⁰⁻⁴² reported this rate to be only 7%, despite using what appears to be the same definition and time point. These differences could be due to surgical technique, but the disparity is striking. Using yet another definition, Catalona and colleagues⁴³ also reported at 12 months that 45% of men under 70 years old claimed total

urinary continence. Indeed, several authors have found that the definition itself influences continence rates. Wei⁴¹ reported continence rates that varied from 43% to 84% depending on whether the definition was total urinary control or zero to one pad per day. Similarly, Krupski et al. found that among men claiming total urinary control, 98% also claimed no pads; however, among those reporting no pads, only 47% reported total control. Hence, total control is the stricter definition.⁴⁴ By 2 years postsurgery, further improvement in urinary control is unlikely. Therefore, men must learn to adapt with any residual incontinence for the rest of their lives. Table 107.1 depicts surgical rates of incontinence.

MANAGEMENT

Posttreatment incontinence may be secondary to bladder dysfunction or sphincteric insufficiency.⁴⁵ The former of these is treated with anticholinergic therapy, timed voiding, and fluid restriction in the evening.⁴⁶ If the etiology of the incontinence is from an incompetent sphincter, bulking agents may be attempted, although long-term results have been mixed at best. Collagen and Durasphere are agents that, if injected in the periurethral space, will increase sphincter competence.⁴⁷ Smith et al.⁴⁸ treated 62 postprostatectomy patients with multiple collagen injections, and one-third achieved social continence. Patients experiencing minimal incontinence (fewer than three pads/day) have the greatest chance of benefiting from a bulking agent.⁴⁹ The definitive therapy for patients with severe incontinence is an artificial urinary sphincter (AUS). After placement of an AUS, 76% were dry.⁵⁰ Appropriate patient selection is important, as mechanical failure, infection, and erosion are known complications.⁵¹

POSTSURGICAL POTENCY

All surgical series have demonstrated that men undergoing radical prostatectomy have more sexual impairment than do age-matched controls.^{43,52,53} The spectrum of reported potency using a similar definition, erections sufficient for intercourse, ranges from 87% to 21% to 14%.^{40,54,55} (Table 107.2).

Because the cavernosal nerves provide the innervation required for erections, the logical assumption would be that preservation of both sets of nerves would lead to higher potency rates. As familiarity and acceptance of nerve-sparing techniques developed, potency rates increased. A community-based urologist employed chart review techniques and reported 71% potency rates after bilateral nerve-sparing

prostatectomy, which is similar to the 86% reported by centers of excellence.^{40,55}

MANAGEMENT

The treatment of erectile dysfunction consists of a stepwise approach beginning with the least invasive therapies progressing to surgical options. The type 5 phosphodiesterase inhibitors (PDEs) constitute the first line of therapy because they are an oral medication. The largest body of evidence surrounds sildenafil, as it has been marketed the longest, and suggests that PDEs increase penile nitric oxide, leading to cavernosal smooth muscle dilation and engorgement.⁵⁶ Younger men who have undergone unilateral or bilateral nerve sparing appear to benefit the most.⁵⁷ Zagaja et al.⁵⁸ found that postprostatectomy patients enjoyed an increasing response rate with highest satisfaction 18 to 24 months after surgery. Local medical therapies require an intraurethral suppository or needle injection into the cavernosal bodies (ICI). The success rate of the intraurethral suppository as measured by successful intercourse at home is reported at 40%.⁵⁹ ICI in postsurgical patients results in 60% to 90% of men developing an erection, but many patients conceptually have difficulty undertaking this therapy.^{60,61} Third-line therapy is a vacuum device; an external vacuum device generates negative pressure, leading to penile engorgement. Soderdahl et al.⁶² randomized groups of men to ICI or an external vacuum device and found a statistical difference in preference for ICI (50%) compared to the vacuum device (27%). Last, a penile prosthesis can result in an active sex life. Although no data specifically relate to postsurgical patients, general function and satisfaction have been reported as around 85%.⁶³ An industry-sponsored multicenter trial demonstrated 5- and 10-year reliability rates of 85% and 71%, respectively.⁶⁴

URETHRAL STRICTURE

Anastomotic stricture has been reported in 0.5% to 10% of patients following surgical treatment of prostate cancer.⁶⁵ Patients will typically present with a decreased force of urinary stream. If left untreated, urinary obstruction and urinary retention may result. Gentle dilation in the clinic is often sufficient, but for more-severe strictures an endoscopic operative procedure is necessary.⁶⁶

External-Beam Radiation

For prostate cancer, the traditional target radiation dose with a four-field box is 70 Gy. The advent of three-dimensional (3-D) conformal therapy allowed radiation oncologists to increase the dose to 78 Gy. However, several studies documented that morbidity is both dose- and volume dependent.⁶⁷ Although the higher dose results in improved biochemical recurrence for men with high-risk disease, increased complications are also seen.^{67,68} The late complications (2–5 years postprocedure) associated with such dosing follow: persistent incontinence, 29%; grade 2 to 3 bladder toxicity, 9% to 20%; grade 2 or higher rectal toxicity, 14% to 26%; and only 51% retained erections adequate for intercourse.^{67,69,70} Ensuring that less than 25% of the rectum receives the higher dose minimizes these complications. Fowler et al.³⁰ assessed complication rates in Medicare beneficiaries treated with external-beam radiation and compared these rates to a previously published sample of Medicare surgery patients. They noted that radiation patients experienced less incontinence (7% versus 32%), more erections (77% versus 44%), and greater bowel dysfunction (10% versus 4%). Tables 107.3 through 107.5 summarize the complication rates by radiation type. An additional side effect of external radiation not seen with

surgery is fatigue. Immediately after initiation of radiotherapy, patients experience increasing symptoms of fatigue. Longer follow-up reveals the fatigue is temporary, with most men returning to baseline by 6 months.^{71,72}

Brachytherapy

Brachytherapy (BT) is touted as having a very low rate of acute or long-term complications. In the initial 6 months all patients suffer from obstructive or irritative symptoms as a consequence of the radiation prostatitis. A randomized prospective comparison of iodine-125 (¹²⁵I) and palladium-103 (¹⁰³Pd) found that American Urologic Association symptom scores (now called the International Prostate Symptom Score, IPSS) peaked at 1 month and were generally higher in the ¹²⁵I patients. ¹²⁵I patients also experienced slightly higher grade 1 and grade 2 urinary and rectal morbidity.⁷³ The literature, in general, suggests that 2% to 18% of patients experience grade 2 or 3 urinary or rectal morbidity. Examples of such complications include stricture, urethritis, cystitis, proctitis, and rectal ulceration.⁷⁴⁻⁷⁹ Urinary retention has been reported at 10% and incontinence was as high as 6% in the Medicare population.^{80,81} Potency with implants alone is 69% to 76% at 1 to 3 years after implantation.^{82,83} Because even the longest modern BT series span only 12 to 15 years, very little literature exists on long-term complications from BT. Merrick et al. commented that long-term urinary morbidity is restricted to patients having a prior transurethral resection of the prostate. Long-term erectile dysfunction ranges from as low

as 29% without use of a phosphodiesterase inhibitor to as high as 70% at 5 years. The most serious and difficult to treat of the reported complications is a prostatic-rectal fistula.⁸⁴⁻⁸⁸

External-Beam Therapy Combined with Brachytherapy

Controversy still exists over the role for combined radiotherapy in prostate cancer.⁷⁶ Patients at low risk for extracapsular disease (Gleason less than 7, PSA less than 10ng/dL, clinical stage less than T2b) are excellent candidates for brachytherapy monotherapy.^{89,90} However, patients at intermediate or high risk for extracapsular disease may be better served by combined radiotherapy or either form of radiotherapy with the addition of androgen ablation.^{24,91,92} The Radiation Therapy Oncology Group has initiated trial P-0232 [external-beam radiation therapy (EBRT) + BT versus BT] to assess these issues.^{93,94}

MANAGEMENT

Following EBRT or BT, patients are started prophylactically on alpha-blockers to decrease the expected side effects of dysuria and frequency that result from radiation prostatitis. Select patients may stay on the alpha-blocker for 6 to 12 months. Nonsteroidals and antiinflammatory suppositories are used to treat proctitis. For a patient with a large prostate gland (more than 50mm³), androgen deprivation therapy is

employed to “downsize” the prostate, facilitating BT.⁹⁵ The added benefit of androgen deprivation therapy is to decrease the risk of postoperative urinary retention. Sacco et al. have also demonstrated that dexamethasone (4 mg twice daily for 1 week then 2 mg twice daily) instead of androgen ablation also decreases the risk of retention in these patients.⁹⁶ Erectile dysfunction is treated in the same manner as for post-surgical patients as already described.

Prostate-Specific Health-Related Quality of Life

Several cross-sectional surveys have compared health-related quality of life outcomes after brachytherapy, external-beam radiation, and radical prostatectomy. Two studies reported that overall HRQOL was similar between brachytherapy and radical prostatectomy patients, with those undergoing brachytherapy having better urinary control but similar bother.^{97,98} However, in a study of 1,400 patients, Wei et al.⁹⁹ found that men receiving brachytherapy experienced worse outcomes in the areas of urinary, bowel, and sexual HRQOL than did those undergoing either of the other two treatments. This finding contrasts with that of Eton et al.,¹⁰⁰ who reported that brachytherapy patients had the least sexual dysfunction and the best physical functioning of all treatment groups, and with that of Davis et al.¹⁰¹ who reported that bowel bother was worst after external-beam therapy. Direct comparison of such studies is difficult because demographic characteristics, clinical factors, and measurement instruments vary from one investigator to another. Van Andel et al.¹⁰² reported that radiation patients, on average, are 7.9 years older, have lower socioeconomic status, and more often have a higher tumor stage. They also found that radiation patients reported more pain and fatigue, lower overall HRQOL, and worse sexual function than men undergoing surgery.

Early-Stage Psychosocial Issues

Partners

Cancer affects family members as well as patients. Prostate cancer, more so than other malignancies, has been labeled a “relationship disease” because it so profoundly impacts both partners.^{103,104} In fact, studies have found that psychologic distress is equivalent in the prostate cancer patient and his partner.¹⁰⁵ Clearly, once the cancer is discovered, both partners experience increased levels of anxiety compared with healthy couples.¹⁰⁶

Although there is evidence that marital status impacts prostate cancer outcomes, the direction of the effect is mixed. The diagnosis of prostate cancer may evoke anxiety or depression in both partners. The response to this stress can nurture or undermine the relationship. A good relationship can foster healthy coping skills, alleviate distress, and encourage optimism. Increased optimism has been shown to correlate with improved cancer outcomes and survival.¹⁰⁷

Depression/Distress

Being diagnosed with cancer naturally evokes a sense of sadness.¹⁰⁸ The difficulty is to distinguish the normal response from a clinical disorder. Symptoms indicative of a

clinical disorder include a sense of failure, social withdrawal, suicidal ideation, and indecision.^{109–111} Few studies have examined depression in patients with early-stage disease. Kornblith et al. studied 163 men with localized prostate cancer and found that 29% reported “worry” and 21% complained of depression. Patients and spouses both had frequent intrusive thoughts and images.¹¹²

Psychologic distress is complicated in prostate cancer because of the dual implications of treatment and distress. Prostate cancer treatment may itself induce sexual dysfunction, which adds further to such distress. Studying traumatic distress in men newly diagnosed with early-stage disease, Bisson et al.¹¹³ found very few depressive symptoms. Instead, patients demonstrated higher anxiety and traumatic stress symptoms. The authors postulated that older men may be more likely to use denial as a defense mechanism. A more holistic approach by the physician, incorporating attention to both psychologic and physical needs, benefits the patient and his spouse. Emotional support allows both members of the couple to target their energies on preparing for the treatment process.

Regret

Decisional regret relates to the notion that another treatment might have been preferable. Davison et al.¹¹⁴ undertook a study to assess how factors such as HRQOL and level of patient involvement in medical decision making impact decisional regret. Higher regret scores did correlate with poorer emotional and urinary function. Although not a direct measure of decisional regret, the Prostate Cancer Outcomes Study that found 92% of patients who chose surgery or radiation would do so again.¹¹⁵ In contrast, Hu et al.¹¹⁶ used the two-item Clark regret scale^{117,118} and discerned that 16% of men with localized prostate cancer experienced decisional regret. College education and worse HRQOL appeared to foster regret, but treatment type did not have an effect.

Fear of Recurrence

Using the CaPSURE database, Mehta et al.¹¹⁹ identified more than 500 men with pre- and posttreatment questionnaires to measure fear of recurrence. All patients, regardless of treatment type, reported the most severe fear of recurrence before treatment. Their levels of fear improved after treatment and remained constant over the next 2 years. Another study utilized the Profile of Mood States (POMS)¹²⁰ in men with and without biochemical recurrence. Urinary tract symptoms were associated with increased cancer fear, but biochemical recurrence alone was not associated. However, men with both urinary tract symptoms and biochemical recurrence reported the highest level of cancer fear.¹²¹ In an attempt to elucidate better the problems faced by men with prostate cancer, Roth et al. developed a new scale to measure anxiety in prostate cancer patients. The Memorial Anxiety Scale for Prostate Cancer (MAX-PC)¹²² comprises three subsections including a prostate cancer anxiety scale, PSA anxiety scale, and fear of recurrence scale. The authors identify the prostate cancer anxiety subscale as being most specific to cancer anxiety while the fear of recurrence captures general distress. Loneliness and general uncertainty about the future heighten

anxiety in prostate cancer survivors. Men who have elected to undergo no treatment (watchful waiting) also experience PSA anxiety. Wallace¹²³ identified 19 men on watchful waiting and found they experienced heightened uncertainty, leading to a higher perception of danger, which impaired their quality of life. Discussions with other men facing similar clinical scenarios promote positive coping skill and diminish anxiety. National and local support groups can help meet the emotional and educational needs of patients concerned with facing a recurrence.^{124,125}

Late-Stage Medical Issues

Demographics

African-American men have a significantly higher mortality rate from prostate cancer than do non-Hispanic white men.¹²⁶ However, the traditional 5-year survival rates are almost irrelevant to men with prostate cancer, given that this rate approaches 100%, regardless of treatment.² This figure includes the 15% to 35% of men who will experience biochemical progression within 10 years of treatment.^{25,127,128} The natural history of disease recurrence following radical prostatectomy was characterized by Pound et al.,²³ who showed that the median time to development of metastatic disease was 8 years and death followed at a median of 5 additional years. The risk factors for progression were time to biochemical progression, Gleason score, and PSA doubling time. The earlier the PSA recurrence, the higher the Gleason score, and the faster the doubling time, the worse the prognosis. No patients placed on early hormone ablation were included in the study.

Definition of Recurrence

After a radical retropubic prostatectomy, PSA levels should be undetectable. Original assays utilized a threshold level of 0.2 ng/dL, and values less than this constituted freedom from disease. Although more-recent assays have lowered this threshold, the PSA should still be undetectable. A detectable PSA preceded clinical recurrence by 6 to 8 years.^{129,130} The definition of recurrence after radiation therapy is three successive rises in PSA based on American Society for Therapeutic Radiology and Oncology (ASTRO) criteria.¹³¹ However, because recurrent patients after either treatment will survive for many years, secondary treatment in the form of hormonal therapy results in additional medical problems.

Androgen Ablation

Medical induction of castration can be obtained through drugs affecting the production of luteinizing hormone-releasing hormone (LHRH), blocking the peripheral effects of androgens (steroidal and nonsteroidal antiandrogens), eliminating all steroid hormone production, and estrogens. The luteinizing hormone-releasing hormone agonists (which paradoxically lower LHRH levels) are typically administered by injection every 3 to 4 months whereas peripheral blocking agents are taken orally every day. However, once androgens are ablated, the prostate cancer begins an inexorable change to hormone independence.¹³² Once a hormone refractory state

has developed, few effective treatment options exist. Therefore, questions arise regarding the timing of androgen ablation and which agents to use.

Hormonal Complications

The predominant treatments are LHRH agonists and nonsteroidal antiandrogens, but these are not without side effects. LHRH agonists cause hot flashes, loss of libido and potency, anemia, fatigue, weight gain, depression, and decreased bone mineral density.^{133,134} Antiandrogens maintain potency in a subset of patients but lead to gynecomastia and nipple tenderness.¹³⁵ Controversy remains over whether these agents are as effective when used alone as when used in combination with LHRH agonists. Two large trials demonstrated prolonged time to progression (by 2 months) in patients with modest disease; however, meta-analysis and other small studies have failed to demonstrate a significant advantage to combined androgen blockade.¹³⁶⁻¹³⁸ Once metastatic bone deposits develop, LHRH agonists appear to be the most cost-effective, efficacious treatment.¹³⁹ However, men with high-risk disease or rising PSA are often started on hormone ablation.^{140,141} To decrease the side effects, intermittent hormone ablation is increasingly being utilized.

Bone Complications

Hypogonadal men are at risk for potentially debilitating bone complications such as osteoporosis and hip fractures.^{142,143} In patients with prostate cancer on androgen ablation, Hatano et al. reported a 6% nonpathologic fracture rate while Townsend et al. found a 9% overall fracture rate.^{144,145} A smaller retrospective studies found even higher fracture rates of 40% after 15 years in 161 men after bilateral orchiectomy.¹⁴⁶ Daniell analyzed 59 men who had undergone bilateral orchiectomy for prostate cancer and found 8 (13.6%) with osteoporotic fractures of the femur or vertebra. However, when he analyzed the 17 patients still alive 5 to 12 years later, he noted that 38% had had one or more osteoporotic fractures.¹⁴⁷

According to the World Health Organization, osteopenia denotes a bone mineral density between 1.0 and 2.5 standard deviations below the mean for young adults and osteoporosis is greater than 2.5 standard deviations below the mean.¹⁴⁸ Using this definition, Finkelstein et al. documented cortical bone density loss at least 2 standard deviations below normal in men with isolated gonadotropin-releasing hormone deficiency.¹⁴⁹ These changes in bone mineral density have been confirmed in men with therapeutic hypogonadism from prostate cancer treatment.^{150,151} Smith et al. reported that trabecular bone mineral density of the spine decreased by 8.6% during the first year of androgen-deprivation therapy (ADT) for nonmetastatic prostate cancer.¹⁵¹ With aging itself leading to decreased bone mineral density, the addition of ADT further places these men at risk.^{152,153}

Management

The agents used in the treatment of osteoporosis and osteopenia depend on whether the etiology of the bone loss is from a benign or malignant process. Disease of benign etiology has been successfully treated with calcitonin, oral bisphosphonates, and a combination of vitamin D and calcium.^{154,155}

However, the bone loss associated with prostate cancer and androgen deprivation therapy is accelerated, requiring additional therapeutic options.^{153,156,157} A prospective randomized controlled trial revealed that intravenous bisphosphonate was effective in increasing bone mineral density in men on androgen deprivation therapy for prostate cancer.¹⁵⁸ Therefore, men with D0 disease as well as metastatic prostate cancer on ADT are candidates for intravenous bisphosphonates.

Fatigue

Throughout the disease trajectory, cancer patients experience fatigue, which is recognized to have a significant impact on quality of life.¹⁵⁹ Indeed, clinical experience with fatigue in hypogonadal men indicates that androgen deprivation therapy should lead to some degree of fatigue.¹⁶⁰ Stone et al.¹⁶¹ used the Fatigue Severity Scale¹⁶² to follow patients before and after treatment with goserelin and cyproterone. Fatigue worsened in 66% of patients after 3 months of androgen deprivation therapy. All patients responded to the therapy with decreasing PSA levels, eliminating disease progression as a possible source of fatigue. On multivariate analysis, only depression remained a significant predictor of fatigue.¹⁶³ The depression literature supports this association.¹⁶⁴ This study did not find any association with anemia, but others suggest that fatigue in prostate cancer patients on androgen deprivation therapy may be because of anemia, a well-known side effect of therapeutic hypogonadism.¹⁶⁵ Patients on androgen deprivation therapy experience not only the expected physical side effects such as hot flashes, loss of libido and potency, weight gain, and anemia but also the psychosocial changes of depression and fatigue. Close monitoring of all these parameters is critical.

Health-Related Quality of Life

The clinical rationale for selecting the method and agent for androgen ablation is controversial. Therefore, the physician must engage the patient in a discussion to decide what balance of side effects, cost, and risk of progression is optimal. Because the patient will likely survive for many years before developing bone metastasis or other evidence of clinical progression, the potential cost in quality of life may be great. Additionally, when the physical side effects of fatigue, sexual dysfunction, and weight are considered, deferment of this potentially emotionally debilitating therapy may promote HRQOL in men living daily with prostate cancer.

Late-Stage Psychosocial Issues

Partners

Researchers have used focus groups to describe the impact of prostate cancer on the couple as a unit. Both patients and partners feel unprepared to manage treatment- and prostate-related changes as they arise. The spousal role is increasingly difficult as the cancer progresses. Often the role shifts to that of a caregiver focusing on three major areas of concern. Caregivers contend with fear of cancer and its spread, helping patients respond to the emotional ramifications of the

disease, and managing the disruptions caused by cancer.¹⁶⁶ For survivors of prostate cancer with late-stage disease, uncertainty prevails. Men with partners may benefit from physical assistance from their partner but bear additional emotional weight from their sense of being a burden. Men without partners experience more of a physical decline and loneliness.¹⁶⁶⁻¹⁶⁸

Depression

The concept that depression is linked to testosterone has been explored in the psychiatric literature. Studies have examined the treatment of elderly males with major depressive disorders with testosterone replacement. The therapy appears to be effective in men with late-onset depression.¹⁶⁹ Therefore, older men receiving androgen deprivation therapy for prostate cancer are an at-risk population. Among 45 men receiving androgen deprivation therapy (ADT) as prostate cancer treatment, the prevalence of major depressive disorder was eight times the national rate.¹⁷⁰ Although cancer progression was not the primary cause of the depression, history of depression was a strong risk factor. Involving experts in depression and palliative care can provide social support and help patients confront end-of-life issues.

Regret

Regret has been evaluated in men who developed metastasis and had initiated androgen deprivation therapy. Almost one-fourth of these men expressed regret. The demographics and time since diagnosis with metastatic disease were similar between men who were and were not regretful; however, men who had undergone orchiectomy were more likely to express regret.¹¹⁹ Clark et al.¹¹⁸ did find that men expressing regret were more likely to have poorer quality of life, particularly in the role and emotional limitations subscales. These men did not have more treatment-induced side effects, yet they perceived themselves as having worse functional status.

End of Life

Quality of life steadily descends in the final months of life.¹⁷¹ Marriage appears to protect men from rapid decline in the physical domains but surprisingly does not offer protection in the emotional domains. Single men may feel the persistent effects of loneliness, while married men may sense being a burden. Higher socioeconomic status has been associated with a slower decline in physical domains but a more acute decline in the emotional domains.¹⁷² Other studies in terminally ill cancer patients have found accelerated HRQOL declines at 1 to 3 weeks before death.¹⁷³ Because prostate cancer death can be so delayed, patients, family, and physicians often neglect to address end-of-life planning issues. Steinhauser et al.¹⁷⁴ evaluated factors considered important for a "good death," emphasizing that this is highly idiosyncratic. Control of symptoms, preparation for death, opportunity for closure, and good relationship with healthcare professionals were factors considered crucial to easing the end-of-life transition for patients and families. One responsibility of the physician is to consider what the patient and caregiver need emotionally and psychologically. This need includes assessing what interventions might be used for long-

or short-term gain or discussing transfer to a hospice or palliative care program. When these issues are adequately addressed, terminally ill patients feel more prepared for death and are better able to live to the fullest degree possible.¹⁷⁵

Conclusion

The high prevalence of prostate cancer and the impact on the partner make the psychosocial aspects of prostate cancer particularly relevant to long-term survivorship. A man's masculinity is intricately intertwined with his personal identity. Therefore, the intimate nature of the treatment-related side effects of early- or late-stage prostate cancer may have far-reaching emotional consequences for these men. They are at risk for anxiety, depression, distress, fatigue, and bone complications at many stages of the disease trajectory. The most effective tool against these sequelae is awareness on the part of physicians and other health professionals in identifying psychosocial needs and directing patients to the appropriate resources.

Physical and Psychosocial Issues in Lung Cancer Survivors

Linda Sarna, Frederic W. Grannis, Jr., and Anne Coscarelli

Lung cancer emerged during the 20th century as an epidemic of enormous proportions.¹ A rare disease at the beginning of the past century, lung cancer continues to be one of the most common cancers in the world, affecting 173,700 Americans (93,110 men and 80,660 women) in 2004.² Mirroring changes in smoking patterns, the incidence of lung cancer among men continues to decline. Large-scale smoking among women occurred almost 20 years after men in the United States, with a subsequent delay in increased cases, peaking in the 1990s. Encouragingly, the most recent evidence demonstrates that lung cancer incidence among women is declining, as are death rates.³ In 2000, approximately 13% of men and 17% of women (age-adjusted, 15% overall) diagnosed with lung cancer were expected to survive at least 5 years (an estimated 26,065 Americans each year).²

There has been minimal (albeit statistically significant) increase in the overall percentage of survivors over the past 30 years (13%, 1974–1976; 14%, 1983–1985; 15%, 1992–1999).² The focus of this chapter is on the emerging data describing the long-term medical and psychosocial consequences of survival from lung cancer and its treatment. In addition to length of survival, the physical, psychological, social, and existential components of health-related quality of life (QOL) data have been recognized as important outcome measures of lung cancer treatment for more than 30 years.^{4,5} These measures are now a common part of clinical trials of patients with lung cancer,⁶ but there is limited information about QOL of long-term survivors. In an extensive review of literature on QOL in patients with lung cancer, 151 studies were identified covering 1970–1995.⁷ Almost all these studies focused on patients in treatment. Only one focused on patients with early-stage disease treated by surgery,⁸ and only one study was identified with long-term survivors.⁹ Since that review, there have been several additional reports^{10–14} on survivors of lung cancer who were disease free and off treatment at the time of the data collection. Details of these studies and others focused on recovery after curative treatment are displayed in Table 108.1.

Lung cancer survivorship, in contrast to breast cancer survivorship, which has shaped the quantity and quality of survivorship research, is in its infancy. For the purposes of this chapter, studies published (in English) since 1980 that

provide data about the physical functional status, QOL, symptoms, and other issues experienced by survivors after curative treatment are reviewed. Studies that only addressed cardiopulmonary function in the brief postoperative period are not included.

Survivorship and Lung Cancer

There are many survivors of lung cancer as a result of the high incidence of this disease when using the National Coalition of Cancer Survivors' definition, which is "from the point of diagnosis forward." However, with a definition that sets a defined time frame of "5-year survival" or "disease-free survival," the field of survivors is narrowed to a smaller number of patients and, thus, a more-limited opportunity for research. Survival following a diagnosis of non-small cell lung cancer depends primarily upon stage and effective treatment. Only 16% of patients are diagnosed with localized disease, 36% with regional disease, and 38% with distant metastasis.³ Although more than 80% of patients with surgically resected stage IA disease may have 5-year disease-free survival, expectation of survival diminishes progressively through stages II and III and is rare in stage IV. If untreated, few patients, even with small peripheral stage IA tumors, survive 5 years.^{15,16} The statistics for long-term survivors of limited-stage small cell lung cancer are even less optimistic. Only 6% of 144 patients with limited-stage disease treated in Canada survived longer than 5 years.¹⁷

Long-Term Impact of Curative Surgical Interventions

The majority of QOL studies including patients with lung cancer have focused on symptoms of and issues facing patients with advanced disease.⁷ The quality of lung cancer survivorship and resulting physical impairment has been minimally addressed. The majority of medical issues surrounding lung cancer survivorship are related to curative surgical therapy and tend to be short term. A major consequence of the successful treatment of lung cancer arises from the

TABLE 108.1. Studies documenting symptoms, functional status, and quality of life of lung cancer survivors since 1980 (in chronological order).

Author	Sample characteristics: mean age, sex, ethnicity, education, marital status, health status	Disease characteristics/treatment/follow-up period	Purpose/method Comparison group	Findings related to survivorship
Nou and Aberg ⁷¹	N = 69 (34% of whom received surgery for cure, n = 21, 30%, survivors) Age: 62 years Ethnicity: Swedish Health status: ND	Histology: bronchial carcinoma (1967 WHO classification) Stage: mixed Surgery: 27% pneumonectomy, 62% lobectomy, 13% nonresectional thoracotomies Follow up: 3-8 years Disease-free status not clear	Purpose: describe QOL and symptoms postthoracotomy, 1-month and at 3-month intervals Method: prospective evaluation of performance status by physicians Instruments: Carlens vitagram index (performance level, including working capacity, ambulation, symptoms, hospital treatment) Comparison groups: 28% nonresectional thoracotomy, 72% deceased patients	Good QOL among 5-year survivors: most capable of full-time work Initial preop QOL highest for long-term survivors Noncurative resection associated with lower QOL Specific information about symptoms not provided
Pelletier et al. ³³	N = 47 Age: 58 Sex: majority male Ethnicity: Canadian Health status: ND	Histology: ND Stage: ND Surgery: 43% pneumonectomy, 57% lobectomy Follow-up: approximately 3 months (mean 73 days postlobectomy, 62 days postpneumonectomy, range 29-200 days)	Purpose: evaluate impact of lung resection on pulmonary and exercise capacity Method: prospective pre- and 3 months postop Instruments: Borg scale Spirometry, exercise testing Comparison: No	Lobectomy: 20% reduction in exercise capacity Pneumonectomy: 28% reduction in exercise capacity due to dyspnea Leg discomfort contributed to decreased exercise capacity postop; none were limited by thoracic pain Decrease in PF is a poor predictor of exercise capacity
Dajczman et al. ⁴⁰	N = 56 (91% with malignant disease) Age: 62 Sex: 50% male Health status: ND	Histology: ND Stage: ND Surgery: lateral thoracotomy by 1 surgeon; 13% received postoperative radiation Rx Follow-up: median 19.5 months (range 2 months-5 years), disease free at time of interview	Purpose: describe prevalence and impact of postop pain Method: cross-sectional Instrument: interview about presence, intensity, functional impact of postthoracotomy pain, and influencing factors; VAS for pain Comparison: none	Persistent pain: 55% 1 year, 45% >2 years postsurgery, 38% >3 years, 30% >4 years Pain group: 33% had constant pain, 43% numbness, 23% shoulder pain Pain interfered with daily lives (44%) Five used medication, 3 had undergone nerve block NS differences in demographic or disease/treatment variables in groups with or without pain Patients with no pain reported functional limitations, numbness
Dales et al. ⁸	N = 91 with lung cancer (of 117) Age: 65 Sex: 71% male Ethnicity: Canadian Health status: 14% had moderate/severe dyspnea preoperatively Tobacco use: 25% current smokers, 72% former smokers	Histology: ND Stage: ND Surgery: 73% Lobectomy, 20% Pneumonectomy Follow-up: up to 9 months	Purpose: compare pre and post (1, 3, 6, and 9 months) operative QOL Method: Prospective self-report Instruments: QL-Index, Sickness Impact Profile Clinical Dyspnea Index, Pneumononcosis Research Unit Index Comparison: n = 26 who underwent thoracotomy without lung cancer	Dyspnea peaked at 3-months (34%), but continued for 10% at 6 and 9 months Patients with cancer had 2x decrease in QOL at 1, 3 months postop ADL returned to baseline at 6, 9 months QOL scores similar for all groups preop, patients with cancer had significantly greater deterioration postop Extent of resection and cancer dx associated with deterioration in QOL in SIP Older age associated with poorer scores on QL-Index

Schag et al. ⁹	<p>N = 57 Mean age: 62 Sex: 56% male Ethnicity: 93% white Education: 68% ≥ HS Marital status: 61% married Health status: 41% hypertension, 32% heart disease, 11% diabetes, 7% skin cancer, 11% alcohol use</p>	<p>Histology: ND Stage: disease-free Surgery: 84% had surgery (details not described) Follow up: Mean 3.4 years since diagnosis, n = 33 short-term (>2-5 years), n = 24 long-term (>5 years) survivors</p>	<p>Purpose: describe and compare QOL among lung, colon, and prostate cancer survivors Method: cross-sectional, self-report Instruments: Cancer Rehabilitation Evaluation System (CARES), QOL-LASA Comparison: survivors of colon (n = 117) and prostate cancer (n = 104)</p>	<p>Lung cancer survivors had more problems than other cancer survivors Disruptions in physical function and pain were frequent and severe problems (46% chronic pain from scars) Short-term survivors noted depression (51%) and anxiety (63%), and distress with body changes (35%), 28% report feeling overwhelmed by cancer 17%–45% report difficulties with partners (e.g., communication, expressions of affection), 79% decreased sexual contact and problems, 7%–27% difficulty in dating, 63% difficulty with memory, 25%–32% with difficulty with thinking clearly Of the 1/4 working at the time of diagnosis, 96% of short-term survivors quit work due to disease and treatment</p>
Cull et al. ⁴⁸	<p>N = 64, >2 years in remission Age: 61 (median) Sex: 51% male Ethnicity: Scottish Education: 19% > HS Health status: ND</p>	<p>Histology: SCLC Stage: 95% limited-stage disease Treatment: 80% PCI (50% with concurrent chemo) Follow-up: 2 to >8 years</p>	<p>Purpose: describe QOL and prevalence of neuropsychologic disturbances in long-term survivors Method: Instruments: clinical and neurologic examination, CT scan, neuropsychologic testing, QOL (RSC; HADS)</p>	<p>Abnormal neuro exams (24% of n = 37), 16% with ataxia, 11% cognitive deficits; no association with abnormalities found on neuropsych testing: 81% (of 59) impaired on ≥1 exam, 54% ≥ 2 Most common QOL disruptions: fatigue (64%), lack of energy (59%), difficulty sleeping (54%), problems with concentration (54%); >1/3 had dryness of mouth, tingling hands/feet, pain/burning in eyes; psychologic distress similar to normative data for cancer survivors HADS (borderline/case level): 19% anxiety, 15% depression</p>
Landreneau et al. ³⁹	<p>N = 142 VATS, N = 97 thoracotomy (<1 year) n = 36 VAT, n = 68 thoracotomy (>1 year postoperative) Age: 60 (VATS), 59 (thoracotomy) Sex: 56% men (VATS), 42% men (thoracotomy) Health status: ND</p>	<p>Histology: malignant group: 66% of thoracotomy patients, 42% VATS Stage: ND Surgery: VATS, thoracotomy Follow-up: <1 year postop, >1 year postop</p>	<p>Purpose: compare prevalence and severity of chronic pain post-VATS vs. lateral thoracotomy Method: cross-sectional Instruments: Visual analogue scale to assess presence and intensity of discomfort, and shoulder limitations on the side of the operation Use of medication: Comparison: None</p>	<p><1 year postop, VATS group had significantly less pain and shoulder dysfunction, but similar use of pain meds No significant differences >1 year postop</p>
Hendriks et al. ²³	<p>N = 100, N = 31 with QOL data (48%) response ND for QOL subset</p>	<p>Purpose: describe QOL 2.5 months postthoracotomy Methods: mailed questionnaire Instruments: EORTC QLQ = 30 Comparison: none</p>	<p>Good/excellent global QOL (56%) Poor/very poor QOL (26%) Higher percent of patients with pneumonectomy had lower scores Dyspnea (29%), pain (29%) no clear relationship of sx to extent of resection</p>	(continued)

TABLE 108.1. Studies documenting symptoms, functional status, and quality of life of lung cancer survivors since 1980 (in chronological order). (continued)

Author	Sample characteristics: mean age ^b , sex, ethnicity ^c , education, marital status, health status	Disease characteristics/treatment/ follow-up period	Purpose/method Comparison group	Findings related to survivorship
Zieren et al. ³⁴	N = 52 (12 months postoperative), n = 20 (pre- and postoperative data) Age: 61 years Sex: 73% male Ethnicity: German Marital status: 12% partnered Health status: ND	Histology: NSCLC Stage: ND Surgery: 81% Lobectomy, 10% pneumonectomy Adjuvant treatment: 25% radiation therapy Follow-up period: 1 year, 19% with recurrence	Purpose: describe QOL post surgery Method: mix of cross-sectional and prospective Instruments: EORTC QOL, Psychologist-rated Spitzer QOL Index Comparison: none	Dyspnea at exertion and pain continued at 12 months Physical dysfunction returned to preoperative level at 12 months postsurgery Emotional, social, and financial dysfunction was less severe, but continued postop Pneumonectomy was associated with more symptom distress and limitations in physical function, but not with greater emotional, social, or financial dysfunction NS differences based upon adjuvant treatment. QOL rated as higher by the external rater as compared to the patient. 12% employed full time Recurrence negatively impacted postop QOL Lobectomy: no change in exercise capacity; PFT significant decreased at 3 months and significant increased at 6 months (10% permanent loss) Exercise capacity limited by leg muscle fatigue and deconditioning Pneumonectomy: 20% reduction in exercise capacity; PFT significant lower at 3 months and did not recover at 6 months (30% permanent loss); significantly lower than lobectomy, exercise capacity limited by Dyspnea
Bolliger et al. ³⁰	N = 68 Age: 61 Sex: 84% males Ethnicity: Swiss Health status: Preoperative FEV ₁ = 2.38 (lobectomy), 2.50 (pneumonectomy)	Histology: ND Stage: ND Surgery: 74% lobectomy, 26% pneumonectomy Follow-up: 3 and 6 months postop	Purpose: compare effect of lobectomy and pneumonectomy on PFT, exercise capacity, and perception of symptoms Method: prospective, pre, 3, 6 months postsurgery Instruments: PFT Comparison group: none	Recurrence negatively impacted postop QOL Lobectomy: minimal change in lung function or exercise capacity Pneumonectomy: decrease in PF, but compensation due to better oxygen uptake; Change in FEV ₁ was a poor predictor of change in exercise capacity Variable changes in PF and exercise capacity with some patient improving postop, some worsening, and some with little change Significant declines in health perceptions, physical function, role-physical, bodily pain, vitality, social function at 6 and 12 months after surgery Improvement in mental health and role-mental function over time By 12 months, physical function, bodily pain, health perceptions were lower than preop levels, but similar to population-based norms Compared to other groups, lung cancer patients continued to have the lowest health perceptions, lower role-physical and social function ratings
Larsen et al. ²⁸	N = 57 with pre and post assessments Age: 59 (pneumonectomy); 67 (lobectomy) Sex: 72% male Ethnicity: Danish Health status: ND	Histology: NSCLC Stage: ND Surgery: 28% pneumonectomy, 72% lobectomy	Purpose: describe postop changes in cardiopulmonary function Methods Instruments: exercise testing, pulmonary function, arterial blood gas	Lobectomy: minimal change in lung function or exercise capacity Pneumonectomy: decrease in PF, but compensation due to better oxygen uptake; Change in FEV ₁ was a poor predictor of change in exercise capacity Variable changes in PF and exercise capacity with some patient improving postop, some worsening, and some with little change Significant declines in health perceptions, physical function, role-physical, bodily pain, vitality, social function at 6 and 12 months after surgery Improvement in mental health and role-mental function over time By 12 months, physical function, bodily pain, health perceptions were lower than preop levels, but similar to population-based norms Compared to other groups, lung cancer patients continued to have the lowest health perceptions, lower role-physical and social function ratings
Mangione et al. ⁴²	N = 123 with lung cancer Age: 64 Sex: 54% male Ethnicity: 97% white Health status: 94% with at least 1 comorbid condition, 49% with >3	Histology: NSCLC Stage: ND Surgery: thoracotomy Follow-up: 6 and 12 months postsurgery	Purpose: examine QOL changes over time and compare QOL of patients undergoing elective surgery Method: prospective, pre- and postsurgery Instruments: SF-36, Specific Activity Scale, health transition questions and rating of general health Comparison: n = 236, with total hip arthroplasty, n = 95, repair of abdominal aortic aneurysm	Lobectomy: minimal change in lung function or exercise capacity Pneumonectomy: decrease in PF, but compensation due to better oxygen uptake; Change in FEV ₁ was a poor predictor of change in exercise capacity Variable changes in PF and exercise capacity with some patient improving postop, some worsening, and some with little change Significant declines in health perceptions, physical function, role-physical, bodily pain, vitality, social function at 6 and 12 months after surgery Improvement in mental health and role-mental function over time By 12 months, physical function, bodily pain, health perceptions were lower than preop levels, but similar to population-based norms Compared to other groups, lung cancer patients continued to have the lowest health perceptions, lower role-physical and social function ratings

Nezu et al. ²⁶	<p><i>N</i> = 82 (including <i>n</i> = 10 undergoing lobectomy with hemodynamic data)</p> <p>Lobectomy:</p> <p>Age: 64</p> <p>Sex: 84% male</p> <p>Ethnicity: Japanese</p> <p>Pneumonectomy:</p> <p>Age: 62</p> <p>Sex: 90% male</p> <p>Ethnicity: Japanese</p> <p>Health status: FEV₁% predicted: 86 (lobectomy) <i>n</i> = 6 hypertension, <i>n</i> = 2 chronic bronchitis</p>	<p>Histology: ND</p> <p>Stage: "operable"</p> <p>Surgery: <i>n</i> = 20 pneumonectomy, <i>n</i> = 62 lobectomy</p> <p>Follow-up: 3, >6 months postop</p>	<p>Purpose: assess effects of resection on exercise limitation</p> <p>Method: prospective, pre- and postop</p> <p>Instruments: exercise testing, spirometry, Borg scale (dyspnea)</p> <p>Comparison: none</p>	<p>Improvement in exercise capacity 3–6 months postop for lobectomy but not pneumonectomy patients</p> <p>Mean loss of exercise capacity (VO₂ max) after 6 months: 28% pneumonectomy, 13% lobectomy</p> <p>Changes in PF did not correlate with exercise capacity</p> <p>Dyspnea was a limiting factor in exercise testing for pneumonectomy (65% at 3 months, 60% after 6 months), leg discomfort continued as the limiting factor for the lobectomy group (58% at 3 months, 64% after 6 months)</p>
Nugent et al. ³⁶	<p><i>N</i> = 106, <i>n</i> = 53 with follow-up data</p> <p>Age: 61–64 (by surgical procedure)</p> <p>Ethnicity: Irish sample</p> <p>Health status: Preoperative FEV₁% predicted ranged from 71% to 82%</p>	<p>Histology: not reported</p> <p>Stage: ND</p> <p>Surgery: <i>n</i> = 13, pneumonectomy, <i>n</i> = 26, lobectomy/wedge resection, <i>n</i> = 13 thoracotomy (inoperable tumor)</p> <p>Follow-up: 3 and 6 months</p>	<p>Purpose: describe and compare the effects of different types of lung resections and thoracotomy alone (inoperable tumor) on exercise capacity</p> <p>Method: prospective, pre-, postsurgery</p> <p>Instruments: PF, exercise testing, Borg dyspnea scale</p> <p>Comparison:</p>	<p>Thoracotomy alone did not significantly affect exercise capacity</p> <p>Pneumonectomy: exercise capacity reduced by 28%</p> <p>Lobectomy: exercise capacity unchanged</p> <p>No significant difference in Borg dyspnea rating pre and post any procedures</p>

requirement for partial ablation of a vital organ. The pneumonectomy has been used successfully for lung cancer treatment since the 1930s.¹⁸ Evidence-based strategies to enhance QOL, improve symptom control, and support recovery after curative surgery for lung cancer are almost nonexistent. Although the normal healthy individual can sustain the loss of one entire lung (pneumonectomy), most patients with lung cancer have comorbid illness. Many patients have sustained cardiopulmonary damage from long-term smoking and have increased risk of mortality following pneumonectomy (or in some cases even after lobectomy or limited resection). When comparing sleeve lobectomy with pneumonectomy, a meta-analysis of published studies from 1990 to 2003, using quality-adjusted life years (QUALYS) as one of the outcomes, found that sleeve lobectomy resulted in better survival, and for patients who did not have recurrence, better QOL.¹⁹ Other studies also support the superiority of lobectomy over pneumonectomy in terms of physical recovery.²⁰

One recent advance in the treatment of early-stage lung cancer is limited resection performed by video-assisted thoracoscopic techniques (VAT) in patients with poor lung function. Patients with limited respiratory reserve are at increased risk for perioperative respiratory complications. Recent experience with the use of thoracoscopic procedures in benign lung disorders, especially emphysema, confirms that limited thoracoscopic lung resections can be performed safely in this setting, under select circumstances. Thoracoscopic pulmonary resection requires less time in hospital and reduces the duration of postoperative pain and disability. Better understanding of pulmonary function tests (PFTs) and limits of resection now allow resection of small peripheral tumors in patients with poor pulmonary function via open segmental resection, thoracoscopic wedge resection, or a combination of reduction pneumoplasty with wedge resection in carefully selected patients. The lung cancer surgery can even serve as a lung volume reduction intervention for these compromised patients. In a small study of 16 stage I non-small cell lung cancer survivors with severe emphysema who underwent a variety of surgical resections, including lung volume reduction, 68% had 5-year survival. These carefully selected patients had improved QOL (as measured by the SF-36), especially in physical functioning and reduction in dyspnea 2 years after surgery.²¹

As displayed in Table 108.1, a number of studies have identified lingering symptoms and issues faced by lung cancer survivors in the months and years after potentially curative treatment. Some prospective studies suggest a pattern of symptom resolution with full recovery 6 months after surgery, but others point to ongoing problems years later. Some studies have included comparison groups of patients with other forms of cancer or patients without cancer who underwent similar surgical procedures (e.g., thoracotomy). Although some studies have included mixed stage and histology of patients with lung cancer, the majority of studies address the issues of survivors of non-small cell lung cancer who underwent surgical resection with minimal attention to those with small cell lung cancer or those who have undergone adjuvant treatment. These posttreatment data, including both physical as well as emotional well-being, identify a range of issues faced by survivors of lung cancer and underscore the need to develop supportive care interventions. The perceptions of QOL by survivors are important, as they are linked to severity of symptom distress and have been associ-

ated with long-term survival.²² Pneumonectomy has been more clearly associated with ongoing symptoms and reduced QOL.²³ Because of the lack of prospective data, few studies have reported patterns of symptom occurrence and resolution after curative treatment. A cross-sectional study of patterns of symptom distress studied 117 patients with lung cancer, enrolled within 100 days of diagnosis and receiving a variety of treatments. It found that those patients receiving surgery ($n = 45$) were noted to have decreased symptoms over a 6-month period.²⁴

Available data describing the prevalence and patterns of lingering symptoms (dyspnea, pain, altered functional status/fatigue, emotional distress, cognitive difficulties, relationships, sexual dysfunction, and alterations in communication abilities) reported in long-term lung cancer survivors are described next.

Dyspnea and Pulmonary Impairment

The loss of functional lung tissue as a result of lung cancer surgery may result in transitory and permanent reductions in pulmonary function and, for some, physical disability. Pulmonary function can be affected by lung cancer and its treatment, by the consequences of the patient's past tobacco use, and by comorbid disease.²⁵ Changes in pulmonary function are variable and not a clear predictor of exercise capacity,²⁶ severity of dyspnea,²⁷ patients' perceptions of physical disruptions in day-to-day activities,²⁸ or even QOL outcomes.^{10,29,30} Larsen et al.²⁸ note the variability of performance of lung cancer patients after resection. Based upon physiologic differences, resection of the right lung (contributing to 55% of overall lung function) might lead to more severe pulmonary consequences.¹⁸ There are clear differences based upon the extent of resection. Bolliger et al.³¹ reported reduction in PFT in the immediate postoperative period with recovery at the 6-month period for patients who underwent lobectomy. This recovery was not seen for patients who underwent pneumonectomy, similar to findings by Nezu et al.²⁶ Several studies support the benefit of the VATS procedure in improved functional recovery as compared to other approaches.³²

Although dyspnea is not always a consequence of surgical treatment, the majority of studies reported ongoing problems of breathlessness in some survivors, often linked with reduction in exercise capacity.^{8,21,23,26,27,29,30,33-35} Dales et al.⁸ reported an increase in the prevalence of severe dyspnea in the first 3 months postthoracotomy, with reductions at 6 and 9 months, but with the continuance of severe dyspnea for 10% of the patients. Nugent et al.³⁶ reported long-term deficits in exercise performance in patients undergoing a pneumonectomy, with limited changes after lobectomy. The symptom dyspnea was the limiting factor in performance in exercise tests for the pneumonectomy group. Pelletier et al.³³ cited dyspnea as a factor attributing to dropout in exercise programs postthoracotomy. Zieren et al.³⁴ also reported continued dyspnea at exertion 1 year after surgery. However, Nugent et al.³⁶ reported no changes in dyspnea after surgery.

In a study comparing VATS to thoracotomy, dyspnea (85% versus 75%) and cough (82% versus 75%) were continuing problems more than a year after surgery for both groups. Aging, tobacco use and comorbid conditions, in particular, may influence respiratory symptoms and level of pulmonary

function. Uchitomi et al.³⁷ report the significant relationship of dyspnea to emotional distress in the postoperative period. This relationship was also reported by Sarna et al.¹⁰ However, there is little research specifically looking at these issues in a systematic way. In addition to dyspnea, respiratory symptoms such as cough, phlegm, and wheezing continue to plague some long-term survivors and diminish QOL.¹¹

Pain

In a recent review,³⁸ Rogers et al. reported on the incidence of chronic mild to moderate postthoracotomy pain, which was described as “under-rated” and affecting approximately 50% of patients. Chronic postthoracotomy pain along the incision line often has neuropathic features. It is less often associated with initial lung cancer surgery, but has been linked with tumor recurrence.³⁸ The etiology of long-term pain is not well established but may be caused by intercostal nerve damage. Several of the studies reviewed (see Table 108.1) describe persistent pain for some long-term survivors.^{9,10,21,23,29,34,35,39–42} Not all studies are limited to patients with lung cancer; some included others who received a thoracotomy. Reports of lingering pain vary. Schag et al.⁹ reported that 46% of survivors experience pain from scars postsurgery and 24% report aches and pains. In a study of 85 patients, 26 had moderate to severe pain 1 month after surgery. Gotoda and colleagues⁴³ reported that female gender and pain immediately postthoracotomy were predictive of pain 1 month and 1 year after surgery. Handy et al.²⁹ reported continued pain 6 months after surgery. Similarly, Pompeo et al.²¹ and Zieren et al.³⁴ reported continued pain for some patients even 1 year after surgery. Pompeo et al.²¹ also identified a subset of patients who continued to have lingering pain. However, Mangione et al.⁴² and Myrdal et al.³⁵ reported that pain scores after surgery were similar to population norms 1 to 2 years after surgery.

Although the prevalence of chronic pain may be expected to differ by surgical procedure, especially with the emergence of the muscle- and nerve-sparing VATS procedure, reports do not consistently support significant differences. Landreneau et al.³⁹ reported less pain and shoulder dysfunction, but not a difference in use of pain medication.⁴⁴ Pain was reported by 71% of the thoracotomy group and 67% of the VATS group. Comparing the VATS with thoracotomy, specific type of pain included thoracotomy pain (74% versus 75%), chest pain (48% versus 29%), and arm or shoulder pain (59% versus 46%). One-third of both groups (33%) reported shoulder dysfunction. Neither Pompeo et al.²¹ or Li et al.⁴⁴ report significant differences in pain when comparing lobectomy and VATS procedures. However, another study did support a beneficial difference.⁴¹ Treatment strategies of postthoracotomy pain vary,⁴⁵ and reports for definitive treatment from clinical trials are not available.

Another painful and disabling condition is frozen shoulder, a potential postsurgical risk⁴⁶ affecting lung cancer survivors. However, there are no known studies describing the prevalence of this condition among survivors of lung cancer.

Altered Functional Status/Fatigue

Level of postoperative physical disability is an important consideration in examining the QOL of survivors. Although it is

often related to dyspnea, decreased functional status may have other contributing factors as well, and the measurement is different. In fact, in surveying the views of a patient population at risk for lung cancer surgery ($n = 64$), many stated they would not undergo life-saving surgery if it resulted in permanent physical disability.⁴⁷ Early studies considering recovery from lung cancer surgery focused almost exclusively on pulmonary and cardiovascular function, exercise capacity, and predictors of those at risk for severe disability. Mangione et al.⁴² note recovery of physical function after thoracotomy at 12 months, but never to preoperative levels. Compared to other surgical groups (hip replacement, repair of aortic aneurysm), survivors of lung cancer had lower physical function. In a small prospective study of recovery after lobectomy, Miyazawa et al.²⁷ reported that recovery to preoperative levels occurred approximately 1 year after surgery for most, but not all, patients. Improvement in exercise capacity also was noted by Nezu et al.,²⁶ but not for those who underwent pneumonectomy.

Many of these studies are limited in that a preoperative assessment was lacking and time since surgery in the postoperative assessment varied. Additionally, multiple factors, including comorbid conditions (e.g., emphysema) and impairments (e.g., arthritis), were not considered as contributors to physical function after surgery. When exercise performance is limited, deconditioning (often described as leg cramps) as well as dyspnea are factors.³³ In an older population of lung cancer survivors, comparison of physical function with other patient populations or normative standards is useful. In the 5-year survival group,¹⁰ QOL scores for physical components showed a somewhat poorer status compared to norms of patients with cancer, older adults, and those with other chronic lung disease.

In addition to functional decline, fatigue has been identified as a troublesome symptom. It is unclear if these are associated with aging or comorbidity because few studies have comparison groups. In the study by Li and colleagues,⁴⁴ fatigue was the most commonly reported symptom more than 1 year postsurgery for patients who underwent a VATS (74%) or thoracotomy (92%), as was the case with long-term survivors of small cell lung cancer.⁴⁸ Fatigue also may accompany other symptoms. In a cross-sectional study assessing symptom distress in women with primary or recurrent lung cancer within the past 5 years, Sarna⁴⁹ found that when fatigue was present, 41% experienced frequent pain, 31% insomnia, 23% breathing difficulties, and 21% cough. No studies have reported fatigue after lung cancer surgery with adjuvant chemotherapy.

There appears to be a subset of survivors that reports reduction in energy and increased fatigue. In a cross-sectional study of 130 older patients with lung cancer 3 months after diagnosis (including 34 treated with surgery), risk for impaired physical functioning was strongly linked to preexisting physical impairment and symptom distress.⁵⁰ In Schag et al.'s study of lung cancer survivors,⁹ almost all the shorter-term survivors reported significant decreases in their energy (84%). Fatigue also was the most common symptom reported by Sarna et al.¹⁰ With the lack of age-matched comparison groups, it is difficult to tell how dissimilar these reports are from the population of older adults without cancer and with/or without other chronic illnesses. Schag reported on this issue comparing cancer patients to health controls using

the same instrument. She notes that 84% of survivors had problems with functional health status compared to 22% of healthy controls in a previous study.⁵¹

Emotional Distress

Presenting evidence on the psychosocial issues and concerns of survivors of lung cancer is both a simple and complicated task. It is simple because there is a paucity of information and it is complicated by the absence of data and the clear definitions of survivor. It is important to note that positive as well as negative consequences may result from the experience of lung cancer.⁵² In the qualitative study,¹² survivors described existential changes prompting them to "seeing life as a gift," "appreciating the little things in life," and "trying to live life to its fullest." However, some reflect that life after lung cancer is not a normal life, and there were multiple statements related to uncertainty. A review of available data provides support for the hypothesis that a subset of survivors experience ongoing psychologic distress such as anxiety and depression. Handy et al.²⁹ reported impaired mental health 6 months posttreatment, but Mangione et al.⁴² noted improvement in mental health over time. Different measures were used to measure depression in the studies reviewed, and it is difficult to know whether the responses reflect a diagnosable depression (major or minor) or reflect a state of depressed feelings. Interestingly, in contrast to differences in physical function, pneumonectomy was not necessarily associated with greater emotional or social dysfunction.³⁴

Depression

It may seem surprising to find reports of depression among the "fortunate few" who do survive lung cancer. The findings of disease-free survivors are surprisingly consistent with other studies that have looked at the global population of lung cancer patients which includes all stages of disease. Depression and emotional distress have been reported as higher among people with lung cancer than people with other cancers.⁵³ It is estimated that the incidence of depression in patients with lung cancer of all stages ranges from 15% to 44%.^{7,14,54-57} Depressed mood in patients with cancer has been linked to increased reporting of symptoms.^{8,57} In a study of 95 patients with newly diagnosed lung cancer of all stages, depression was linked to poorer prognosis.⁵⁸

Interestingly, in a prospective study of survival and positive attitude (optimism) before a randomized clinical trial of chemotherapy and radiation therapy for unresectable non-small cell lung cancer,⁵⁹ mood did not influence or correlate with overall survival. According to Uchitomi's findings, depression did decrease over the year after surgery.^{14,37,60} However Sarna et al.¹⁰ reported that one of five long-term survivors required further workup for depression because of high CES-D scores and this score was also a major predictor of ratings of QOL. These reports underscore the importance of screening for depression as part of follow-up care. Depression is treatable, but it is unknown how many lung cancer survivors have this clinical diagnosis and are treated.

Anxiety and Fears of Recurrence

Many patients who survive a first lung cancer develop a second cancer, either a second primary lung cancer or a local recurrence. Additionally, patients with prior lung cancer are at high risk of development of second tobacco-caused cancers other than lung cancer. A few prospective studies³⁴ have noted significantly lower QOL scores for survivors who experienced recurrence compared to scores of those who remained disease free. The threat of recurrence is not unique to lung cancer survivors, and this fear has been noted in studies of disease-free survivors. In Schag et al.'s study,⁹ 63% of lung cancer survivors reported anxiety, and 58% had worries about a cancer recurrence. Sarna et al.¹⁰ reported 30% with anxiety, with 12% of survivors fearful of a second cancer, 11% fearful of a recurrence, and 11% fearful of metastatic disease.

Ongoing and quality communication with the healthcare team is essential throughout to course of treatment and during recovery. Because lung cancer has been so frequently fatal for patients, communications around survivorship issues and QOL may seem less important than for other patients with a better prognosis. However, it is important to recognize that there are phases of treatment, and it may be important to identify fears and issues facing survivors that lead to education, information, and interventions. For example, discussions about the potential consequences of curative treatment do not have to be limited to informing patients of potential risks.^{61,62} It also can be an opportunity to prepare patients for survivorship. Resources available for rehabilitative support, including psychological support, can be included in the plan for care.

Cognitive Difficulties

A meta-analysis of seven clinical trials demonstrated that prophylactic cranial irradiation (PCI) increased disease-free survival and decreased risk of brain metastasis for patients with small cell lung cancer.⁶³ Since the 1980s neurologic toxicity has emerged as a concern for some long-term survivors.⁶⁴ These problems include a range of abnormalities including problems with memory, concentration, parasthesias, and gait.^{48,65-67} However, the etiology of cognitive impairment is not clear, with suggestions of abnormalities present before treatment.^{17,67} Comprehensive information about the impact of cognitive impairment on QOL is needed in this population.

Cognitive problems also have been reported in survivors of non-small cell lung cancer. In Schag's study⁹ (including patients with both small cell and non-small cell lung cancer), the majority (63%) of the short-term survivors noted that they had difficulty remembering things. Diminished ability to think clearly was associated with a diminished interest or pleasure in a recent study evaluating somatic symptoms of patients with lung cancer with major depression.⁶⁸ Sorting out cognitive difficulties from the effects of depression is an ongoing issue in cancer research but may be particularly relevant for this population.

Relationships

There are limited data describing the impact of lung cancer on marital and other relationships. In many studies information about marital status or living situations is unknown. Dif-

difficulties with relationships with families and friends were uncovered both by Schag et al.⁹ and Sarna et al.,¹⁰ but it is hard to determine if social support changed and whether there is an ongoing impact. This is clearly an area that could use additional investigation. Additionally, information about the impact of lung cancer on employment is limited.

Sexual Dysfunction

Disruptions in sexual function may be an issue for survivors of lung cancer as a result of diminished physical functional status, but data are practically nonexistent. Schag's study⁹ reported on a range of activities related to intimacy among married and single individuals. In a study of 69 women with lung cancer,⁶⁹ including 38% treated with curative intent, sexual disruptions were reported by more than 20% of the sample.

Communication Ability

Complications of surgical treatment of lung cancer also could include vocal cord paralysis, although data about the prevalence of this condition among long-term survivors are lacking. Recurrent laryngeal nerve damage resulting from pneumonectomy, mediastinoscopy, or tumor invasion can result in laryngeal paralysis or paresis, causing hoarseness and soft whispery voice. This problem can have a profound impact on communication and ultimately QOL. In a rare study of 28 patients with vocal cord paralysis from cancer or its treatment (including 25% with lung cancer), QOL improved after thyroplasty.⁷⁰ Cancer patients had QOL and voice improvement similar to that of patients who received treatment for benign conditions. Improvements in QOL included physical function aspects that could be negatively affected by glottic incompetency.

Economic Impact

A few studies reviewed noted employment status and the impact of the disease on work situation, although many patients were retired at the time of diagnosis.^{9,10} In some studies, return to work was viewed as a proxy for QOL among long-term survivors.^{71,72} The impact of altered physical functional capacity after curative treatment and the long-term economic consequences on these survivors are unknown.

Support and Psychosocial Intervention

There is limited evidence as to the impact of community resources on the recovery and adaptation of lung cancer survivors. Community-based and philanthropic organizations have historically provided cancer patients and their families with essential services that have been unavailable from traditional medical sources, and reliance on these organizations is growing. A recent study⁷³ evaluated the resources that are available nationwide to provide support for patients with cancer and their family members, how these resources are used, and whom they serve. The primary mission of the organizations that participated in the study (32 of the 41 identi-

fied) was information/referral centered. Of the 31 organizations reviewed, not 1 was devoted to patients with lung cancer, although two-thirds were specifically dedicated to patients with cancers other than lung. Problems identified for the one database of patients indicated that there is a strong need for assistance with personal adjustment to illness, financial concerns, home care, and transportation. The study also noted that the patients that are at the highest risk for developing cancer and dying of it are the least likely to utilize formal support networks. In addition, there were gaps noted in service provision. As medical environments provide less assistance for psychosocial needs, it will become incumbent upon these communities to provide assistance for patients, especially for those with lung cancer.

The Ted Mann Family Resource Center at UCLA's Jonsson Comprehensive Cancer Center has developed an approach to helping patients cope with the diagnosis of lung cancer at all phases of the disease. Funded by the surviving spouse of a patient who died of lung cancer, the Ann and John Nickoll Lung Cancer Support Program has established a variety of services for patients and family members. Patients and family members receive individual contact and psychosocial evaluation by a psychologist or social worker. Patients are offered a variety of services, including informational booklets with a library of resources, a support group for patients with lung cancer and their family members, lectures by healthcare professionals on the topic of lung cancer, individual and group programs to teach relaxation exercises and cognitive coping skills, and assistance with access to reliable web sites. Patients who are depressed receive individual counseling and are referred to psychiatry for medication evaluation if they are amenable to this type of intervention. Patients have welcomed this program of support. Some of the patients have commented, "Now we have what the breast cancer patients have," the standard by which all cancers are currently measured. The greatest difficulty that patients with lung cancer face, however, is the fact that so many cancers are found at a late stage, and patients must not only deal with the diagnosis of cancer but may have to grapple with declining function and the loss of their life in a relatively short period of time after the diagnosis. Although as yet untested, this resource may provide a model for comprehensive support for people living with lung cancer.

There is a small, but growing, network of patients and families who are participating in advocacy efforts that are primarily Internet based, as displayed in Table 108.2. Each of these organizations provides information about disease and treatment, organizes political advocacy efforts, and has a mission oriented toward better care and research for patients with lung cancer and links to other resources. These resources offer tips and suggest areas of need and intervention for survivors of lung cancer.

Although research on psychosocial interventions for a variety of types of cancer patients is not reviewed here, there is an extensive literature documenting the efficacy of a variety of interventions in diverse patient populations. These interventions are oriented toward improving the quality of life of patients with cancer through education, individual support, and groups. A recent meta-analysis of 37 published controlled studies that investigated the effectiveness of psychosocial interventions on QOL in adult cancer patients found that psychosocial interventions with durations of more

<i>Organization</i>	<i>Web site</i>	<i>Purpose/mission</i>
Alliance for Lung Cancer Advocacy, Support, and Education	www.alcase.org	National not-for-profit organization dedicated solely to helping people with lung cancer, and those who are at risk for the disease, to improve quality of life through advocacy, support, and education
American Cancer Society	www.cancer.org	Nonprofit provides general cancer educational and support services, including a Lung Cancer Resource Center that describes lung cancer, its risk factors, prevention, causes, detection, symptoms, diagnosis, staging, and treatment
American Society of Clinical Oncology	www.asco.org; www.plwc.org	Site run by the American Society of Clinical Oncology; provides up-to-date scientific information about lung cancer treatment, including links to many patient-focused resources
Cancer Care	www.lungcancer.org	Informational website sponsored CancerCare
Lung Cancer Online Foundation	www.lungcanceronline.org	Focus on improving the quality of care and quality of life for people with lung cancer by funding lung cancer research and providing information to patients and families; provides a comprehensive, annotated directory to Internet information and resources for patients and families
Lung Cancer Survivors for Change	www.lchelp.com/mambo	An organization composed of ordinary people who have survived lung cancer as well as family members of people living with lung cancer
National Coalition of Lung Cancer Survivors (NCCS)	www.canceradvocacy.org	Survivor-led advocacy organization working exclusively on behalf of this country's more than 9 million cancer survivors and the millions more touched by this disease; founded in 1986, NCCS continues to lead the cancer survivorship movement
Roy Castle Foundation	www.roycastle.org	Provides patient support and information network throughout Great Britain; every lung cancer patient and their family will have access to a comprehensive support, information, and advocacy service for all issues concerning lung cancer
Ted Mann Family Resource Center, UCLA Jonsson Comprehensive Cancer Center	www.CancerResources.mednet.ucla.edu	Provides education through streaming video as well as articles on all phases of the disease, including survivorship, and caregiver-oriented materials
Women Against Lung Cancer	www.4walc.org	Special focus on women with lung cancer, educates the public and health care professionals about women and lung cancer; provides a web listing of many lung cancer resources

than 12 weeks were more effective than interventions of shorter duration.⁷⁴

Health Behaviors

Little is known about the health behaviors (tobacco use, alcohol use, nutrition/weight) and changes that may occur in response to the diagnosis or the perceived health status of lung cancer survivors. In an analysis of these factors, Evangelista et al.¹³ reported that 70% of 5-year survivors reported their health to be good to excellent. Continued smoking, exposure to second-hand smoke, current alcohol use, and being overweight (body mass index of 25 or more) were significant predictors of poor health perceptions.

Tobacco Use and Cessation

Assessment of current and former smoking of lung cancer survivors is relevant because of the potential impact on recurrence, second primaries,⁷⁵⁻⁸⁰ and comorbid conditions.

Smoking cessation can slow the decline in pulmonary function, and if smokers quit before extensive pulmonary damage, they may never develop clinically significant chronic obstructive pulmonary disease (COPD).⁸¹ Approximately 90% of lung cancer cases are attributed to lifetime smoking.^{82,83} Smoking continues to be the leading cause of preventable death in the United States,⁸⁴ and tobacco control is a priority for the American Society of Clinical Oncology.⁸⁵

Rarely included in analysis of clinical trial data on survivorship are data about tobacco use. Amount of smoking (30 or more pack-years) has been shown to be an independent prognostic factor in a study of 375 patients who underwent complete surgical resection for stage I non-small cell lung cancer from 1981 to 1993.⁸⁶ Smoking is receiving special attention during clinical trials investigating efficacy of lung cancer screening.⁸⁷ At the time of surgery for lung cancer, many smokers may quit. However, some are unable to do so,^{78,88-94} and others restart smoking during recovery. In Dresler et al.'s report,⁹³ 23% of patients who quit within the 2 weeks before surgery relapsed, and 61% who did not quit before surgery continued to smoke. She reports that 89% of

smokers acknowledged receiving physician advice to stop smoking. Patients at highest risk for return to smoking were those with the briefest quit time before surgery. In a study of long-term survivors,¹³ 13% continued to smoke after curative surgery. There have been several attempts to provide targeted smoking cessation interventions for survivors of cancer, including lung cancer.^{79,95,96} However, it is important to note that former smokers continue to be at lifelong increased risk for lung cancer.^{78,97} Minimal attention has been given to the risks of exposure to second-hand smoke, also a risk factor for lung cancer. This exposure was reported among 28% of disease-free survivors.¹³

Patients with lung cancer, including long-term survivors, may receive more attributions of blame and responsibility for their disease because of their smoking behavior. Clinically, patients have noted that they feel a judgment that comes from others (healthcare providers, family members, and friends) that they are responsible for their disease if they smoked. Additionally, patients who never smoked or who quit long before their diagnosis may feel unfairly judged. In a qualitative study of 45 patients with lung cancer, patients reported feeling stigmatized because of their smoking. Regardless of current smoking status, patients believed that that past or current smoking affected their quality of care, and for this reason, some concealed their diagnosis.⁹⁸ The individual smoker is blamed for his or her illness; even though he or she may have become addicted as a youth, little blame is aimed at the tobacco industry that misled the public about health risks. Only a few studies have explored causal attributions that might affect a patient's response to the diagnosis of lung cancer, especially in the case of a smoking history. There are data to suggest that medical staff's attitudes toward patients may be influenced by these factors as well.⁹⁹ In a study that looked at lung cancer patients' own attributions for the cause of their illness, it was found that while smoking cigarettes was the most frequently suggested causal factor, patients also tried to minimize the impact.¹⁰⁰ Eighty-one percent of patients put forward at least one statement that served to qualify or argue the relevance of smoking as the cause. For example, 41% of the patients indicated that "they didn't really know where the disease came from," others argued "they had always led a normal/healthy life, that non-smokers also got lung cancer, that there must be other causes for lung cancer, and that they had always been healthy." Patients are able to reduce their sense of guilt by diluting the cause of the disease; this allows the person to feel some responsibility without shouldering the full sense of blame. Despite the potential causes and responsibilities, there is a need to understand more about these processes and their impact on coping; however, understanding what patients must cope with is a significant concern.

Alcohol Use and Substance Abuse

Although tobacco use is associated with increased risk of alcohol use, few studies have reported on alcohol use or substance abuse among people with cancer, including lung cancer survivors. Among 5-year survivors,¹³ 58% were reported to have had a drink in the previous month, with 3% reporting more than 8 drinks in one sitting. As described previously, alcohol use among survivors was associated with poorer perceptions of health.

Nutrition and Weight

There are limited data about weight, nutritional intake, and physical activity that can be used to recommend lifestyle changes for lung cancer survivors. Evangelista et al.¹³ reported that 51% of survivors were overweight, including 23% with a body mass index of 30 or more. Recently, a panel of experts convened by the American Cancer Society reviewed the available scientific evidence regarding the benefit of nutritional and activity interventions to decrease recurrence, improve overall survival, and increase QOL. They concluded (with an indication of the strength of the evidence as "probable" or "possible" benefit) that lung cancer survivors should strive for a healthy weight during treatment and recovery, and increase fruit, vegetable, and omega 3 fatty acids uptake (especially in the face of weight loss).¹⁰¹ Additionally, increased activity after treatment was recommended to increase overall survival and QOL. There was insufficient evidence for recommendations regarding total fat intake or intake of fiber or soy. The negative impact of tobacco use on decreasing nutrition was noted. Limited information is available about nutritional supplements and the lung cancer survivor, although two previous trials of beta-carotene pills demonstrated an increased risk of lung cancer in smokers.^{102,103} A current clinical trial is investigating the potential benefit of selenium supplements in reducing risk of lung cancer recurrence.¹⁰⁴

Factors Associated with Increased Problems

Although prognostic variables associated with survival have been well studied, factors associated with increased morbidity and diminished QOL among disease-free survivors have received limited attention. Age, sex, race/ethnicity, socioeconomic status, and comorbidity have been suggested to contribute to differences.

Age

Older age at diagnosis may influence recovery needs as well as occurrence of long-term sequelae. With the growing number of older Americans, many of whom have had a lifetime of tobacco use and exposure, lung cancer incidence among the elderly can be expected to climb along with the burden of other tobacco-related comorbidities.⁸⁴ In a study of patients with limited small cell lung cancer, older patients were more likely to have poorer performance status, more likely to experience poorer survival, and less likely to receive the full extent of optimal treatment.¹⁰⁵ However, older age and comorbidity were not directly related to survival. In Sarna's study,¹⁰ older age was associated with poorer physical function. In a study of physical functioning among older cancer patients, patients who were 3 to 6 weeks post lung cancer surgery ($n = 32$) had significantly lower physical function and more limitations than older patients who had undergone surgery for breast, colon, or prostate surgery.¹⁰⁶ In a cross-sectional study of 133 older patients with lung cancer (over 65 years of age) with various stages of disease and treatment ($n = 26$, including 11 with adjuvant treatment), prior

physical function, symptom severity, and older age were predictors of diminished physical functioning.¹⁰⁷

Sex Differences

As reviewed by Patel et al.,¹⁰⁸ there are important sex differences in lung cancer that may affect survivorship, including the generally female advantage for long-term survival, and differential response to treatment. However, women may be at increased susceptibility to the carcinogens of tobacco¹⁰⁹ and are more likely to be diagnosed with adenocarcinoma.^{108,110} Additionally, younger female nonsmokers appear to be at increased risk for lung cancer.¹¹¹ However, sex differences in physical and psychologic dimensions of QOL are less clear among long-term survivors. None of the studies reviewed supported sex differences in pulmonary function or exercise capacity, although many had only a small subset of women. Sarna et al.¹⁰ reported that women survivors were more likely to live alone and had significantly higher ratings in the existential/spiritual domain of QOL as compared to men. In the study by Uchitomi et al.,⁶⁰ findings indicate that female patients, but not male patients, did benefit from physicians' social support.

Race/Ethnicity and Socioeconomic Status

Lung cancer incidence varies by race/ethnicity and social status, and these differences have been attributed to differences in lung cancer survivorship.¹¹² Over 45 million Americans continue to smoke. The gap between smoking among the higher and lower socioeconomic classes is widening, with 32.9% of those below the poverty line smoking as compared to 22.2% at or above the poverty level.¹¹³ Lung cancer is fast becoming a cancer of the impoverished, poorly educated, and ethnic minorities,^{114,115} but it is not clear how these factors influence survivorship. Tobacco use has been suggested as a cause of the large differential in male black cancer deaths over the past several decades.¹¹⁶ African-Americans are less likely to be diagnosed with localized disease as compared to whites (14% versus 16%), and there has been minimal change in survivorship over time (1974–1976, 11%; 1983–1985, 11%; 1992–1999, 12%).² A variety of factors have been suggested to account for this disturbing difference, including differences in access to care. Using Surveillance, Epidemiology, and End Results (SEER) data between 1985 and 1993 for black ($n = 860$) and white ($n = 10,124$) patients with resectable non-small cell lung cancer, 12.7% fewer black patients in comparison with white patients received potentially curative resection.¹¹⁷ This unequal treatment resulted in racial differences in survival, as has been reported by others.¹¹⁸

Long-term survivors of lung cancer are more likely to come from higher socioeconomic groups.¹¹² Socioeconomic status has been related to stage at diagnosis and, thus, survivorship.^{118,119} Using SEER data for all races from 1995–1999, for those below the poverty rate, 25.3% and 59% of lung cancer patients were diagnosed with regional and distant disease, respectively. Additionally, in a prospective cross-sectional study of 129 newly diagnosed patients with non-small cell lung cancer (including 6 who received surgery), those with lower socioeconomic status, regardless of clinical status, had more health problems and poorer quality of life than those who were affluent.¹²⁰

Comorbidity

In evaluating the QOL and health status of survivors, the presence of comorbid conditions, especially those associated with tobacco-related illnesses, may more directly affect QOL ratings than the cancer or its treatment. However, there has been limited investigation in this area. Few studies reviewed have adequately documented comorbid conditions among patients who have undergone surgery for lung cancer.¹²¹ In a survey (including preoperative patient history) of 2,189 patients who underwent surgery for lung cancer in Spain, 73% reported at least one comorbid condition, including 50% COPD, 16.5% hypertension, 13.5% heart disease, 10% peripheral vascular disease, and 9% diabetes. Comorbidity was higher in older age groups, but smoking status was not reported. These findings of comorbidity were similar to findings of Sarna et al.¹⁰ among 142 disease-free survivors, in which 70% reported one or more conditions: 28.9% heart disease, 17.6% COPD, 16.9% peptic ulcer disease, 13.4% diabetes, and 16% with reports of other cancers. Fewer comorbid conditions were significantly related to higher physical QOL scores, especially for survivors with known heart disease, and contributed to the statistical model for overall QOL. Schag et al.⁹ found similar results: 32% cardiovascular disease, 41% hypertension, 11% diabetes, and 28% other illnesses; however, a comorbidity index was not predictive of QOL for the lung cancer survivors. The Karnofsky performance status was significant, which may be in part a surrogate for the combined effect of comorbid illnesses.

Long-term tobacco use can complicate recovery from lung cancer and its treatment¹²² and increase the potential for other and tobacco-related comorbid conditions. Because smoking is a major risk for cardiovascular disease and increases the risk of disease in the presence of other risk factors (e.g., untreated hypertension),¹²³ the assessment of the impact of tobacco-related comorbidity is essential to survivorship concerns. Additionally, chronic obstructive pulmonary disease (COPD), now the fourth leading cause of death in the United States, continues to increase, especially among women.¹²³ Similar to lung cancer, more than 90% of cases of COPD are due to smoking; 15% of smokers develop significant COPD.⁸¹ Additionally, COPD has been postulated as a risk factor for lung cancer.¹²⁴ Lung function declines more rapidly in smokers as compared to nonsmokers and is associated with progressive disability.¹²⁵ Twenty-five percent of patients with small cell lung cancer were noted to have COPD at diagnosis, and 15% had heart disease; however, the prevalence among the 60 long-term survivors is not reported.⁷² In a cross-sectional study of 129 older patients with lung cancer at various stages of disease, an average of 3.1 comorbid conditions was reported.¹⁰⁷

Limits to Current Studies of Lung Cancer Survivors

There are numerous limitations to the current studies describing issues facing lung cancer survivors. A variety of instruments have been used, limiting comparisons across studies. Several have used standardized instruments such as the Center for Epidemiology Status-Depression (CES-D) to assess depression that allow score comparison with normal

populations. Other studies have allowed comparison of scores across cancer survivors. Comparing survivors of lung cancer to other populations of survivors of cancer and to populations without major illness is essential in evaluating generalizability of research among survivors. However, further qualitative studies also are needed that provide details about the survivors' lives, identifying positive and negative outcomes.

To determine if these findings are different from or similar to those in others with chronic illness or others with cancer, comparison groups are important. These differences are beyond the extent of surgery alone, as long-term survivors were noted to have higher preoperative QOL, when compared to those who suffered recurrence.⁷¹ A health utility score, a global indicator of health reflecting QOL, allows for comparisons across studies. This strategy was used in a study using population-based cross-sectional data from the National Health Interview Survey (1998 cohort) of 692 long-term survivors recovering from surgical cancer treatment: breast ($n = 377$), colon ($n = 169$), melanoma ($n = 92$), and lung cancer ($n = 54$, 50% females). In the acute less than 1-year time period, the scores for the lung cancer survivors (0.42, with 1.0 indicating perfect health), were significantly lower than for the other survivor groups.¹²⁶ However, the scores in the longer term cohort (more than 5 years) increased by 47% to 0.62. The presence of pain and angina contributed to poorer scores in long-term survivors. In Schag's study,⁹ there was a greater frequency of psychologic distress in patients with lung cancer than the survivors of colon and prostate cancer.

Recommendations to Support Recovery of Lung Cancer Survivors

Based on the available evidence, several interventions are essential to decrease morbidity and promote QOL among lung cancer survivors. As a diagnosis of any life-threatening illness such as lung cancer offers clinicians a "teachable moment", recovery can be the impetus for important life changes and behavioral interventions. (1) All lung cancer survivors who smoke must be offered/referred to support and resources to promote tobacco cessation. (2) Because a significant number of survivors experience serious emotional distress in the face of curative treatment, vigilant attention is needed in the ongoing assessment to detect psychosocial problems and to ensure referral for subsequent treatment of those with clinical symptomatology. (3) There should be ongoing assessment and treatment of postthoracotomy pain. (4) Physical rehabilitation must be promoted, especially among those with evidence of disability before curative treatment. (5) Interventions to provide interventions to support relief of dyspnea should be offered to those with this symptom. (6) Changes in lifestyle including healthy diet and activity to promote QOL and reduce disability should be supported. (7) There should be identification of and intervention with high-risk patients with known risk factors for morbidity after curative treatment.

A comprehensive wellness approach to survivorship requires that clinicians challenge existing nihilistic views of the curability of lung cancer in general, including negative attitudes toward investing in efforts to support QOL regardless of the length of survival. Many of these interventions may be synergistic, such as the decrease in depression asso-

ciated with exercise. Additionally, those with stable disease may live for many years with lung cancer. Although they may not be "disease free," they should not be neglected in the efforts to improve coping and living with uncertainty while reducing physical and emotional distress.

Future Research

The excellent survival of individuals treated with adequate surgical resection in stage 1 non-small cell lung cancer suggests that increasing survivorship is linked with early detection. Henschke and her colleagues at Cornell University conducted a prospective single-arm trial of low-dose noncontrast spiral computerized tomography (CT) in high-risk patients and demonstrated that CT is three times as sensitive in the detection of small pulmonary nodules as chest roentgenogram and that 80% of lung cancer is detected by this methodology in stage IA.¹²⁷

The National Lung Screening Trial is underway to evaluate current and former smokers aged 55 to 74 at risk for cancer.¹²⁸ Findings from standard chest X-rays will be compared with spiral computed tomography (CT) scans to see if early detection of small potentially curable lesions will result in reduced deaths from lung cancer. Thus, an increased number of disease-free survivors might be anticipated, making information about the issues associated with survivorship all the more important. Regardless of efforts to prevent tobacco use and to support cessation, former smokers will continue at higher risk. Hundreds of thousands of Americans will be at risk for lung cancer in the next decades. It is also important to acknowledge the lack of information about long-term survivors with advanced-stage disease. For example, in a few selected cases of patients with isolated brain metastasis, long term survival (more than 10 years) occurred after surgical removal of tumor.¹²⁹

Much more evidence is needed to provide a clear understanding and support for interventions to prevent or reduce physical and psychosocial sequelae of lung cancer and its treatment.¹³⁰ Further research is needed to monitor the course of symptoms post treatment and to evaluate strategies for reducing overall symptom burden and improving QOL. The studies reviewed are limited primarily because of small sample size and the cross-sectional nature of the design. There are almost no prospective studies documenting the course of survivors who have received adjuvant treatment. Although Schumacher et al. reported that preoperative chemoradiation did not significantly reduce QOL in 54 patients in the immediate posttreatment time frame, data for long-term survivors were not available.¹³¹ There is almost no information available about the issues of survivors of small cell lung cancer. Although smoking cessation is included in recommendations for follow-up and surveillance,¹³² it is clear from this review of the literature that there is strong evidence to support monitoring physical and emotional well-being after treatment as well.

There are minimal reports of efforts to promote wellness after curative treatment or to examine the efficacy of rehabilitation programs for lung cancer survivors. Future research needs to address the wide range of problems with an eye toward developing a body of literature in which one study can be compared with another. Further research is needed to eval-

uate available instruments and determine how to get the most information, to provide opportunities for comparison and generalizations across studies, and to not overburden respondents. The work to date represents a start in the understanding of the needs of lung cancer survivors, but it raises more questions than it answers. Some have expressed concerns that if the perception of the physician is that surgery would result in substantial reduction in QOL, curative treatment would not be offered, regardless of the patient's view.¹³³ There are subsets of patients who have significant difficulties in a range of areas. More research is needed in nonwhite samples, from a variety of socioeconomic strata, and the inclusion of family members will provide a more complete view of the impact and needs of survivors.

Intervention studies such as targeting depressed patients might involve both psychologic interventions oriented toward cognitive coping as well as medication trials. The role of multidisciplinary care teams involved in the coaching, support, and physical reconditioning posttreatment need to be explored. The interaction between beliefs and behaviors on the part of the medical team with the patients' belief systems may lead to ways to create greater support and interaction. Additionally, the involvement of survivor participants in the development and monitoring of this research would be useful.

Limiting research for survivors of lung cancer to the disease-free period after 5 years is far too narrow. There is limited knowledge about the period after treatment is completed and before recurrence or second primaries. Newer therapies for advanced non-small cell lung cancer have resulted in improved QOL and symptom relief.¹³⁴ These needs and issues faced by these survivors with stable disease also need attention.

The evidence base for frequency and type of screening test is important. This information is important in exploring the need for rehabilitation and support. According to findings from available research, lung cancer survivors are diverse, with different profiles of comorbidity, and different vulnerabilities and needs for rehabilitation. Future studies are needed to explore the need to test tailored assessments and interventions so that those at highest risk are appropriately treated to prevent unnecessary short- and long-term morbidity. Because of the relatively small number of lung cancer survivors, the development of a database through a clinical trial mechanism would be useful. Additionally, the quality and the impact of the explosion of web-based sources for cancer survivors, including lung cancer survivors, on QOL has not been evaluated.

Cancer Survivorship Issues in Colorectal Cancer

Clifford Y. Ko and Patricia A. Ganz

Epidemiologic Trends That Will Influence the Number of Colon and Rectal Cancer Survivors

Colon and rectal cancers (CRC) are among the most common adult malignancies worldwide, and for a variety of reasons, the numbers of survivors of colorectal cancer are likely to increase in coming years. The incidence of these cancers doubles with each successive decade of life beyond 50 years, and with the expansion of the older population in the coming years, the absolute numbers of CRC patients in the United States will grow substantially.¹ It is estimated that by the year 2030 the number of persons over the age of 65 years will have doubled and the number of persons over the age of 85 years will have quadrupled.² Given this expanding and aging population, projections suggest that the numbers of CRC patients may increase by as much as 30%.³ Thus, with these profound demographic changes, it will be imperative to have a better understanding of the late effects and health care needs of long-term CRC survivors.

In addition to the increased incidence of colorectal cancer, advances in the detection and treatment are contributing to improved survival outcomes for patients with this disease. Earlier detection of CRC leads to better survival through downstaging of the disease. Several large population-based studies have demonstrated that increasingly more colon and rectal cancers are being detected at an earlier stage through screening.⁴⁻⁹ Data from the Surveillance, Epidemiology, and End Results (SEER) program¹⁰ demonstrate an increasing proportion of localized colon cancers for the population 65 years and older: in the 1970s, 36% of tumors were localized; in the 1980s, 39% were localized; and in the 1990s, this increased to 42%. Similarly, the proportion of localized rectal cancers has increased from 46% to 49% from the 1970s to the 1990s.

In addition, there is an anticipated growth for the number of CRC survivors secondary to secular trends in screening for this disease. As CRC screening becomes more widespread through current health promotion campaigns, there will be an accelerated shift to earlier-stage disease, contributing further to a stage-related increase in the numbers of long-term survivors. The benefits of earlier stage on survival are demonstrated by looking at data on survival by stage (1992-1998):

the 5-year survival for regional tumors (i.e., AJCC stage III) is 65.2%, while for localized colon and rectal cancers (i.e., AJCC stage I and II) the survival rate is 90.1%.¹⁰ Overall, we can be optimistic about better outcomes and long-term survival for CRC patients in the decades ahead.

Finally, there are increasing numbers of CRC survivors because of advances in medical treatments. For example, the surgical technique of total mesorectal excision for rectal cancers has significantly decreased the likelihood of local recurrence,¹¹ and the use of radiation therapy in the disease both decreases local recurrence and improves overall survival.^{12,13} Studies have also demonstrated the efficacy of various adjuvant chemotherapy regimens for improving survival in colon cancer patients.¹⁴⁻¹⁶ The benefits of these improvements in detection and treatment are also reflected in population-based survival rates for CRC. In reviewing the latest data from the SEER program database, the overall 5-year survival rate for colon and rectal cancer for all races and both sexes is 61.9%.¹⁰ This rate is significantly better than 1974-1976, which was 49.8% (P less than 0.05). Furthermore, the survival for patients under 65 years of age versus over 65 years is not dramatically different (63% versus 61.3%), which shows that the elderly with colorectal cancer achieve long-term survival as well. Data for survival beyond 5 years are also available through SEER and have shown similar improvements. For example, the 10-year survival for colon and rectal cancer patients improved from 44.7% in 1975 to 55.3% in 1989. For all these cited reasons, there will be a growing number of CRC survivors in the decades ahead.

Given that the number of CRC survivors is increasing, there are a number of important issues pertinent solely to this cancer site—some that are related to the CRC treatments, and others that are related to specific characteristics of the population that survives colorectal cancer (e.g., the level of comorbidity in this elderly population). The following sections address these survivorship issues. First, the treatment-related issues are discussed, including prevalence, symptomology, and quality of life. The subsequent sections examine issues related to the comorbidity and use of medical services for the CRC survivors population as a whole. The last part of this chapter discusses strategies that may help to improve survivorship outcomes now and in the future.

Treatment-Specific Survivorship Issues

Treatment of colorectal cancer is often multidisciplinary, depending on the stage of disease and whether or not the cancer arises in the colon or the rectum. More specifically, the treatment modalities can include surgical resection and chemotherapy for colon cancer and surgical resection, chemotherapy, and radiation therapy for rectal cancer. Although the current first-line chemotherapeutics do not have appreciable long-term effects on survivors, surgery and radiation therapy can have associated lasting morbidities that affect the function and quality of life of survivors long after the cancer is treated. A description of the pertinent effects related to surgical resection and radiation therapy is presented next.

Survivorship Issues Related to Surgery

Surgical resection is the mainstay of curative treatment for colon and rectal cancers.¹⁷ The surgical procedure requires removal of a segment of colon and/or rectum where the tumor is located, as well as the associated blood vessels and draining lymph nodes.^{11,18} In addition, if there is evidence of metastatic disease, this tissue (e.g., liver, omentum) is also removed or biopsied at the time of initial surgery.¹⁹ Currently, most operations are performed through an open vertical incision up to 30 to 40 cm in length through the abdominal wall. This open approach has associated risks of complications that may be important for colorectal cancer survivors in relation to function status and quality of life. Of note, trials have been reported regarding laparoscopic colon cancer resections. This latter issue is discussed at the end of the chapter.

LONG-TERM COMPLICATIONS OF ABDOMINAL SURGERY

Several possible surgery-associated problems can occur in the short and long term that will affect colorectal cancer survivors. In the acute period, clinical complications may include wound infections (3%–26%), intraabdominal infections (2%–5%), and anastomotic leaks (2%–10%), all of which may require rehospitalization and possible additional invasive (e.g., surgical) procedures.^{20–22}

However, more important for longer-term survivors of CRC are the issues that occur beyond the acute period: three important issues are bowel obstructions, abdominal wall hernias, and functional problems. Complications from bowel obstruction can occur any time after surgery (e.g., weeks to years), and the presentation can range from imminent bowel necrosis that requires immediate surgery to chronic cyclic episodes of debilitating pain that may require hospitalization, intravenous hydration, and gastrointestinal decompression with use of nasogastric drainage. In one study of 472 consecutive patients operated on for colorectal cancer who were followed for a median period greater than 5 years, small bowel obstruction necessitating an operation occurred in 10% after resection with curative intent and in 4% after a palliative operation.²³ Obstruction is particularly relevant to survivors of CRC because it always has the potential of being a sign of tumor recurrence. In this same study, although benign adhesions accounted for 51% of the obstructions, local tumor recurrence and carcinomatosis accounted for 49%.

Another potential surgical complication for colorectal cancer survivors is an *abdominal wall hernia*. Abdominal wall hernias can potentially lead to pain, limitation of activities, and the need for emergent surgery for possible bowel strangulation. It has been estimated that hernias at the incision site (i.e., incisional hernias) occur in approximately 4% to 10% of patients after open surgical procedures.^{24,25} However, the rate increases to as high as 20% for patients whose wounds are infected. As only 50% of incisional hernias become evident within 6 months after an operation, many will continue to have this problem much beyond the acute recovery of their surgery. Overall, more than 100,000 incisional hernia repairs are performed each year in the United States, and the rate of reoperation for such repairs is high (the 5-year reoperative rate was 24% after an initial operation).^{26,27}

Although intestinal obstruction and incision hernias are two of the most common (and generic) potentially chronic problems associated with open colon or open rectal cancer surgery, there are some unique factors that are specifically pertinent to survivors of rectal cancer who have undergone complete or partial proctectomy, especially if radiation therapy is also used. These issues include functional problems in three areas: fecal dysfunction and incontinence, sexual dysfunction, and urinary bladder dysfunction. These areas, which may substantially affect survivors, are discussed next.

BOWEL CHANGES/DYSFUNCTION

One role of the rectum is storage of fecal material. When the rectum is resected for cancer, the storage capacity of the rectum's replacement, the colon (e.g., usually the descending or sigmoid colon), is substantially less, and therefore frequent, clustered, and/or incomplete bowel movements can ensue.²⁸ Also, because of possible nerve damage from surgery or radiation therapy, anal sphincter function may be further affected, and the degree of incontinence may be worsened.²⁹

Many providers and patients alike strongly prefer a sphincter-sparing procedure; however, it is necessary for the patient/survivor to understand that bowel dysfunction may occur even in the presence of sphincter preservation. In part, the level of the anastomosis is extremely relevant to subsequent function. A low colorectal or a coloanal anastomosis (i.e., an anastomosis performed immediately adjacent to the sphincter muscles) is associated with a higher frequency of defecation and more fecal leakage and incontinence than a high colorectal anastomosis. In addition, defecatory problems can occur as a result of surgical trauma or the effects of radiation therapy to the anal sphincter and its innervation, even when sphincter preservation is performed.

Overall, the most common bowel-related symptoms following rectal resection are increased frequency of bowel motion, urgency, fecal leakage, and incontinence. However, also reported by patients to some degree are diarrhea, constipation, and excessive flatus. These are clearly important issues for rectal cancer survivors because even though their cancer may be cured, their function and quality of life may be severely diminished as a result of bowel-related symptoms, even if the anal sphincter is spared.

A short-term single-institution series recently reported that 56% of patients who underwent sphincter preservation for rectal cancer reported unfavorable function and were all

TABLE 109.1. Bowel dysfunction in rectal cancer survivors.

<i>Bowel dysfunction (overall)</i>	<i>56%–60%</i>

dissatisfied with their quality of life.³⁰ Although few long-term data are available, small case series have shown that bowel dysfunction and incontinence is often a chronic issue for many rectal cancer survivors who undergo sphincter preservation. Table 109.1 highlights some of the functional outcomes in rectal cancer survivors.

OSTOMY ISSUES

In patients who undergo abdominoperineal resection, not only do pelvic dissection and rectal resection influence survivorship issues, but the presence of a permanent colostomy also has strong influence on survivors. First, stoma-related problems are common. In a series of 203 patients with end sigmoid colostomies, the 13-year actuarial risk of paracolostomy complications was 58%. Paracolostomy hernia was the most common complication (36% at 10 years).³¹ Other stoma-related complications may occur in survivors, including stomal prolapse (12%), skin-related problems (e.g., excoriation) (12%), and stenosis of the stomal opening (7%).^{31,32} In a survey study of almost 400 ostomates, 51% had skin problems (e.g., rashes) and 36% had leakage; 80% reported some change in lifestyle³³ (Table 109.2).

In addition to complications, several studies have compared postoperative psychosocial adjustment and quality of life in ostomy and nonostomy patients, including concerns regarding sexuality, limitations of activity, and bowel function. These quality of life issues related to ostomy are discussed later in this chapter. It is important that clinicians make use of referral of patients to enterostomal therapists who are able to address both the physical and psychosocial sequelae of having a stoma. Their consultation is valuable throughout the course of survivorship from preoperative to short- and long-term periods. Stoma support groups exist in many communities and are another resource.^{34,35}

SEXUAL DYSFUNCTION

Sexual problems are associated with surgical and radiation therapies that affect the tissues/organs of the pelvis and the

TABLE 109.2. Colostomy problems in rectal cancer survivors.

nerves that innervate them (Table 109.3). The potential sexual dysfunctions for males include erectile dysfunction and ejaculatory difficulties (inability to ejaculate or retrograde ejaculation).³⁶ Disruption of the parasympathetic nerve network interferes with penile erection, and sympathetic nerve disruption impairs normal ejaculation. The incidence of sexual dysfunction increases with advancing patient age and is higher after abdominoperineal resection (i.e., removal of the rectum and placement of a permanent colostomy) than after anterior resection. A conventional rectal cancer resection in men is associated with postoperative impotence and retrograde ejaculation or both in 25% to 100% of cases.^{37–39}

In females, the most common postoperative sexual complaint is dyspareunia, which may include loss of vaginal lubrication and inability to achieve orgasm. Although somewhat difficult to objectively assess, sexual activity has been used as a surrogate measure. Of those women who are sexually active before surgery, 47% to 86% remain sexually active after surgery. Other studies have demonstrated that while 55% to 58% of women remain sexually active after sphincter preservation surgery, only 10% to 39% remain sexually active after an abdominoperineal resection.^{37,38,40} In some women who have undergone a posterior vaginectomy in addition to an abdominoperineal dissection, sexual intercourse may be impossible because of a stenotic vaginal introitus.

Havenga et al.³⁸ surveyed 54 women after total mesorectal excision (i.e., a surgical technique that removes the rectal mesentery and is associated with lower cancer recurrence rates) with autonomic nerve preservation for carcinoma of the rectum (44 low anterior resection, 10 abdominoperineal resection) and found that 95% of women remained interested in sex, 86% remained sexually active, 85% continued to experience vaginal lubrication during arousal, and 91% maintained their ability to achieve orgasm postoperatively. Although the most common postoperative sexual complaint was dyspareunia, the incidence was not significantly changed from the preoperative to postoperative periods.³⁸ Just as with men, the best possible outcome is achieved by careful sharp dissection with preservation of the pelvic autonomic nerves. Additional data regarding nerve-preserving surgery are presented at the end of the chapter.

UROLOGIC DYSFUNCTION

Bladder dysfunction has been reported to occur in 7% to 68% of patients after low rectal cancer resection; however, the incidence is generally quoted to be around 30% in most series.⁴¹ Urologic dysfunction includes problems such as incomplete emptying, urgency, overflow or stress incontinence, loss of bladder sensation, dysuria, and chronic urinary

tract infections. Similar to sexual dysfunction, the majority of voiding difficulties have been shown to be neurogenic in origin. Parasympathetic denervation is specific to urologic dysfunction in this setting. Although a neurogenic bladder may occur in as many as 50% of men after abdominoperineal resection, voiding difficulties resolve in the majority within 3 to 6 months after surgery.^{41,42} In addition to neurogenic problems, mechanical and physiologic issues plays a role as bladder neck angulation following surgery, and the presence of benign prostatic hypertrophy (particularly in this age group) also contributes to urologic dysfunction.

As with sexuality, urinary difficulties are more often associated with abdominoperineal resection than with anterior resection. Balslev and Harling⁴³ identified urologic symptoms such as dysuria and incontinence in 29 of 31 patients who underwent abdominoperineal resection. As with sexual dysfunction, favorable outcomes may be achieved by careful sharp dissection with preservation of pelvic anastomotic nerves.

Survivorship Issues Regarding Radiation Therapy

According to National Cancer Institute (NCI)-developed guidelines, stage II and III rectal cancer patients should receive radiation therapy.⁴⁴ Studies have subsequently shown that radiation therapy decreases local recurrence as well as increases survival.¹² However, radiation therapy can have potentially serious late effects for the rectal cancer survivor. While short-term (acute) complications of radiotherapy may include lethargy, nausea, diarrhea, and skin changes (i.e., erythema and/or desquamation), and also develop to some degree in the majority of patients during treatment, they are generally self-limiting.⁴⁵

For the long-term rectal cancer survivor who underwent radiation therapy, it is important to evaluate the morbidity, pelvic floor function, and quality of life. In this regard, delayed radiation toxicities have been reported and include radiation enteritis (4%), small bowel obstruction (5%), and rectal stricture (5%); this is in addition to the bowel, sexual, and urinary dysfunction discussed earlier that may be compounded by radiation-induced pelvic nerve injuries.⁴⁶ Regarding the latter two issues, although sexual and urologic function is poorly studied, data suggest that radiation has a negative impact in both men and women.⁴⁷

Bowel function after radiation therapy is an important functional issue. There are several studies that are generally consistent and show that bowel function, as measured by frequency, urgency, evacuation, sensation, and/or continence, is impaired after radiation therapy when compared with patients not treated with radiation.⁴⁷

The Swedish Rectal Cancer randomized controlled trial¹² has shown that preoperative high-dose radiotherapy improves survival and decreases local recurrence; they have also studied the long-term bowel function following radiation therapy (XRT) and anterior resection. The authors found that the median frequency of bowel movements was higher in the XRT plus surgery group versus the surgery-only group (20 versus 10 bowel movements per week; P less than 0.0001).^{12,48} Additionally, urgency, emptying difficulties, and incontinence for loose stools were more common in the XRT plus surgery group (all P less than 0.0001). In terms of quality of life, 30% of the XRT plus surgery group stated that their

TABLE 109.4. Bowel issues in rectal cancer patients following radiation.

Diarrhea	39%
Nocturnal defecation	36%
Use of pad/diaper	32%
Number of bowel movements per day	0.5–3.5

Source: References 45–50, 84.

social life was impaired because of bowel dysfunction compared to 10% of the surgery-only group (P less than 0.01).⁴⁸

Another study of rectal cancer patients undergoing surgical resection with or without radiation therapy found similar results that the irradiated group had more diarrhea (39% versus 13%; $P = 0.005$) and more nocturnal defecation (36% versus 15%; $P = 0.03$) compared with the nonirradiated group.⁴⁹

Looking at slightly longer outcomes, a recent study examined rectal cancer patients between 2 and 8 years following surgical resection with no radiation, preoperative radiation, or postoperative radiation.⁵⁰ They found that the postoperative radiation group had more episodes of clustered bowel movements (P less than 0.02) than either the preoperative radiation group or the no-radiation group. The authors attributed the adverse effects of postoperative radiation therapy to irradiation of the neorectum, which is spared when radiation is given preoperatively (Table 109.4).

Along these same lines, manometric studies of low anterior resection patients with and without chemoradiation shows that resting pressure, resting volume, and maximal tolerable volume of the neorectum was significantly worsened in the irradiated group after radiation compared with before radiation. These same parameters did not change in the nonirradiated group.⁵¹

Quality of Life in Colorectal Cancer Survivors

Some of the earliest studies of quality of life (QOL) in cancer patients were done by Ganz and colleagues using a newly developed instrument called the Cancer Inventory of Problem Situations (CIPS), which was later renamed the Cancer Rehabilitation Evaluation System (CARES).^{52–56} These studies were conducted with heterogeneous samples of cancer patients and survivors, with several common cancers being represented, including 277 CRC patients and survivors.⁵⁵ In one of the first published studies to examine quality of life in adult cancer survivors, Schag et al.⁵³ reported on a sample of lung, colon, and prostate cancer disease-free survivors that compared QOL outcomes across disease sites as well as by length of survivorship (short-term, less than 2 years after diagnosis; intermediate-term, 2–5 years after diagnosis; long-term, more than 5 years after diagnosis). This particular study included a total of 117 CRC survivors, with 27 of them being long-term survivors. In comparing the CRC survivors across the three time periods of survivorship, the long-term survivors reported significantly better QOL on a global single-item rating of QOL, as well as better psychosocial functioning on the CARES, compared with the short- and intermediate-term survivors. Specific problems that were frequent and severe in CRC survivors were difficulty in doing physical activities, reduction

TABLE 109.5. Proportion of colon cancer survivors with issues rated as frequent/severe.

Difficulty with bending or lifting	42%
Difficulty with walking/moving around	26%
Difficulty doing physical activities	50%
Difficulty driving	5%
Not engaged in recreational activities	33%
Has frequent pain	30%
Difficulty thinking clearly	45%

Source: Reference 53.

in energy, difficulty doing recreational activities, having trouble gaining weight, worry about whether treatments worked, body image problems, problems with sexual interest and functioning, and at-work concerns such as difficulty talking to others about the cancer, difficulty asking for time off from work for treatment, and worrying about being fired (Table 109.5). Across all the CRC survivors, significant predictors of QOL were the Karnofsky Performance Status score, type of hospital setting in which treatment was received (higher QOL in a private hospital in comparison to a VA, teaching hospital, public hospital, or HMO), gender (males better QOL than females), and work status (nonworking survivors reported better QOL). In this model, comorbid conditions nearly reached significance, with better QOL associated with fewer comorbid conditions.⁵³ These findings suggest that a variety of factors influence QOL in CRC survivors and that they are important to address in treatment planning (Table 109.6).

A more-recent study of 227 colorectal cancer survivors by Ramsey et al. examined the quality of life after more than 5 years of survivorship. They found that survivors report a relatively uniform and high QOL. In addition, the presence and severity of comorbid conditions and low income status were more predictive of overall QOL than the stage of cancer. Interestingly, compared to age-matched controls, long term survivors reported higher overall QOL, although problems remained such as frequent bowel movements (16%), diarrhea (49%), and depression.⁵⁷

With the advent of new surgical techniques that allow for the performance of lower-level anastomoses for rectal cancer resection, there has been a strong push for sphincter-sparing procedures. In a review of quality of life articles regarding the presence of an ostomy, Sprangers⁵⁸ identified studies that addressed at least one of four aspects (i.e., physical, psychologic, social, and sexual) for stoma versus nonstoma patients. The authors found that both patient cohorts were troubled by

TABLE 109.6. Treatment strategies for improving survivorship quality of life, function, and outcomes.

1. Informed discussion of expectations following treatment
2. Address coexistent disease throughout care and survivorship
3. Consider laparoscopic approach if appropriate
4. If colostomy will be performed, consider marking the site preoperatively.
5. Consider ostomy support group.
6. Consider transanal excision if appropriate
7. Consider neoadjuvant radiation (vs. adjuvant)
8. Autonomic nerve preservation techniques
9. Create neorectum with coloplasty or colonic J pouch

frequent or irregular bowel movements and diarrhea. Also, although both patient groups reported restrictions in their social functioning, colostomy patients reported a higher prevalence of these problems. Finally, stoma patients reported higher levels of psychologic distress as well as more impaired sexual dysfunction. Overall, this review shows that although both stoma and nonstoma survivors have impaired function and quality of life, nonstoma patients might fare better than do stoma patients.

Increasingly more sphincter-preserving procedures are being performed, but other recent studies show that it remains unclear whether quality of life has definitively improved.⁵⁹ It should be noted that these studies comparing sphincter-sparing resection with abdominoperineal resection/permanent colostomy are nonrandomized and therefore may be biased with regard to patient selection. The results are nonetheless interesting, particularly because a randomized controlled trial will likely never be performed.

A study by Grumann et al.⁶⁰ examined 73 rectal cancer patients and compared quality of life in patients undergoing anterior resection (AR; e.g., sphincter preservation) or abdominoperineal resection (APR). All patients were treated for cure and were disease free throughout the study. QOL was evaluated before surgery and at two time points following surgery (6–9 months, and 14–15 months). The findings revealed that on most scales the rectal cancer survivors who had an APR had superior, although not significantly better, scores than the AR patients. Of note, APR patients had significantly less constipation and diarrhea than AR patients, and also had significantly less sleeplessness; for example, the AR patients reported significantly more sleep disturbances than APR patients. On further comparison of low anterior resection versus high anterior resection, low anterior resection patients had significantly lower total QOL, role function, social function, body image, and future perspective, and more gastrointestinal- and defecation-related symptoms, than patients undergoing high anterior resection.

In another quality of life study of ostomates versus nonostomate rectal cancer survivors, a 4-year prospective study by Engel et al. examined 329 rectal cancer patients in Germany and demonstrated somewhat different findings.⁶¹ Overall, survivors who underwent anterior resection had better QOL scores than APR patients (i.e., stoma patients had significantly worse QOL scores than nonstoma patients). High anterior resection patients had significantly better scores than both low anterior resection patients and APR patients. Interestingly, APR patients' QOL scores did not improve over time.

The somewhat inconsistent findings of these studies highlight the likely selection bias that is inherent in nonrandomized observational studies. These studies do illustrate, however, the importance of having informed discussions between the patient and provider regarding options, benefits, risks, and overall expectations.

Role of Comorbid Conditions in CRC Survivors

With the earlier detection of colorectal cancer due to improved screening, there will be increasing numbers of older survivors who have a greater likelihood of comorbid condi-

tions. Healthcare providers for these survivors will have to address the disease of colorectal cancer (including the follow-up surveillance) as well as issues related to comorbid diseases. Coordinating the efforts of disease prevention, disease surveillance, and addressing the active issues of comorbidities is a complex task that requires good coordination among healthcare providers.

Few studies are available that have specifically characterized the burden of comorbid conditions in colorectal cancer survivors, partly because of the difficulty of obtaining this type of data. One study of colorectal cancer survivors (5+ years following diagnosis) using a mailed survey found the most common comorbid conditions were arthritis/rheumatism (20%), congestive heart failure (6%), hypertension (5%), angina (5%), and myocardial infarction (4%).⁵⁷

In another study using a large population-based, nationwide, patient interview, comorbidities and use of services were characterized in colon cancer patients who were 1 to 3 years past diagnosis.⁶² The study showed that 75% of survivors had reported having a major comorbid disease. The most common comorbid condition was cardiovascular related (55%), followed by hypertension (46%), arthritis (44%), coronary heart disease (13%), and pulmonary-related comorbidity (11%). Of note, almost 1 of 10 survivors reported having a history of a myocardial infarction. Also prevalent was diabetes, which was present in 14% of survivors, of which 57% were insulin dependent.

The potential significance of having diabetes is seen in a study by Meyerhardt et al.,⁶³ which showed that at 5 years, colon cancer patients with diabetes mellitus, compared with colon cancer patients without diabetes, had a significantly worse disease-free survival, overall survival, and recurrence-free survival. Median survival was 6 years and 11.3 years for diabetics and nondiabetics, respectively. Although cause of death was not explicitly studied in detail, compared with patients without a history of diabetes, those with diabetes had a 42% increased risk of death from any cause (P less than 0.0001). Further studies are needed to determine if better management of a comorbid condition such as diabetes will influence survival after a diagnosis of colon cancer.

While the available evidence in this regard is sparse, these studies highlight the potential issues related to the prevalence, detection, and need for treatment of comorbid conditions in a colorectal cancer survivor cohort. This is especially relevant as survival times increase from colorectal cancer; it is likely that the comorbidity prevalence and severity will increase as well.

Healthcare Utilization in CRC Survivors

There have been relatively few studies that have characterized the colorectal cancer patient's use of healthcare services following treatment of the cancer. One important study has examined the use of surveillance related to colorectal cancer survivors. A study by Lafata et al. examined the use of CRC surveillance tests in more than 250 colorectal cancer survivors enrolled in a large managed care organization.⁶⁴ The specific surveillance tests included colonic examinations, carcinoembryonic antigen (CEA) testing, and metastatic disease testing. The study demonstrated that within 18 months of treatment, 55% of the cohort received a colon examination,

71% received CEA testing, and 59% received metastatic disease screening tests. While it may be difficult to evaluate these findings without the breakdown of cancer stage, it is noteworthy that race/ethnicity disparities were demonstrated. Whites were more likely than minorities to receive CEA testing ($P = 0.04$) and also tended to be more likely to receive a colon examination ($P = 0.09$). Moreover, socioeconomic disparities were apparent. As the median household income increased, so too did the likelihood of colon examination and metastatic disease testing ($P = 0.03$, $P = 0.01$, respectively). The presence of disparate care is an important issue for colorectal cancer survivors.

One other study provides limited characterization of the use of services of colon cancer patients 1 to 3 years after diagnosis.⁶² In this survey-based study, the report showed that 95% of the cohort had a usual source of care and that 66% saw a primary care provider in the past 12 months. Of note, 84% saw a specialist in the past 12 months, and 68% were in the emergency room at least once during that same time period. Eighteen percent reported having had home care in the prior year. It is evident that these survivors need and obtain medical care, both for cancer surveillance as well as the comorbid conditions. It appears, however, that there may be room for improvements. Using the receipt of preventive care measures as a rough proxy for appropriate receipt of health care, the study found that only 53% of the survivors received a flu shot in the past year. Moreover, further pulmonary and/or new cancer concerns arise because the study shows that 33% still smoked tobacco, with 27% overall reported to smoke daily.

Ongoing Issues: Changes in Treatments to Minimize Treatment Morbidity

From the discussions presented here, one can see that there are considerable short- and long-term problems associated with CRC treatment. As such, there is great interest in using efficacious treatments with less morbidity. Treatment modifications that are continually being clinically defined and used include laparoscopic-assisted surgery, the use of local excision of rectal cancers, the use of nerve-sparing surgical techniques, possibly using radiation therapy less frequently, and the use of chemoprevention. The following section briefly summarizes the current issues that surround these treatments.

Laparoscopic Surgery

Although an open approach has been the traditional method of performing colorectal cancer surgery, recently there have been studies that have demonstrated the advantages of laparoscopic resection. In brief, the advantages are smaller incisions, less pain, decreased length of stay, a decrease in the incisional hernia rate, and possible less adhesion formation. A recent randomized controlled trial (RCT) compared the efficacy of laparoscopic-assisted colectomy with open colectomy and found that patients having the former approach recovered faster, had lower blood loss, and had lower morbidity (P less than 0.001). Finally, the authors report that the probability of cancer-related survival was higher in the laparoscopic-assisted group ($P = 0.02$), as the Cox model showed that laparoscopic-

assisted approach was independently associated with reduced risk of tumor relapse, death from any cause, and death from a cancer-related cause compared to open colectomy.⁶⁵

A trial of the laparoscopic versus open approach for colon cancer treatment has also been performed in North America. Regarding quality of life issues, Weeks et al. demonstrated that the global quality of life was significantly higher at 2 weeks following the laparoscopic approach.⁶⁶ Additionally, the laparoscopic patients required significantly fewer days of parenteral and oral narcotics. Of note, however, is that no differences in QOL were demonstrated at 2 months following surgery. Importantly, the survival and recurrence results of this trial were not statistically different, which thus suggests that in appropriately performed operations, laparoscopic colon cancer resections can be performed safely.⁶⁷

In the future, it is likely that increasingly more laparoscopically assisted surgical resections of colon and rectal cancers will be performed; however, it remains a priority that, with the laparoscopic approach, appropriately indicated and safe cancer resections are performed.

Local Excision for Rectal Cancer

Several researchers have reported that local excision with or without chemoradiation therapy is an alternative approach for sphincter preservation in patients with locally invasive rectal carcinoma.⁶⁸⁻⁷¹ While local excision has been performed in the past for early-stage rectal cancers, complete indications, appropriateness, and long-term results have not been finalized at this point. Local excision is performed transanally and is fundamentally a wide excisional biopsy. The rationale for this procedure is that for those patients with favorable prognosis rectal tumors confined to the bowel wall where removal of the draining lymphatic tissue would not add any oncologic benefit, local excision would be adequate and appropriate.

The technique can be relatively simple or very difficult, depending on such things as body habitus and the location and size of the tumor. In brief, using retractors or an operating proctoscope, the lesion is excised transanally with an adequate margin of normal tissue. Currently, local excision of T1 lesions with good prognostic factors (e.g., well differentiated) yields good results, and the use of adjuvant therapy in T2 lesions and lesions with high-risk factors has also been associated with favorable results. This literature is discussed in further detail in other chapters. Regarding survivors, however, meticulous follow-up is essential for early detection of local recurrences, which possibly allows for good results from salvage surgery.

In terms of function and quality of life, what is clearly advantageous regarding a transanal excision of a rectal cancer is that the potential morbidity associated with either a low anterior resection, coloanal, or an abdominoperineal resection (e.g., fecal incontinence, sexual and urologic dysfunction) is virtually eliminated (unless adjuvant radiation therapy is also performed).

Surgical Creation of a Neorectum to Improve Bowel-Related Function

One of the functions of the rectum is storage, and in this regard the rectum is a capacitance organ. When the rectum is

resected for rectal cancer and the colon is put in its place, it is understandable that bowel function is worsened. In this regard, to overcome the functional deficiencies attributed to the loss of rectal capacity and decrease in compliance, studies have demonstrated how the creation of a neorectum improves bowel function. The two most common techniques to create a neorectum are the colonic J pouch and the coloplasty.

Creation of a J pouch involves folding over the lower 6 to 8 cm of the colon to make a "J" configuration. This J pouch basically doubles the lumen diameter over the straight colon. The J pouch has been compared to straight colon anastomoses in several RCTs and has been shown to result in better function. Bowel movement frequency, continence to liquids and gas, and cancer-specific quality of life are better with the J pouch.^{28,72,73}

Another option is the coloplasty, which has been described and primarily developed in the past 5 years. Creation of a coloplasty involves making a 6- to 8-cm longitudinal incision in the lower colon and then suturing the incision closed in a transverse direction. This technique creates a larger pouch toward the lower end of the colon, just above the site of the anastomosis. RCTs of coloplasty versus J pouch have basically demonstrated an equivalent outcome in terms of bowel function (stool frequency, clustering of bowel movements, and urgency), continence, and quality of life.^{73,74} What may be advantageous for the coloplasty is the maintenance of bowel length for performance of an anastomosis and a less bulky neorectum for patients with an especially narrow pelvis. In an unpublished review, the use of neorectal pouches in rectal cancer patients is below 25%.

Necessity of Radiation Therapy: When Not to Use It

The excellent results reported by Heald^{11,75} and others utilizing "optimal surgery" (i.e., total mesorectal excision) without routine adjuvant therapy, the results of the NSABP R-02 trial, and other work bring to the forefront the controversy of omitting radiation therapy in the face of optimal surgery. Because the main purpose of radiation therapy is to improve local control, can optimally performed surgery in appropriately selected patients obviate the need for radiation therapy?

Heald examined this issue performing total mesorectal excisions for his patients with rectal cancer.^{11,75} Total mesorectal excision involves complete removal of all the rectal mesentery, which includes the lymph nodes adjacent to the rectum. In a series of 419 consecutive rectal cancer patients, cancer-specific survival of all surgically treated patients was 68% at 5 years and 66% at 10 years. The local recurrence rate was 6% at 5 years and 8% at 10 years. In 405 "curative" resections, the local recurrence rate was 3% at 5 years and 4% at 10 years. Disease-free survival in this group was 80% at 5 years and 78% at 10 years. In his series overall, Heald found that rectal cancer can be cured by surgical therapy alone in 2 of 3 patients undergoing surgical excision in all stages and in 4 of 5 patients having curative resections [it should be noted that a small percentage of the series did receive chemotherapy (6%) and preoperative radiation (9%)].

A similar case series study of a specific tumor stage (i.e., T3N0M0) has demonstrated that adequate surgery will result in superb oncological outcomes, without use of adjuvant radiation therapy. In a single institutional series, Merchant et al.

showed that sharp mesorectal excision for T3N0M0 rectal cancers results in a local recurrence rate of less than 10% without the use of adjuvant therapy.⁷⁶

Although not specifically tested, the National Surgical Adjuvant Bowel Program's R-02 trial is consistent with the nonuse of adjuvant radiation therapy. In this RCT, eligible patients ($n = 694$) with Dukes' B or C carcinoma of the rectum were randomly assigned to receive either postoperative adjuvant chemotherapy alone ($n = 348$) or chemotherapy with postoperative radiotherapy ($n = 346$).⁷⁷ The results showed that postoperative radiotherapy resulted in no beneficial effect on disease-free survival ($P = 0.90$) or overall survival ($P = 0.89$), regardless of chemotherapy. It should be noted, however, that radiation therapy did reduce the cumulative incidence of locoregional relapse from 13% to 8% at 5-year follow-up ($P = 0.02$).

In a review of the literature, Meagher et al.⁷⁸ reported that radiotherapy has only been demonstrated to significantly improve survival in one individual study and one recent meta-analysis. Although the local recurrence rates in the no-radiotherapy arm of these studies were 27% and 21% to 36.5%, respectively, in more-recent studies, with lower local recurrence rates reflecting modern surgical standards, no survival advantage has been found. While it is currently unknown whether radiotherapy improves patients' quality of life, studies have demonstrated that radiotherapy does bring about both acute and long-term detrimental effects on quality of life. Finally, these authors report that 17 to 20 patients need to undergo adjuvant radiotherapy to prevent 1 local recurrence,⁷⁸ questioning the appropriateness of radiation therapy as a general rule.

Data are available that supports the opposite sentiment. In contrast to the foregoing views, an important and recently published interim report from the Dutch Colorectal Cancer Group compared preoperative radiotherapy (20Gy over 5 days) followed by total mesorectal resection (924 patients) with total mesorectal excision alone (937 patients), that is, no radiation therapy.¹³ At 2 years, no difference in overall survival was demonstrated; however, the rate of local recurrence at 2 years was significantly lower in the radiation group (2.4% versus 8.2%; P less than 0.0001). This study demonstrates that local recurrence is lessened with adjuvant radiation therapy, even with the use of "optimal surgery."

Overall, several issues remain regarding the use of radiation therapy in rectal cancer. First, will differences in local recurrence rates affect survival rates when examined in the long term? Second, is the toxicity of radiation therapy warranted with a decrease in local recurrence? Finally, can we select patients based on preoperative stage or tumor grade who should (and should not) receive radiation therapy?

Surgical Nerve-Sparing Techniques

Nerve preservation is important when performing rectal cancer surgery. Havenga et al.³⁷ evaluated sexual and urinary function after total mesorectal excision with autonomic nerve preservation was performed in patients with tumors situated within 12 cm of the anal verge. The ability to engage in intercourse was maintained by 86% of the male patients under 60 years of age and 67% of those age over 60 or undergoing APR, with a mean of 80% of preoperative penile rigidity. The ability to achieve orgasm was retained in 87%

of men and 91% of women, with arousal and lubrication present in 85% of the women. There were no severe urinary dysfunctions.

Masui et al.⁷⁹ evaluated sexual function in 134 men who had histologically curative resections with varying degrees of autonomic nerve preservation. All were under 65 years of age and all were sexually active preoperatively; 49% had tumors above the peritoneal reflection and 52% below. These patients were interviewed at least 1 year after surgery. Erection was maintained in 93% of those with complete nerve preservation, 82% when there was a hemilateral nerve preservation, and 61% with only pelvic plexus preservation. The respective proportions with erectile rigidity and duration sufficient for vaginal insertion were 90%, 53%, and 26%. Ejaculation potencies were 82%, 47%, and 0%. Although 96% of patients reported orgasm preoperatively, 94% of men with complete preservation, 65% with hemilateral preservation, and 22% with plexus preservation reported orgasm postoperatively. The combining of total mesorectal incision with autonomic nerve preservation is essential to reducing the long-term genitourinary morbidity of rectal cancer resection. These results suggest that preservation of sexual function is dependent on careful operative technique with preservation of the pelvic autonomic nerves. The low incidence of injury after curative total mesorectal incision also stands in contradiction to earlier admonitions that if erection and ejaculation were maintained then the operation was not curative.

Chemoprevention for Survivors

An important area of cancer research that may potentially impact the medical treatment for colorectal cancer survivors is chemoprevention. Chemoprevention is the use of specific agents to prevent, inhibit, or reverse tumorigenic progression to invasive cancer. It is not intended to treat invasive carcinomas and therefore should be clearly distinguished from chemotherapy. The main goals of chemoprevention are to block the original initiation of the carcinogenic process, to arrest or reverse further progression of premalignant cells into becoming invasive or metastatic. Agents that have been investigated for chemopreventative activity in CRC include NSAIDs, calcium, antioxidant vitamins, and selenium.

Most of the work in chemoprevention of CRC has been performed in NSAIDs because of biologic evidence of the role of the cyclooxygenase pathway in CRC pathogenesis. More specifically, animal studies have demonstrated that NSAIDs function to stop colorectal carcinogenesis by blocking prostaglandin synthesis. Of the various available NSAIDs, sulindac is the most extensively studied. One study by Waddell et al. demonstrated that at doses ranging from 150 to 400 mg per day, colorectal polyps in FAP were eliminated. Importantly, the polyps regrew after sulindac was stopped, but then the polyps disappeared again after sulindac was reinstated.⁸⁰

Other studies have shown contrary results. A more recent RCT of 41 young (age 8 to 25 years) familial adenomatous polyposis (FAP) patients who were phenotypically unaffected received either 75 or 150 mg sulindac orally twice a day or identical-appearing placebo tablets for 48 months. This study found that after 4 years of treatment, adenomas developed in 9 of 21 subjects (43%) in the sulindac group and 11 of 20 subjects in the placebo group (55%) ($P = 0.54$). There were no

significant differences in the mean number ($P = 0.69$) or size ($P = 0.17$) of polyps between the groups. While this study was performed in FAP patients and not in survivors, it did demonstrate that standard doses of sulindac did not prevent the development of adenomas.⁸¹

The role and effect of NSAIDs are still to be determined. Important to their use of NSAIDs for chemoprevention is the level of associated toxicity. A recent Japanese study of sulindac 300 mg per day showed that five of six patients had drug related complications, which ranged from severe nausea and vomiting to multiple ulcers of the small bowel and stomach.⁸²

Recently, aspirin, which irreversibly affects the cyclooxygenase pathway, has been reported to decrease adenoma formation. In a randomized controlled study, 1,121 patients with a history of biopsy-proven adenomas were randomized to receive placebo (372 patients), 81 mg aspirin (377 patients), or 325 mg aspirin (372 patients) daily. Follow-up colonoscopy demonstrated that the incidence of one or more adenomas was 47% in the placebo group, 38% in the group given 81 mg aspirin per day, and 45% in the group given 325 mg aspirin per day (global $P = 0.04$). Unadjusted relative risks of any adenoma (as compared with the placebo group) were 0.81 in the 81-mg group (95% confidence interval, 0.69–0.96) and 0.96 in the 325-mg group (95% confidence interval, 0.81–1.13). For advanced neoplasms (adenomas measuring at least 1 cm in diameter or with tubulovillous or villous features, severe dysplasia, or invasive cancer), the respective relative risks were 0.59 (95%, 0.38–0.92) and 0.83 (95% confidence interval, 0.55–1.23).⁸³

A separate randomized controlled trial of 635 colorectal cancer survivors who were randomized to receive either 325 mg aspirin per day or placebo corroborates these findings. The mean (\pm SD) number of adenomas was lower in the aspirin group than the placebo group (0.30 ± 0.87 versus 0.49 ± 0.99 ; $P = 0.003$ by the Wilcoxon test). The adjusted relative risk of any recurrent adenoma in the aspirin group, as compared with the placebo group, was 0.65 (95% confidence interval, 0.46–0.91). The time to the detection of a first adenoma was longer in the aspirin group than in the placebo group (hazard ratio for the detection of a new polyp, 0.64; 95% confidence interval, 0.43–0.94; $P = 0.022$).⁸⁴

For colorectal cancer survivors in the future, chemoprevention appears to be a promising modality. There are ongoing large randomized controlled trials to address these issues and define the optimal prevention strategy.

Future Work

It is clear that there is a paucity of good evidence regarding colorectal cancer survivorship issues. Because the number of survivors will be increasing, this will be an important topic of study in the future. Specific issues include addressing the morbidities associated with the different treatment modalities, identifying and focusing on the presence of comorbidities in this elderly patient population, and improving the performance of CRC surveillance (without disparities).

Medical and Psychosocial Issues in Transplant Survivors

Karen L. Syrjala, Paul Martin,
Joachim Deeg, and Michael Boeckh

Survival rates for hematopoietic cell transplantation (HCT) have improved with advances in supportive care that have reduced acute, transplant-related mortality. More than 40,000 transplants were performed worldwide in 2002, mostly for the treatment of leukemia, lymphoma, or multiple myeloma¹ (see Chapters 63 through 69 for discussions of specific diseases). The probability of successful transplantation is generally greater for patients transplanted early in their disease course, for younger patients, and for patients who receive stem cells from donors whose human leukocyte antigens (HLA) match the patient's. For survivors who receive HCT for acute leukemia or chronic myeloid leukemia and who remain free of disease after 2 years, the probability of living 5 or more years is 89%.²

HCT survivors experience short and long-term problems similar to those of many other cancer survivors who receive systemic high-dose therapy. In addition, patients receiving stem cells from a related or unrelated donor (allogeneic) rather than receiving their own stem cells (autologous) experience complications related to the immunologic reaction of donor cells against the patient's cells and tissues. Chronic graft-versus-host disease (GVHD) occurs in about 60% of patients who survive the acute transplant-related toxicities and can persist for years. It is generally treated with immunosuppressive medications, often including high-dose glucocorticoids. Extended immunosuppression leads to several other vulnerabilities in allogeneic HCT recipients beyond that which is seen in other cancer survivors. Some of these effects result from GVHD itself; others are a consequence of the treatments used for GVHD.

Although evidence-based conclusions from HCT clinical trials are plentiful, research on survivor medical and quality of life issues is limited and largely descriptive. Randomized controlled trials are few, in part because they are difficult to accomplish with widely dispersed patients who, until recently, represented a small percentage of the cancer survivor population. Effective treatment of chronic GVHD without dependence on high-dose glucocorticoids is a

primary need for improving both survival and quality of life for allogeneic transplant survivors. Evidence is needed regarding the risks and effective treatments for fungal and pulmonary complications as well as bone- and joint-related problems such as osteoporosis and avascular necrosis.

Chronic Graft-Versus-Host Disease

Chronic GVHD is a pleiotropic syndrome with onset generally occurring between 3 and 24 months after HCT from an allogeneic donor.³⁻⁵ Clinical manifestations of chronic GVHD are highly variable and resemble an overlap of several collagen vascular diseases, with frequent involvement of the skin, liver, eyes, mouth, sinuses, and esophagus, and less-frequent involvement of serosal surfaces, lungs, lower gastrointestinal tract, female genitalia, and fascia. Major causes of morbidity include scleroderma, contractures, ulceration, keratoconjunctivitis, esophageal and vaginal strictures, obstructive pulmonary disease, and weight loss with or without malabsorption. Uncontrolled chronic GVHD interferes with immune reconstitution and is strongly associated with increased risks of opportunistic infections and death.

Studies have provided a good understanding of risk factors for development of chronic GVHD and risk factors for mortality among patients with newly diagnosed GVHD. Five-year survival rates for patients with newly diagnosed *standard-risk* chronic GVHD have remained at approximately 70%, and 5-year survival rates for those with "high-risk" chronic GVHD have remained at 40% to 50%. In aggregate, only 50% of patients with chronic GVHD are able to discontinue immunosuppressive treatment within 5 years after the diagnosis, and 10% require continued treatment beyond 5 years. The remaining 40% die or develop recurrent malignancy before chronic GVHD resolves. Prolonged treatment with high-dose glucocorticoids causes considerable morbidity, leading to a desperate need for agents that can decrease the dependence on steroids for controlling the disease.

Prevention of Chronic GVHD

Results of retrospective analyses and Phase 3 clinical trials have identified a variety of risk factors for the development of chronic GVHD after allogeneic HCT (Table 110.1). Risk factors that cannot be controlled as part of medical management include older age of the patient, the use of a female donor, and the use of an unrelated donor or HLA-mismatched related donor as opposed to an HLA-identical sibling.^{3,5} Risk factors that can be controlled as part of medical management are related to the use of marrow versus growth factor-mobilized blood as the source of hematopoietic cells, the numbers of T cells and CD34-positive cells in the graft, the use of prednisone for prevention of GVHD after the transplant, and the duration of cyclosporine administration.

The use of growth factor-mobilized peripheral blood as opposed to marrow as a source of stem cells clearly increases the risk of chronic GVHD⁶ and may prolong the duration of immunosuppression needed to control chronic GVHD.⁷ These results are consistent with findings that the risk of chronic GVHD increases after administration of nonmobilized buffy coat cells to prevent rejection after marrow transplantation for treatment of aplastic anemia.⁸ Despite these observations, the choice between mobilized blood cells and marrow depends primarily on the evaluation of other endpoints, such as survival or relapse-free survival, which are more important than the risk of chronic GVHD per se.

The increased risk of chronic GVHD after transplantation with mobilized blood could reflect the 10-fold-higher number of T cells in the graft as compared to marrow. However, results of retrospective studies that correlated the cellular composition of mobilized apheresis products with a variety of outcomes after transplant did not support this interpretation. Instead, chronic GVHD was associated with high numbers of CD34-positive cells in the graft.^{9,10} Mechanisms to explain this unexpected association remain to be defined.

Results of an early randomized trial¹¹ and many Phase 2 studies have suggested that depletion of T cells from the graft decreases the risk of chronic GVHD, and this suggestion was initially confirmed by results from a large retrospective review of data from the International Bone Marrow Transplant Registry (IBMTR).¹² A subsequent review of data in the IBMTR, however, unexpectedly showed a higher risk of chronic GVHD among patients who received HLA-mismatched marrow treated with "narrow specificity" antibodies compared to those who received marrow that was treated by other methods or that was not treated.¹³ Preliminary results of a recent randomized controlled trial showed that T-cell depletion did not decrease the risk of chronic GVHD.¹⁴ Recent evidence has suggested that depletion of donor T cells by *in vivo* administration of rabbit antithymocyte globulin (ATG) may reduce the risk of chronic GVHD.¹⁵

Taken together, the T-cell depletion trials and ATG trials have produced inconsistent results regarding the relationship between the T-cell content of the graft and risk of chronic GVHD, making it difficult to reach a general conclusion. The possible association between the number of CD34 cells in the graft and risk of chronic GVHD needs confirmation from additional studies.

Four randomized clinical trials have evaluated the effects of prophylactic glucocorticoid administration after allogeneic

marrow transplantation.¹⁶⁻¹⁹ In each of these studies, the primary endpoint was the development of acute GVHD, and chronic GVHD was a secondary endpoint. Results with respect to chronic GVHD were inconsistent, despite enrollment of 108 to 186 patients in each study. The weight of the evidence suggests that prophylactic administration of glucocorticoids after marrow transplantation is likely to increase rather than decrease the risk of chronic GVHD.

Two randomized trials^{20,21} and one sequential cohort study²² have evaluated the risk of chronic GVHD as related to the duration of cyclosporine administration. Taken together, the consistent results of these trials suggest that prolonged administration of cyclosporine might yield a modest reduction in the risk of chronic GVHD, but the effect was too small to reach statistical significance in the two randomized trials.

Results from Phase 2 studies suggested that thalidomide might be effective for treatment of chronic GVHD, but results from a Phase 3 study showed that mortality was increased when thalidomide was administered before the onset of chronic GVHD.²³

Treatment of Chronic GVHD

Anecdotal experience and retrospective reviews during the 1970s and early 1980s demonstrated that untreated clinical extensive chronic GVHD generally causes severe disability related to scleroderma, contractures, strictures, pulmonary disease, and keratoconjunctivitis (Table 110.2).³⁻⁵ Administration of prednisone late in the natural history of the disease provided little benefit. Early administration of prednisone appeared to prevent disability but did not greatly affect survival. Retrospective reviews have identified a variety of factors associated with an increased risk of mortality from causes other than recurrent malignancy among patients with chronic GVHD.^{3,5} The most consistently reported findings indicate an increased risk of transplant-related mortality among patients who have direct progression from acute to chronic GVHD or a platelet count less than 100,000/ μ L at the diagnosis of GVHD. The term high-risk chronic GVHD has been used to describe cases with either of these characteristics, whereas standard-risk chronic GVHD excludes cases with either of these characteristics.

An early double-blind randomized trial was carried out to determine whether administration of azathioprine together with prednisone might be more effective than prednisone alone for treatment of newly diagnosed chronic GVHD.²⁴ The results unexpectedly showed inferior outcomes for patients in the azathioprine arm. The difference in survival was attributed to an increased incidence of infections in the azathioprine arm.

Results of sequential Phase 2 studies suggested that survival among patients with high-risk chronic GVHD might be improved by combined treatment with cyclosporine and prednisone.^{24,25} In a subsequent randomized prospective trial, however, cyclosporine did not provide a survival benefit, although the incidence of avascular necrosis was decreased in the cyclosporine arm, suggesting a steroid-sparing effect.²⁶

Results of several Phase 2 studies suggested that thalidomide might be effective for treatment of steroid-refractory chronic GVHD, but subsequent randomized trials showed no benefit with the use of thalidomide.^{27,28}

TABLE 110.1. Clinical trials of prevention of chronic graft-versus-host disease.

Author	Reference	Year	No. of patients	Randomized (Y/N)	Diagnosis/ stage of disease	Intervention/design	Follow-up	Relative risk/outcomes	Survival statistics	Conclusions/ comments
Mitsuyasu et al.	11	1986	40	Y	Leukemia	T-cell-depleted marrow compared with unmodified marrow; methotrexate or cyclosporine also given to prevent GVHD; RCT	1-2 years	Decreased incidence of chronic GVHD with T-cell-depleted marrow (5% versus 25%)	No significant difference between arms	T-cell depletion increased the risk of recurrent malignancy after the transplant
Marmont et al.	12	1991	3,211	N	Leukemia	T-cell-depleted marrow compared with unmodified marrow; retrospective multicenter cohort study	3-8 years	Relative risk of chronic GVHD = 0.56 with T-cell depletion compared to unmodified marrow ($P < 0.0001$)	Decreased leukemia-free survival with T-cell depletion	T-cell depletion increased the risk of recurrent malignancy after the transplant
Champlin et al.	13	2000	1,868	N	Leukemia	T-cell-depleted marrow compared with unmodified marrow; depletion with "narrow specificity" antibodies compared to other methods; retrospective multicenter cohort study	4 months to 11 years	Relative risk of chronic GVHD = 1.5 for marrow treated with "narrow specificity" antibodies compared to untreated marrow ($P < 0.0003$)	Leukemia-free survival better after T-cell depletion with "narrow specificity" antibodies compared to other methods; no significant difference in leukemia-free survival with "narrow specificity" antibodies compared to unmodified marrow	The use of "broad specificity" methods that deplete natural killer cells and T cells from HLA-mismatched donor marrow appeared to have detrimental effects on outcome
Wagner et al.	14	2002	410	Y	Mostly leukemia	T-cell-depleted marrow and immunosuppression with cyclosporine compared with unmodified marrow and immunosuppression with methotrexate and cyclosporine; multicenter RCT	2-6 years	Incidence of chronic GVHD = 24% with T-cell depletion and 29% with unmodified marrow	T-cell depletion was associated with an increased risk of recurrent malignancy among patients with chronic myeloid leukemia; leukemia-free survival was similar in the two arms for patients with other diseases	T-cell depletion decreased the risk of severe acute GVHD but did not improve survival
Bacigalupo et al.	15	2001	109	Y	Hematologic malignancies	Conventional pretransplant conditioning with or without rabbit antithymocyte globulin administered at two different doses; two consecutive RCT		Incidence of chronic GVHD = 39% with ATG and 62% without ($P = 0.04$)	No difference in survival between arms	Use of ATG at the higher dose was associated with an increased risk of infections
Storb et al.	16	1990	147	Y	Mostly leukemia	Posttransplant immunosuppression using methotrexate plus cyclosporine, with or without prednisone administered throughout the first 35 days after transplant; two studies, one RCT and the other a prospective cohort study	1.5-3 years	Incidence of chronic GVHD = 62% with prednisone and 40% without ($P = 0.01$)	No difference in survival between arms	Use of prednisone increased the risk of chronic GVHD

Deeg et al.	180	1997	122	Y	Hematologic malignancy	Posttransplant immunosuppression with cyclosporine with or without methylprednisolone administered between days 7 and 72 after transplant; RCT	0.5–3.5 years	Incidence of chronic GVHD = 44% with methylprednisolone and 21% without ($P = 0.02$)	No difference in survival between arms	Incidence of acute GVHD was 60% with methylprednisolone and 73% without ($P = 0.01$)
Chao et al.	18	2000	193	Y	Leukemia	Posttransplant immunosuppression using methotrexate plus cyclosporine with or without prednisone administered between days 7 and 180 after transplant; RCT	1–6 years	Incidence of chronic GVHD = 46% with prednisone and 52% without ($P = 0.38$)	No difference in survival between arms	Incidence of acute GVHD was 18% with prednisone and 20% without ($P = 0.6$)
Ruutu et al.	181	2000	108	Y	Hematologic malignancy	Posttransplant immunosuppression using methotrexate plus cyclosporine with or without methylprednisolone administered between days 14 and 110 after transplant; RCT	4–9 years	Incidence of chronic GVHD = 35% with methylprednisolone and 48% without ($P = 0.17$)	No difference in survival between arms	Incidence of acute GVHD was 19% with methylprednisolone and 56% without ($P = 0.0001$)
Storb et al.	20	1997	103	Y	Mostly leukemia	Posttransplant immunosuppression using methotrexate plus cyclosporine administered to day 60 or day 180 among patients who did not have GVHD on day 60; RCT	1–10 years	Incidence of chronic GVHD = 54% in the day 60 arm and 43% in the day 180 arm ($P = 0.26$)	Possible increase in transplant-related mortality in day 60 arm among patients with GVHD before day 60	No benefit from prolonged administration of cyclosporine among patients who did not have acute GVHD
Kansu et al.	21	2001	162	Y	Mostly leukemia	Patients eligible if they had a prior history of acute GVHD or if skin biopsy showed histologic evidence of GVHD on day 80; RCT comparing administration of cyclosporine for 6 or 24 months	2–9 years	Incidence of chronic GVHD = 39% in the 24-month arm and 51% in the 6-month arm ($P = 0.24$); hazard ratio = 0.76 ($P = 0.25$)	No difference in survival	Prolonged administration of cyclosporine did not greatly decrease the incidence of chronic GVHD
Mengarelli et al.	22	2003	57	N	Hematologic malignancy	Patients received peripheral blood cells from an HLA-identical sibling, and cyclosporine was administered for either 6 or 12 months in two consecutive retrospective cohorts	1–4 years	Incidence of chronic GVHD = 25% in the 12-month group and 69% in the 6-month group; hazard ratio = 0.2 (adjusted $P = 0.008$)	No difference in survival	Prolonged administration of cyclosporine appeared to decrease the incidence of chronic GVHD
Chao et al.	23	1996	59	Y	Hematologic malignancy	Administration of thalidomide or placebo beginning at day 80 after transplant; double-blind RCT	6 months to 3 years	Incidence of chronic GVHD = 64% with thalidomide and 38% with placebo ($P = 0.06$)	Increased mortality in the thalidomide arm ($P = 0.006$)	Administration of thalidomide was unexpectedly found to be harmful

GVHD, graft-versus-host disease; RCT, randomized controlled trial; ATC, antithymocyte globulin.

TABLE 110.2. Clinical trials of chronic graft-versus-host disease.

Author	Reference	Year	No. of patients	Randomized (Y/N)	Diagnosis/stage of disease	Intervention/design	Follow-up	Relative risk/outcomes	Survival statistics	Conclusions/comments
Sullivan et al.	25	1988	126	Y	Newly diagnosed chronic GVHD and platelet count >100,000/ μ L	Prednisone with or without azathioprine; double-blind RCT	Minimum of 3.8 years	Not stated	47% survival at 5 years with prednisone plus azathioprine, 61% with prednisone plus placebo ($P = 0.03$)	Results demonstrate inferior outcomes when azathioprine was used to treat chronic GVHD
Koc et al.	26	2002	287	Y	Newly diagnosed chronic GVHD and platelet count >100,000/ μ L	Prednisone with or without continued administration of cyclosporine; RCT	4–14 years	Incidence of nonrelapse mortality at 5 years = 17% with prednisone plus cyclosporine, 13% with prednisone; hazard ratio = 1.55 ($P = 0.11$)	67% survival at 5 years with prednisone plus cyclosporine, 72% with prednisone; hazard ratio = 1.35 ($P = 0.13$) 61% survival without recurrent malignancy at 5 years with prednisone plus cyclosporine, 71% with prednisone; hazard ratio = 1.51 ($P = 0.03$)	Subset analysis suggested increased mortality among patients with chronic GVHD that evolved directly from acute GVHD Incidence of avascular necrosis was lower with prednisone plus cyclosporine than with prednisone alone
Arora et al.	27	2001	54	Y	Newly diagnosed chronic GVHD	Prednisone and cyclosporine with or without thalidomide (200–800 mg/day); double-blind RCT	0.5–4.8 years	Incidence of partial or complete response at 2, 6, and 12 months = 83%, 88% and 85% with thalidomide, 89%, 84%, and 73% without thalidomide	66% at 2 years with thalidomide, 54% without thalidomide ($P = 0.85$)	High response rate was observed in both groups; study was terminated early due to low accrual rate
Koc et al.	28	2000	52	Y	Newly diagnosed chronic GVHD with platelet count <100,000/ μ L or progressive onset from acute GVHD as high-risk features	Prednisone and cyclosporine or tacrolimus with or without thalidomide (200–800 mg/day); double-blind RCT	Not reported	No statistically significant difference in transplant-related mortality	49% survival at 4 years with thalidomide, 47% without thalidomide ($P = 0.87$)	Thalidomide caused intolerable side effects, leading to premature discontinuation of administration in 92% of patients; the duration of thalidomide administration was not sufficient to allow assessment of efficacy

Phase 2 studies have been carried out to evaluate the use of many immunosuppressive agents for treatment of steroid-refractory chronic GVHD. The small number of enrolled patients, the widely divergent enrollment criteria and poorly defined efficacy criteria, and the lack of controls hamper the interpretation of these studies. Efficacy is generally reported as improvement in symptoms or signs of chronic GVHD at any time after introduction of the additional immunosuppressive treatment. The duration of clinical improvement is typically not taken into account, and survival data are difficult to interpret because of variable follow-up and possible selection biases in enrollment. In the absence of pharmacokinetic evaluation, studies of this type typically do not add useful information to the available safety profile of approved immunosuppressive agents. Trial designs with prior specification of criteria for judging efficacy according to robust and meaningful endpoints would help to make the results of Phase 2 studies more informative.

Emerging Challenges in Chronic GVHD

Advances in supportive care have reduced morbidity, but survival for patients with newly diagnosed chronic GVHD has not changed since the mid-1980s.^{3,5} In the past, investigators have taken the highly empirical approach of testing virtually any available immunosuppressive agent for treatment of chronic GVHD, because the pathophysiology of chronic GVHD is complex and poorly understood. Development of a more-direct approach will require an improved understanding of the pathophysiologic mechanisms leading to chronic GVHD.

Infections

A susceptibility to late infectious complications persists because of residual immunodeficiency that is observed in all HCT recipients, not only those with allogeneic donors,²⁹ although infection risk is increased with the additional immunosuppression associated with chronic GVHD and its treatment (Table 110.3).

Bacterial

There is a significant risk for severe infection with encapsulating bacteria (*Streptococcus pneumoniae*, *Haemophilus influenzae*) after HCT in the setting of chronic GVHD.³⁰ Patients may develop rapidly progressive disease, which is often fatal. The presumed explanation for bacteremic pneumococcal infections is that HCT patients lose and do not subsequently make opsonizing antibody to encapsulated gram-positive organisms, even after recovery from infection.³⁰ Patients also respond poorly to immunization with prototype pneumococcal vaccines for the first 1 to 2 years after transplant, although response again improves with time.^{31,32} Immunization with the available pneumococcal vaccines provides incomplete protection for those most in need, that is, patients with chronic GVHD.³³

Antibacterial prophylaxis is recommended in patients with chronic GVHD to prevent both bacteremic pneumococcal and other infection, although no randomized placebo-controlled trials have been performed.³⁴ The 23-valent

pneumococcal polysaccharide vaccine (12 and 24 months after transplantation) and the *Haemophilus influenzae* B conjugate vaccine (12, 14, and 24 months after transplantation) are recommended in standard guidelines.³⁴ However, these vaccinations are not 100% protective; the 7-valent conjugated pneumococcal vaccine has not been evaluated in transplant recipients.

Although penicillin appears to work for this indication, the recent emergence of penicillin-resistant pneumococci make it a less preferable choice.³⁵ Rather, trimethoprim-sulfamethoxazole (TMP-SMX) given once daily (80mg TMP component) provides protection both against *Pneumocystis jiroveci* pneumonia (PCP), encapsulated bacteria, and possibly also against toxoplasmosis. Controlled trial data are not available to evaluate the efficacy of such prophylaxis, but retrospective study of nonrandomized treatment groups indicates that patients with chronic GVHD who receive TMP-SMX prophylaxis have a significantly lower incidence of infection.²⁹ Oral penicillins should be reserved for patients who are unable to tolerate daily TMP-SMX. No reports exist about new quinolones or macrolides for this indication.

Because infection with other organisms including both *Staphylococcus* species and gram-negative aerobic bacteria also occurs, empirical antibiotic treatment of HCT patients admitted with clinical sepsis should include broad-spectrum coverage until the identity of the infecting organisms is known.

Viral

Varicella-zoster virus (VZV) disease is the most common viral infection late after HCT.³⁶⁻⁴⁰ Median time of onset is 5 months after transplant, and most cases occur within the first year. However, VZV disease can occur up to several years after transplantation, especially in the setting of chronic GVHD. A subgroup at particularly high risk for VZV infection is VZV-seropositive allogeneic transplant recipients of age greater than 10 years who received total-body irradiation (TBI). In one study, the risk of VZV disease was 44% during the first 3 years after transplant among these patients.⁴¹ Abdominal infections without skin manifestations are observed occasionally. These manifestations carry a high mortality, and the clinical hallmark is rapidly rising transaminases. In an unpublished randomized double-blind trial, oral acyclovir at a dose of 800mg twice daily for 1 year prevented VZV infection after HCT without rebound disease after discontinuation of prophylaxis. This treatment may be particularly useful in patients with continued chronic GVHD.³⁷ Strategies that used lower doses for a shorter duration resulted in a high number of infections after discontinuation of prophylaxis.⁴²

Cytomegalovirus (CMV) seropositive transplant recipients and recipients of stem cell products from a seropositive donor continue to be at risk for late CMV disease if they have chronic GVHD and/or have reactivated CMV during the first 100 days after transplantation.⁴³⁻⁴⁶ The majority of late disease occurs during the first year after transplantation, but there may be cases until 3 years after transplant if immunosuppression continues. Clinical manifestation of late CMV disease may differ from the typical pneumonia and gastrointestinal disease seen earlier. Cases of retinitis, late marrow failure, and encephalitis have been described.⁴⁷ Outcome of late CMV disease is poor, with pneumonia having the highest

TABLE 110.3. Infections after hematopoietic cell transplantation (HCT).

Author	Reference	Year	No. of patients	Randomized (Y/N)	Diagnosis/ stage of disease	Intervention/design RCT	Median follow-up 12 months	Relative risk/hazard ratio	Conclusions/results
Ljungman et al.	42	1986	42	Y	Various			Not reported	Acyclovir prophylaxis given for 6 months leads to prevention of HSV and VZV infection during prophylaxis but frequent recurrence of VZV after discontinuation

mortality.⁴⁶ About one-third of patients who survive the first episode of late disease will suffer a relapse after a median of 3 months.⁴⁶ Continued monitoring [pp65 antigenemia, polymerase chain reaction (PCR) for CMV DNA] and use of preemptive therapy in high-risk patients is useful in the management of patients at risk for late CMV disease.^{46,48}

HCT recipients with chronic GVHD continue to be at risk for acquisition of respiratory virus infections such as respiratory syncytial virus, influenza viruses, and parainfluenza viruses. Seasonal vaccination of close contacts with the inactivated vaccine is recommended.³⁴ Recipient vaccination starting at 6 months after transplantation is also recommended.³⁴ Less commonly, late impaired graft function has been described in association with human herpes virus (HHV)-6 and human parvovirus B 19.

Fungal

Late invasive aspergillosis is an increasingly frequent event in allogeneic graft recipients with chronic GVHD and preceding viral infections (i.e., CMV, respiratory viruses), possibly due to an immunosuppressive effect of these viruses.⁴⁹ Recipients of lower-dose conditioning regimens who have GVHD are also at risk for late mold infections.⁵⁰ In contrast, invasive candidiasis occurs infrequently after day 100.^{50,51} The outcomes of both mold and candidal infections in this setting remain poor. Mold-active drugs are now available (itraconazole, voriconazole). However, the efficacy and toxicity of long-term prophylaxis have not been tested in randomized fashion in this setting. Sensitive diagnostic tests (aspergillus galactomannan assay, PCR) can be used for early diagnosis of disease.

Pneumocystis jiroveci Pneumonia (PCP)

With the availability of effective prophylaxis, early cases of *Pneumocystis jiroveci* pneumonia (PCP) are only rarely seen late after transplant.⁵² Most cases occur in a setting of poor adherence or in patients who are unable to tolerate TMP-SMX because of side effects or allergy, or who received ineffective alternative prophylaxis regimens.⁵³ Standard guidelines following allogeneic transplantation recommend prophylaxis for the duration of drug-induced immunosuppression.³⁴ However, the optimal duration of prophylaxis after autologous transplant is currently poorly defined, as recent data suggest that there is late PCP in autologous graft recipients as well.⁵⁴ Approximately 15% to 30% of HCT recipients require alternative prophylaxis regimens at some time after transplantation.⁵⁵ Reasons for requiring alternative prophylaxis include allergy to TMP-SMX, gastrointestinal intolerance, increased transaminases, and neutropenia. Very few data exist on the efficacy and toxicity of alternative prophylaxis regimens. Daily dapsone appears to be superior to inhaled pentamidine.⁵⁵ As it has overall superior results, TMP-SMX should be given whenever possible. Desensitization should be attempted in all patients with allergy to TMP-SMX.⁵² Only limited data exist on atovaquone.⁵⁶

The clinical syndrome of PCP is indistinguishable both clinically and radiologically from other nonbacterial pneumonias. The diagnosis is established either by bronchoalveolar lavage (BAL), induced sputum, or thoracoscopic or open

lung biopsy. The treatment of choice is high-dose intravenous TMP-SMX in combination with a short course of corticosteroids based on results in human immunodeficiency virus (HIV)-infected patients.⁵⁷ Of the alternative agents used in the HIV setting (intravenous pentamidine, atovaquone, clindamycin/primaquine, dapsone/trimethoprim, and trimetrexate), clindamycin/primaquine appears to be most effective for treatment of disease.⁵⁸

Distinctions in Adult and Pediatric Presentation, Course, and Treatment

Virtually no data exist on differences in infection risk and outcome among survivors of HCT. Whether immune reconstitution is faster in younger individuals has not been studied. However, if chronic GVHD is present, all available data suggest that children have the same infectious risk as adults. The exposure to respiratory viruses may even be higher if children are exposed to group settings. Certain contraindications for use of antimicrobials (e.g., quinolones) should be considered in the management of children.

Emerging Challenges in Infection

The major challenge is to design infection prevention strategies for survivors of HCT with persistent severe immunosuppression. These patients are not only at risk for VZV, PCP, and encapsulated bacteria but also for CMV and invasive mold infections. Strategies need to be easy to administer, effective, and well tolerated. With increasing long-term use of antimicrobials, resistance may become a challenge in the future.

Other Medical Complications

Pulmonary

Chronic pulmonary complications affect at least 15% to 20% of patients after HCT, and pulmonary dysfunction is an important risk factor for delayed mortality. However, current knowledge is based exclusively on retrospective analyses (Table 110.4).

LATE-ONSET PNEUMONITIS

Late-onset interstitial pneumonitis usually occurs in patients with chronic GVHD.⁵⁹ Most require therapy with immunosuppressive agents; treatment with bronchodilators is usually ineffective. However, late pneumonias occur also in the absence of GVHD, and even after autologous transplantation in patients who have not previously had pulmonary disease, with an incidence of 31% at 4 years. The prognosis is generally good with bacterial etiology, but mortality reaches 80% with fungal or polymicrobial pneumonia.⁵⁴

RESTRICTIVE PULMONARY DISEASE

Pretransplant and posttransplant abnormal pulmonary function tests (PFTs), in particular decreased diffusing capacity (DLCO) and increased oxygen gradient [P(A-a) O₂], are associated with higher posttransplant mortality than seen in

TABLE 110.4. Pulmonary complications after HCT.

Author	Reference	Year	No. of patients	Randomized (Y/N)	Diagnosis/stage of disease	Intervention/design	Follow-up	Relative risk/outcomes/predictors	Disease-free survival (or survival statistics)	Conclusions/results
Chien et al.	63	2003	1,131	N	Various	Retrospective cohort study	1–11 years	AFO associated with decrease in FEV ₁ >5%/year, decreased pretransplant FEV ₁ /FVC, acute and chronic GVHD, respiratory virus infection Among patients with chronic GVHD, those with AFO have a higher risk of mortality (HR 2.3, 95% CI 1.63–3) than patients without AFO Risk increases with increasing age (RR 1.7–2.5) for patients more than 20 to more than 60 years of age and patients with quiescent (RR 1.6) or progressive onset (RR 1.9) of chronic GVHD	AFO attribution to mortality, all patients (those with chronic GVHD): 9% (22), 12% (27), 18% (40) at 3, 5, and 10 years, respectively	75% of AFO occurred in patients with chronic GVHD AFO is more frequent than previously reported and has a major negative impact on long-term survival, particularly in patients with chronic GVHD
Chen et al.	54	2003	1,359	N	Various	Retrospective cohort study	0.01–5 years	Risk factors include: patient age, HLA non-identity, and chronic GVHD among allogeneic recipients (none identified for autologous)	Cumulative incidence of first pneumonia at 4 years was 31% (18% for autologous, 34% for HLA-identical allogeneic, 39% for other allogeneic/unrelated) Survival rates were best with bacterial (71%), and worst with multimicrobial pneumonias (8%)	Pneumonia is frequent, even late after transplantation and poses a significant risk, particularly among patients more than 40 years of age, and in patients with chronic GVHD

Crawford et al.	60	1995	906	N	Various	Retrospective cohort study	1-9 years	Restrictive lung defect at 3 months after transplant or $\geq 15\%$ decline in total lung capacity from baseline was associated with a twofold increase in risk of nonrelapse mortality (respiratory failure)	Death from respiratory failure occurred in 1.9% of patients with normal or unchanging total lung capacity, compared to 5.3% in patients with restrictive ventilatory defects; chronic GVHD did not appear to influence the rate of death with respiratory failure	Impaired total lung capacity, impaired airflow, and decreased diffusing capacity all had a negative impact on survival
Sullivan et al.	68	1996	250	Y	Various	IV immunoglobulin (500mg/kg/month) between days 90 and days xvs. none; RCT		No difference in systemic infections; localized infections marginally more frequent in controls ($P = 0.07$); after 2 years total infections less common in controls ($P = 0.03$)	No difference	Prophylactic administration of IV immunoglobulin, in the absence of in the absence of hypogammaglobulinemia, has no demonstrable benefit, and in fact may delay endogenous immune recovery
Freudenberger et al.	69	2003	49 patients 161 controls	N	Various	Case-control study	Sequentially	Risk factors for bronchiolitis obliterans organizing pneumonia (BOOP): acute ($P = 0.002$) and chronic ($P = 0.02$) GVHD; progressive onset chronic GVHD ($P = 0.001$); skin involvement with acute (HR 4.6), and oral (HR 5.9) and gut involvement (HR 6.6)	5-year survival 31% in patients with BOOP vs. 45% in controls ($P = 0.05$)	BOOP is more frequent in patients with acute or chronic GVHD Steroid treatment has no recognizable therapeutic effect

AFO, air flow obstruction.

patients with normal tests.⁶⁰ Restrictive defects, defined as a decrease in total lung capacity to less than 80% of predicted values, are present in one-third of all patients studied. Changes are not correlated with the type of conditioning regimen or with chronic GVHD and generally do not produce severe symptoms. However, because they are associated with an increase in late mortality, routine evaluation of lung function after HCT is warranted.⁶¹ Aggressive therapy of any infection of the respiratory tract is indicated.

OBSTRUCTIVE PULMONARY DISEASE

Air flow obstruction (AFO), defined as decreased expiratory airflow, in particular, a decrease in the proportion of air that can be exhaled over the first second of expiration, may represent sequelae to extensive restrictive changes in the small airways or may be related to small airway destruction.⁶² Both acute and chronic GVHD are important risk factors for AFO, and thereby affect long-term survival, with 75% of AFO cases occurring among patients with chronic GVHD, particularly those with quiescent or progressive onset (see Table 110.4).⁶³ There is generally no response to bronchodilator treatment; 30% to 40% of patients improve on glucocorticoids. Few patients with end-stage disease have been treated successfully with cadaveric lung transplants.^{64,65}

BRONCHIOLITIS OBLITERANS

Progressive bronchiolitis obliterans has been reported in 10% of patients with chronic GVHD.^{66,67} Chest radiographs may show hyperinflation of the lungs and flattening of the diaphragm, but abnormalities are best identified by high-resolution computed tomography (CT) scans (inspiratory and expiratory cuts). PFTs show a reduction in forced midexpiratory flow to 10% or 20% of predicted values and moderate to severe reduction in forced vital capacity. The diffusion capacity is usually normal. Pulmonary ventilation scans show decreased activity patterns corresponding to areas of obliteration of bronchiolar walls along with atelectatic areas. Histologic changes are thought to be due to a graft-versus-host reaction, possibly aggravated by infections.

The clinical course of bronchiolitis varies from mild, with slow deterioration, to diffuse necrotizing fatal bronchiolitis. Severe disease may not respond to glucocorticoids, but corticosteroids in combination with calcineurin inhibitors or possibly azathioprine can stabilize PFTs and improve outcome. It is of note that a randomized trial examining the effect of intravenous immunoglobulin on chronic GVHD and bronchiolitis showed a marked decrease in the incidence of obliterative bronchiolitis in all patients such that an effect of intravenous Ig was not apparent.⁶⁸

Bronchiolitis obliterans organizing pneumonia (BOOP) histologically shows polypoid masses of granulation tissue in the bronchioles and alveolar sacs as well as infiltration of alveolar septa by mononuclear cells. A recent analysis of results in 6,523 patients transplanted at the Fred Hutchinson Cancer Research Center revealed 51 cases of BOOP, all but 2 after allogeneic transplants.^{69,70} BOOP was diagnosed at 5 to 2,819 (median, 108) days after HCT. The chest radiograph was abnormal in 47 patients. Most patients presented with fever, dyspnea, or cough, but 23% were asymptomatic. Most patients respond to glucocorticosteroids (1–2 mg/kg), which often must be continued for 6 months or longer.

Osteoporosis

Dual-energy X-ray absorptiometry (DEXA), a semiquantitative method to assess bone mineral density (BMD), is a validated method commonly used to detect osteoporosis [as defined by a Z-score of less than or equal to 2.5 standard deviations (SD) below sex- and age-related mean bone mineral density (BMD)] and osteopenia (defined by a Z-score of 1.0 to 2.4 SD below sex- and age-related mean BMD). Reduction of bone mass using DEXA has been reported in approximately 40% of men and women at 1 year after allogeneic HCT, with nontraumatic fractures in 11% by 3 years.⁷¹ Risk factors include number of days and dose of glucocorticoids and number of days of cyclosporine or tacrolimus used for treating chronic GVHD.

In women, supplementation with estrogens and medroxyprogesterone can increase bone mass after HCT.⁷² However, there may be increased risks of cardiovascular diseases (venous thrombosis, strokes, pulmonary emboli) and breast cancer in postmenopausal women given conjugated equine estrogen (0.625 mg) with medroxyprogesterone (2.5 mg).⁷³ This possibility is of concern because HCT recipients are at risk for secondary malignancies even without hormone therapy. Thus, the overall risks and benefits of hormone replacement in this situation remain to be determined. Lower doses of estrogen alone (after hysterectomy) or combined with progestin (in women with uterus intact) have been used for the management of bone loss in other patient populations.⁷⁴ Alternative regimens of bisphosphonates or hormone therapy have not been tested in clinical trials for efficacy or safety in women after HCT either for osteoporosis prevention or for postmenopausal symptoms.

Aseptic Necrosis

Avascular necrosis, especially in weight-bearing joints, is a classic side effect of glucocorticoid therapy and has been reported in 4% to 10% of allogeneic HCT survivors as early as 2 months and as late as 10 years posttransplant.^{75–77} The hip is the joint most frequently affected (two-thirds of all cases). In most patients more than one joint is affected. One-third of patients with this disease required joint replacement at 2 to 42 months.⁷⁶ A case-control study of 87 patients with avascular necrosis found that posttransplant glucocorticoid use and TBI given in preparation for HCT were significant risk factors.⁷⁸ In addition to glucocorticoid therapy, male gender (relative risk, 4.2) and age greater than 15 years (relative risk, 3.8) were risk factors.

Endocrinology

THYROID

Overt or compensated hypothyroidism and the “euthyroid sick syndrome” [ETS; low free triiodothyronine, free thyroxine, or both, along with normal or low thyroid-stimulating hormone (TSH)] are the most frequent thyroid abnormalities following transplantation (Table 110.5).⁷⁹ In one study ETS was associated with a significantly lower survival than observed in patients not affected by ETS (34.5% versus 96.2%; *P* less than 0.0001).^{80,81} The risk of hypothyroidism is increased in patients who received pretransplant cranial

TABLE 110.5. Endocrine function, and growth and development.

Author	Reference	Year	No. of patients	Randomized (Y/N)	Diagnosis/stage of disease	Intervention/design	Follow-up	Relative risk/outcomes/predictors	Conclusions/results
Leung et al.	182	2000	43	N	Various with chemotherapy alone vs. chemo + cranial irradiation vs. chemo +TBI HCT	Retrospective cohort study	Median 13 years	Decreased height by 0.21 SD with chemo vs. 1.2 with chemo + cranial vs.1.33 with HCT	Importance of irradiation; growth hormone deficiency only with HCT
Thomas et al.	183	1993	49	N	Various	Retrospective cohort study	1-3 years	TBI 1,000 cGy single vs. 1,200-1,440 cGy fractionated dose; decrease in height of 0.2-0.9SD vs. 0.09-0.2SD; accentuated by cranial irradiation	Irradiation impairs growth; more so as single dose, and even further with cranial irradiation; growth hormone is helpful, should be instituted early (before the growth lag is >1.5 SD); dose should be adjusted for puberty
Sanders	184	1991	63 (55) (154)	N	Various	Retrospective cohort study	>12 years	Cyclophosphamide alone leads to little delay; TBI, single dose (71%; 83%) more than fractionated (49%; 58%) delays development	Cyclophosphamide by itself is well tolerated; little if any delay and normal rates of pregnancy Busulfan has intermediate effect TBI results in marked impairment
Sanders	83	2004	145/93 (128/98)	N	Various	Retrospective cohort study	1-12 years	Cyclophosphamide alone, 54% of women recover normal function; among men, 95% normal Sertoli cellfunction, 61% normal FSH; with busulfan/cyclophosphamide, only 2 of 93 women recovered ovarian function. Among men 65% showed azoospermia	Significant impairment of gonadal function with busulfan-containing regimens; less so with cyclophosphamide
Sanders	83	2004	562 (498)	N	Various	Retrospective cohort study	1-14 years	1,000 cGy single or 1,200-1,575 fractionated TBI; 83 women recovered ovarian function at 3-7 years; in men Leydig cell function was generally preserved, but Sertoli cell function was impaired in the majority	TBI has major impact; high frequency of sexual dysfunction, decrease in libido (associated with decreased testosterone in men) Chronic GVHD further impairs function. In women, systemic and topical vaginal hormone application is indicated

TBI, total-body irradiation; FSH, follicle-stimulating hormone.

irradiation or irradiation to the neck (e.g., for Hodgkin's disease).⁸² All patients who have received irradiation to the thyroid should be followed for life with annual physical evaluation and thyroid function studies as indicated.⁸²

ADRENAL GLANDS

Many HCT patients receive glucocorticoid therapy. Endogenous cortisol production is suppressed, and any superimposed stress may cause a relative adrenal insufficiency. However, lasting adrenal dysfunction appears to be uncommon. One study in 78 patients showed 24% to have subnormal 11-deoxycortisol levels following discontinuation of glucocorticoid therapy at 1 to 8 years posttransplant. No patient was symptomatic, and the proportion of patients affected did not increase with time posttransplant.^{83,84}

HYPOTHALAMIC-PITUITARY AXIS

Cranial irradiation, with or without TBI, affects the pituitary gland.⁸⁵⁻⁸⁷ Thyrotropin-releasing hormone (TRH) may be low early posttransplant, and TRH-induced TSH responses may be subnormal and delayed.⁸⁵ Release of gonadotropin in response to luteinizing hormone-releasing hormone (LHRH) may be elevated.⁸⁵ Prolactin secretion and the pituitary-adrenal axis are usually intact. Growth hormone levels are decreased after cranial irradiation, and deficiency becomes apparent earlier with younger age at transplant.^{83,86}

GONADAL FUNCTION, PUBERTY, AND FERTILITY

Chemotherapy and TBI regimens used before hematopoietic transplantation for malignancies usually cause gonadal failure. Puberty and menarche are markedly delayed or may not occur, and fertility is infrequently regained in either men or women.

In men, testosterone levels usually decline as a result of transplant conditioning, but recover by 1 year posttransplant. Decreased libido, reduced bone mineral density, and low testosterone levels after transplant are indications for testosterone replacement unless contraindicated for other reasons. Risk for short stature is increased in males and those who are younger if they also receive TBI.⁸⁸

Permanent ovarian failure invariably occurs in women who receive busulfan and cyclophosphamide pretransplant, whereas recovery of ovarian function has been observed after transplant in 54% of younger patients less than 26 years conditioned with cyclophosphamide only, and in 10% of younger patients who received more than 1,000 cGy TBI with cyclophosphamide. Pregnancy, although not common, has occurred following high-dose HCT, with increased risk for spontaneous abortion after TBI and preterm delivery of low birth weight babies. However, no increased risk of congenital abnormalities has been observed.^{89,90} Lack of hormone therapy by 1 year after HCT for women with ovarian failure is a risk factor for sexual dissatisfaction at 3 years after HCT.⁹¹ Vasomotor and sexual complaints 6 months after HCT improve after the start of hormone therapy, based on results from a nonrandomized pre-post cohort study.⁹²

Safety of hormone therapy after transplantation has not been reported; thus, hormone replacement for survivors must be individualized. Males treated with testosterone may be at increased risk for prostate hypertrophy and prostate

carcinoma. A nonrandomized cohort study has reported that hormone therapy in women does not influence chronic GVHD activity between 3 and 24 months after starting the hormone therapy (most of whom were also receiving cyclosporine) after allogeneic HCT.⁹³ Unfortunately, combined estrogen and progestin was recently found to increase the risk of cardiovascular disease and to increase the risk of invasive breast cancer after 3 years of therapy in naturally postmenopausal older women who had not had transplants, but no effect on survival was observed.⁷³ Human pituitary growth hormone replacement has been associated with increased risk of mortality from colorectal and Hodgkin's disease in a cohort study, a study not conducted in survivors of HCT.⁹⁴ These relative risks versus the consequences of delayed pubertal development, extremely short stature, attainment of peak bone mass, osteoporosis, and other quality of life factors need to be weighed along with hormone alternatives. If hormone therapy is elected, duration of treatment and a monitoring plan for complications should be part of the treatment plan.

Emerging Challenges in Medical Complications

Most treatment strategies for pulmonary, bone, and endocrine complications in transplant survivors are empirical rather than evidence based. Safety and toxicity of hormone therapies and efficacy of treatments for all medical complications need to be examined further, but in general are those that apply to the population at large.

Late Medical Complications

As large numbers of survivors live longer, late complications are being recognized. With fractionated TBI, 30% to 47% of HCT recipients have cataracts by 5 to 7 years; without TBI, 10% to 16% have cataracts, most often those who received corticosteroids for longer than 3 months.^{95,96} Keratoconjunctivitis sicca syndrome is seen in up to 40% of patients with chronic GVHD. Other risk factors include female gender, older age, and methotrexate for GVHD prophylaxis.⁹⁷ Other than hepatitis, iron overload is the primary identified hepatic late effect; 22% of survivors showed fibrosis at a median follow-up of 5 years.⁹⁸ After mean follow-up of 7 years for four randomized trials comparing busulfan plus cyclophosphamide regimens with cyclophosphamide plus TBI in 488 survivors, late complications have not been noted to differ, with the exceptions of cataracts (more common after busulfan) and alopecia (more common after TBI).⁹⁶ Of greatest concern because of their potential lethality are second cancers and cardiovascular effects of transplantation.

Second Cancers

Lymphoproliferative disorders after HCT [posttransplant lymphoproliferative disorder (PTLD)], generally of B-cell lineage, occur mostly in allogeneic transplant recipients.^{99,100} T-cell PTLD, non-Hodgkin's lymphoma and Hodgkin's disease have also been reported (Table 110.6). More than 80% of cases of PTLD are diagnosed within 1 year of transplantation, with peak occurrence (120 cases/10,000 patients/year) at 2 to 5 months.¹⁰¹ The incidence is highest in patients

TABLE 110.6. Malignancies after HCT.

Author	Reference	Year	No. of patients	Randomized (Y/N)	Diagnosis/ stage of disease	Intervention/ design	Duration of follow-up	Relative risk/outcomes/ predictors	Conclusions/results
Metayer et al.	109	2003	56 patients, 168 controls	N	Hodgkin's disease; non-Hodgkin's lymphoma	Multicenter retrospective case-control study	Not reported	Pretransplant use of mechlorethamine ($P = 0.04$) or chlorambucil ($P = 0.009$) significantly increased the risk of MDS/AML after autologous transplantation; conditioning with TBI $\geq 1,320$ cGy increased risk ($P = 0.03$)	The risk of MDS/AML after autologous transplants for Hodgkin's disease or non-Hodgkin's lymphoma is significantly increased with pretransplant use of alkylating agents and high-dose TBI in preparation for transplantation
Curtis et al.	110	1997	19,229	N	Various	Retrospective multicenter cohort study	Median 3.5 years	Ratio of observed/expected cases was 2.7. The risk was 8.3 fold increased in patients surviving >10 years. Younger age, higher doses of TBI, chronic GVHD, and male sex were risk factors	Solid tumors, in particular malignant melanoma, cancers of the buccal cavity, liver, brain, thyroid, bone, and connective tissue were increased. Cancers of the buccal cavity were prominent among male patients and patients with chronic GVHD. Lifelong surveillance is indicated
Curtis et al.	101	1999	18,014	N	Various	Retrospective multicenter cohort study	<1 month to >10 years	Cumulative incidence 1% at 10 years. Unrelated or HLA non-identical transplants, T-cell depletion of donor marrow, use of ATG or anti-CD3 monoclonal antibody, acute GVHD, and conditioning with TBI were risk factors	Most lymphoproliferative disorders occurred within 5 months of transplantation; late cases rare. Risk factors are cumulative. The use of broadly reactive monoclonal antibodies was associated with a lower risk than narrowly reactive anti-T-cell antibodies

DS, myelodysplasias; AML, acute myeloid leukemia.

transplanted for immunodeficiency disorders. Risk factors include the use of ATG or anti-CD3 monoclonal antibody (MAB) for acute GVHD prophylaxis or in the preparative regimen, use of TBI in the conditioning regimen, T-cell depletion of donor marrow, unrelated donor or HLA nonidentical-related donor, and primary immunodeficiency disease. The impact of risk factors is additive (or synergistic). Increasing intensity of posttransplant immunosuppression in patients who are otherwise at low risk significantly increases the incidence of PTLD.¹⁰⁰ The best approach to prevent Epstein-Barr virus (EBV)-related PTLD currently is close monitoring and preemptive therapy with anti-CD20 monoclonal antibody (325 mg) in patients with rising EBV titers. Additional doses of anti-CD20 antibody can be given if high EBV titers persist.

Rare T-cell proliferative disorders with or without EBV association have been reported.¹⁰² None was associated with HTLV1, HIV, or HHV-6 infection. Several cases of late-occurring lymphomas have been reported,¹⁰³⁻¹⁰⁵ some linked to EBV infection (just as early-onset PTLD), and others associated with T-cell depletion of the graft.

"Secondary" myelodysplasias (MDS) and acute myeloid leukemia (AML) occur after conventional chemotherapy with or without radiotherapy for Hodgkin's disease, non-Hodgkin's lymphoma, and solid tumors,¹⁰⁶ as well as after autologous HCT.^{103,107,108} After autologous HCT, incidence rates of 4% to 18% have been reported.

A case-control study analyzed data on 56 patients who developed MDS/leukemia and 168 controls within a cohort of 2,739 patients with Hodgkin's disease or non-Hodgkin's lymphoma transplanted at 12 institutions.¹⁰⁹ MDS/AML was significantly correlated with the intensity of pretransplant chemotherapy, specifically mechlorethamine [relative risk (RR), 2.0 and 4.3 for doses of less than 50 or 50 mg/m² or more, respectively], and chlorambucil (RR, 3.8 and 8.4 for duration of less than 10 or 10 months or more; $P = 0.0009$) compared to cyclophosphamide. Also, higher doses of TBI (more than 1,200 cGy) used for transplant conditioning tended to carry a higher risk (RR, 4.7).

A spectrum of tumors including glioblastoma, melanoma, squamous cell carcinoma, adenocarcinoma, hepatoma, and basal cell carcinoma has been reported. A recent study analyzed results in 19,220 patients (97.2% allogeneic, 2.8% syngeneic recipients) transplanted between 1964 and 1992.¹¹⁰ There were 80 solid tumors for an observed/expected (O:E) ratio of 2.7 (P less than 0.001). In 10-year survivors, the risk increased eightfold. The tumor incidence was 2.2% at 10 years and 6.7% at 15 years. The risk increased significantly for melanoma (O:E, 5.0), cancers of the oral cavity (11.1), liver (7.5), central nervous system (CNS) (7.6), thyroid (6.6), bone (13.4), and connective tissue (8.0). The risk was highest for the youngest patients and declined with age. Preliminary data from an ongoing nested case-control study in a cohort of 29,737 patients suggest that duration of chronic GVHD for more than 2 years and prolonged therapy are risk factors, in particular for the development of squamous cell carcinoma.

Cardiovascular Effects

Cardiac insufficiency and coronary artery disease are known complications of intensive cytotoxic therapy, in particular, high-dose anthracycline and mediastinal irradiation. Cardiac insufficiency may also be seen in patients conditioned with cyclophosphamide 200 mg/kg, usually early, sometimes

before conditioning is completed, although the overall incidence is low and approximately 0.7% are life threatening or fatal.¹¹¹ Late cardiomyopathy has occasionally been observed and treated successfully by orthotopic cardiac transplantation.¹¹²

Coronary artery disease and thrombotic events have been reported at various time intervals after HCT.^{113,114} Hyperlipidemia and hyperglycemia are common in patients treated with calcineurin inhibitors, rapamycin, and glucocorticosteroids. Although data are lacking, potential risk factors for the development of coronary disease in long-term survivors of HCT include treatment with estrogen/progesterone and inactivity due to fatigue or other causes.

Functional and Quality of Life Outcomes

Many cross-sectional cohort studies, and a smaller number of prospective longitudinal cohort or case-control studies, have defined functional and psychosocial outcomes after HCT. These investigations consistently find that 85% to 90% of survivors of HCT do well in their return to "normal" life in the domains of physical, psychologic, social, existential, and overall subjective quality of life, although specific residual problems remain for many.^{2,115,116} Physical recovery returns to pretransplant levels by 1 year for most survivors. However, return to work and emotional recovery may take longer.¹¹⁷⁻¹¹⁹ Although physical recovery is more rapid for autologous transplant recipients, results are inconsistent as to whether function continues better for autologous survivors after 1 year.^{118,120} Risk factors for poorer quality of life include older age, being female, and chronic GVHD.^{118,121-124} Specifically, females have a more difficult time in the areas of sexuality, fatigue, emotional adaptation, and return to work.^{116,123-126} After resolution of chronic GVHD, survivor function seems to be equal to those patients who did not have chronic GVHD.^{118,127} Cross-sectional studies of survivors 5 to 18 years after HCT do not suggest deterioration over time in quality of life.^{124,128,129} Residual symptoms that are most common and remain after 5 years in at least a third of survivors, based on a survey of 125 adults, include sexual dysfunction, emotional reactivity and fears, fatigue, joint and muscle pains, eye problems, sleep disruption, financial and insurance worries, cognitive concerns, and social roles and relationships.¹²⁸ Only 7% of this cohort was disabled and 74% was employed; the number who considered home-making their job was not reported, but only 3 survivors were seeking employment.

Rates of return to work continue to rise until 5 years after HCT. By 3 or more years after HCT, between 72% and 89% of patients have returned to full-time work or school.^{96,119,124,127} Survivors who are older, female, have had chronic myeloid leukemia, or have had extensive chronic GVHD are at risk for incomplete resumption of work or school activity after 5 years.^{124,127} A nonrandomized cohort-controlled trial found that HCT survivors who received a 3- to 4-week inpatient rehabilitation program demonstrated no difference in employment when compared with a group of patients who did not receive this rehabilitation.¹³⁰

Pediatric survivor quality of life is similar to adults. A cohort study compared 120 survivors who had HCT as children 5 or more years previously, with 114 survivors of childhood leukemia who had received chemotherapy without

transplant, and 149 age- and gender-matched nontransplanted comparison subjects.¹³¹ The HCT survivors reported more major illness, physician visits, diabetes, second malignancies, and poorer physical health than participants in either of the other two cohorts. Both survivor groups reported more health or life insurance refusals (25% and 33% versus 3% for comparison subjects). Marital status and mental health did not differ between cohorts, and other psychosocial factors also did not differ.¹³¹ Other researchers have found comparable results. Investigators who compared adolescents and young adults 2 to 13 years after HCT or bone cancer found that¹³² the groups did not differ in adjustment or perceived quality of life, with the exception that HCT survivors reported higher anxiety and feelings of sensitivity and vulnerability. Other researchers have reported that pediatric survivors do better than their peers in psychosocial domains.¹³³ The rate of successful return to school (85% to 95%) is similar to rates of return to work in adult survivors.¹³⁴

Fatigue

Fatigue is the one of the most persistent symptoms beyond the first year after HCT. A multicenter longitudinal cohort study of fatigue and sleep disturbance in 172 adult survivors more than 12 months after HCT, followed again 18 months after the first assessment, found that a majority reported at least mild problems at both time points, with 15% to 20% reporting moderate to severe problems.¹³⁵ Risk factors for sleep but not fatigue included older age, receipt of TBI, and female sex. Problems did not resolve over time, and no specific risk factors for fatigue were identified. Other studies have reported age to be a risk factor for fatigue.¹²⁸ A cohort study of breast cancer 20-month survivors after autologous HCT found significantly higher levels of fatigue than in a matched noncancer cohort of women,¹³⁶ and another longitudinal cohort study reported that more than 80% of survivors at both 100 days and 1 year reported "I tire easily".¹³⁷ Many biologic mechanisms have been postulated to explain fatigue following HCT or other cancer treatments. Considered among potential causes are effects of interleukins and interferons, anemia, metabolic abnormalities, infection, immunosuppression, gonadal insufficiency, TBI, sleep disruption, lack of physical activity, depression, systemic medications such as corticosteroids, and other medications. However, evidence does not clearly support any of these causes over others in HCT survivors.¹³⁸ Treatments for fatigue and physical strength have been tested in randomized or nonrandomized trials using exercise, erythropoietin, or coping skills that included relaxation training. Results show improved fatigue and reduced medical complications.¹³⁹⁻¹⁴¹ However, these studies have focused on the acute phase of treatment, not fatigue in survivors.

Neurologic and Cognitive Deficits

Neurologic complications are numerous during acute treatment and as a consequence of chronic GVHD treatment. Neuroradiologic studies have determined that changes such as cortical atrophy and ventricular enlargement occur in some patients after HCT conditioning chemotherapy or total body irradiation.¹⁴² Chronic GVHD-related CNS neurotoxicities

seem to resolve with discontinuation of the drug causing the problems unless stroke or other permanent brain events occur.¹⁴³⁻¹⁴⁶ An adult cohort study¹⁴⁶ tested 66 patients with neurologic examination, magnetic resonance imaging, and neuropsychologic exams from 8 months to 5 years after transplant. Neuropsychologic deficits did not correlate with pathology seen in neurologic or imaging tests. Pathology on neuroradiologic examination was greater for patients with progressive-onset chronic GVHD or corticosteroid or cyclosporine use. Meanwhile, long-term cyclosporine use and age increased the risk for neuropsychologic impairment.

Twenty percent to 56% of patients enter transplant with cognitive deficits that could interfere with function.¹⁴⁷⁻¹⁴⁹ Thus, without knowing the pretransplant function of a patient, it is not possible to determine whether long-term problems are a consequence of transplantation, or of treatment predating HCT, or instead are outcomes of depression, anxiety, or fatigue. Patient complaints about cognitive difficulties following transplantation are prevalent. However, complaints do not always match objective neuropsychologic test results^{150,151} and more likely correlate with subjective anxiety, depression, and fatigue.

Mechanisms underlying cognitive impairment related to chemotherapy remain uncertain but include (1) direct neurotoxic injury, (2) secondary inflammatory response, (3) microvascular injury leading to obstruction, and (4) altered neurotransmitter levels.¹⁵² Data indicate that TBI has significant diffuse effects on neuropsychologic function in the short term, but toxicities resolve with time if doses are 12 Gy or less.¹⁵³⁻¹⁵⁶ A study of patients tested pretransplant and at 80 days and 1 year after transplantation found major decrements at 80 days, but recovery of function to pretransplant levels by 1 year, in most neuropsychologic areas tested.¹⁴⁹ A cross-sectional study reported impairment in 25% of allogeneic transplant recipients 2 or more years posttransplant.¹⁵¹

Among survivors of pediatric transplantation, a prospective longitudinal cohort study of 102 pediatric survivors found no declines at 1- or 3-year follow-up testing of patients over the age of 5 at the time of transplant.¹⁵⁷ However, younger patients, particularly those under 3 years of age, do have some risk of IQ decline over time posttransplant.¹⁵⁷⁻¹⁵⁹ Testing of children before and at 1 year and 3 years after transplant indicates no difference in performance based on whether the child received TBI.^{159,160}

To date there is no indication that adult cognitive abilities decline more rapidly after HCT when compared with nontransplanted adults.¹⁵⁵ By 1 or 2 years posttransplant, approximately 55% to 60% of adult allogeneic HCT survivors and 32% of autologous breast cancer survivors have some evidence of neuropsychologic impairment on objective tests versus 17% of standard-dose chemotherapy recipients.¹⁴⁹⁻¹⁵¹ Surprisingly, few risk factors specific to HCT have been identified as predictors of long-term deficits. Rather, accumulated difficulties in overall health, fatigue, mood, and physical function predict deficits (Table 110.7).

Sexual Function

Both men and women report lower rates of sexual activity and satisfaction after HCT than before transplantation and in comparison with either the general population or patients who receive chemotherapy without transplantation (Table 110.8). This result is consistent across time points after

TABLE 110.7. Neuropsychologic function after HCT.

Author	Reference	Year	No. of patients	Disease/stage	Intervention/design	Follow-up	Relative risk/outcomes	Conclusions/results
Arvidson et al.	158	1999	26	Pediatric hematologic malignancies with autologous HCT	Cohort study	8–10 years post-HCT	Risk for impairment increased with younger age, longer follow-up time	Children treated with auto HCT had average IQ; however, deficits in memory and attention were seen
Harder et al.	151	2002	40	Progression-free adult survivors of allogeneic HCT including TBI	Cohort study	22–82 months after HCT	Predictors of poor performance included fatigue, global health, educational level, subjective cognitive complaints, physical functioning, social functioning, mood, employment status	Mild to moderate cognitive impairment found in 60% compared with healthy population norms, areas most likely to be affected were selective attention and executive function, information processing speed, verbal learning, and verbal and visual memory. HCT may lead to cognitive complaints and late cognitive deficits in long-term adult survivors
Kramer et al.	159	1997	67: 1 year after HCT 26: 3 years after HCT	Pediatric HCT	Prospective cohort study	1 year or 3 years	Not reported	Significant decline in IQ was seen between baseline and 1 year. Although IQ was lower at 1 year, no further changes were evident at 3-year follow-up
Padovan et al.	146	1998	66	Various adults	Cohort study	Mean 34 months post-HCT	Risk factors for neuropsychologic impairment were age, long time post-HCT, intrathecal methotrexate, long-term cyclosporine, progressive chronic GVHD	Mild cognitive deficit, especially impaired memory, seen in more than 1/3 of allogeneic-HCT patients; lower risk of pathologic neurologic exam after auto-HCT
Peper et al.	154	2000	14: before TBI and HCT 20: after TBI and autologous HCT 11: controls with renal insufficiency	Adult acute leukemias, lymphoma	Cohort and case-control study	32 months and 8.8 years	Brain atrophy increase was associated primarily with pretransplant irradiation or methotrexate. No medical factors were associated with cognitive deficits	Neurologic deficits seen in one new case after HCT. All brain atrophy measures were within normal range, but were slightly increased after TBI. Cognitive deficit levels were not significant. Power may have been inadequate to detect clinically meaningful differences. Some tests were associated with ventricle index results. No decline in cognitive function seen long term.

Phipps et al.	157	2000	102 survivors to 1 year with 54 followed to 3 years	Pediatric HCT	Prospective cohort study	3 years	Younger age showed more decline over time; <3 years particularly vulnerable	No significant changes on global measures of VC intelligence or academic achievement at either 1 or 3 years after an HCT HCT with or without TBI entails minimal risk of late neurocognitive sequelae in patients who are 6 years of age or older
Simms et al.	160	1998	122	Pediatric HCT recipients with no previous cranial irradiation	Prospective cohort study	1 year	None identified	No statistically significant differences between the two groups Regression analysis failed to identify treatment, age, or gender effects Suggests that neuropsychologic functioning 1 year after HCT was not detrimentally affected by chemotherapy or TBI
Syrjala et al.	149	2004	142	Adults with malignancy receiving first allogeneic HCT	Prospective cohort study	80 days and 1 year	2.76 RR (CI = 1.01-7.55) for impaired motor dexterity in patients actively receiving cyclosporine, tacrolimus or mycophenolate mofetil vs. not 2.99 RR (CI = 1.08-8.30) for impairment on any test pretransplant in patients with no previous chemotherapy, or only hydroxyurea before HCT	Performance on all tests declined from pretransplant to 80 days and improved by 1 year to pretransplant levels on all tests except strength and dexterity Verbal fluency and memory recovered by 1 year but remained below norms suggesting that these long term cognitive decrements were not a result of HCT treatment in most patients
van Dam et al.	150	1998	34: autologous HCT 36: standard dose 34: controls, stage I, no chemotherapy	Adult breast cancer	Case-control and cohort study	Mean 2 years, minimum 6 months	8.2 RR (CI = 1.8-37.7) for HCT vs. control 3.5 RR (CI = 1.1-12.8) for HCT vs. standard chemotherapy	Patients with high-dose chemo have a greater risk of cognitive impairment than patients with standard dose
Wenz et al.	155	2000	58	Adult hyperfractionated TBI with autologous HCT	Prospective cohort study	Median 27 months	None found	No measurable radiation damage found

TABLE 110.8. Sexual function after HCT.

Author	Reference	Year	No. of patients	Randomized (Y/N)	Diagnosis/stage of disease	Intervention/design	Follow-up	Relative risk/outcomes	Conclusions/results
Balleari et al.	93	2002	39 received hormone therapy; 32 controls	N	Premenopausal women treated with autologous transplant for hematologic malignancies	Case-control study	24 months	No increased risk of chronic GVHD activity with hormone therapy	No differences observed in chronic GVHD activity score between HRT and controls after 3, 6, 12, and 24 months
Chatterjee et al.	169	2002	8	N	Males after HCT for lymphoma, with hypogonadism, erectile dysfunction, diminished libido and ejaculatory disorders; all had Leydig cell insufficiency with or without frank serum testosterone insufficiency; all but one had cavernosal arterial insufficiency	Case series Patients received intramuscular testosterone cypionate (250 mg 4× weekly) and 50–100 mg of sildenafil orally one to two times per week for 6 months	6 months	Not reported	All patients responded favorably; results suggest therapy is a safe and effective approach in recipients of high-dose therapy with erectile dysfunction after HCT
Chatterjee et al.	185	2000	24 HCT survivors 10 healthy controls	N	Males after HCT with hypogonadism and erectile dysfunction	Case-control study	Mean 34 months	TBI increases risk for Leydig cell insufficiency; cavernosal vascular insufficiency increased risk of erectile dysfunction	Testosterone levels were lower than controls but within normal range Cavernosal arterial insufficiency found in 11/14 of TBI-treated and 3/10 chemotherapy treated patients Testosterone therapy improved libido but not erectile dysfunction
Molassiotis et al.	164	1995	29 HCT survivors 30 non-HCT cancer survivors 119 controls	N	Males after autologous and allogeneic HCT	Case-control study	Mean 35.6 months	Risk increased with TBI	FSH and LH increased throughout years after HCT Hyperprolactinemia observed only in the second year after HCT; testosterone levels were normal Long-term HCT survivors had similar psychosexual adjustment to non-HCT cancer survivors Major problems were erectile difficulties (37.9%), low sexual desire (37.9%), altered body image (20.7%)

Mumma et al.	186	1992	26 HCT survivors 33 non-HCT survivors	N	Acute leukemia	Cohort study	Mean 47 months for HCT; 64 months for non-HCT	Longer time since cancer treatment predicted greater frequency of sexual activity in women but poorer body image for both men and women	No differences between HCT and conventional chemotherapy Compared with controls, women had decreased sexual frequency and satisfaction; both men and women had poorer body image
Syrjala et al.	91	1998	407	N	Various	Prospective cohort study	1 and 3 years	Male sexual dissatisfaction at 3 years was predicted by older age, not being married, pretransplant sexual dissatisfaction, and poorer psychologic function Females were more dissatisfied at 3 years if they did not receive hormone therapy by 1 year and if they were less satisfied at 1 year	Pretransplant men and women did not differ in sexual satisfaction. After 1 and 3 years women were more dissatisfied and had more problems. No pretransplant factors predicted 3-year outcomes for women. At 3 years, 80% of women and 29% of men had at least one sexual problem
Syrjala et al.	166	2000	185 HCT survivors 94 non-HCT survivors 121 controls	N	Various	Cohort study	1-10 years	Risk of poorer sexual function for: HCT survivors vs. controls, females, shorter time since HCT for females, postmenopausal status for females, extensive chronic GVHD for males	Hormone therapy was not associated with sexual function. HCT survivors and females have high levels of sexual dysfunction
Watson et al.	165	1999	168 HCT, 311 non-HCT	N	AML	Cohort study	Median 14 months	Sexual function worse in HCT, females, older	Sexual function correlated with fatigue and emotional function
Wingard et al.	163	1992	126	N	Various HCT survivors	Cohort study	Mean 47 months	Sexual satisfaction correlated with serum estrogen or testosterone levels though levels were within normal range Satisfaction increased with younger age and satisfaction with appearance, life, and partner relationship	22% were dissatisfied with sexual function. 24% of men had erectile difficulty; 13% had ejaculation difficulty For women, hormone therapy was not associated with satisfaction

HCT, and across ages at time of transplantation, in both prospective longitudinal and cohort comparison studies.^{91,115,120,123,161-165} Before HCT, 42% of females and 14% of males report one or more sexual problems, compared with 17% to 35% of the general population of females and up to 19% of males.⁹¹ By 3 years after HCT, the prevalence of problems increases to 80% of females and 29% of males. Risk factors include, for women, initiation of hormone therapy after 1 year posttransplantation and chronic GVHD, and, for men, older age, chronic GVHD, and psychologic function before HCT.^{91,165,166}

Long-term problems for females are presumably caused by ovarian failure and consequent endocrine changes or by chronic GVHD-related vaginal introital stenosis and mucosal changes.¹⁶⁷ Prospective cohort studies indicate that hormone therapy with oral estrogen improves or prevents more serious decline in sexual function in women after HCT but does not eliminate problems.^{91,93} Because hormone replacement has been widely prescribed after HCT, vasomotor symptoms and other menopausal syndromes have been less commonly reported than sexual dysfunction. However, with new concerns about the long-term risks of hormone therapy, menopausal symptoms and hormone alternatives need to be reconsidered. We have found no clinical trials comparing treatments for female sexual dysfunction after HCT despite the well-recognized prevalence of problems. Descriptions of clinical interventions for women recommend vaginal lubricants to improve comfort as well as counseling with sexual partners. Some couples do well after brief counseling that provides education, facilitates communication, and encourages gradually increasing intimacy behaviors and relearning pleasurable sexual strategies rather than avoiding sexual activity.¹⁶⁸

Male sexual problems have been attributed to gonadal and cavernosal arterial insufficiency, with resulting libido and erectile dysfunction.¹⁶⁹ Results from a small case-series of eight patients 6 months after HCT suggested that testosterone injections and sildenafil one to two times per week improved sexual performance for men with erectile dysfunction, low libido, and ejaculatory disorders.¹⁶⁹ However, other data indicate that most males recover testosterone levels and sexual function between 6 months and 1 year after transplantation.¹⁷⁰ Thus, without controlled clinical trials, it is unclear whether sexual function in the treated men would have recovered without treatment.

Psychologic Adaptation

Rates of depression and anxiety among HCT recipients are higher than population norms. Prospective studies have reported depressive symptoms in 43% to 53% of survivors at some time during or after HCT.^{127,137} Rates of both general anxiety and depression decline from pretransplant to 1 year and then stabilize.^{117,127} Depression is of particular concern because studies have found it to be a risk factor for mortality and poorer long-term physical and psychologic functioning after HCT.^{117,127,171,172} More prevalent than clinical syndromes of depression or anxiety are subclinical elevations in emotions that continue long term.¹²⁸ Worries and concerns related to health and survival decline gradually between discharge and 3 years.^{127,173} However, other concerns increase after the first year, including work, relationships, finances,

and social and family issues.¹³⁷ Children, similar to adults, appear to be distressed during treatment but then to recover psychologically.¹⁷⁴

Emerging Challenges in Functional and Quality of Life Outcomes

Evidence related to functional and quality of life outcomes indicate that physical capability improves within 1 year whereas treatment-related distress and return to work resolve by 2 to 3 years. Other problems do not resolve without treatment; for instance, sexual dysfunction, fatigue, and reduced social activities persist past 5 years. Long-term impact of HCT on cognitive function remains undefined for adults. The clearest challenge is to increase testing of treatments to improve outcomes for those problems that persist.

Emerging Issues

Nonmyeloablative Transplants

Both the pretransplant conditioning regimen and posttransplant donor immune-mediated mechanisms account for elimination of malignant cells in the recipient. Conventional high-dose, myeloablative pretransplant conditioning regimens have been designed to prevent graft rejection and to eliminate as many malignant cells as possible, but these regimens are not well tolerated in older patients or in those who are not in good medical condition at the time of the transplant. During the past 5 years, improvements have been made in posttransplant immunosuppressive regimens so that low-dose, nonmyeloablative pretransplant conditioning regimens are sufficient to prevent graft rejection. This treatment strategy relies heavily on immune-mediated mechanisms to eliminate malignant cells when immunosuppressive medications are gradually withdrawn after the transplant.

Results from many Phase 2 studies have suggested that low-dose, nonmyeloablative pretransplant conditioning regimens cause much less posttransplant morbidity than conventional, high-dose myeloablative conditioning regimens during the first month after the transplant. This impression has been confirmed by comparing skin, liver, and gastrointestinal morbidity between two cohorts of patients who had either a myeloablative or nonmyeloablative conditioning regimen.¹⁷⁵ Morbidity after the first month, however, was similar in the two groups. The proportion of patients who needed treatment for either acute or chronic GVHD was lower among patients who received a nonmyeloablative conditioning regimen, and the time to onset of GVHD was delayed. Randomized trials have not yet been carried out to compare results with the two types of conditioning regimens.

Caregiver and Family Needs

Caregiving by a spouse, parent, or other family member or friend is vital to recovery after HCT. Longitudinal studies find that emotional distress in caregivers peaks during the first 2 weeks of treatment¹⁷⁶ while fatigue peaks at 3 months.¹⁷⁷ Mothers of pediatric HCT patients seem to suffer

the greatest emotional strain in the course of their child's treatment.¹⁷⁸ In a case-matched, longitudinal, prospective cohort study that also included nontransplant controls, spouse caregivers reported greater depression and anxiety than patients throughout the first year after HCT.¹⁷⁹ Female caregivers also were at higher risk of marital dissatisfaction than male caregivers. Little else has been published about the financial or family costs of HCT. Particularly lacking is information on family responses after an HCT recipient dies.

Conclusions

Medical and quality of life issues facing survivors of HCT have been well described, as have risk factors for major medical complications. In contrast, few randomized controlled trials have tested efficacy of treatments for chronic GVHD or infectious, pulmonary, endocrine, or functional problems. For most medical complications, treatment choices are based on Phase 2 data or historical case-control studies. Evidence for treatment of functional or quality of life problems such as fatigue, sexual dysfunction, or cognitive deficits must be extrapolated either from studies during the acute phase of treatment, as for fatigue, or from research with other populations of patients, as with sexual dysfunction, cognitive deficits, or psychosocial adaptation.

The foremost risk factors for mortality and morbidity in survivors are chronic GVHD and its treatment, infection, or malignancy recurrence. However, if transplant recipients survive without malignancy recurrence, their physical and psychosocial quality of life is excellent for more than 80%, whether they have autologous or allogeneic transplant, whether or not they have clinical extensive chronic GVHD, and regardless of age. Although males have higher rates of mortality, female survivors are at greater risk for functional and psychosocial complications. Recent descriptive studies indicate that most survivors perceive long-term benefits as well as losses as a consequence of their disease and HCT. Although second cancers are more prevalent in survivors and problems with insurance and cataracts have been documented, few other late effects of HCT have been detected thus far.

Second Malignancies After Radiation Treatment and Chemotherapy for Primary Cancers

Lydia B. Zablotska, Matthew J. Matasar,
and Alfred I. Neugut

Cancer survivors have been shown to have an increased risk for second malignant neoplasms (SMN). These increased risks result from genetic predisposition, harmful environmental exposures, or cancer treatment therapies. Regardless of their cause, SMNs now comprise the sixth most common group of malignancies after skin, prostate, breast, lung, and colorectal cancers.¹ It is important to emphasize that the fear of SMN related to the treatment of the first cancer diagnosis should not outweigh the positive effects of curative therapy for the first cancer. Both physicians and patients should, however, be aware of the consequences of the cancer treatment regimens, specifically radiation therapy (RT) and chemotherapy, and consider them while devising follow-up plans.

Radiation Therapy

The following are general criteria for attributing a malignancy to the effects of radiation, defined by Goolden in 1951: (a) a history of prior irradiation; (b) malignancy occurring within the prior irradiation field; (c) gross or microscopic pathologic evidence of radiation damage to the surrounding tissues; and (d) a long, latent interval between the prior irradiation and the development of the malignancy.²⁻⁵ Only the first two criteria are considered essential.

External-beam radiation therapy has the potential for the induction of mutations in normal cells because of the harmful effects of the radiation used to kill cancer cells. Years or decades later, such mutated cells may give rise to new primary cancers.

Although ionizing radiation has been shown to cause most types of cancer, some organs and tissues appear to be more susceptible than others. Based on radiation epidemiologic studies, the most radiation-sensitive solid tissues and

organs are the bone marrow, thyroid, and female breast. Bone and soft tissue sarcomas also can occur following radiation therapy.⁶ In addition, cancers of the lung, stomach, colon, bladder, and esophagus have been conclusively associated with ionizing radiation exposure. Possible links have been described for cancers of the kidney, ovary, brain, and central nervous system (CNS). Cancers of other sites have not been correlated with radiation exposure.⁷

In addition to individual susceptibility, the risk of second cancers after radiation therapy depends on the total dose of radiation delivered during the course of treatment, as well as on the type and energy of the radiation. Megavoltage treatments currently in use deliver concentrated high energy to tumors, with low scatter of the radiation to areas outside of the treatment field (low peripheral doses). Orthovoltage treatments, which were used in previous decades, on the other hand, frequently injured the skin and delivered higher doses of radiation to the bone than to the surrounding tissues, and in the process produced substantial peripheral doses.

The type of dose delivery (protracted or instantaneous) also plays a role in the carcinogenesis of second malignancies. It is generally recognized that, as the exposure time for a given total dose is extended, the biologic effect is reduced. Protracted delivery of a dose over hours or days, in general, will result in less severe consequences because of reduced tumorigenic effectiveness as compared to the instantaneous delivery of the total dose.

Finally, the risks of second cancers depend on the volume of irradiated tissues and organs. Current treatment guidelines recommend that smaller fractions should be used when larger volumes need to be irradiated to decrease the acute side effects of radiation treatment. The late effects of radiotherapy could be lessened by "hyperfractionation" of radiation therapy (smaller doses twice per day over the same treatment period).⁶

Recent technologic advances (shielding, collimation of the radiation beam, use of multivoltage beams, more precise localization of tumors) have significantly reduced the irradiation of normal tissues and the risk of posttherapy new cancers. However, because radiation-associated cancers tend to appear at the same age as spontaneous cancers, patients who were exposed many years ago at young ages may, potentially, be at risk of developing SMN cancers due to radiation exposure.

Individual risks for patients are modified by such factors as their age at the time of exposure, time since exposure/survival time, gender, exposure to other carcinogens (including chemotherapy), as well as by immune and hormonal status. Although the risks associated with radiation exposure are substantially less than the risks posed by the initial tumor, it is important to know them before the start of the radiation therapy to make informed decisions about treatment regimens that might minimize the side effects of radiation therapy. This information is also important for counseling patients who are at increased risk of developing second malignancies due to other risk factors, as well as for continuing surveillance of those treated. Our knowledge of the possible adverse effects associated with radiation therapy should be used for the development of surveillance programs aimed at the early detection of cancers and campaigns to decrease negative behaviors and exposures that have been shown to promote the development of second cancers after radiation therapy.

Individual Cancers

In our review, we look at the subjects who received irradiation for treatment of nine specific primary malignant diseases and summarize the evidence from the descriptive (case reports and case series) and analytical (case-control, cohort, and randomized controlled trials) epidemiologic studies to show the current state of knowledge on the consequences of the treatment for each of the nine diseases.

After reviewing epidemiologic studies for the nine primary cancers, we compare and contrast their findings. We show that they add to our knowledge of the effects of high-dose exposures and can be used for risk estimation purposes as well as to provide both physicians and patients with the necessary information to make informed decisions regarding radiation therapy for primary cancer.

Pediatric Cancers

Various epidemiologic studies have shown that the incidence of the majority of cancers increases with age. Based on data from the Japanese survivors of the atomic bombings of Hiroshima and Nagasaki, the effect of radiation exposure is to multiply age-specific solid cancer rates by a constant radiation dose-dependent factor through lifetime. Thus, those with absorbed dose of 0.20Sv experience a 10% increase in the risk of solid cancer above background rates. Estimates of risk also depend on age at exposure (increase by 10 years decreases relative risk for solid cancers by 130%).⁸ Based on the same data, most organizations have adopted a multiplicative risk model for most solid cancers, which states that after a specified latency period, "the excess cancer risk is given by a constant factor applied to the age-dependent inci-

dence of natural cancers in the population"⁹ (p. 108) (in other words, the relative risk remains constant as subjects are followed over time).

The majority of cancers that are associated with radiation exposure, thus, will appear at the same time when spontaneous cancers of the same organ appear. The difference between exposed and unexposed populations, then, will be in the number of new incident cases. Researchers, therefore, have combined subjects with specific types of first childhood cancers and studied them as a group named "pediatric cancers."

The significance of the problem of second malignancies after pediatric cancers is underscored by the fact that survival following childhood cancer has improved markedly and now approaches 70%.¹ Thus, it is important to compare the carcinogenic potential of different treatments for primary pediatric cancers. Some pediatric cancers are more likely to be treated with radiation than others and, as a consequence, they are associated with second malignancies within the radiation field. First reports about second cancers following primary pediatric cancers started appearing in the late 1970s with the advent of new radiation treatment regimens. A large study of pediatric patients who were followed for at least 2 years after initial treatment of the primary tumor showed no association between RT and the subsequent development of leukemia.¹⁰ Although large, this study had a very small proportion of subjects who received only RT; the majority of subjects also received chemotherapy. Thus, the effects of RT could have been obscured by the effects of treatment by various alkylating agents. In a more-recent study of childhood cancer survivors, the risk of second leukemia after RT was significantly increased eightfold.¹¹ The difference between the two studies could be explained by the size of the irradiation field. Patients with HD usually receive more targeted radiation treatment, whereas the cumulative doses for radiotherapy for NHL are usually smaller than the doses delivered for treatment of HD. Nevertheless, in the process of treatment, larger areas of radiosensitive tissues, such as bone marrow, are exposed to radiation.

Other second cancers that have been associated with RT for primary childhood cancers include cancers of the bone,¹² skin,¹³ nervous system,¹⁴ and thyroid gland.¹⁵ As one would expect with solid cancer, in these studies the incidence increased with time since treatment. For example, in The Late Effects Study Group, which followed 9,000 survivors of childhood cancer, a lifetime risk of thyroid gland cancer after RT for primary childhood cancer was almost 4% after 26 years of follow-up.¹⁵ To avoid problems associated with low power of individual studies, Ron et al. pooled data from seven individual studies to evaluate the risk of thyroid cancer following exposure to external radiation. Individual estimates of increased risk of thyroid cancer varied from 1.4 to 33.5 per Gy¹⁶; that is, those who were exposed to 1 Gy of radiation during RT for primary cancer had a much higher risk of developing second primary thyroid cancer compared to those who did not receive RT. This study provided strong evidence that, along with the breast and bone marrow, the thyroid gland is one of the most radiosensitive organs.

Population-based study of the occurrence of second cancers following primary childhood cancer in the five Nordic countries showed that childhood cancer survivors have a fourfold-higher risk of second cancers compared to the

general population.¹⁷ The largest increase was observed during the first 10 years following RT; however, risks remained increased throughout their lifetimes and the absolute excess of second cancers increased with time. This result probably reflects the promotional effect of radiation on the carcinogenic effects of environmental exposures.

Several publications from the large Childhood Cancer Survivor Study cohort show an increased risk of second malignant neoplasms more than 20 years after RT for primary childhood cancer. In comparison with the general population, their risk of bone second cancers, in particular bone sarcomas and breast cancer, was increased sixfold.¹⁸

In summary, the effects of radiation treatment for childhood cancers start to increase in early adolescence and early adulthood and continue to be increased later in life. Bone marrow, bone and soft tissues, and breast and thyroid gland appear to be the most radiosensitive. Risk of second tumors depends on the age at exposure (the risk is greatest among those exposed at the youngest ages) and on the time since exposure. Current knowledge of the effects of ionizing radiation had an important influence on RT practices. Specifically, lead aprons and shields are currently being used to protect the most radiation-sensitive organs and tissues. In addition, advances in technology, such as utilization of wedge compensators or half-beam blocks, minimize scattering of radiation to adjacent tissues. Finally, because of the greater awareness of the effects of radiation, survivors of childhood cancers are being constantly monitored and screened for second cancers during follow-up.

Bone Marrow Transplantation

High-dose total-body irradiation (TBI) is part of the conditioning regimen for bone marrow transplantation used for treatment of leukemia and other diseases. One of the mechanisms of development of second cancers following TBI is thought to be due to radiation-induced immunosuppression.¹⁹ In addition to radiation-associated effects, it is also necessary to consider the effects of immunosuppressive drugs that are used concomitantly with radiation. Curtis et al. showed that patients who received TBI had an increased risk of subsequent new solid cancers compared to those who did not receive radiation treatment.²⁰ High doses of TBI were associated with increased risks of melanoma and cancers of the brain and thyroid. The risk was higher for recipients who were younger at the time of transplantation than for those who were older (*P* for trend less than 0.001).

Another registry-based study found that high-dose TBI increased the risk of subsequent solid tumors threefold [95% confidence interval (CI), 1.1, 10.3].²¹ Younger age at the time of treatment increased the risk of brain and thyroid tumors. In addition, cancers of the salivary gland, bone, and connective tissues were also increased.

In summary, various studies show the trend toward an increased risk over time after transplantation and the greater risk among younger patients. Second cancers could be related to both transplant therapy and to chemotherapy treatments given before it. All these factors indicate the need for lifelong surveillance of the patients who received irradiation as part of the bone marrow transplantation.

Hodgkin's Disease

Introduction of intensive radiotherapy and chemotherapy to treat Hodgkin's disease (HD) three decades ago dramatically changed survival times and prognosis for patients with this disorder. Long-term sequelae of treatment have become increasingly important as patients now survive for several decades. HD is a systemic cancer and radiation treatment frequently consists of irradiation of mantle fields, including all lymph node regions ('total lymphoid irradiation' with cumulative doses 20–40 Gy) or only some regions ('subtotal lymphoid irradiation' with doses less than 20 Gy), by external-radiation beams.²² Dose-response analysis of the effects of radiation is frequently confounded by the concurrent chemotherapy in the majority of patients.

Several studies looked at breast cancer incidence and mortality, the most frequently seen second malignancy following treatment for HD. Table 111.1 summarizes the results of the most influential studies. In general, risk of breast cancer was increased and ranged from 2 to 75 times compared to the risk in the general population. Most cancers appeared within or at the margin of the radiation field, and the risk increased with dose. Investigators from the Late Effects Study Group estimated that the cumulative probability of breast cancer at age 40 following radiation exposure for HD in childhood is close to 35% (following a median dose of radiotherapy of 40 Gy).²³

Clemons et al.²² reviewed 18 epidemiologic studies on the risk of breast cancer in patients treated with radiation for Hodgkin's disease. They concluded that women between the ages of puberty and 30 years are at the highest risk. Data on the use of exogenous estrogen hormones, age at first pregnancy, and prevalence of early menopause were not available

TABLE 111.1. Studies of breast cancer risk among patients treated for primary Hodgkin's disease.

<i>Reference</i>	<i>Year</i>	<i>RT and follow-up</i>	<i>Age at the time of first treatment</i>	<i>SIR and 95% CI</i>
Hancock et al. ¹¹⁴	1993	1961–1989	Mean age 25 years	SIR = 4.1 (2.5, 5.7)
Bhatia et al. ²³	1996	1955–1986, follow-up till 1996	Younger than 16 years old	SIR = 75.3 (44.9, 118.4)
Tinger et al. ¹¹⁵	1997	1966–1974 treatment era	Mean age 30 years	4.7
Tinger et al. ¹¹⁵	1997	1974–1985 treatment era	Mean age 28 years	2.2
Hudson et al. ¹¹⁶	1998	1968–1990	—	SIR = 1.33 (1.12, 1.72)
Wolden et al. ¹¹⁷	1998	1960–1995	Younger than 21 years	SIR = 1.26 (1.15, 1.42)
Swerdlow et al. ²⁷	2000	1963–1993	60% younger than 35 years old	SIR = 2.5 (1.4, 4.0)
Van Leeuwen et al. ⁷⁰	2000	1966–1986	Younger than 40 years old	SIR = 7.7 (4.3, 12.7)

RT, radiotherapy; SIR, standardized incidence ratio; CI, confidence interval.

to control for possible confounding effects of these variables. Breast cancers due to irradiation tend to appear after a 15-year latency period at the age from 30 to 40. Breast cancer risk is highly dependent on age at irradiation, time since irradiation, dose, and concurrent chemotherapy. These findings, along with the finding that no cases of breast cancer after radiation therapy for HD have been reported in men, suggest that the actively growing and differentiating cells of female breast tissue are particularly vulnerable to radiation exposure.

A nested case-control study of lung cancer among patients previously treated for HD found that radiation doses greater than 5 Gy increased the risk sixfold (95% CI, 2.7, 13.5).²⁴ Smoking acted in a multiplicative way with radiation exposure [relative risk (RR) comparing moderate-heavy smokers to nonsmokers and light smokers among those without radiation treatment was 6.0; RR comparing those with radiation treatment to those without among nonsmokers and light smokers was 7.2; RR comparing those with radiation treatment to those without among all subjects adjusting for smoking was 20.2]. Treatment with alkylating agents, on the other hand, acted additively with radiation therapy (individual risks added up to perfect additivity). Similar to other studies, increased age at diagnosis of HD was associated with an increased risk of lung cancer.

Birdwell et al.²⁵ noticed that high doses to the abdomen from radiation for HD cause multiple gastrointestinal (GI) cancers, including stomach, pancreas, and small intestine (RR for all GI cancers, 2.0, 95% CI, 1.0, 3.4). Risks started to increase after a latency period of 10 years and were highest among younger patients. GI cancers were similarly increased in the large study based on the International Database on HD (more than 12,000 cases)²⁵ and in the study of atomic bomb survivors (53% of all incident cancers in the atomic bomb study were due to cancers of the digestive system).²⁶

Findings of increased risk of second cancers are further supported by the largest current study of 5,519 British patients with HD who were followed for more than 30 years.²⁷ Irradiated patients had a 1.7 fold (95% CI, 1.0, 2.5) higher incidence of GI cancers, 2.5 fold (95% CI, 1.4, 4.0) higher incidence of breast cancer, and 2.9 fold (95% CI, 1.9, 4.1) higher incidence of lung cancer than the general population. Risk of leukemia was increased in patients who received combined modality treatment (chemotherapy with radiotherapy) or chemotherapy alone compared to those who received RT alone. Similar to previous studies, relative risks tended to increase 5 to 10 years after treatment and decreased with increasing age at first treatment. Women older than 25 years were not at risk of increased breast cancer [RR_{<25 years}, 14.4 (95% CI, 5.7, 29.3) and RR_{25-44 years}, 1.6 (95% CI, 0.5, 3.7)]. A combined study of 16 population-based cancer registries in Europe and North America, which included HD patients diagnosed before the age of 21 years, also found that the risk of second malignancy decreased with increasing age at HD diagnosis and treatment on a relative scale.²⁸ High estimates of relative risks of second cancers in this cohort were due to low background rates in the relatively young cohort.

In summary, it appears that radiation treatment for HD increases the risk of second malignancies. Long-term risks depend on age at exposure and time since exposure. Latency periods differ from study to study, but a major increase in risks appears at 10 to 14 years of follow-up. Second cancers sometimes appear at a much younger age than similar

cancers. Radiation treatment for HD is linked to cancers of the GI tract, breast, lung, bone, and soft tissue, melanoma, and thyroid gland (Table 111.2).

Breast Cancer

Standard treatment for invasive breast cancer includes high, concentrated doses of radiation to the chest and to the lymph nodes (about 40–60 Gy total).²⁹ Initially, localized radiotherapy was combined with radical mastectomy, but since the mid-1980s treatment consists of breast-conserving surgery and radiotherapy. Women irradiated before the mid-1980s received higher doses of radiation to the lungs, contralateral breast, thoracic bone, and bone marrow. A small increase in risk of leukemia was shown in a cohort of women from the Connecticut Tumor Registry irradiated between 1935 and 1972.²⁹ Following an average dose of 5.3 Gy to the bone marrow, the risk was 16% higher in irradiated women than in nonirradiated women (90% CI, 0.6, 2.1). A larger study based on five population-based cancer registries in the United States (1973–1985)³⁰ found a 2.4 times increased risk (95% CI, 1.0, 5.8) of acute nonlymphocytic leukemia after radiation treatment with an average dose of 7.5 Gy over the total active bone marrow. They observed a positive dose-response relation in the data (those exposed to doses higher than 9 Gy had a 7-fold-higher risk). Increase in risk was first seen 2 years after initial treatment, and it persisted, albeit at a much lower level, 7 years after treatment. The authors described a statistical multiplicative interaction effect of radiotherapy and treatment with alkylating agents on the development of ANLL (RR for radiotherapy alone, 2.4; RR for alkylating agents therapy, 10.0; RR for combined therapy, 17.4).

Boice et al.³¹ described an increase in the risk of cancer in the contralateral breast in patients from the Connecticut Tumor Registry diagnosed between 1935 and 1982. An average dose of 2.8 Gy was associated with a twofold increase in risk in 10-year survivors. Risk was significantly higher among women who were younger than 45 years at the time of radiation treatment. The investigators estimated that the absolute excess risk of contralateral breast cancer was 4.4 cases per 10,000 person-years per Gy (compared to 6.7 cases per 10,000 person-years per Gy for atomic bomb survivors).²⁶

Several studies have shown a significantly increased risk of lung cancer following radiation therapy (RT) after total mastectomy. Ten-year survivors from the Connecticut Tumor Registry who were diagnosed with histologically confirmed primary invasive breast cancer between 1935 and 1971 had an 80% higher risk (95% CI, 0.8, 3.8) of developing lung cancer if they received radiotherapy as part of their initial treatment regimen compared to those not receiving initial RT (mean dose to both lungs, 9.8 Gy).³² Risk continued to increase with time and after 15 years reached 2.8 (95% CI, 1.0, 8.2). The excess relative rate was 0.20 per Gy (95% CI, -0.62, 1.03) compared to an estimate of 0.95 per Gy (95% CI, 0.60, 1.4) for trachea, bronchus, and lung in the atomic bomb study.²⁶ In a case-control study from this cohort, Neugut et al.³³ assessed risk of lung cancer in relation to radiation treatment and smoking in 10-year survivors. They observed a multiplicative interaction effect if both exposures were present (OR for RT alone, 3.2; OR for smoking and no RT, 17.7; OR for both RT and smoking, 32.7).

OR, odds ratio; NHL, non-Hodgkin's lymphoma; RR, relative risk; ChT, chemotherapy; RT, radiation therapy; SMN, second malignant neoplasm.

* P value of significance.

As was noted earlier, radiation treatment regimens have changed over the past two decades, lowering radiation doses to the lungs.³⁴ In a large population-based study from the SEER (Surveillance, Epidemiology, and End Results) database of subjects diagnosed and followed up from 1973 till the end of 1998, the risk of cancer in the ipsilateral lung 10 to 14 years after RT and radical mastectomy was increased by 2.06 (95% CI, 1.53, 2.78), whereas the risk of ipsilateral lung cancer 10 to 14 years after conservative surgery (lumpectomy) and adjuvant RT was not increased (RR, 0.80; 95% CI, 0.23, 2.84).³⁵

Studies of other cohorts also showed increased risk of second cancers following breast cancer.³⁶ Another SEER-based

study showed that the standardized incidence ratio (SIR) of esophageal cancer after RT for primary breast cancer was 54% higher than in the general population (95% CI, 1.27, 1.84).³⁷ Risk increased with time, reaching 5.42 (95% CI, 2.33, 10.68) for esophageal squamous cell carcinoma 10 years after radiotherapy. No information on smoking or alcohol consumption was available.

Gynecologic Cancers

Hormones, in general, in these cancers could play an important role in the timing of late effects of radiation treatment,

their dependence on the age at exposure, and time since exposure. Some studies do not have data on the use of exogenous estrogen hormones, age at first pregnancy, time of menopause, and other factors related to hormonal status. Therefore, possible confounding effects of these variables could not be evaluated.

CANCER OF THE UTERUS

Curtis et al. examined the relationship of leukemia risk to radiation dose following radiotherapy of the uterine corpus in a nested case-control study based on a cohort of women drawn from nine population-based registries in the United States and Europe.³⁸ After external-beam therapy (mean dose, 9.88 Gy), cases were two times more likely to develop leukemia (excluding chronic lymphocytic leukemia) than matched controls (ERR, 0.13 per Gy; 95% CI, 0.04, 0.27).

Based primarily on data from the cohort of atomic bomb survivors, the association between radiation exposure and development of leukemia appears to depend on total dose to the bone marrow, total percent of the person's bone marrow exposed to radiation, and the dose rate at which radiation was delivered. As was mentioned earlier, the dose response for atomic bomb survivors is linear-quadratic for doses below 4 Gy (ERR, 4.8 per Sv).³⁹ The difference between the estimates from the Curtis et al. study and the estimate from the LSS cohort can be partly explained by the killing of stem cells of the bone marrow at high doses. Treatment regimens with low-dose-rate radiation (e.g., brachytherapy) were more leukemogenic per unit dose than external-beam therapy, perhaps due to the repair of radiation damage in protracted exposure regimens.

As a result of a wide field of radiation encompassed by the partial-body radiation treatment (only parts of the body are irradiated as opposed to the total-body irradiation as in bone marrow transplantation) of cancer of the corpus uteri, patients are also at risk of developing second solid cancers. Subjects with primary cancer of the uterine cervix from a Swedish cancer registry had a 20% higher risk of developing a second malignancy compared to the population rates.⁴⁰ Organs situated in the immediate proximity to the radiation field had the highest risk of second cancer (colon, vulva, and bladder) 9 years after initial treatment. A fourfold increase in leukemia was observed 3 to 9 years after exposure, but it was based on a small number of cases (95% CI, 1.68, 8.59).

OVARIAN CANCER

A SEER-based study of long-term survivors of ovarian cancer found a twofold-increased risk of leukemia 5 to 9 years after radiotherapy,⁴¹ although several case-control studies did not.^{42,43} A twofold increase in risk was also observed for all solid cancers 10 to 14 years after exposure (*P* less than 0.05).⁴¹ Significant associations were seen for cancers of connective tissue, bladder, and pancreas. A case-control study of ovarian cancer survivors who later developed bladder tumor showed that those treated with radiotherapy alone had a twofold-higher risk (95% CI, 0.77, 4.9).⁴⁴

In summary, RT for gynecologic cancers has been linked to the development of various second primary malignancies. They mainly experience increased risks of second malignan-

cies of the organs situated in immediate proximity to the radiation field as well as leukemia.

Testicular Cancer

Testicular cancer is the most common cancer in men in the age group 20 to 44 years.¹ Early reports showed that these patients are at increased risk of second cancers following 10 to 15 years after radiotherapy.⁴⁵ Significant increases were observed for all solid cancers (RR, 1.6; 95% CI, 1.3, 2.1), gastrointestinal cancers (RR, 2.6; 95% CI, 1.7, 3.9), and leukemia (RR, 5.1; 95% CI, 1.4, 13.0).

A large population-based study of testicular cancer survivors in 1997 confirmed an increased risk of stomach, bladder, and pancreatic cancers by twofold. Overall risk was similar after seminomas (SIR, 1.42) or nonseminomatous tumors (SIR, 1.50). The largest investigation to date of leukemia following testicular cancer was done in the follow-up of the same cohort.⁴⁶ Those treated with radiotherapy had a three times higher risk of developing leukemia (95% CI, 0.7, 22.0). This risk is similar to the risks estimated after radiation therapy for cancers of the cervix,⁴⁷ breast,³⁰ or Hodgkin's disease.⁴⁸ Although atomic bomb survivors received lower doses of radiation, they experienced higher risks than medically irradiated subjects mainly because the dose was delivered to the entire body without dose fractionation.⁴⁹

In summary, because testicular cancer is a disease of men under the age of 40 years, they are at increased risk of developing second malignancies later in life. In particular, both physicians and patients should be aware of increased risks of second cancers located in the bladder, lungs, connective tissue, and stomach. These patients should be under continuous surveillance for possible second cancer. In addition, because of the high risks of lung cancer, patients should be advised to quit smoking.

Prostate Cancer

In a large population-based retrospective cohort study of survivors of first primary prostate cancer in the Detroit metropolitan area who were diagnosed between 1973 and 1982, the overall risk of second malignancies was similar to the rates of cancer in the general population.⁵⁰ Subanalyses, however, showed that prostate cancer survivors were at increased risk of bladder cancer (SIR, 1.49; 95% CI, 1.07–2.02) when compared to the Detroit-area male population. Researchers concluded that the magnitude of relative and absolute risks did not suggest the presence of large risks associated with radiation treatment. In another large population-based study from the database of the Connecticut Tumor Registry, comparison of the risk of developing a SMN cancer following prostate irradiation compared to the underlying risk in patients with prostate cancer showed that the risks were not significantly different, at any time period and in all age groups, between the two groups of patients.⁵¹ Short follow-up (mean follow-up under 4 years) could have contributed to these negative findings. However, more careful investigation of the cases who survived more than 10 years again showed no significantly

increased risk of second malignancy following radiation therapy for primary prostate cancer.⁵²

In the largest to date epidemiologic study of second cancers after prostate cancer based on the SEER database, a cohort of patients who received radiation treatment sometime between 1973 and 1990 showed a significant 50% increase in risk of second primary bladder cancer.⁵³ Risk remained increased for at least 8 years after initial radiation treatment. There was no increased risk of rectal carcinoma or leukemia after this type of radiation exposure.

In summary, prostate cancer is the most common male cancer in the United States, with nearly 200,000 men diagnosed annually.¹ Findings regarding the effect of RT for prostate cancer have been conflicting. If present, risks are probably significantly lower than risks described for other first cancers. This fact could be explained by smaller doses and less-aggressive treatments.

Lung Cancer

In a large retrospective cohort study of 2-year survivors of primary small cell lung cancer, patients who received RT experienced a 13-fold increase in the risk of second primaries among those who received chest irradiation, whereas non-irradiated patients experienced only a 7-fold increase compared to that of the general population.⁵⁴ The highest risk was observed among those who continued smoking, with evidence of an interaction between chest irradiation and continued smoking (RR, 21). Risks continued to increase with time after radiation treatment.

In a large population-based study based on the Finnish Tumor Registry lung cancer patients treated with RT between 1953 and 1989, there was a significant increase in the risk of esophageal cancer and leukemia among lung cancer patients subject to radiotherapy.⁵⁵ The risk of a second cancer among lung cancer patients increased with the length of follow-up.

Colorectal Cancer

In the past, radiotherapy was not widely used to treat colorectal cancer. There are, consequently, only a few epidemiologic studies of the effects of radiation in colorectal cancers. These studies have shown that patients with primary cancers of the colon and rectum have small increases in risks of SMN cancers as a result of radiation therapies. In particular, irradiation increases the risk of second primaries of the breast, uterus, ovaries, and other pelvic organs in the radiation field.^{1,56}

Chemotherapy

That only a small percentage of individuals receiving a given chemotherapeutic regimen will go on to develop a SMN suggests that individual variations play a role in this process. Indeed, it has become apparent that a number of individual factors contribute in part to this risk. Germ-line mutations have long been recognized to predispose to primary malignancies; indeed, more than 40 genes have been cloned that, when mutated from the wild-type, are known to increase the susceptibility to malignancy.⁵⁷ Although the mechanisms of this increased susceptibility are variable, it has become appar-

ent that many individuals with these germ-line mutations are at heightened risk of SMN and, specifically, treatment-associated malignancies.

Next we explore the various factors that contribute to the risk of SMN among patients treated with systemic chemotherapy, including the organ affected by the primary cancer, the chemotherapeutic agents employed, and host factors such as environmental exposures and immune status.

Individual Cancers

Although the use of chemotherapeutic alkylating agents imparts a risk of secondary malignancy, particularly secondary leukemia, the concern regarding SMNs is not restricted to their use alone. Indeed, for many of the hematologic and solid malignancies, there are concerns about the potential for patients to experience treatment-related neoplasms. Evidence for such an association is stronger for some malignancies, weaker for others; in some malignancies, there are as yet no convincing data regarding an elevated risk of SMN as a result of treatment. Whether this lack of effect is due to an inability of cancer chemotherapy to significantly prolong life, or whether it reflects a truly low oncogenic potential of the agents employed, is difficult to determine; what is clear, however, is that as chemotherapeutic regimens continue to become both more complex and more effective, the challenge of treatment-related SMN will require ongoing vigilance.

Pediatric Cancers

ACUTE LYMPHOCYTIC LEUKEMIA

A number of reports have been published regarding the risk of treatment-associated malignancies following treatment of childhood acute lymphocytic leukemia (ALL). Children treated with all the most common protocols in ALL therapy, including the Berlin–Frankfurt–Munster (BFM) protocol, Children’s Cancer Group protocol, and the Dana–Farber protocol, experience an estimated risk of SMN within 15 years of treatment ranging from 2.5% to 3.3%, although children receiving weekly or twice-weekly epipodophyllotoxin have been found to have a 12% cumulative incidence of secondary myelogenous leukemia.^{14,58–60} Despite these concerning statistics, the BFM study failed to find an association between a specific chemotherapeutic agent and subsequent acute myeloid leukemia (AML); 12 of the 16 cases of secondary AML they report had not received epipodophyllotoxin.⁶⁰ Patients in these groups who also received craniospinal radiation were found to be at an increased risk of a number of radiation-induced SMNs, including primary CNS malignancy, thyroid cancer, and skin cancers; more-recent ALL protocols have rejected craniospinal radiotherapy in favor of intrathecal chemotherapy for younger patients without evidence of CNS involvement at initiation of therapy.

An additional risk of SMN among patients treated during childhood for ALL is that of malignant melanoma. It had been reported that patients receiving monthly maintenance therapy of vincristine and prednisone, weekly methotrexate, and daily 6-mercaptopurine (6-MP) were found to have an increased number of melanocytic nevi and dysplastic nevi; on this basis, concern was raised that these patients may be at

higher risk of subsequent malignant melanoma than the general population.⁶¹ Whether such an effect will be seen with more modern maintenance regimens has not yet been determined.

SARCOMA

In contrast to the specific case of RB-associated sarcoma, the treatment and sequelae from therapy of primary pediatric sarcoma have been well studied. Among these patients, a consistent and long-lasting rate of SMN following intensive chemotherapy of sarcoma has been identified. The reported cumulative incidence of solid SMN among patients treated for Ewing's sarcoma ranges from 5% at 15 years of follow-up to more than 20% at 20 years, whereas the risk of leukemia has been estimated in the range of 2%.⁶²⁻⁶⁴ These patients went on to develop a variety of hematologic complications, including myelodysplasia (MDS) as well as AML and ALL, between 1 and 8 years after therapy for Ewing's sarcoma. Secondary sarcomas within the field of radiotherapy have been described as well; no clear association with systemic chemotherapy has yet been established for these SMNs.

Treatment of pediatric rhabdomyosarcoma has also been associated with the development of SMNs. The latency period for these patients appears to be slightly longer, with a median time to diagnosis of between 5 and 11 years following initial treatment.^{65,66} The cumulative incidence of SMN following rhabdomyosarcoma appears to be similar to that found in Ewing's sarcoma, but unlike the case of Ewing's sarcoma, this risk seems to be at least in part attributable to a potentiating effect of systemic chemotherapy.^{62,67} Although solid tumor SMNs appear to be salvageable with multimodal therapy, hematologic SMNs following treatment for pediatric sarcoma appear to share the generally poor prognosis of secondary leukemias more commonly seen with epipodophylotoxins and alkylating agents.^{64,66}

WILM'S TUMOR

Long-term follow-up data gathered by the National Wilms Tumor Study Group (NWTSG) demonstrated that, between 1969 and 1991, patients treated in childhood for Wilms' tumor went on to develop an eightfold-greater risk of SMN.⁶⁸ These malignancies consisted of both solid tumors, largely within the field of irradiation, and hematologic malignancies, including both lymphomas and leukemias. The NWTSG reported that their cohort had developed carcinomas of the breast, thyroid, colon, and parotid gland, hepatocellular carcinoma, and primary CNS malignancies. The study group concluded that it appeared that treatment of these patients with doxorubicin increased the risk of SMN, potentiating the oncogenic effect of the administered ionizing radiation.

Hodgkin's Disease

Patients treated for Hodgkin's disease with chemotherapy, ionizing radiation, or both have a risk of developing a variety of SMNs that, cumulatively, is 2 to 4 times greater than unaffected individuals.^{23,27,28,48,69-71} The relative risk of developing specific solid tumors as SMNs shows a great variability, ranging from 2 to more than 50 times greater, depending upon the tissue of origin as well as the chemotherapeutic agents used and whether ionizing radiation was administered con-

comitantly. The cumulative incidence of SMN following the treatment of Hodgkin's disease thus shows a great variability as well, from as low as 2% to as high as 27% within 30 years of treatment.

Specific tissues of origin for these secondary SMNs include thyroid, breast, and skin (melanoma and non-melanoma). Thyroid cancer remains the most common SMN following the treatment of Hodgkin's and is affected by both chemotherapeutic agents as well as the dose of ionizing radiation.¹⁸ And, although the risks associated with ionizing radiation have already been discussed, the risks associated with alkylating agents apply to patients treated for Hodgkin's disease as well. Indeed, up to 25% of SMNs among these patients are either lymphomas or leukemias.^{27,28,48,69,70} The risk of hematologic malignancy as an SMN is, in large part, attributable to the chemotherapeutic agents included in the management of the disease, that is, alkylators versus others. Risks of leukemia, demonstrating the dose-response relationship as discussed, continue to rise with additional chemotherapy, and thus patients requiring retreatment for recurrence of Hodgkin's disease are at higher risk yet of SMN. Given the significant concerns regarding long-term risk of SMNs from therapy, pediatric oncologists have begun modifying treatment regimens, with boys receiving fewer alkylating agents and girls receiving less chest wall irradiation.

Breast Cancer

Women with breast cancer are known to be at higher risk for SMN malignancies within the contralateral breast, as well as at least a slightly elevated risk of primary malignancies of many other organs, including the ovaries, endometrium, and lower gastrointestinal tract; this risk elevation, however, appears to be independent of the treatment modalities used in the primary malignancy.⁷²⁻⁷⁴ These associations suggest that these organs share one or more common risk factors for malignancy with the breast, including hormonal status, diet, and adiposity. A subset of patients with breast cancer carries a heritable risk due to mutations in *BRCA1* and *BRCA2*; these patients are also at greatly increased risk for ovarian neoplasms and second primary breast cancer. Among patients with a history of breast cancer, rigorous screening for SMN within the breast is universally advocated, and many experts argue for screening for both ovarian and endometrial neoplasms as well.^{31,74}

The modalities employed in the treatment of breast cancer have the ability to impact the frequency of SMNs within and beyond the breast. However, unlike each of the organs discussed so far, treatments of breast cancer can either raise or lower this risk. There appears to be an increased risk among patients receiving radiotherapy administered for breast cancer of ipsilateral lung cancer, particularly among smokers.^{33,75} When alkylating agents or anthracyclines are used in the adjuvant setting, an increased risk of treatment-associated leukemia has been seen, an effect that appears to be augmented by concomitant radiotherapy.^{30,76}

Anti-estrogenic therapy has been well documented in its ability to both decrease the mortality from primary breast cancer as well as diminish the frequency of second breast cancers.⁷⁷⁻⁷⁹ This chemoprotective effect has been observed in the high-risk subgroup of patients with *BRCA1* and *BRCA2* mutation-associated primary malignancies, with odds ratios

of between 0.4 and 0.6, odds that approach those seen with prophylactic oophorectomy.⁸⁰ Data from the largest randomized clinical trial, however, have to date been unable to confirm this observation. Although limited by an extremely small number of incident cancers among *BRCA* mutation carriers in the trial, the investigators were unable to show a protective effect among *BRCA1*-positive patients (RR, 1.67; 95% CI, 0.32, 10.7) and only found a trend toward efficacy among *BRCA2*-positive patients (RR, 0.38; 95% CI, 0.06, 1.56).⁸¹ Newly emerging data suggest that the protective benefit of tamoxifen's antiestrogenic effect on breast tissue can be further prolonged by the use of aromatase inhibitors after the discontinuation of tamoxifen. Tamoxifen, however, acts in certain tissues, such as breast tissue, as an estrogen receptor antagonist, whereas in others as an estrogen receptor agonist, tissues that include the ovaries and endometrium.⁸² Research has consistently found that women who undergo long-term tamoxifen therapy are at approximately twice the risk of endometrial cancer, or about 80 excess cases per 10,000 tamoxifen-treated individuals.^{83–85} Early suggestions that tamoxifen may confer an additional risk of ovarian, colorectal, and stomach cancers as SMNs have not been borne out by additional investigation.^{82,85} Although there is some debate concerning the potential value of screening for endometrial cancer via transvaginal ultrasonography or endometrial biopsy among breast cancer patients taking tamoxifen, experts agree on the value of annual visits to an experienced gynecologist for these patients and on the importance of an expeditious evaluation of abnormal vaginal bleeding.^{1,86}

Testicular Cancer

Etoposide is a mainstay of chemotherapy in testicular malignancies, often at high doses, and it comes as little surprise that long-term survivors demonstrate an elevated risk of hematologic malignancy. Estimates have placed the cumulative incidence of AML or non-Hodgkin's lymphoma as SMNs following treatment of testicular cancer at between 1.3% and 2%.^{46,87–89} Although the development of metachronous contralateral testicular cancer remains a concern for patients cured of a primary unilateral cancer, the incidence of contralateral testicular cancer as an SMN does not appear to be influenced by the treatments chosen for the first primary malignancy.⁹⁰

Survivors of primary testicular cancer have also been described as having an increased incidence of solid tumors involving the stomach, colon, rectum, pancreas, prostate, kidney, bladder, and thyroid, as well as soft tissue sarcomas and cutaneous malignancies. All of these, with the possible exception of cutaneous malignancies, have been found to be solely associated with the dose of ionizing radiation administered.⁹¹ The association of both melanoma and non-melanoma skin cancers with chemotherapy of testicular cancer has been reported but remains incompletely elucidated.⁹²

Lung Cancer

Both non-small cell lung cancer (NSCLC) and small cell lung cancer (SCLC) have been clearly associated with an increased risk of developing SMNs. However, the elevated risk of

second upper aerodigestive tract tumors, including head and neck tumors, esophageal cancers, and second primary lung cancers, has been clearly and closely linked to smoking status^{93,94} and the field cancerization that can ensue following continuous exposure to the carcinogens present in cigarette smoke.^{95,96} No association has been identified to link the treatment of a primary NSCLC with an increased risk of SMN. This stands in contrast to the case of SCLC, for which such an association does appear to exist.

Although long-term survival in SCLC patients with extensive disease (ED) rarely exceeds 5 years, more-favorable results have been reported in patients with limited disease (LD); disease-free survival at 2 years in some reports has approached or exceeded 50%.^{97–99} Among SCLC survivors, there has been noted a markedly greater risk of subsequent development of an SMN, as has been noted. However, this risk is not limited to those patients undergoing therapeutic irradiation. An early retrospective analysis of long-term SCLC survivors had found a markedly elevated risk of SMN, with an overall risk of 10.3% per person-year and an 8-year actuarial risk of 50.3%.¹⁰⁰ Although all SCLC patients have an increased rate of second lung cancers (typically NSCLC in histology), this risk rises from approximately 7 times that of unaffected patients to approximately 13 times among patients treated with any of a number of combination chemotherapy protocols.⁵⁴

Prostate Cancer

Although some reports concerning the risk of therapy-associated SMN with radiotherapy of prostate cancer have emerged, far less attention has been either merited or received from the risk of SMN from chemotherapy for prostate cancer. While systemic chemotherapy has a limited role in the treatment of prostate cancer, there is some use of nitrogen mustard, which has been associated with increased risk of myelodysplastic syndrome in patients receiving it for the treatment of prostate cancer.⁹² The use of antiandrogenic therapy in controlling this malignancy is far more common than traditional chemotherapeutic agents, and the theoretical possibility exists that such agents could predispose to tumors that are suppressed by the androgenic state. Suggestion of such a possible phenomenon can be found in a recent report of an increased risk of male breast cancer among patients treated for prostate cancer.¹⁰¹

Gastrointestinal Cancers

It is interesting to note that among the most prevalent gastrointestinal cancers—colorectal cancer, gastric cancer, and pancreatic cancer—there are no convincing data suggesting linkage between chemotherapy and SMN. The reasons underlying this lack of convincing connections undoubtedly vary by malignancy (see Chapters 41 and 43).

Gynecologic Cancers

Analyses of the common gynecologic malignancies—cervical, uterine, and ovarian—have established some patterns of increased risk of SMNs. However, there lacks a robust literature addressing the attributable risk of systemic chemotherapy in patients with cancer of either the uterine cervix or the

corpus uteri; that chemotherapy has at this time a limited role in the treatment of these malignancies both makes the identification of such an association difficult and renders any findings clinically unimportant.

Ovarian cancer presents a different scenario altogether, as it is often treated with a multimodal regimen that includes systemic chemotherapy. Historically, associations had been seen between melphalan-based chemotherapeutic regimens that would now be considered outdated and risk of secondary leukemia in patients treated for ovarian cancer.^{43,102} A Swedish record-linkage study from 1995 found a relative risk of 7 for leukemia among patients with ovarian cancer, likely reflecting the common use of melphalan during the time period under investigation, 1958–1992.⁴⁰ Although an elevated risk of acute nonlymphocytic leukemia has been suggested to exist for patients treated for ovarian cancer with cyclophosphamide, chlorambucil, or regimens containing doxorubicin and cisplatin,^{102–105} a retrospective analysis stratified by decade demonstrated that the risk of leukemia following treatment of ovarian cancer has decreased from 40 during the 1970s to 17 from 1980 to 1992.⁴¹ While this suggests that more modern regimens, largely cisplatin based, may be less leukemogenic, clearly more data are needed to more thoroughly clarify this risk relationship more thoroughly.

Transplantation and Oncogenesis

An additional predisposing factor toward treatment-induced SMN that has recently emerged is immunosuppression. Over the past two decades we have seen a dramatic improvement in the ability to suppress immunologic transplant rejection thanks to new, potent immunosuppressive agents, including cyclophosphamide, cyclosporine A, tacrolimus, and mycophenolate mofetil, but it has become apparent that the long-term administration of such medications can dramatically increase the risk of developing late neoplasia, both hematologic and solid malignancies.^{106,107}

Risk of hematologic malignancy has been noted to be dramatically elevated among transplant recipients, both allogeneic bone marrow transplant (BMT) recipients as well as patients receiving solid organ donation. Indeed, the name posttransplantation lymphoproliferative disorder (PTLD) has emerged in the literature to report and describe such patients. PTLD as a diagnostic category includes a spectrum of pathology ranging from atypical marrow hyperplasia to frank non-Hodgkin's lymphoma; what the constituent diagnoses share is a common association with Epstein–Barr virus infection, either acute seroconversion or reactivation of latent infection.¹⁰⁷ Rates of lymphoma are dramatically increased by bone marrow ablation and hematopoietic stem cell transplant in the treatment of malignancy; these rates are higher yet when the stem cell transplant was given for an indication of an underlying immunocompromised condition, such as Hodgkin's disease or chronic myelogenous leukemia (CML).¹⁰⁸ These PTLDs can occur quite rapidly following BMT, with a median time to onset of 2.5 months, whereas secondary leukemias have an almost equally rapid arrival, with a median time to onset of 6.7 months.^{109,110} PTLD complicates solid organ transplant as well; while most studies place the cumulative "de novo" tumor incidence among

recipients of solid organs at between 5% and 15%, PTLD accounts for 15% to 25% of these malignancies, a marked elevation of risk as compared to the general population.^{111,112}

Although the rise in risk of lymphoproliferative disorders among transplant recipients is striking, there have been noted elevated risks of a number of solid tumors as well in this population. Kaposi's sarcoma, another malignancy with a viral pathogenesis (human herpesvirus 8), is seen among transplant recipients, as are hepatomas among patients with chronic infection by hepatitis B or C virus. And while some solid tumors (renal carcinoma in renal transplant patients, for example) are largely attributable to the underlying conditions necessitating transplantation (e.g., analgesic nephropathy), it is clear that others are strongly associated with the induction of an immunocompromised state. This connection is most clear in the case of squamous cell skin cancer: the cumulative incidence of this malignancy 10 years after transplant is 10% and 20 years after transplant rises to 40%. In Australia, where the baseline incidence is higher than that in the United States because of more-intense solar UV exposure, these numbers rise to 45% and 70%, respectively.¹¹³

Psychosocial Rehabilitation in Cancer Care

Richard P. McQuellon and
Suzanne C. Danhauer

Prevalence data on psychosocial morbidity indicate that from 30% to 50% of cancer patients may experience distress significant enough to warrant professional intervention at some time during survivorship.^{1,2} These patients may require professional attention to manage the debilitating effects of diagnosis, treatment, and morbidity that can wax and wane over time depending upon a host of other variables. It is in this group that some form of psychosocial rehabilitation may be useful.^{3,4}

Psychosocial Rehabilitation in Cancer Care

The formal definition of rehabilitation is “the process by which physical, sensory and mental capacities are restored or developed in (for) people with disabling conditions.”⁵ This definition implies some type of disabling condition that requires rehabilitation. Not all cancer patients experience a disability and not all cancer patients require rehabilitation of any sort. The founders of cancer rehabilitation were physicians trained in rehabilitative medicine largely focused on physical needs of cancer patients with interdisciplinary teams.^{6,7} The Oncology Nursing Society in 1989 defined cancer rehabilitation as “a process by which individuals within their environments are assisted to achieve optimal functioning within limits imposed by cancer.”⁸ Psychosocial rehabilitation in cancer care has a more specific focus than rehabilitation in general⁹ and is often described by the broader term psychosocial intervention.

The diagnosis, treatment and survivorship of cancer often involves much more varied rehabilitation needs than those experienced following most other medical problems.¹⁰ There are more than 100 cancer diagnoses that can elicit a multitude of psychosocial responses. Hence, there may be wide variability in the needs for rehabilitative intervention in the psychosocial area. For example, the patient with radical head and neck surgery left with significant disfigurement is very different than the early-stage breast cancer patient expected to have complete cure with no significant appearance alteration who may require minimal or no psychosocial intervention. The irony of this situation is that although we would expect one patient to experience intensive psychosocial distress and

the other not, depending upon a host of mediating variables (social support, natural resilience, effective communication with healthcare team, etc.), the outcome may be not what one would predict. This variability of psychosocial needs and experiences illustrates but one challenge for the psychosocial care of patients: How can patients who need and want services be identified?

The National Comprehensive Cancer Center Network has developed definitions and guidelines to help treat distressed cancer patients.¹¹ Distress has been defined as “a multifactorial, unpleasant experience of an emotional, psychological, social, or spiritual nature that interferes with the ability to cope with cancer, its physical symptoms, and its treatment. Distress extends along a continuum ranging from normal feelings of vulnerability, sadness and fear to disabling conditions such as clinical depression, anxiety, panic, isolation and existential or spiritual crisis” (p. 369). In the context of cancer care, the term psychosocial refers to the psychologic and social adaptation and reaction of the patient to the diagnosis of cancer, treatment, and survivorship.¹²

Scope of the Field

Psychosocial rehabilitation could include all psychosocial interventions that are designed to positively influence patient psychosocial adaptation and adjustment to diagnosis, treatment, and survivorship. For example, physical and occupational therapists play a significant role with patients undergoing debilitating treatment. To illustrate, bone marrow transplantation and cytoreductive surgery plus intraperitoneal hyperthermic chemotherapy often leave patients deconditioned physically and distressed psychologically.^{13,14} Such patients might benefit significantly from a physical rehabilitation program without explicit emphasis on psychosocial care or intervention. An example of a physical rehabilitation program (walking) following bone marrow transplantation has been reported as effective.¹⁵ Such interventions do not explicitly focus on psychologic outcomes with the use of targeted psychosocial interventions but may measure them as secondary endpoints. This chapter focuses primarily on randomized clinical trials specifically designed

to address psychosocial deficits in patients that have been the result of initial diagnosis, treatment, and morbidities of treatment and survivorship.

Models for Understanding Psychosocial Rehabilitation

The biopsychosocial model of medical care is most useful in conceptualizing the rehabilitation of the patient with cancer and holds that health or illness outcomes are a consequence of the relationship between biologic, psychological, and social factors.^{16,17} Both macro forces (e.g., culture–subculture, family) and micro forces (e.g., organ systems, cells) interact with the person to determine health outcomes. For example, attention to the psychologic and social aspects of a patient's life can direct attention to macro-level processes such as the existence of social support or the presence of a helpful caregiver. The presence or absence of caregiver support can interact with micro-level events (cellular disorders) such as anemia. Low hemoglobin may result in significant fatigue, mild depression, and/or waning social support associated with a failure to return to normal functioning following hematopoietic cell transplantation.¹³ The biopsychosocial model takes account of both health and illness and provides the conceptual framework for understanding patient adaptation following rigorous medical treatments. In this situation, a biopsychosocial approach would direct providers to test for anemia and inquire about social support in the home, perhaps leading to both a medical (e.g., epoetin alpha injection) and a behavioral intervention (e.g., caregiver consultation).

The Kornblith Vulnerability Model of Psychosocial Adaptation of Cancer Survivors suggests that adaptation to cancer (psychologic, vocational, sexual, and social) and its treatment is influenced by a host of mediating variables, medical management of late effects, and psychosocial interventions¹⁷ (Figure 112.1). Patients who adapt well will not need rehabilitation. It is likely that mediating variables such as the patient's communication with the medical team can have a powerful effect on the patient's need for psychosocial rehabilitation.¹⁸ For example, the patient who is upset by the

way the diagnosis was conveyed can experience debilitating anxiety and depressive symptoms that require psychologic intervention. Also, fear of recurrence, which is heightened by an obsessive-compulsive personality style, can hinder healthy adaptation.

Historical Perspective

One of the earliest studies to assess cancer rehabilitation needs identified 805 patients who were comparable to a national study sample.¹⁹ This group was screened to identify (1) rehabilitation problems experienced with different cancer diagnoses; (2) need for rehabilitation services; and (3) significant gaps in the delivery of rehabilitation care. Psychologic problems were found to be fairly common and appeared to be more severe in patients with concomitant physical disabilities. The percentage of patients with psychologic problems varied from a low of 30% in patients with bladder cancer to a high of 78% in patients with central nervous system tumors. The authors concluded that psychologic and physical rehabilitation problems were common in patients with most cancer diagnoses and that many of these problems would likely be amenable to therapeutic intervention. However, at the time of the study there were many barriers to optimal rehabilitative care.

Over a decade ago, Ivan Barofsky provided an eloquent description of the status of psychosocial research in the rehabilitation of the cancer patient.²⁰ A basic assumption in the literature is that the patient sustains some type of loss (physical, psychologic, social). Rehabilitation involves an attempt to restore the person to previous functioning. The definition of rehabilitation implies that restoration is possible; how and if restoration can occur becomes the fundamental issue in rehabilitation research.

Much of the research on the psychosocial dimension of cancer care involves the management of anxiety and depressive symptoms as well as distress, a term favored by many researchers because it is less stigmatizing. Not all patients with cancer need psychosocial rehabilitation in the form of a systematic intervention delivered by a professional. However,

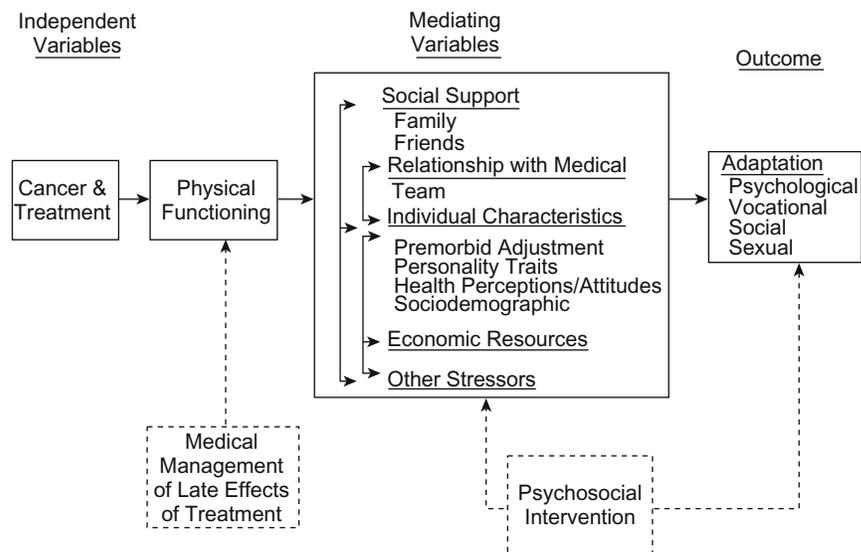

FIGURE 112.1. Kornblith vulnerability model. (From Kornblith,¹⁷ by permission of Oxford University Press.)

it is likely that all patients will require a time period to be restored to normal functioning following the diagnosis and treatment of their illness. Moreover, the psychosocial rehabilitative process is further complicated by the fact that the treatment of cancer is rarely a single event but often consists of a series of different treatments over time.

The most economical approach may be to assume that a certain percentage of patients will develop psychosocial distress over the course of diagnosis, treatment, and survivorship. Some patients may be more or less vulnerable depending upon a host of individual factors.²¹ Some researchers have proposed a screening process early in treatment to detect those experiencing abnormal levels of distress^{22,23} to be targeted for interventions.

Systematic Reviews and Meta-Analyses of Psychosocial Interventions

There are a number of excellent reviews²⁴⁻²⁶ as well as meta-analyses²⁷⁻²⁹ of the effects of psychosocial interventions in cancer care. Newell and colleagues²⁴ conducted a comprehensive, systematic review and analysis of psychologic therapies for cancer patients. They identified 627 relevant papers that reported on 329 intervention trials. More specifically, they identified 34 trials with psychosocial outcomes. These trials were aimed at reducing patient anxiety or depression or at improving functional ability (e.g., overall quality of life) or the interpersonal relationships of patients. The authors applied a rigorous criteria of evidence that has been established by the Cochrane Collaboration.³⁰ The Cochrane Collaboration recommends that randomized trials should be assessed on 10 methodologic quality indicators that specify whether potential threats to the trial's internal validity have been adequately controlled. Largely due to the failure of nearly all trials to gain a good rating based on this assessment, the authors' recommendations for psychological therapies are somewhat guarded. This review applied the most rigorous standards for evidence and, unfortunately, only one trial evaluated achieved a quality rating of good for its methodology. This study, a pilot project on reducing patient anxiety,³¹ was followed by a larger RCT with a similar methodology³² that was not reported in the review. The dearth of findings suggests that the evidence supporting the effectiveness of psychological therapies with cancer patients needs further development.

The authors used a method they term "decision process" to analyze the results and to produce recommendations for or against each intervention strategy. This method of analysis

resulted in the following five outcome recommendations: (1) strong recommendation for the intervention strategy, (2) a tentative recommendation for it, (3) a tentative recommendation against it, (4) a strong recommendation against it, or (5) no recommendation for or against it. With regard to patient anxiety, the authors concluded that music therapy can be tentatively recommended for reducing a patient's anxiety levels. Additionally, a number of therapist-delivered interventions (e.g., individual therapy, cognitive behavior therapy, communication skills training, guided imagery, and self-practice of a cognitive intervention) warrant further exploration before a recommendation for or against their use can be made. The authors concluded that no intervention strategy reviewed could be recommended for reducing a patient's levels of depression. However, group therapy, education, structured counseling, cognitive behavior therapy, communication skills training, and self esteem building warrant further assessment before recommendation either for or against could be made.

A widely cited meta-analysis by Meyer and Mark yielded a more positive conclusion regarding psychosocial interventions.²⁷ They identified 45 studies that reported 62 treatment-control comparisons. This sample of studies included only published randomized experiments conducted on adult cancer patients receiving a psychosocial, behavioral, or psychoeducational intervention. Five categories of dependent measures were developed in this analysis: (1) emotional adjustment, (2) functional adjustment, (3) treatment or disease-related symptoms, (4) medical measures category, and (5) global measures, which combine core aspects of more than one of the preceding categories. The results and effect sizes reported by Meyer and Mark are shown in Table 112.1.

While all five of the categories of dependent measures have relevance for psychosocial rehabilitation, it is emotional adjustment that is most relevant to this chapter. The overall average effect size was 0.31 (95% confidence interval defined by $-0.13 \sim 0.31 \sim 0.75$), for emotional adjustment, was recorded. A score in the 0.20 to 0.40 range is considered typical of effective psychologic interventions. The authors were cautious in their conclusions, particularly because the studies included in their meta-analysis were made up predominately of white women from the United States. It is difficult to know just to what extent the results of these studies can be generalized to the broader population. A further limitation of Meyer and Mark's study was that they grouped all psychological therapies (in this case five different categories) into one and further reduced all possible outcomes increasing overall sample size and thereby the chance of significant findings.

Another meta-analysis of studies examined the effects of psychosocial interventions on quality of life in adult cancer

TABLE 112.1. Weighted effect sizes for dependent measure categories.

Measure	Studies	Comparisons	Total N	d	d 95% CI
Emotional Adjustment	41	56	2,840	0.24	0.17/0.32
Functional Adjustment	16	21	940	0.19	0.06/0.32
Treatment- and disease-related symptoms	28	39	1,606	0.26	0.16/0.37
Medical	5	7	232	0.17	0.10/0.44
Compound and global	5	7	373	0.28	0.08/0.49

CI, confidence interval; d, weighted average effect sizes.

Source: Data from Meyer and Mark.²⁷

patients.³³ The stated hypothesis was that cancer patients treated with adjuvant psychosocial intervention experienced a higher level of subjective quality of life (QOL) compared to those without additional psychosocial intervention. The authors identified 37 studies that included a total of 3,120 cancer patients. The overall effect size on QOL in this study was 0.31 [95% confidence interval (CI), $0.13 \leq 0.31 \leq 0.75$]. The authors concluded that psychosocial interventions have a positive impact on quality of life in adult cancer patients, and the effect was moderated by duration of treatment, suggesting that psychosocial interventions should be planned for at least 12 weeks.

A study of psychological interventions for patients with symptoms of anxiety and depression has particular relevance for this chapter.²⁸ In this study, two meta-analyses were conducted with anxiety and depression examined as separate outcome measures. Even though the majority of trials included in the analysis were preventive (i.e., not targeted to patients with identified abnormal symptoms of anxiety or depression), these studies can shed some light on the rehabilitation process. Nineteen trials on anxiety had a combined effect size of 0.42 favoring treatment against "no treatment controls" (95% CI, 0.08–0.74; $n = 1,023$). Twenty trials on depression had a combined effect size of 0.36 as well, favoring the treatment (95% CI, 0.06–0.66; $n = 1,101$). Four trials focusing on patients who were identified as "at risk" had particularly significant effects, suggesting that targeted interventions were more likely to demonstrate beneficial effects. However, the mean effect size for depression was weak to negligible (0.19), prompting the authors to state that preventive psychological interventions with cancer patients may have a moderate effect on anxiety but little effect on depression. The authors concluded that resources should be directed toward those patients demonstrating psychological or psychosocial deficits, and that group therapy trials appear to be equally effective relative to individual interventions and are likely more economical. Finally, relatively short, intensive interventions delivered by more-experienced counselors appear to be more effective than interventions delivered by less-experienced counselors over a long period of time.

Measurement Tools in Psychosocial Rehabilitation

A number of assessment tools are widely used by researchers and clinicians for examining the psychosocial impact of cancer and its treatment as well as the impact of psychosocial interventions on patient functioning. These tools include measures of general mood (e.g., Profile of Mood States, Positive and Negative Affect Scale), depression (e.g., Center for Epidemiologic Studies Depression, Beck Depression Inventory, Hamilton Depression Inventory), anxiety (e.g., State-Trait Anxiety Inventory), and general mental health symptoms (e.g., Brief Symptom Inventory).²² These instruments have been used largely because of their psychometric properties and ease of administration.

The interest in overall patient QOL has spawned the Functional Assessment of Cancer Therapy (FACT) and the European Organization for Research and Treatment of Cancer (EORTC) questionnaires. These methods include modules that measure symptoms of specific cancers or characteristics

of treatment situations (e.g., bone marrow transplantation). For example, the FACT includes many disease site-related subscales (breast, colon, brain, etc.)^{34,35} and treatment- or symptom-related modules (bone marrow transplantation, etc.).^{36–38} The SF-36 has also been used in the assessment of cancer patients because it provides normative values for the nonmedical patient population;³⁹ this allows for comparison of patients undergoing treatment with normative samples in the U.S. adult population. Such comparisons can be helpful when patients ask what they might expect in terms of healthy functioning following specific treatments.^{40–42} These instruments have been particularly useful as they allow for comparisons over time because of their sensitivity to change. Thus, one would be able to look at baseline levels of emotional well-being with the FACT or mental health functioning on the EORTC and compare these with posttreatment functioning in longitudinal studies. These instruments, however, were not developed with the intent of measuring outcomes of psychosocial rehabilitation following cancer treatment.

In contrast, the Cancer Rehabilitation Evaluation System (CARES) allows patients to identify problems and to indicate with which problems they want help.⁴³ For example, one item on the CARES reads something like the following, "I have difficulty doing physical activity such as running." Patients are asked to answer on a 5-point scale from "not at all" to "very much" and then to indicate "yes" or "no" to the question, "Do you want help?" The 139 items on the CARES cover nearly every conceivable problem situation. It has been used in a number of studies attempting to assess rehabilitation needs and success in patients.^{44–46} Because of the depth of coverage of items in the CARES, it is not typically used in clinical trials where the emphasis must necessarily be on rapid assessment and fewer items, but one of the most significant strengths of the CARES is that it directs patients to identify problems (including psychosocial problems) that they want to address. This coverage can be very useful to providers trying to focus scarce resources, because as few as one-third of patients actually are interested in a counseling intervention⁴⁷ even though a significant number of cancer patients may experience psychosocial distress.¹

Randomized Controlled Trials

We systematically searched Pub Med and PsychInfo with the following descriptors: psychosocial rehabilitation and cancer, psychosocial intervention and cancer, psychological intervention and cancer, and behavioral intervention and cancer. After compiling this list we also looked for relevant studies in the reference sections of studies identified in the searches. We selected studies based on two criteria: (1) for the most part, the intervention was targeted toward a current or anticipated need or deficit exhibited by the patient (e.g., high distress, anxiety, or depression); and (2) assignment to treatment was made randomly. We have selected representative studies that provide evidence for the effectiveness of psychosocial interventions in modifying and potentially improving outcomes for patients in the psychological and social domains. The studies reviewed, including caregiver studies, are summarized in Table 112.2.

TABLE 112.2. Randomized control trials.

Reference	Year	n/dx	Intervention/source/duration	Measures/timing	Outcomes
Gordon et al. ⁴⁸	1980	217/Breast = 71 Lung = 37 Melanoma = 109	Three interventions: (1) patient education re: how to live with disease; (2) general counseling; (3) environmental manipulation, e.g., consultation with other professionals vs. usual care/a single oncology counselor Average of 11 20-minute sessions	Problems (number, intensity severity); MAACL; LPIS; SREs; HLC; ADL (modified version); API. Hospital admit., hosp. d/c, 3 and 6 months post d/c.	Intervention group showed improvement of some problems, more rapid decline of neg. affect, more realistic outlook, return to previous vocational status and more active pattern of time usage.
Cheung et al. ⁴⁹	2003	59/Colorectal	Progressive muscle relaxation training (PMRT) vs. standard care/therapist and audiotape/two face-to-face teaching sessions before intervention of listening to tape Two to three times/1-week interval period	STAI; QOL-Colostomy; WHO QOL measure abbreviated version (all instruments Chinese version for Chinese population). Within 1 week of surgery, week 5, and week 10 postsurgery.	Reduced state anxiety; no significant difference between groups over time on disease-specific QOL; both groups improved with time. Improved general QOL for experimental group.
Mishel et al. ⁵¹	2002	239/Prostate	Three intervention groups: uncertainty management direct, uncertainty management supplemented (family support person received phone call also), and control/trained nurse Eight consecutive weekly phone calls	Mishel Uncertainty in Illness scale, Self-Control scale (problem solving and cognitive reframing subscales), the Symptom distress scale, and two study specific measures, i.e., the Cancer Knowledge Scale and a measure of patient-provider communication. Baseline, 4 and 7 months.	Improvement in cognitive reframing and problem solving at 4 mos. for intervention groups; decrease in symptom intensity for all groups, no difference by intervention. Impact of impotence was modified for some in intervention group. Some differences between African-Americans and Caucasians described.
Lepore et al. ⁵²	2003	250/prostate	Three groups: group education (GE); group education + discussion (GED); usual care control/content experts, i.e., oncologist, urologist, etc. Six weekly 1-hour sessions	Prostate cancer knowledge; ratings of lectures; health behavior index; SF-36; CES-D; UCLA Prostate Cancer Index. Baseline, 2 weeks, 6 months, and 12 months.	Both interventions increased prostate ca. knowledge. GED group had fewer sexual problems than controls. Among noncollege graduates, GED and GE results in better physical functioning than controls and GED resulted in more positive health behaviors. No differences in these variables for college graduates.
Goodwin et al. ⁵³	2001	235/breast	Two groups: supportive expressive group therapy or usual care control/two professional counselors Weekly group sessions of 90 minutes for 1 year	POMS; LASA pain; EORTC-QLQ-30; Survival. Baseline, 4, 8, and 12 months.	No increased survival; improved mood and reduced pain for intervention group.
Molassiotis et al. ⁵⁵	2002	71/breast	Two groups: progressive muscle relaxation training, including individual audiocassettes and 30-minute video training program or control/therapist trained in PMRT Thirty-minute sessions daily beginning 1 hour before chemotherapy and for 6 days following	POMS; STAI; MANE; Karnofsky Performance Index/baseline (POMS, STAI, Karnofsky). At 7 and 14 days postchemotherapy (MANE).	Significant decrease in duration and trend toward lower frequency of N/V in intervention group; significant decrease in total mood disturbance.

TABLE 112.2. (continued)

<i>Reference</i>	<i>Year</i>	<i>n/dx</i>	<i>Intervention/source/duration</i>	<i>Measures/timing</i>	<i>Outcomes</i>
McArdle et al. ⁵⁶	1996	272/breast	Three groups: support from breast care nurse; support from voluntary organization; support from both nurse and organization; routine care control/breast care nurse and Tak Tent (Take Care) volunteer organization Variable	GHQ; HADS. First postoperative visit, 3, 6, and 12 months.	Psychological morbidity fell for all groups over 12 months. Compared to other groups, support from breast care nurse resulted in significant declines in depression, anxiety, and insomnia.
Winzelberg et al. ⁵⁷	2003	72/breast	Two groups: internet-based social support group with moderator; wait-list control health care professional Twelve weeks	CES-D, PCL-C, STAI, PSS, Cancer Behavior Inventory, Mini-MAC. Baseline (before randomization), post termination of group session.	Significantly greater decreases in depression, cancer-related trauma, and perceived stress in intervention compared to control group.
Helgeson et al. ⁵⁸	2001	312/ breast	Four groups: education; peer discussion; education + peer discussion; control/facilitators and content experts Eight weekly 45-minute sessions	SF-36/six assessments. Baseline (after diagnosis, before randomization). Time 6 was mean 3.6 years postdiagnosis.	Long-term follow-up (mean, 3.6 years): higher vitality and physical functioning and lower bodily pain in education group. No long-term benefits on health-related QOL in peer discussion or education + peer discussion groups.
Antoni et al. ⁵⁹	2001	100/ breast	Two groups: cognitive-behavioral stress management group (intervention) and seminar (control)/postdoctoral fellows and graduate students Ten weekly 2-hour sessions (intervention) and 1 day (control)	POMS-SF; CES-D; IES; LOT-R; novel measures of perceived benefits and emotional processing. Baseline; postintervention; 3 and 9 months postintervention.	No overall effects of intervention on distress for intervention group; however, reduced depressive symptoms for those with higher depressive symptoms at baseline. Intervention group increased in benefit finding and optimism, particularly those with lower scores at baseline.
Edelman et al. ⁶⁰	1999	121/ breast	Two groups: cognitive-behavioral group intervention; control group/professional therapists Twelve 2-hour sessions	POMS; Coopersmith Self-Esteem Inventory; Survival. Baseline, immediately postintervention, and 3, 6, and 12 months postintervention.	Reduced depression and total mood and disturbance and increased self-esteem in intervention compared to control group. No group differences at 3- or 6-month follow-up. No survival effects.
Fukui et al. ⁶¹	2000	50/ breast	Two groups: cognitive-behavioral therapy group; wait-list control group/one psychologist and one psychiatrist Six weekly 90-minute sessions	POMS; MAC; HADS Baseline, 6 weeks (postintervention), and 6 months.	Significant decreases in anxiety and depression for tx group but no group differences for these outcomes. Tx group had lower mood disturbance, greater vigor, and greater fighting spirit at both follow-ups compared to control group.
Edmonds et al. ⁶²	1999	66/ breast	Two groups: psychological intervention, (supportive therapy + cognitive-behavioral techniques); control group (received information on coping and relaxation audio tapes)/trained therapists Weekly 2-hour sessions for 35 weeks + one weekend	POMS; POMS-SF; FLIC; MAC; RED; DUFSS; RED; M-C. Baseline, 4, 8, and 14 months.	No group differences for mood, QOL, social support, or repression. In intervention group, greater anxious preoccupation and less helplessness; no survival effects.

TABLE 112.2. Randomized control trials. (continued)

Reference	Year	n/dx	Intervention/source/duration	Measures/timing	Outcomes
Classen et al. ⁶³	2001	125/ breast	Two groups: supportive-expressive group + educational materials; educational materials only (control)/a psychiatrist, psychologists, and social workers Weekly 90-minute sessions for 1 year	POMS; IES. Baseline, every 4 months for 1 year, every 6 months thereafter.	Greater decline in traumatic stress symptoms for intervention group but no group difference for mood at 1 year. When data excluded in year preceding death, mood disturbance and traumatic stress symptoms declined more for treatment group.
Bultz et al. ⁶⁴	2000	36 breast cancer partners	Two groups: psychoeducational and control/cofacilitated by two psychologists Six weekly 1.5- to 2-hour sessions	POMS; Index of Marital Satisfaction; DUFSS; MAC. Pre- and postintervention, 3 months postintervention.	Partners in intervention group had less mood disturbance than controls 3 months post-intervention. Women whose partners received the intervention reported less mood disturbance, and greater confident support and marital satisfaction.
Toseland et al. ⁶⁵	1995	40 cancer patients and spouses	Two groups: intervention (support, problem-solving, coping skills) and usual treatment (control)/experienced oncology social worker Six 1-hour sessions with patient's spouse	For caregivers: CES-D; STAI; Dyadic Adjustment Scale; Social Functioning Subscale from Health & Daily Living Form; SF-20; Zarit Burden Inventory; Help-Seeking Coping Index; Index of Coping Responses; Pressing problems (cancer caregiving); drug/EtOh use; Personal Change Scale. For patients: FLIC; ECOG Global Performance Scale. Baseline, postintervention.	No significant between-group differences found for any measures. Intervention appeared to be effective only for distressed subsample of caregivers.

n/dx, number of patients/diagnosis; MAACL, Multiple Affect Adjective Checklist—state form; LPIS, Langer Psychiatric Impairment Scale; SRE, Schedule of recent events; HLC, Health Locus of Control; ADL, activities of daily living; ADPI, Activity Pattern Indicators; STAI, State-Trait Anxiety inventory; QOL, quality of life; WHO, World Health Organization; SF-36, Short Form 36 (Rand Medical Outcomes Study); CES-D, Center for Epidemiologic Studies—Depression scale; POMS, Profile of Mood States; LASA, Linear Analog Scale Assessment; EORTC-QLQ-30, European Organization for Research and Treatment of Cancer—Quality of Life Questionnaire—30; PMRT, progressive muscle relaxation training; MANE, Morrow Assessment of Nausea and Emesis; GHQ, General Health Questionnaire; HADS, Hospital Anxiety and Depression Scale; PCL-C, posttraumatic stress disorder (PTSD) Checklist—Civilian Version; PSS, Perceived Stress Scale; Mini-MAC, mini-mental adjustment to cancer scale; SF-36, Medical Outcomes Study Short-Form 36; SF-20, Medical Outcomes Study—20; IES, Impact of Events Scale; LOT-R, Life Orientation Test—Revised; MAC, Mental Adjustment to Cancer Scale; FLIC, Functional Living Index for Cancer; ECOG, Eastern Cooperative Oncology Group performance status scale; DUFSS, Duke-UNC Functional Social Support Questionnaire; RED, Rationality/Emotional Defensiveness Scale; M-C, Marlowe Crowne Social Desirability Scale; N/V, nausea/vomiting.

In one of the earliest randomized clinical trials measuring the efficacy of a psychosocial intervention, cancer patients with diagnoses of breast or lung cancer or melanoma were studied.⁴⁸ The intervention group ($n = 157$) was given one of three types of psychosocial intervention: (1) patient education about how to live with the disease effectively; (2) a more generic counseling intervention focusing on patients' reactions to and feelings about their disease; and (3) environmental manipulation, including consultations with other healthcare personnel and referral for additional services as necessary. The control group ($n = 151$) received usual care and evaluations only. The most notable effects of the intervention included amelioration of psychosocial problems reported by the patient, a more-rapid decline of negative affect (anxiety, hostility, and depression), a more realistic outlook on life, a greater proportion of return to previous vocational status, and a more-active pattern of time usage.

Another study examined the effect of progressive muscle relaxation training (PMRT) on anxiety and quality of life following stoma surgery in Chinese colorectal cancer patients.⁴⁹ Subjects were randomly assigned to a control group ($n = 30$)

and the experimental group utilizing PMRT ($n = 29$). This procedure significantly decreased state anxiety and improved overall quality of life in the experimental group. These findings are notable particularly because patient baseline state anxiety scores were higher than reported norms.⁵⁰ Thus, this sample would constitute one that needed psychosocial rehabilitation, assuming that premonitory state anxiety was lower than that reported at baseline here.

In a unique study with prostate cancer patients, Mishel et al. examined effects of a nurse-delivered psychoeducational intervention over the telephone in helping patients to manage uncertainty and treatment side effects.⁵¹ A total of 239 men were randomly assigned to one of the three treatment conditions: (1) uncertainty management with the patient, (2) uncertainty management with the patient and a family member (supplemented group), and (3) the control group. The intervention consisted of eight weekly telephone calls by a nurse who was trained in this specific intervention. Patients in each of the two treatment groups (individual or supplemented) received the same intervention. However, in the supplemented group, a spouse or designated significant other from

the family also received a weekly telephone call and a similar intervention was applied. The majority of intervention effects were seen at 4 months after baseline, a time when treatment side effects were also most intense. Both uncertainty management approaches were useful in producing cognitive reframing and problem solving. When both individual and supplemented intervention groups were combined for analysis, there was measured improvement in control of incontinence at the 4-month assessment. Furthermore, the negative impact of impotence could be modified for some of the men who had received the intervention. This study represents an economical and convenient intervention in a population with significant morbidity, particularly in terms of sexual functioning and incontinence following treatment for localized prostate cancer. The telephone intervention method is also portable and has great potential for psychosocial interventions with cancer patients.

Lepore et al. attempted to improve the QOL of men recently treated for prostate cancer.⁵² Two hundred and fifty patients were randomly assigned to a control group, a group education intervention (GE), or a group education-plus-discussion intervention (GED). Both GE and GED increased prostate cancer knowledge. In the year following the intervention, men in the GED condition were less bothered by sexual problems than men in the control condition, and they were more likely to remain steadily employed than men in the GE or control conditions. Both the Mishel and Lepore studies support the idea that relatively straightforward interventions can be useful for improving psychosocial functioning in prostate cancer patients.

Breast Cancer Studies

Breast cancer patients are the most extensively studied group in randomized clinical trials conducted in the area of psychosocial rehabilitation. The literature is extensive, and we only cite representative studies here. There is an excellent review of health-related QOL results that does include 20 studies with psychosocial outcomes in breast cancer.⁵³

In a study of women with newly diagnosed breast cancer ($n = 96$) about to begin chemotherapy, patients were randomized to an intervention (standard care plus relaxation training and imagery) or to a control condition (standard care only).⁵⁴ The goal of this study was to develop and evaluate a simple and easily administered intervention to help women cope with the diagnosis and treatment of breast cancer. Those in the intervention group practiced relaxation and imagery daily for the 18 weeks of their chemotherapy. No significant between-group differences were noted for anxiety and depression. Using intention-to-treat analyses, between-group effects were found with women in the intervention group reporting fewer psychologic symptoms and higher quality of life during chemotherapy.

Molassiotis and colleagues assessed the effectiveness of progressive muscle relaxation training (PMRT) in the management of chemotherapy-related nausea and vomiting, mood disturbance and anxiety.⁵⁵ Women diagnosed with nonmetastatic breast cancer ($n = 71$) were randomized to the PMRT intervention or to a control condition. The PMRT intervention was administered by a trained therapist six times for 30 minutes before receiving chemotherapy. The

total mood disturbance score of the POMS decreased in the intervention group and increased in the control group when assessed at 7 and 14 days postintervention. No between-group differences were observed for POMS subscales or for anxiety.

McArdle et al. examined the effects of support from a nurse specialist and from a volunteer support organization in breast cancer.⁵⁶ Women under 70 years of age diagnosed with breast cancer ($n = 272$) were randomized to one of four groups before undergoing surgery for breast cancer: (1) standard support from ward staff and information booklet; (2) standard support from ward staff plus support from a specialist breast care nurse; (3) standard support from ward staff plus support from a voluntary organization (included any combination of information, counseling, and group meetings); and (4) standard support from ward staff plus support from a specialist breast care nurse and from a voluntary organization. Individuals in the treatment group receiving support mainly from the nurse specialist reported improved depressive symptoms, anxiety symptoms, somatic symptoms, and social dysfunction compared to all other groups, including the group that had support from *both* the nurse specialist and the voluntary organization.

Another RCT employed a newer technologic approach to providing psychosocial support to women with breast cancer.⁵⁷ Women with breast cancer ($n = 72$) were randomly assigned to a 12-week internet-based social support group moderated by a healthcare professional or to a wait-list control group. Participants in the intervention group reported significantly decreased depressive symptoms, cancer-related traumatic stress, and perceived overall stress when compared to the control group. No changes were found for anxiety or coping measures.

Helgeson and colleagues examined the long-term effects of participation in a psychosocial group intervention on health-related quality of life (measured with the SF-36)⁵⁸ in which 312 women with early-stage breast cancer were randomly assigned to one of four conditions: education, peer discussion, education plus peer discussion, and control. The length of the intervention was 8 weeks with participants meeting once each week. The education group focused on the provision of information to enhance sense of control while the peer discussion group focused on the expression of feelings and self-disclosure. Intent-to-treat analysis was used in this study. Follow-up with those who had no recurrent disease at 3 years revealed that the women in the education-only group retained higher levels of vitality (energy and lack of fatigue) and physical functioning and lower bodily pain than women in the control group. No benefits of the peer discussion group or the education plus peer discussion group were observed at 3-year follow-up.

Antoni et al. examined distress as well as positive outcomes in women who had recently been treated for early-stage breast cancer.⁵⁹ Patients were randomly assigned to take part in a 10-week cognitive-behavioral stress management intervention (met weekly for 2 hours over 10 weeks) or to a more-limited control condition (1-day informational seminar). Findings showed that while there were no overall effects of the intervention on measures of distress, participation in the 10-week intervention reduced the prevalence of moderate depressive symptoms for those whose levels were higher at baseline. Also, benefit-finding and optimism increased for those taking part in the intervention, with the

effects most pronounced in women with low baseline scores. Findings from this study underscore the notion that psychosocial rehabilitation is most likely to be useful for those patients who report the most psychosocial distress and/or the least psychosocial resources.

In a study with metastatic breast cancer patients, 124 patients were randomized to take part in a group cognitive behavioral therapy (CBT) intervention or to a no-therapy control group condition.⁶⁰ Participants in the CBT group attended eight weekly group sessions, followed by a family night and three additional monthly sessions. Immediately following participation in the CBT group, data indicated significant improvements in depression, total mood disturbance, and self-esteem. However, no significant differences between the CBT and control groups were evident at 3- or 6-month follow-up.

A similar study of a short-term psychosocial intervention was conducted with lymph node-positive breast cancer patients in Japan.⁶¹ Patients ($n = 50$) were randomized to a 6-week structured psychosocial group intervention (included health education, coping skills training, stress management, and support) or to a wait-list control group. Analyses were conducted on the 46 women who completed the intervention. Anxiety and depression decreased significantly over the course of the study for the treatment group; however, no significant between-group differences emerged for these outcomes. Significant between-group differences were found for POMS total mood disturbance score at both the 6-week (immediately following the intervention) and 6-month assessments. The experimental group had significantly lower scores than the controls for total mood disturbance and significantly higher scores for vigor on the POMS, and significantly higher scores for fighting spirit on the MAC at the end of the 6-week intervention. These improvements were sustained over 6 months of follow-up.

Several of the previously described studies demonstrated that short-term psychosocial interventions resulted in improvement in quality of life and psychosocial distress. There has been little evidence, however, for the efficacy of longer-term psychosocial interventions. In a study of longer duration, patients with metastatic breast cancer were randomized to an 8-month weekly psychologic intervention ($n = 36$; group discussion, emotional support, coping skills training, and relaxation) or to a control group ($n = 30$; received information on coping and relaxation audio tapes).⁶² Study outcomes included mood, quality of life, and adjustment to cancer measured at baseline, 4 months, 8 months, and 14 months. Participation in the long-term psychologic intervention did not result in significantly improved mood or quality of life in comparison to those in the control group, although there were short-term clinical gains reported by therapists that were not quantified.

A group of 125 metastatic breast cancer patients was randomized to a 1-year weekly supportive-expressive group psychotherapy intervention with additional educational materials or to a control group offered only educational materials.⁶³ Data from all participants who completed at least one follow-up assessment ($n = 102$) regardless of level of group attendance were included in study analyses. Women in the group intervention reported a significantly greater decline in traumatic stress symptoms at 1 year, but no difference in overall mood when compared with women randomized to

the control condition. However, when data from final assessments that took place during the year before participants' deaths were excluded, both mood disturbance and traumatic stress symptoms declined significantly more for those in the treatment compared to the control condition.

Caregiver Studies

The patient has long been the primary focus for psychosocial rehabilitation or psychosocial interventions. However, the diagnosis and treatment of cancer can have far-reaching effects, evoking distress and feelings of helplessness in spouses/partners and other close family members. Role transitions in spousal and family relationships are often required. Relatively few interventions and even fewer RCTs to date have focused on psychosocial rehabilitation issues in close family members of cancer patients. The following several studies are representative examples of high-quality research that has sought to empirically validate methods for helping family members increase their understanding of cancer and treatment, normalize their responses to a loved one's cancer, and provide a safe place for relatives to express emotional distress.

One RCT examined the effects of a brief psychoeducational support group intervention for male partners of women with early-stage breast cancer ($n = 36$ pairs).⁶⁴ The intervention was offered to partners of breast cancer patients weekly for six sessions by two experienced psychologists and focused on two primary components: education and support. Results indicated that total mood disturbance score had improved by 3-month follow-up for both patients and partners who in the intervention group; however, these findings did not reach statistical significance.

Another RCT offered a six-session intervention to spouses ($n = 40$ male, $n = 40$ female) of patients with various types of cancer.⁶⁵ Spouses were randomly assigned to the intervention that included support, problem-solving, and coping skills or to a usual care condition. At baseline and within 2 weeks of completing the intervention, spousal caregivers completed measures of depression, anxiety, marital satisfaction, social support, health status, burden, help-seeking behavior, coping (perceived stressfulness of 17 cancer-related caregiving problems), and drug/alcohol use. At the same time points, patients completed measures of functional and physical status. Taking part in the group did not significantly improve any of the psychosocial outcomes for those in the intervention versus the control group. However, post hoc subgroup analyses revealed that for those caregivers who were more distressed at baseline (lower marital satisfaction, higher burden), greater improvements were found in the intervention group compared to the control group. This type of result, once again, highlights the usefulness of targeting psychosocial rehabilitation interventions to those individuals most in need of them.

Rehabilitation Programs

A number of programs have been developed and tested over the past 15 years directed at psychosocial care of patients.⁶⁶⁻⁶⁸ Examples of such programs include Gilda's House, The Well-

ness Community, and the Commonweal Help Program. Even though there are programs for posttreatment cancer survivors that have a psychosocial component (e.g., the posttreatment resource center at Memorial Sloan Kettering Cancer Center), there is a need for dissemination of research outcomes so that programs can integrate evidence-based rehabilitation strategies. Additionally, specific programs have been developed to attend to particular difficulties of patients.

In a review article, Ronson and Body described the psychosocial rehabilitation of cancer patients after curative therapy.⁶⁹ They reported that even though the majority of cancer survivors do quite well, there is a substantial minority of patients who have significant psychosocial distress and/or psychiatric disturbance. A number of factors seem to predict psychosocial difficulty or adjustment, including a past history of psychiatric disturbance (especially depression), comorbid physical problems, poor social support, low social or economic status, and individual psychologic factors (including certain coping styles and personality traits). An important observation they make is that "no effective psychosocial rehabilitation can be achieved without simultaneous efforts to promote improvement of the physical condition." Physical and psychosocial functioning may be so closely related that it is impossible to talk about one without reference to the other. It is safe to say that patients returning to predisease physical functioning are less likely to experience severe psychosocial distress, although this cannot be stated with 100% certainty. Under the best of conditions, when patients return to health, fear and anxiety can act to rob the patient of the present when a feared future looms ahead in the form of recurrent disease.

Specific psychologic disorders and symptom entities that were summarized from the literature by Ronson and Body with estimated prevalence rates were posttraumatic stress disorder (as high as 14% to 21%), fear of recurrence (ranging from 10% to 89%), conditioned nausea/vomiting (no estimates given; highly dependent on emetogenic potential of chemotherapy and antiemetic agents used), treatment-related body image disturbances (no estimates given; related to area of surgery, timing of assessment, and premorbid functioning), and general psychosocial functioning (ranging from 18% to 40% depending on tumor type and treatment). They also identified aspects of physical functioning that have a psychosocial impact. Although attention to the literature on physical functioning is beyond the scope of this paper, it is important that the reciprocal relationship between physical and psychosocial functioning in general be understood, as well as the psychosocial issues related to specific tumor types and their treatment.

There are few randomized prospective studies of rehabilitation programs described in the literature. One such study is the "Starting Again Group Rehabilitation Program"⁶⁷ that enrolled a total of 199 patients ($n = 98$ intervention; $n = 101$ control) in the program. The intervention (called the "Starting Again Program") consisted of eleven 2-hour sessions that emphasized physical training, information, and coping skills. Outcomes that improved following the intervention included appraisal of having received sufficient information, physical strength, and fighting spirit. The psychosocial area of this study consisted of coping skills training and role playing (employed to help study participants understand the issues of returning to work, as well as problem situations that may

arise with return medical appointments). One session devoted to anxiety management included coping strategies such as relaxation, distraction, and cognitive techniques. Depressive symptoms for program participants diminished significantly over time. The authors pointed out that the study included patients at low risk for psychosocial disturbance, thereby making it more difficult to measure appreciable change. Furthermore, spontaneous recovery is common for those experiencing psychosocial morbidity in low-risk patients, and it would be difficult for an intervention to achieve superior results under these circumstances. In other words, many people simply improve with time with regard to sadness and depressive symptoms related to the diagnosis and treatment of cancer.

The Tapestry Program is an example of a novel method for providing psychosocial support for persons living with cancer.⁶⁸ It consists of a 5-day residential retreat program focusing on the following areas: creating a safe environment for patients, providing a daily narrative group, the use of arts and medicine therapy, providing yoga and meditation sessions, discussions about complementary therapies and pain control, death and dying, and use of rituals to foster a supportive collegial atmosphere. A primary method within this group involves general support provided by patients undergoing similar difficulties together. The Tapestry group has attempted to measure patient improvement following participation in the program with pre- and posttest measures that generally favor the impact of this program. There have been other promising reports of the effectiveness of these types of programs.⁷⁰

Returning to Normal

Returning to "normal" is a prominent theme in the clinical care of patients. Although there has been some work in this area,⁷¹ there is little research on returning to normal from a psychosocial standpoint only. Indeed, some patients comment that "things will never be normal again," because the issue of recurrence is always present even after a declaration of survival at the 5-year posttreatment time point. However, although some patients may carry a constant sense of foreboding and worry about cancer recurring, others may claim not only a return to normality but a deeper appreciation for life.⁷²⁻⁷⁴ Such patients not only return to normal but actually find some benefits and, perhaps, improved psychosocial functioning in the form of deeper appreciation and meaning in everyday living. This finding has been incidental, although researchers are now focusing more on benefits that patients experience following a cancer diagnosis and treatment.⁷⁴ Typically, such benefit finding is in the area attitudinal shifts and/or improved social relations. For example, one attitudinal shift might be reflected in a change of career or a change of work habits in the direction of increasing time with family or friends as a consequence of recognition of mortality. Even though benefit finding is not a particularly common approach in psychosocial rehabilitation, it is an important area to consider because it could be that one psychosocial deficit such as fear of recurrence is balanced by a benefit in the form of deeper meaning noted by the patient or other family members.

Concluding Comments

There is a growing body of literature supporting the effectiveness of psychosocial interventions in the rehabilitation of cancer patients. Interest in this area is driven by the increasing number of cancer survivors living 5 years or longer, less stigma attached to utilizing psychosocial services such as support groups or individual coaching/counseling, research initiatives of the National Cancer Institute (NCI) emphasizing psychosocial care, efforts of the National Coalition for Cancer Survivorship and Office of Cancer Survivorship of the NCI, growing consumer interest, effective intervention techniques, and validated measurement tools for assessing the usefulness of such interventions. Another force operating within the community of cancer medicine is the emphasis on quality of life as an important outcome in addition to survival.

There are specific types of treatments that have been shown to be effective for a variety of patients for reasons of their ease of administration as well as face validity. These interventions include cognitive behavioral therapy, progressive muscle relaxation, structured psychoeducational interventions including problem solving, and supportive-expressive therapy. For the most part, such interventions have been demonstrated with breast cancer patients, possibly because of funding opportunities provided by the Department of Defense and the Komen Foundation. There are few RCTs with psychosocial interventions in most other cancer sites. Patients with head and neck and pancreatic cancer, as well as those with brain tumors, remain little researched for a variety of reasons. Most of the excellent randomized clinical trials that have been conducted are associated with major medical centers. However, the vast majority of cancer care is delivered in communities. Patients treated in community settings are most likely to find psychosocial care with mental health counselors and the clergy, American Cancer Society programs, and in Wellness Communities. These settings are hard pressed to devote the resources necessary to conduct a clinical trial on psychosocial care.

If psychosocial rehabilitation is to move forward, more clinical trials with a broader range of patients need to be developed and conducted. There has been progress made. Cognitive behavior therapy and structured supportive educational approaches have promise, as do telephone interventions. Yet, the central question remains: What interventions for what patients along what point of their trajectory of survivorship and care, delivered by what type of professional, can offer the promise of reduced suffering and return to full-quality living following the diagnosis and treatment for cancer?

Cancer Advocacy

Ellen L. Stovall

Thousands of individual citations using the expression *cancer advocacy* can be found in contemporary medical and scientific literature as well as in the popular press and on Internet websites. For purposes of this chapter, the term *cancer advocacy* is used to describe a skill set that has been documented in previously published work by Clark and Stovall.¹ This chapter also includes specific examples of how self-described advocacy organizations are involved with research organizations and how they influence cancer research and related health policy.

In 1996, Clark and Stovall described a cancer-related advocacy skill set that could be acquired through a learning process and would ideally be incorporated into care plans for cancer patients. Their article proposed a definition of cancer advocacy that most easily correlated with the terms “cancer survivor” and “cancer survivorship” first used by the founders of the National Coalition for Cancer Survivorship (NCCS) in 1986.² NCCS defines a cancer survivor as anyone with a diagnosis of cancer—from the time of its discovery and for the balance of life. NCCS further defines cancer survivorship as a process that begins when an individual is diagnosed with cancer and continues until their death. NCCS believes that, at the time of diagnosis, an individual with cancer [and/or a significant person in his or her life—known as the “other survivor”(s)] can play a very active role in assuring that they receive quality care. This is the first step in the cancer advocacy continuum and is further defined by Clark and Stovall as “personal advocacy or self-advocacy.” The next step in the continuum is “advocacy for others.” This is where some of the most effective advocacy occurs for individuals with cancer, and it is where many people with cancer find a role for themselves as advocates in their own community. The third part of the advocacy paradigm described by Clark and Stovall is national advocacy, or public interest advocacy.

Over the past decade, relative survival data for all cancer types have ranged from 6 to 10 million survivors in any given year, and estimates are that of that number, more than half are living 5 years or more postdiagnosis.³ With this epidemiology alone, it is likely that this cohort (and their primary caregivers and healthcare providers) could be the most likely beneficiaries of a greater understanding of the role that advocacy can play as part of a successful adjustment to a cancer diagnosis. To accept the notion that advocacy can play a role in enhancing the quality of one’s survivorship, a shared understanding of cancer advocacy and its relationship to cancer survivorship among healthcare professionals and sig-

nificant others involved with a cancer patient’s adjustment postdiagnosis is desirable.

The term *cancer survivorship* was a term of art rather than science when the founders of NCCS used it to describe the condition of living with the consequences of a diagnosis of cancer. Now commonly referred to as the cancer survivorship movement, several of its early founders and adopters crafted the language and gave definition to terminology frequently used today for what has become a burgeoning field of study called *cancer survivorship research*. Mullan wrote about cancer survivorship as the “act of living on.”⁴ Carter and Leigh have written about survivorship in terms of “going through” and “the experience of living with, through or beyond cancer.”^{5,6} These dynamic concepts of survivorship suggested that more research was needed to focus on cancers whose prognosis could be defined as protracted and/or episodic, rather than as an acute diagnosis followed by death. It was also noted that the degree to which a history of cancer affects the life of an individual is largely dependent on many qualitative variables with respect to how they experience their illness. These variables include, but are not limited to, their familial and cultural relationships, their religious beliefs, how their cancer is treated, and how their disease progresses or is resolved.

Previous chapters in of this section elaborate on the survivorship issues and deal specifically with the myriad of medical and psychosocial sequelae of many cancers. The challenges posed by these changes in one’s biologic and psychologic condition suggest that although each person’s cancer is an individual experience, there are overarching issues with which many survivors contend.⁷ We also know from the literature and from the cancer survivorship movement that the skills necessary for positive adaptation to cancer have been identified and that survivors must become self-advocates and viewed by health professionals as partners in making the very important decisions that will impact on their medical, social, psychologic, and vocational well-being. What follows is a suggestion by Clark and Stovall that successful adaptation to cancer involves acquiring advocacy skills that will enhance each survivor’s sense of self-determination throughout his or her survivorship. The skill set is neither gender- nor age-specific and does not suggest an impact on longevity, but rather on quality of life across several domains.

Using advocacy as an approach to adjusting to cancer calls for establishing a competency model that has skill-building and coping strategies at its core. This approach is suggested

as a way of preventing or overcoming psychosocial limitations and promoting expectations for effective living.^{8,9} The notion of learning an advocacy skill set is especially useful if one agrees that the psychosocial dimensions of a cancer diagnosis may cause a time-limited state of diminished functioning. Maher¹⁰ defines a diagnosis of cancer as an anomic situation for many, suggesting it is "a temporary state of mind occasioned by a sudden alteration in one's life situation, and characterized by confusion and anxiety, uncertainty, loss of purpose, and a sense of separateness from one's usual social support system." Clark¹¹ suggests that the concept of crisis is useful for adaptation to cancer in terms of both situational requirements and the various phases over time of the mobilization of resources. The tasks facing the individual, as well as the strategies selected for attempted management of these tasks, become important parts of the process for resolving crises. These tasks and the strategies for managing them, such as seeking information or support, can be integrated into a method of skills training.

Skills training is used across many diverse professional settings, including education, psychology, sociology, and social work, and is distinguished from competence by McFall,^{12,13} who associates skills with the specific underlying component processes that enable a person to perform in a manner which has been identified as competent. Skills are task specific and are acquired through a learning process.

Skills training is especially useful because of the complexities of the cancer experience. Drawing from a body of evidence found largely in the psychosocial research literature and derived from educational programs developed by cancer advocacy organizations, four interrelated skills have been identified as integral to the advocacy skills model: (1) information-seeking skills,¹⁴⁻¹⁶ (2) communication skills,¹⁷⁻²¹ (3) problem-solving skills,²²⁻²⁸ and (4) negotiation skills.²⁹⁻³¹

The founders of many patient advocacy organizations widely agree that providing reliable and timely information as well as providing decision support to people with cancer are among the most pressing needs of the public who are in touch with them when dealing with a diagnosis of cancer. Information needs are variable among cancer patients and change over the course of their illness. Also variable are the methods used by people when they seek health- and medical-related information. Books and articles about cancer can be found in public, university, hospital, and medical school libraries, and public access to the Internet is widely available. If anything, the amount of cancer information is daunting, and there are few compendia that annotate the information available, often making it difficult to identify what are the most suitable and reliable cancer-related resources. The Internet Health Care Coalition³² offers an excellent guide for evaluating the reliability of online health information and advice, including cancer information. Being a wise medical consumer involves asking questions, seeking answers, gathering and organizing data, and the ability to access resources. Training for the development of information-seeking skills involves well-developed communication and negotiation skills.

Communication skills-building is an aspect of medical consumerism that is frequently complicated by the patient's need to learn a new lexicon of terms to increase his or her comprehension and understanding of cancer. At the critical time of learning about and understanding the diagnosis, the goals of treatment, and decision making about which treatment is most suitable, shared responsibility for communi-

cating clearly between the healthcare provider and patient is important. The quality of communication should be characterized by equity, reciprocity, and a mutual understanding of hope and goals, wherein both patient and professional have input into care decisions.³³

The literature on effective communication skills is widely available and adaptable to a clinical setting. The American Society of Clinical Oncology (ASCO) and the Oncology Nursing Society (ONS) are excellent resources of information on patient/provider communications skills building, and both associations provide workshops to their members on effective communication strategies.

Problem-solving skills are especially helpful when utilized to more carefully consider a situation with no clear and evident resolution. A diagnosis of cancer is one of those situations that can benefit from employing a number of problem-solving methods including modeling and role-playing.³⁴ Modeling is a form of observational learning in which the behavior of an individual or group acts as a stimulus for similar thoughts, attitudes, and behavior on the part of another individual. Role-playing relies on the re-creation of real or hypothetical situations. Cancer survivors use role-playing effectively in group settings where peer support and critique for their interactions with role-playing professionals can be supported.

It is common to hear cancer survivors use words such as "powerless" or "out of control" when describing how they felt when diagnosed with cancer. Because these feelings of temporary impotence frequently accompany a diagnosis of cancer, how one advocates for one's own needs during this time may be compromised. Especially relevant to a diagnosis of cancer is negotiation skills training if one must contend with employment, insurance, and financial institutions. Advocating in the occupational setting or with insurers often includes negotiations that go beyond anyone's ordinary mastery of skills and requires the involvement of legal counsel.^{35,36} Because conflict is inherent in many well-intended interactions, conflict resolution through negotiation bears attention as part of a good self-advocacy model. Effective communication, resourcefulness, open-mindedness, and understanding alternative positions are central to all negotiation efforts.³⁷

The advocacy continuum as described by Clark and Stovall may begin at a personal level wherein the previously outlined skill sets are most relevant. As the survivorship continuum changes, so do the advocacy needs of the individual and his/her support system. Self-advocacy may evolve into wanting to participate or interact with small groups or organizations at the community level, and, for some, public policy activities at the national level. Succinctly stated, Clark and Stovall describe an advocacy paradigm as follows: (1) Personal Advocacy; (2) Advocacy for Others; and (3) Public Interest Advocacy.

Personal advocacy or self-advocacy is a way of taking charge in an otherwise portentous environment of tests, surgery, radiation, chemotherapy, and office visits. From arming oneself with good information about one's diagnosis, to seeking second opinions, to locating resources for identifying and obtaining support, to knowing how to ask the right questions and negotiate the terms of one's employment while undergoing treatment, a cancer patient can become self-efficacious. This type of self-determination can mean the difference between maintaining a positive future outlook and

enhancing one's quality of life or feeling helpless and less certain of the desirability of survival.^{38,39}

For many cancer survivors, the 5 years following diagnosis and treatment mark a time of reentry and reevaluation of one's life. Many significant relationships in the lives of survivors change during this time as family and friends cannot understand why survivors are not simply jubilant with their survival. Support systems that were intact during the initial workup and treatment period may diminish or disappear. It is at this time in survivorship that many seek out others with whom they can identify. This transitional period, whether at age 20 or 70, calls for another kind of self-advocacy. With the notion that they may want to "give something back" in gratitude for their survival, many survivors seek to share their experiences with others.⁴⁰ The idea that shared information can be both powerful and validating—the veteran helping the rookie—is what the survivorship movement is largely about. When occurring in the context of a support group, this transmission of wisdom from a more-seasoned survivor to the newcomer provides a strong foundation for people who have had cancer to play a more-proactive role in making the myriad decisions that will follow them the rest of their lives.

The second part of the advocacy paradigm is characterized by cancer survivors going on to relay their experiences beyond one-on-one counseling interventions or small group interactions. Involvement in one's community can range from speaking to civic or religious groups and to the local media, participating in runs/walks for cancer awareness and cancer research, enrolling in advocacy training courses such as the National Breast Cancer Coalition's Project LEAD, to inquiring about participation on local Institutional Review Boards, etc. By speaking about one's experience to groups of medical students, for example, cancer survivors have an opportunity to educate them about the complex interpersonal and psychosocial issues that dominate their lives after treatment. This public speaking becomes a testimony that affirms one's survival, defies the myths and stigmas about cancer, and perhaps reaches others who are silently struggling with similar issues.

The last part of the cancer advocacy paradigm is Public Interest Advocacy. Largely a consequence of improved diagnostic tools and treatments for cancer that resulted in months and years of survival beyond initial diagnosis, issues related to adult cancer survivorship emerged as an agenda for advocacy and activism in the mid-1980s. These issues principally fall into three areas: economic/vocational, psychosocial/spiritual, and physiologic.

Compared with the number of cancer survivors, relatively very few engage in this type of advocacy, although breast cancer survivors have been visible and notable in the way they have brought about policy change through political advocacy and activism. A distinction is being made between the visibility or awareness of breast and other cancers through mass cause-related marketing campaigns and the work of cancer advocates and activists who participate in focused activities to change or initiate public policies.

Although *cancer advocacy* is not a contemporary phenomenon and includes much public education and outreach to diverse constituencies, *cancer activism* is in its relative infancy. Cancer survivors as advocates became very visible during the mid-1980s and 1990s when national breast cancer activists petitioned the federal government to target research in breast cancer and petitioned Congress to earmark funds

through an unprecedented appropriation from the Department of Defense. Their petitioning not only increased federal funding for research, but led to a change in the peer-review process for granting monies to research under this program. The distinguishing characteristic of this example was the involvement of cancer survivors at every step of designing the Department of Defense Breast Cancer Program. Their activism laid the groundwork and set an example for participation of advocates at all levels of government-funded cancer research programs.

The 1990s and the new millennium ushered in an era that witnessed the creation of many organizations that self-identify themselves as cancer advocacy groups. Often founded by survivors and/or their supporters, these groups represent the voices of people with commonly diagnosed cancers, for example, breast, colon, lung, lymphatic, and prostate, as well as less-common cancers, such as ovarian, head and neck, brain, pancreatic, and kidney, and provide a valuable resource for people with cancer and their families. Increasingly, their representation can be found sitting on review groups, on the boards of cancer centers, on federal advisory commissions, and walking the halls of Congress to educate their elected officials about the needs of those they represent.
