hepatoblastoma with alpha fetoprotein levels in children starting at age 5 years. For primary prevention of FAP, the recommended strategy is colectomy, usually in the second decade of life. Subtotal colectomy with ileorectal anastomosis, total proctocolectomy with Brooke ileostomy, or proctocolectomy and ileoanal pull-through are acceptable surgical options. Those who choose subtotal colectomy require frequent endoscopic evaluation of the rectum because of the persistent risk of rectal adenomas and carcinomas. The use of specific or nonspecific cyclooxygenase (COX)-2 inhibitors, such as celecoxib, has been recommended as an adjunct to endoscopic surveillance following subtotal colectomy.⁹¹ Upper endoscopic surveillance, as well as thyroid examination, are also recommended by some.

HNPCC is an autosomal dominant condition caused by the germ-line mutation of one of several DNA mismatch repair genes, *hMSH2* on chromosome 2p16, *hMLH1* on chromosome 3p21, *hPMS1* and *hPMS2* on chromosomes 2q31 and 7q11, respectively, *hMSH6* on chromosome 2p16, and *hMSH3* on chromosome 5q11.2–q13.2.⁹² The function of these genes is to maintain the fidelity of DNA during replication. When mismatch repair is faulty, somatic mutations occur throughout the genome that can ultimately trigger the carcinogenic pathway.⁸⁹ It is estimated that germ-line mutations in the HNPCC account for 3% to 5% of all colorectal cancers.⁹³

Individuals with HNPCC have a lifetime risk of developing colorectal cancer of 70%, with a mean age at diagnosis of 44 years. Both synchronous and metachronous tumors are common, and both tumors and polyps are often right sided. Extracolonic cancers, including endometrial, ovarian, gastric, urinary tract, kidney, biliary tract, central nervous system, and small bowel, are also increased.⁸⁹ Criteria for HNPCC, the Amsterdam criteria, were developed by the International Collaborative Group in 1990 and subsequently revised to include other HNPCC-associated cancers, such as endometrial cancer, small bowel cancers, and ureteral or renal pelvis cancers, whose relative risk ranges from 3 to 25 times that of the general population (Table 25.6).^{22,94}

Because tumor DNA from individuals with HNPCC often have a distinct phenotype with changes in the length of nucleotide repeat sequences, termed MSI, the analysis of MSI in the tumor specimens is often recommended as the first step of evaluation before proceeding to full genetic sequencing for *MLH1* or *MSH2*. Clinical indications for testing a

TABLE 25.6. The Amsterdam criteria for hereditary nonpolyposis colorectal cancer (HNPCC).

The Amsterdam Criteria I:

Histologically confirmed colorectal cancer in at least three relatives, one of whom is a first-degree relative of the other two.
Occurrence of disease in at least two successive generations.
Age at diagnosis below 50 years in at least one individual.
Exclusion of familial adenomatous polyposis.

Amsterdam Criteria II:

Histologically confirmed HNPCC-related cancers (colorectal cancer, or cancer of the endometrium, small bowel, ureter, or renal pelvis) in at least three relatives, one of whom is a first-degree relative of the other two.
Occurrence of disease in at least two successive generations.
Age at diagnosis below 50 years in at least one individual.
Exclusion of familial adenomatous polyposis.

Source: From Vasen et al.,⁹⁴ by permission of *Gastroenterology*.

TABLE 25.7. The revised Bethesda guidelines.**Tumors from individuals should be tested for MSI in the following situations:**

- Colorectal cancer diagnosed in a patient who is less than 50 years of age.
- Presence of synchronous, metachronous colorectal, or other HNPCC-associated tumors, regardless of age.
- Colorectal cancer with the MSI-H histology diagnosed in a patient who is less than 60 years of age.
- Colorectal cancer diagnosed in one or more first-degree relatives with an HNPCC-related tumor, with one of the cancers being diagnosed under age 50 years.
- Colorectal cancer diagnosed in two or more first- or second-degree relatives with HNPCC-related tumors, regardless of age.

colonic tumor for MSI are outlined in the Bethesda criteria (Table 25.7) and include early age at onset (less than 50 years), an individual with multiple primary cancers, and a family history of colorectal and/or endometrial cancer.^{23,89} Of note, tumors that are positive for MSI (MSI high) are characterized by a better clinical outcome compared to tumors with low or no expression of MSI.⁹⁵ Newer assays include immunohistochemistry staining of tumors using antibodies to the *MLH1* and *MSH2* protein products. Histopathologic features of HNPCC-related colorectal cancer include mucinous or signet-ring types, poor cellular differentiation, and peritumoral lymphocytic infiltration.⁹⁶ The polyps that precede cancer are more often villous with areas of high-grade dysplasia than sporadic polyps.⁹³ Other rare genetic syndromes associated with an increased risk for colon polyps and cancers are Turcot syndrome, Peutz–Jeghers syndrome, and juvenile polyposis.

Management strategies for HNPCC are based on the observed natural history of the diseases included in the syndrome. Because of the early age of onset of colorectal cancers, it is recommended that annual screening colonoscopy be initiated by age 25, or 5 years younger than the youngest affected individual in the family, and continued at frequent intervals for known mutation carriers. Those relatives who have a 50% chance of being a mutation carrier, but have not undergone genetic testing, are recommended to begin colonoscopy every 1 to 2 years, starting between 20 and 30 years, and annually after age 40. Because of the predominance of right-sided tumors in HNPCC, flexible sigmoidoscopy is not a sufficient screening tool. Because of the significantly increased risk for endometrial cancer in women with an HNPCC mutation, some form of screening of the uterus is recommended starting at age 25, although the optimal screening tool is not clear.⁹³ Current options include annual transvaginal ultrasound or endometrial aspirates.⁹⁷ Because of the high rate of metachronous tumors seen with HNPCC mutations (25%–40%), subtotal colectomy with ileorectal anastomosis rather than standard colectomy is recommended for individuals at the time of diagnosis of colon cancer.⁹³ As in the case of *BRCA1/2*, oophorectomy (with hysterectomy) may be presented as an option for women with HNPCC.

Multiple Endocrine Neoplasias (MEN) Types 1 and 2

The familial MEN syndromes are characterized by clustering of benign and malignant endocrine tumors and other systemic manifestations. MEN type 1 includes combinations of more than 20 different types of tumors, but the most characteristic are tumors of the parathyroid, pituitary, and pancreatic glands. The term multiple refers both to the occurrence of multiple tumors in the same gland and to multiple different kinds of tumors in the same individual and/or family. MEN1 is inherited as an autosomal dominant disease with variable penetrance and a prevalence of 1 in 30,000 to 1 in 50,000.⁹⁸ The *MEN1* gene has been localized to chromosome 11q13 and encodes a protein called menin. Menin is thought to interact with one or more transcription factors in the nucleus, and loss of its function is thought to be the mechanism of tumor formation in the syndrome.⁹⁹ Much of the morbidity associated with this syndrome is attributable to the excess production of hormones. Hyperparathyroidism from parathyroid tumors is the most common (more than 90%) and earliest manifestation of the syndrome, occurring in the third decade of life and involving three or all four parathyroid glands. Enteropancreatic islet cell tumors occur in 30% to 75% of MEN1-affected individuals and usually present with symptoms of hormone excess after age 40 years. Tumors occur both in the pancreas and in the duodenum and are commonly multicentric. Hormones secreted by pancreatic islet cell tumors can include chromogranin A and B, pancreatic polypeptide, glucagons, insulin, proinsulin, somatostatin, gastrin vasoactive intestinal polypeptide (VIP), serotonin, calcitonin, growth hormone (GH)-releasing factor, and neurotensin.⁹⁹ The prevalence of pituitary adenomas in MEN1 ranges from 10% to 60%, and most are less than 1 cm in diameter. Other rare manifestations of MEN1 include carcinoid tumors, adrenal cortical hyperplasias, lipomas, and angiofibromas.

MEN1 germ-line mutation testing is recommended for index cases with clinical MEN1 manifestations and their at-risk relatives. Periodic biochemical testing for hormone excess is a less efficient alternative. Management of MEN1 tumors includes surgery as well as medical management of hormone-secreting tumors. The treatment of choice for primary hyperparathyroidism is total parathyroidectomy, with immediate autotransplantation of parathyroid tissue to an accessible site, usually the forearm.¹⁰⁰ Subtotal parathyroidectomy is associated with a high rate of subsequent recurrence. Insulinomas are often treated with surgical resection because of the difficulty in achieving medical management. Surgery for other islet cell tumors is controversial, as most are multicentric and can often be managed medically. Treatment of pituitary tumors depends on the type of adenoma but does not differ from that for sporadic pituitary tumors. Regular screening for hormone excess in known or suspected mutation carriers is controversial. If elected, annual biochemical screening should begin in early childhood and continue for life. Tumor imaging [e.g., magnetic resonance imaging (MRI) of the pancreas and pituitary] are recommended every 3 to 5 years.⁹⁹

As in MEN1, the MEN2 syndromes represent several variants of benign and malignant tumors, all of which, however, show a high penetrance for medullary thyroid cancer (MTC), a rare calcitonin-producing tumor of the parafollicular cells of the thyroid gland.⁹⁹ All MEN2 syndromes are caused by

germ-line mutations that activate the *RET* proto-oncogene, located on chromosome 10q11.2, which encodes the RET (rearranged during transfection) protein, a tyrosine kinase receptor expressed in tumors of neural crest origin.¹⁰¹ RET activates several downstream pathways involved in cell growth, survival, and differentiation.¹⁰² MEN2A, which accounts for 90% of all MEN2 cases, is characterized by MTC in 90% of mutation carriers, unilateral or bilateral pheochromocytomas, tumors of the adrenal chromaffin cells, in 50% of carriers, and multicentric parathyroid tumors in 20% to 30%. MEN2B accounts for 5% of MEN2 cases and is characterized by MTC, pheochromocytoma, and developmental abnormalities including mucosal and intestinal ganglioneuromatosis, marfanoid habitus, neurofibromas, and medullated corneal nerve fibers. MTC in MEN2b occurs at an earlier age and is thought to have a more aggressive course. MTC in multiple family members (four cases or more) is the only manifestation of familial MTC (FMTC) and is thought to have a more benign course. Other rare variants include MEN2A with cutaneous lichen amyloidosis and MEN2A or FMTC with Hirschsprung's disease.

DNA sequencing for *RET* mutations is clinically available and is indicated for all index cases and their at-risk relatives. Approximately 2.5% to 7% of mutations in RET are spontaneous new mutations, and therefore, genetic screening is recommended for all individuals with MTC, regardless of family history. *RET* mutations exhibit a characteristic genotype-phenotype correlation, with specific mutations associated with each variant of the syndrome. Because C cell hyperplasia is a precursor lesion to MTC, serum calcitonin levels provide an excellent tumor marker, particularly to monitor the tumor status of those diagnosed with MTC. Primary prevention is recommended in mutation carriers, however, with total thyroidectomy in childhood (before age 5 years in MEN2a and before 1 year in MEN2B). Pheochromocytomas usually present at a later age than MTC (between 30 and 40 years) with intractable hypertension and/or hypertensive crisis. Screening for pheochromocytoma is done by measurement of plasma metanephrines or 24-hour urinary catecholamines or metanephrines.⁹⁹ Abdominal MRI is performed to confirm the diagnosis in suspected cases. Prophylactic adrenalectomy is not recommended because of the dangers of adrenal insufficiency. Hyperparathyroidism may present with hypercalciuria or renal calculi but is often asymptomatic. MEN2-associated hyperparathyroidism is managed in a manner similar to sporadic forms.

There are several other rare genetic syndromes associated with cancer susceptibility, including basal cell nevus syndrome, von Hippel-Lindau syndrome, retinoblastoma, and neurofibromatosis (see Table 25.1), which are described in depth by Offit.¹

Future Directions

The rapidly evolving insights into the molecular genetic pathways of carcinogenesis will have broad application to the future of clinical oncology. The availability of predictive genetic testing to extend beyond the small number of highly penetrant genes will depend on the identification of an increased number of low penetrant genes that alter susceptibility to cancer in all individuals. Although the genes

involved in complex carcinogenic pathways are likely to have a small individual effect on risk, their attributable risk can be high because they affect a large segment of the population.

The relatively new field of molecular epidemiology is capitalizing on the existence of genetic polymorphisms to identify genetic clues of exposure to carcinogens or particular vulnerabilities to carcinogens. Genetic variation in the metabolism of carcinogens can alter response to environmental carcinogens by changing the rate of metabolism of procarcinogens or the catabolism of carcinogens. Genetic polymorphisms can also result in DNA damage or alterations in signal transduction pathways and represent an important component to cancer susceptibility.¹⁰³ In addition to their role in carcinogenesis, genetic polymorphisms may also contribute to treatment toxicities and are likely to explain why some patients suffer severe adverse reactions to chemotherapy and/or radiation therapy. Furthermore, drug-metabolizing enzymes may also determine patterns of response in individual patients. A better understanding of the role of these polymorphisms and their complex interactions will ultimately permit individualized estimates of risk and lead to targeted prevention as well as therapeutic strategies.

The application of a genetic approach to cancer diagnosis not only will lead to a better understanding of the pathophysiology of cancer, it will also provide tools for more accurate diagnosis and prognosis that will translate into more appropriate and targeted therapeutic approaches. Microarray technology is beginning to emerge as a powerful tool that allows both qualitative and quantitative screening for sequence variations in genomic DNA for thousands of genes in a biologic sample. Current tools for diagnosing cancer rely heavily on the histopathologic appearance of a tissue specimen, resulting in a limited classification scheme with inherent tumor heterogeneity. Microarray technology has the potential to create a taxonomy of tumors that will reflect their molecular diversity.

Microarray technology is being applied in the area of cancer prognosis to better classify tumors and to predict outcome.¹⁰⁴ The ability to create a genetic taxonomy for each cancer will greatly enhance our ability to match patients to appropriate treatment regimens.¹⁰⁵ In breast cancer, for example, both the overexpression of HER2/neu and abnormal p53 expression are associated with decreased survival. In colon cancer, the presence of high-frequency microsatellite instability in the tumor is associated with early age of onset, a predominance of tumors in the proximal colon, increased sensitivity to chemotherapy, and improved survival.

In addition to cancer prevention and early detection, genetic status will provide clinicians with the possibility of suitable, novel therapeutic options. Historically, cytotoxic therapies have been designed to capitalize on the increased cell proliferation rates generally manifested by cancer cells, a feature also shared by many benign cells, thus resulting in significant, dose-limiting toxicities. To improve the current state of cancer treatment, therapies specifically designed to reverse the specific genetic defect(s) expressed by a tumor are needed. The relatively new field of pharmacogenomics applies genome-based technologies to identify genetically determined targets for new drug development and to tailor drug regimens and schedules to individual genetic profiles.¹⁰⁶

Cancer treatment resistance, a major barrier to effective therapy, is still poorly understood but is acknowledged to be

largely attributable to gene expression variability. This is another area where microarray technology will be applied to stimulate progress in understanding cellular and subcellular resistance mechanisms. These and other targeted therapeutic advances likely represent the tip of the iceberg for rational drug design and will be followed by gene-based strategies using ribozymes, other growth factor receptor antibodies, immunotoxins, signal transduction inhibitors, and antiangiogenic molecules, to name a few.

Finally, as we move from the setting of single gene identification, the possibility of whole-genome screening looms large on the horizon. The possibility of complete genomic sequencing as a routine clinical test on every individual to be used for predictive and preventive medicine will become feasible as the work of the Human Genome Project proceeds. However, its adoption as a part of routine medical practice must consider the criteria for the adoption of population screening on a public health basis. Widespread genetic screening for a disease should be restricted to those diseases that are relatively common and serious, for which the natural history is defined and consistent, and for which effective primary and/or secondary prevention interventions exist. The associated gene(s) must be well characterized and accurately identified through existing detection methods. Genetic testing must be relatively inexpensive, acceptable to the population, and associated with pre- and posttest counseling. Genetic screening for diseases that selectively affect a segment of the population should be targeted specifically to that group and not offered to the population as a whole. As we move into an era characterized by genetic identity, ethical and social concerns must be carefully considered.¹⁰⁷

Conclusions

As the importance of cancer prevention and control grows in recognition, cancer risk counseling services are becoming a standard component of primary health care. Individuals are becoming increasingly aware of the role of their family history in their own personal cancer risk. The growing sophistication in the process of risk identification, including the use of genetic tests for cancer susceptibility genes, is stimulating research to develop risk modification and cancer prevention strategies. Several registries of high-risk families are being assembled to provide prospective data on the epidemiology and natural history of familial cancers and the effectiveness of a variety of cancer control interventions. Optimal screening protocols for members of high-risk families are being developed and evaluated. Long-term follow-up of mutation carriers will help to define the spectrum of cancer risk, the clinical course of hereditary cancer, and response to treatment. Central to these research efforts are ongoing studies of the short- and long-term effects of cancer risk counseling on health behaviors and quality of life. Coincidental with this are the many new educational initiatives to prepare health-care professionals to become part of the cancer risk counseling team.

Behavior Modification

Christopher N. Sciamanna

There is no question at this point in our medical knowledge that health behaviors play a prominent role in morbidity and mortality from cancer and other diseases. The seminal paper by McGinnis and Foege “Actual causes of death in the United States” in 1993 did a great deal to put health behaviors on the map as significant public health problems. In their analysis, the authors concluded that approximately half of all deaths are due to health behaviors. The three most prominent behaviors in their analysis, tobacco (19%), diet and physical activity patterns (14%), and alcohol (5%), could be linked to more than one-third of all deaths in 1990.¹ A reanalysis of the same question reached basically the same conclusions using data from the year 2000.² This chapter takes a similar examination of the available evidence for the most common health behaviors that are implicated as contributing to cancer. We focus the analysis on tobacco use, diet, physical activity, being overweight, and sun exposure, as each is quite common and has been the subject of significant study. For each behavior, this chapter discusses one or more cancers with which the behavior is purported to be associated, yet the discussion focuses on behaviors, rather than cancers. For each behavior, this chapter examines (1) the evidence linking changes in the health behaviors to reducing cancer morbidity and mortality, (2) the effectiveness of physician counseling as a commonly used method of behavior modification, (3) the recommendations of professional groups regarding what individuals can do to improve these health behaviors, and (4) methods for improving the quality of physician counseling for behavior modification.

Efficacy of Risk Reduction

The contributions of adverse health behaviors to cancer morbidity and mortality are substantial and well documented. A World Cancer Research Fund panel estimated that 30% to 40% of all cancers are attributable to inappropriate diet, physical activity, and high body weight.³ In this section, we review the evidence linking changes in several established cancer risk behaviors to changes in cancer morbidity and mortality. This review is not meant to be exhaustive, but intends to review the most common cancers, primarily those for which the most data exist.

Efficacy of Risk Reduction: Tobacco Use

There is a large body of evidence from prospective cohort and case-control studies showing that many of the health risks of

tobacco use can be reduced by smoking cessation. As compared with smokers, the excess risk of lung cancer decreases sharply in ex-smokers after approximately 5 years since quitting. Although an excess risk from smoking most likely persists through life, the excess risk approaches that of a never smoker after 15 to 20 years since quitting.⁴ After quitting, the risk of oral, pharyngeal, and laryngeal cancers decreases, approaching that of a never smoker in approximately 15 years.^{5,6} Also, within 2 years of quitting, the risk of pancreatic cancer decreases by approximately 50%.⁷⁻⁹

Efficacy of Risk Reduction: Diet

Differences in dietary intake are thought to account for approximately 30% of cancers in Western countries, although less in developing countries.¹⁰ Although many studies have examined the association of different dietary components on cancer risk, very few have examined the likely effect of changing the diet on subsequent risk or survival from cancer.

Early data showed that an increase in the polyunsaturated fatty acid concentration in membranes stimulated the oxidation of precarcinogens to reactive intermediates.¹¹ The largest study to date, however, a pooled analysis on roughly 350,000 women, found no association between replacing monounsaturated, polyunsaturated fats with carbohydrates on the incidence of breast cancer.¹² In this same study, a weak positive association was identified between replacing saturated fats with carbohydrates on breast cancer incidence. There is little evidence linking dietary fat to the incidence of colorectal cancer. A single large randomized trial, however, showed no effect of a diet low in fat and high in fiber, fruit, and vegetables on the recurrence of colorectal adenomas.¹³

Fruit and vegetable intake is negatively associated with incidence of many cancers, including those of the oral cavity, esophagus, pharynx,¹⁴ stomach,¹⁵ colorectal region,¹⁶⁻¹⁸ lung,¹⁹ cervix,¹⁴ and kidney.¹⁴ Intervention trials, however, in which fiber and fruit and vegetable intake have been augmented, have failed to slow the recurrence of colorectal adenomas.^{13,20,21} Similarly, a study of beta-carotene supplementation failed to decrease the incidence of lung cancer.²² Similar to other food groups, very little evidence exists to understand the effect of changes of fruit and vegetable intake on cancer incidence. The three studies that have examined increases in fruit and vegetable intake, including the Polyp Prevention Trial as mentioned previously, have not found decrease in the recurrence of colorectal adenomas.^{13,20,21} An ongoing randomized trial, the Women’s Healthy Eating and Living Study, will add

to our understanding of the effect of a diet high in vegetables, fruits, and fiber and low in fat on breast cancer survival.²³

Efficacy of Risk Reduction: Physical Inactivity

In the United States, fewer than half of adults attain recommended levels of physical activity.²⁴ There is conflicting evidence supporting a link between physical inactivity and cancers of the prostate, endometrium, and lung,²⁵ and there have been no intervention trials showing a decrease in the incidence or recurrence of any cancer. Furthermore, little evidence exists examining the effect of changes in physical activity level on risk of cancer.

Efficacy of Risk Reduction: Alcohol Abuse

Nearly one-third of U.S. adults drink an excessive amount of alcohol.²⁶ Excessive alcohol use appears to be associated with cancers of the breast, oropharynx, pharynx, esophagus, and liver.²⁷⁻³¹ Little evidence exists examining the effect on changes in alcohol consumption on the risk of breast or other cancers. Two studies from Italy observed that, although stopping smoking decreased the risk of laryngeal cancer within only a few years, stopping drinking led to a much smaller decline in laryngeal and esophageal cancer risk after more than a decade.^{32,33}

Efficacy of Risk Reduction: Overweight and Obesity

There is no end in sight for the epidemic of overweight and obesity in the United States. In 2001, a national survey observed more than 67% of adult men and 50% of adult women to be overweight [body mass index (BMI) greater than 25], and of those an equal number of men and women (21%) were classified as obese (BMI greater than 30).³⁴ Although overweight and obesity are associated with breast cancer incidence, few studies have examined the effect of weight loss on the incidence of cancer, which precludes any firm conclusions.^{35,36} Although firm conclusions are not possible, some evidence can be found in the Nurses' Health Study, in which women who gained more than 20 pounds from age 18 to midlife doubled their risk for breast cancer, compared to women who maintained a stable weight.³⁷

Efficacy of Risk Reduction: Sun Exposure

Exposure to the sunlight has been implicated in the high incidence of skin cancers, which most commonly include cutaneous melanoma, basal cell carcinoma, and squamous cell carcinoma.³⁸⁻⁴⁰ There is no direct evidence, however, that personal sun protection behaviors can reduce the incidence of melanoma, and evidence that sun protection behaviors modify the incidence of other skin cancers is mixed.^{41,42} For example, a randomized controlled trial of daily sunscreen use in a general population in Australia showed no effect on risk of basal cell carcinoma over 5 years of intervention and follow-up.⁴³ Another randomized controlled trial, however, of sunscreen applied daily to the head, neck, hands, and arms reduced the number of new squamous cell carcinomas over a 5-year period.⁴⁴ A third randomized trial observed that sunscreen use decreased the incidence of, and increased the regression rate of, solar keratoses.^{45,46}

Effectiveness of Physician Counseling

This section highlights the evidence, and the strength of that evidence, regarding the efficacy of physicians in bringing about changes in health behaviors (intermediate outcomes) and in changing cancer incidence or survival (distal outcomes).

Effectiveness of Physician Counseling: Tobacco Use

Of all the health behaviors, the most agreement exists regarding the efficacy of physician counseling. Several well-designed randomized controlled trials have established that physician counseling helps smokers quit.⁴⁷ Providing self-help brochures without clinical advice has limited efficacy, but physician advice alone can increase quit rates by as much as 10%.^{48,49} Cummings and colleagues observed that training internists for 3 hours and providing self-help books to smokers increased smoking cessation rates by approximately 2%.⁴⁸ The 1996 and 2000 Clinical Practice Guidelines contain a summary of this evidence.^{47,50} The guidelines emphasized the role of (1) identification of smokers in practice, such as using smoking as a "vital sign,"⁵¹ (2) physician advice to quit, and (3) the use of medications to assist smokers in their quitting attempts. Several studies have also shown that feedback about smoking-specific risk factors such as pulmonary function and carbon monoxide testing by physicians can double smoking cessation rates.⁵²⁻⁵⁴

Effectiveness of Physician Counseling: Poor Diet

There is inconclusive evidence that physician counseling can lead to dietary changes.⁵⁵⁻⁵⁹ In one such study, physicians gave patients a self-help booklet and a brief motivational message, which led to significant changes in the intake of fat and fiber, compared with a usual care comparison group.⁵⁶ Most studies, however, have included several hours of physician education and training on diet counseling, as other studies have shown that physicians receive little training on diet and may often not be aware of the effect of dietary modifications.⁶⁰⁻⁶³ Similar studies have observed that brief training of physicians can lead to changes in blood cholesterol,⁶⁴ saturated fat intake,⁶⁵ and fruit and vegetable intake.⁵⁵ Some studies, however, have found no effect of physician counseling, and many primary care-based studies have also employed office systems, computer-tailored print messages, and counseling by nutritionists and nurses, which make it difficult to understand the independent effects of physician counseling.^{55,57,65-67}

Effectiveness of Physician Counseling: Physical Inactivity

There is inconclusive evidence that physician intervention counseling can also lead to changes in physical activity, as studies have shown the effects to be mixed.^{57,68-72} A 2002 review by the United States Preventive Services Task Force identified only eight studies on which to base their conclusion.⁷³ Most studies have tested low-intensity interventions such as 3 to 5 minutes of counseling in a routine outpatient visit and included several hours to several days of provider training. In some of the studies, the patients completed a self-

report tool on physical activity levels or answered questions from a validated survey in the office waiting room or at home. In many of the studies, a research assistant or nurse conducted a baseline assessment and placed it in the chart for the physician to use during the clinical encounter. As such, it is difficult from many of the studies to understand the independent effects of physician counseling. In the six studies that compared an intervention condition, including physician counseling to a usual care control group, the effects on physical activity were mixed. Only one of the studies met all the methodological criteria for a quality rating of "good."⁷³ The U.S. Preventive Services Task Force (USPSTF) study found the available evidence to be inconclusive.⁷³

Effectiveness of Physician Counseling: Alcohol Abuse

There is a reasonable amount of evidence that physician counseling can decrease drinking in patients who abuse alcohol. At least three randomized trials have been conducted, all showing that counseling led to a decreased amount of drinking.⁷⁴⁻⁷⁶ In one such study, providers were trained to provide a brief (5 to 10 minutes) counseling intervention, and an office support system was used that screened patients and cued providers to intervene, in addition to making patient education materials available.⁷⁶ The intervention led to a decrease of 5.8 drinks per week compared with a usual care condition.^{76,77} Two other large studies showed decreases in the range of 10 drinks per week in the intervention condition, compared to the control condition.^{74,75} Although not all studies have shown positive effects,⁷⁸ two meta-analyses have shown that brief interventions, typically conducted by physicians, are effective at decreasing alcohol intake among heavy drinkers in outpatient settings.^{79,80}

Effectiveness of Physician Counseling: Overweight and Obesity

There is inconclusive evidence about the effects of physician counseling to help patients lose weight.^{65,81-85} In one such study, physicians counseled patients and incorporated meal replacements and nurse visits, which led to losses of approximately 4% of body weight, equal to the effects of two nutritionist-led intervention conditions.⁸¹ There have been few studies, however, and many studies that showed an effect on weight loss were actually designed to improve dietary patterns, such as decreasing saturated fat intake.^{64,65,86} A significant barrier to physician counseling for overweight and obesity is the apparent complexity of counting calories, which is the basis of all weight loss recommendations.⁸⁷ Training programs have been developed and user-friendly reminder cards have been developed, but many barriers remain and conclusions based on the available evidence are difficult to make.^{87,88}

Effectiveness of Physician Counseling: Sun Exposure

Very little evidence exists to understand the effects of physician counseling on sun protection behaviors. At least one intervention has been shown to increase healthcare provider counseling, but the effects of physician counseling on

patient's use of sun protection behaviors or on subsequent development of skin cancer is not yet known.⁸⁹ A randomized trial of a community-based, multiintervention program, including office-based counseling by physicians, showed that the intervention increased sun protection behaviors in the intervention towns.⁹⁰ More parents recalled receiving advice to use sun protection behaviors in the intervention towns, giving some indirect evidence that the increased use of sun protection behaviors was due to more physician counseling. The United States Preventive Services Task Force concluded, in October 2003, that there was insufficient evidence to recommend for or against routine counseling by primary care clinicians to prevent skin cancer.⁹¹

Recommendations of Professional Groups

This section attempts to summarize the recommendations, including the similarities and differences, of recommendations from guidelines published by professional groups, such as the USPSTF, American Lung, American Heart, and health insurance companies, regarding the expected standards of care and reimbursement for behavioral counseling.

Recommendations of Professional Groups: Tobacco Use

Professional groups are in broad agreement that tobacco use in any form and in any amount is not safe and should be discontinued. No safe level of smoking has ever been identified.¹⁰ Groups agree that tobacco use in the form of cigarette smoking, cigar smoking, snuff, and chewing are all carcinogenic and should be discontinued.^{47,50,92,93} Professional groups agree that physicians should advise their patients to discontinue tobacco use and to use pharmacotherapy as appropriate.^{47,50,92,93}

Recommendations of Professional Groups: Poor Diet

Professional groups differ on some of the specifics of diet, but generally recommend that patients limit the intake of high-fat (especially saturated and trans-unsaturated fat) and high-sugar foods and eat a sufficient amount of fruits and vegetables (e.g., five or more servings) and whole grains. There are differences, however, in the specifics. For example, the United States Department of Agriculture's 2000 "Dietary Guidelines for Americans" suggests eating no more than 30% of calories from fat, while the American Heart Association suggests eating between 25% and 35% of calories from fat.^{94,95} The American Cancer Society guidelines, released in 2002, are less specific but generally recommend the same above changes as other groups.⁹⁶

Recommendations of Professional Groups: Physical Inactivity

Professional groups generally agree that physical activity is an important part of staying healthy. The American College of Sports Medicine and the Centers for Disease Control released joint recommendations in 1995, suggesting that most Americans could benefit from regular physical activity,

defined as at least 30 minutes of moderate or vigorous activity on most, or at least 5, days of the week.⁹⁷ These recommendations have not changed in any significant manner since 1995. The 2002 American Cancer Society Guidelines are consistent with these recommendations.⁹⁶ The USPSTF also recommends that lower amounts of vigorous activity, 20 minutes for 3 days each week, are acceptable levels of activity.^{73,98}

Recommendations of Professional Groups: Alcohol Abuse

Recommendations for alcohol use differ in several ways between organizations, mainly based on the group toward which the recommendations are targeted. No safe level of alcohol intake has been identified, as the epidemiologic studies typically compared high versus low intake, rather than examining a possible threshold effect.²⁷ Given the data supporting the cardiac benefits of moderate alcohol and the effects of alcohol on blood pressure, the American Heart Association recommends a limit of one drink per day for women and a limit of two drinks per day for men.⁹⁹ The American Cancer Society is less specific, noting only "if you drink alcoholic beverages, limit consumption."⁹⁶

Recommendations of Professional Groups: Overweight and Obesity

In the year 2000, the National Heart, Lung and Blood Institute, in partnership with the North American Association for the Study of Obesity, released "The Practical Guide: Identification, Evaluation and Treatment of Overweight and Obesity in Adults."¹⁰⁰ These guidelines defined a healthy body weight, based on the body mass index (BMI) [weight in kilograms/(height in meters)²] between 18.5 and 25.0.¹⁰⁰ According to these guidelines, individuals are considered to be overweight if the BMI is between 25 and 30 and obese if the BMI is greater than 30.¹⁰⁰ The guidelines contain specific recommendations, including thresholds for considering various weight loss methods, such as caloric restriction, physical activity, medications, and surgery. These BMI recommendations are consistent with those of the American Heart Association,¹⁰¹ which also recommend that children and adolescents maintain a BMI less than the 85th percentile, according to age-appropriate growth charts. The American Cancer Society guidelines are less specific, suggesting to "maintain a healthful weight throughout life," "balance caloric intake with physical activity," and "lose weight if currently overweight or obese."⁹⁶

Recommendations of Professional Groups: Sun Exposure

The American Cancer Society,¹⁰² the American Academy of Dermatology,¹⁰³ the American Academy of Pediatrics,¹⁰⁴ and the American College of Obstetricians and Gynecologists¹⁰⁵ all recommend patient education about sun protection behaviors (SPBs), such as sun avoidance, clothing, hats, and sunscreens. The American Academy of Family Physicians recommends sun protection for all with increased sun exposure.¹⁰⁶ The American College of Preventive Medicine (ACPM) concluded that sun-protective behaviors are probably

effective in reducing skin cancer but that the evidence does not support physician counseling about SPBs with every patient.¹⁰⁷ ACPM concluded that evidence does not support advising patients to use chemical sunscreens and that their use may actually increase the risk of malignant melanoma.¹⁰⁸

Improving the Quality of Physician Counseling for Behavior Modification

Although little direct evidence exists from randomized trials to inform us of the best ways to counsel patients to modify health behaviors, much can still be learned and applied from the available evidence. The way that a doctor communicates with a patient has a strong influence on patient satisfaction and patient adherence. There are several communication patterns in particular that appear to lead to positive outcomes. First, patients whose physicians encourage them to participate actively in their medical treatment decisions have improved health outcomes.¹⁰⁹⁻¹¹² Second, building rapport, through a discussion of psychosocial issues that help the physician understand the "whole person," is associated with improved patient satisfaction and adherence to physicians' recommendations.^{113,114} Third, providers who support motivations that are initiated by patients, also known as being "patient centered," have patients who are more satisfied with their care and who take a more active role in their care and have better outcomes.^{110,114,115} Regardless of the interaction, these communication patterns are best to employ whenever possible. This is particularly true of health behavior counseling, which can be stressful for both the doctor and the patient, given patient resistance to change and the overall low likelihood of success of behavior change.

A commonly used framework for organizing brief behavior counseling is the "5 A's"^{116,117}: "Address the Agenda," "Assess," "Advise," "Assist," and "Arrange."⁴⁷ We try to highlight these five activities and the previously mentioned communication patterns in a case study, adapted and reprinted with permission.⁶³ This case study is related to diet, but the process (the 5 A's) are the same for changing any health behavior.^{47,117-119}

Case

Mrs. R is a 55-year-old woman whom you have seen in your practice for the past 3 years. She has a history of previous cholecystectomy, and had a stage 2 infiltrating ductal carcinoma of the breast treated 2 years ago. She also has high blood cholesterol with the following profile 1 month ago: total cholesterol = 255, LDL = 176, HDL = 48, triglycerides = 155. She has no hypertension, no diabetes, no family history of myocardial infarction, and a BMI of 29. She is returning today to discuss the results of her lipid profile.

1. Address the Agenda:

Express the desire to talk about the patient's eating habits. For example, "I'd like to talk with you about how you are eating, because it can affect your blood cholesterol, your weight, and may affect the chance that your breast cancer returns." Sometimes, behavior modification discussions can seem as if they come out of nowhere—this helps to get it on the table in a friendly way that makes no assumptions as to the quality of their diet.

2. Assess:

a. Behavior level

Before giving nutrition advice, you need to know the patient's current eating pattern. Just because someone has high blood cholesterol or is overweight does not necessarily mean that they eat the wrong foods. It is difficult to accurately assess someone's diet with a question or set of questions. One approach is to ask patients to describe their dietary pattern with a question such as "What do you eat in a typical day?" However, there are several formal written self-assessments that patients can complete in the waiting room that provide more detailed information to help you understand what changes, if any, are needed.^{88,120-124} One specific example is "Rate Your Plate," developed by researchers at the Center for Primary Care and Prevention (CPCP) at Memorial Hospital of Rhode Island. This instrument assesses eating patterns by asking about 21 food habits (e.g., intake of meat, milk, sweets, etc.).^{88,124} This tool can be used for counseling and goal setting as well as assessment and has accompanying patient education materials.

Based on your diet assessment, you learn that Mrs. R. eats a diet high in saturated fat (e.g., fatty cuts of red meat several times a week, cheese daily, high-fat snacks and desserts daily), and eats fewer than two servings of vegetables and fewer than two servings of fruits each day. Given the possible link between dietary fat and breast cancer, it seems prudent to counsel Mrs. R about decreasing her dietary fat to lower her risk of breast cancer recurrence. In addition, her cholesterol is high, so there may be more than one behavioral target for dietary counseling. It is important to discuss the results of the diet assessment with her as it will form the basis of much of the behavioral counseling to follow.

b. Readiness to change

- "Have you thought about changing your diet at all?"
- "How much do you want to change your diet right now, on a scale of 1 to 10?"

An open-ended question such as the first will often lead to an eye-opening discussion about the patient's attitudes toward behavior change, their experience with past behavior change, and their plans for future behavior change. A closed-ended question such as the second can also be useful and can be later followed up by asking "What would make you more ready to change your diet right now?"

c. History of change efforts

- "Have you ever tried to cut down on the amount of fat you eat?"
- "What was that like?"

Behavior change is a process where repeated trial and error provides the learning necessary to change for good. If you find that, for example, the patient ate lower-fat snacks and desserts for 6 months, you should congratulate them (build their confidence), and ask how they did it and what led to them to change back to higher-fat choices. If, for example, the patient went back to eating more fatty snacks and sweets after the holiday season of eating out at parties and restaurants, this is a great chance to do problem solving and help them overcome a barrier that could impede their progress toward a healthy eating pattern.

d. Knowledge of risks

- "What do you know about the link between what you eat and breast cancer?"
- "I see that your cholesterol is high. What do you know about how your eating habits can affect your cholesterol?"

Nutrition knowledge varies widely. Data from 1994 showed that 60% of people knew about the dietary fat–heart disease link, although less than 10% knew about the saturated fat–heart disease link.¹²⁵ The recent emphasis on dietary fat restriction has covered up the important differences between types of fat, and this is a chance to make those clear. In counseling, every opportunity to personalize the message to the patient should be taken, so including a discussion about cholesterol and weight, two issues specific to Mrs. R, is very useful.

e. Reasons for changing or maintaining behavior.

- "What are the positive (negative) things about the way you eat now?"
- "What are the positive (negative) things about making a change in your eating habits?"

Understanding the patient's attitudes and motivations are important. Mrs. R may have had a brother who had been diagnosed with heart disease or another incentive for changing her diet that you could not have imagined but is critical to her. Many people are aware that they have unhealthy eating habits but are ambivalent about it. Allowing them to discuss both sides of the issue can help them to convince themselves to change, but it can also uncover barriers to changing (e.g., someone who eats many meals away from home) or opportunities to changing (e.g., has trouble affording cholesterol medications) that may not have been revealed otherwise. Letting the patient discover these issues is much more powerful than preaching them yourself.

3. Advise:

- "As your doctor, I need you to know that reducing the fat, saturated fat, and calories you eat is important for your health because it will help you decrease your cholesterol, maintain a healthy weight, and may decrease the chance that your breast cancer returns."

Strong, clear, and personalized advice is best.⁴⁷ Personalizing the message plays to the strengths of the clinician who knows the patient and his or her medical history well. Given the frequency of diseases related to diet, most patients in adult practice will have a specific reason for changing their diet.

4. Assist:

- Offer to correct misunderstandings and provide new information.
 - "Would you like to talk about food choices that would be better for your health?"

The above quote may seem too passive for many physicians, but it helps to keep the focus of the counseling on the patient instead of on the physician. Although the word *physician* means teacher, you must first know whether you have a willing pupil in front of you. If the answer is "yes," you may use it as a chance to explain the differences between saturated and unsaturated fats and how replacing high-fat snacks and sweets with lower-fat substitutes or using vegetable oils such as canola or olive

oil, or liquid or tub margarine, would be better choices than butter or stick margarine. If they say “no,” then this may not be the right time for a detailed discussion. Keeping the door open for future discussions then becomes the goal.

b. Express empathy

- “It’s understandable that you might not want to take steps to change right now.”
- “Changing your diet can be very difficult.”

Empathy is one of the most critical skills toward building a strong doctor–patient relationship.^{110,114} Some people believe that empathy may give the patient an “easy way out”; that is, if you prepare them for the possibility of failure, they will fail. If Mrs. R tries to change her eating habits, and fails, she may feel uncomfortable the next time she comes to see you or might cancel her appointment altogether. This discomfort is a barrier to the therapeutic doctor–patient relationship. Empathy for the human condition and the difficulty of behavior change is a part of successful behavior counseling.

c. Address barriers to change.

- “What might make it difficult for you to eat less fat?”
- “Can you think of ways to overcome your craving for sweets, or choose sweets that may be lower in fat?”

Problem solving is a critical part of behavior change, either done at home or with the doctor in the office. Two important skills in problem solving are to identify two types of barriers to making the change: (1) attitudes that maintain the problem behavior (e.g., “I don’t like vegetables”) and (2) triggers, that is, situations or feelings that lead to the problem behavior (e.g., “When I go out to dinner, I always eat too much.”). After helping to identify the problems, discuss ways that the patient may overcome the barrier. It is not critical that you have all the answers: remember that the patient has many of them. In this capacity, the physician may serve as a “facilitator” rather than a “lecturer.” People who have more positive attitudes about dietary change or who feel more confident about dealing with their triggers are more likely to go on to change their behavior and, ultimately, to succeed in making behavior changes.

d. Consider smaller steps toward the ultimate goal

- “It is difficult to make big changes in how you eat all at once. Can you think of any small changes you can make now?”

This is especially true for people who are not ready to change. For them, simply thinking about the reasons they have for changing would qualify as a step forward, as they are most likely still defending their habits. For someone like Mrs. R, with five separate behaviors to consider for diet counseling alone (meat, cheese, sweets, fruit and vegetable intake, and calorie intake), focusing on more than one behavior may be counterproductive. Encouraging more fruits and vegetables is often a good first step, as this is a positive change rather than a sacrifice. Increases in fruits and vegetables can lead to decreases in other higher-fat foods such as sweets and meats. Be as specific as possible: “How do you think you could eat more fruits and vegetables?” For example, eating a larger portion of vegetables at dinner, adding a fruit at breakfast and for a snack, etc.

e. Make goal(s) clear

- “Now I’d like us to set a goal for what you will do before you see me again. From what you have told me, you are going to add fruit to your breakfast, eat fruit for a snack, and eat a larger portion of vegetables at dinner. Does that sound like a reasonable goal?” Again, be as specific as possible, so the next time you see the patient, you’ll know exactly where to start and won’t have to go through a lengthy assessment a second time. You’ll be able to say: “When I last saw you, you agreed to work on adding a serving of fruit to your breakfast, eat fruit for a snack, and eat a larger portion of vegetables at dinner. How did that go?” In addition, when the goal is clear, you can give targeted patient information, instead of a generic guide to healthy eating. The patient will be more likely to listen, believing that it is more specific to their situation.

f. Refer interested patients

- “It seems that you’re eating too much saturated fat, which may be the reason why your cholesterol is high. First, I would like to help you try to improve your eating habits, before I consider giving you medications. Medications may have side effects and you may have to take them for the rest of your life. A nutritionist can really help you make changes in your eating habits. Do you think you would be interested in seeing a nutritionist?” For patients who have health problems that can be improved via a dietary change, strong consideration should be given to referral to a qualified dietitian. Given the fact that many patients will not follow through with referrals, asking about their interest in a nonjudgmental way allows you to save time and keep the patient feeling involved in the decision process.

5. Arrange follow-up:

a. Keep the door open for further dialogue.

- “Is this something you are willing to talk about again at your next visit?” Setting the stage for future discussions is critical to maintaining a therapeutic doctor–patient relationship. Repeated “doses” of behavioral counseling are often necessary over months or years and on a variety of topics aside from nutrition. Thus, neither the patient nor physician should view the counseling session as particularly stressful. This approach also reminds patients that they are an active member of their care team, thereby encouraging autonomy.¹¹⁵

b. Schedule follow-up appointment or phone call to further discussion.

- “Would you be willing to schedule another appointment to talk about how your dietary changes are going and recheck your cholesterol?” Scheduling a return visit will help the patient to understand the importance of making dietary changes and, like a student held accountable for homework, will encourage the patient to follow through on the goals set above.

Providing counseling or advice to your patients takes time, but it is worth the effort in helping your patient to achieve better health as well as improving the doctor–patient

relationship. Even if you cannot do everything this chapter suggests, physician advice alone has been shown to be more effective than no intervention at all,⁴⁷ and these strategies are likely to improve patient adherence and satisfaction.

SECTION FOUR

Cancer Imaging

Central Nervous System Imaging

Dima A. Hammoud and Martin G. Pomper

Brain tumor imaging has four main goals, namely, evaluating lesion extent, estimating tumor grade, identifying associated complications, and defining a comprehensive differential diagnosis. It assesses the relationship of the lesion to various brain structures and identifies associated findings, such as increased intracranial pressure, impending herniation, hydrocephalus, hemorrhagic transformation, and mass effect. A comprehensive differential diagnosis is usually established based on the patient's age, tumor location, and specific imaging findings.

Cross-sectional imaging with computed tomography (CT) or magnetic resonance imaging (MRI) is necessary for accurate brain tumor characterization. Plain film imaging has virtually no role. Before the advent of CT scan and MRI, imaging techniques, such as pneumoencephalography and plain film X-rays of the skull, were the only options for neurosurgeons in the preoperative evaluation of brain tumors. Cross-sectional imaging has significantly facilitated the task of preoperative evaluation and planning of brain tumor surgery.

Computed Tomography

Since its introduction in the 1970s, CT has enjoyed wide application within all the radiologic subspecialties. In fact, CT has effectively replaced conventional tomography and many other radiologic procedures (e.g., lymphangiography and pneumoencephalography). CT has undergone major changes in the past few years, with incremental improvements in hardware and software technologies, including refinement of spiral CT systems, overcoming limitations. In a typical modern spiral or "helical" CT scan, instead of obtaining data using sequential single exposures by moving the gantry, the patient is moved through a rotating, continuous fan-beam exposure, and a block of data in the form of a corkscrew or helix is obtained.¹ Improvements, such as the introduction of higher heat capacity X-ray tubes, subsecond X-ray tube rotation times, detector technologies, and real-time image reconstruction computer hardware and software, transformed CT scan into a very fast, large-volume, multi-beam acquisition technology.

CT, however, currently plays a limited role in brain tumor imaging. Its availability in the emergency department makes it the first-line technique for evaluating patients presenting with signs and symptoms of increased intracranial pressure, seizures, and other neurologic symptoms that could be caused intracranial neoplasms. Inevitably, if a tumor is discovered on

CT, the patient will need further imaging, usually with contrast-enhanced MRI for adequate evaluation. Patients with contraindications to MRI, such as severe claustrophobia, a pacemaker, or severe obesity may have to undergo a contrast-enhanced CT scan instead of MRI.

One of the advantages of CT is its ability to depict hemorrhagic and calcific findings, which could narrow the differential diagnosis of a detected lesion in certain cases (Figure 27.1). It also provides information about bony lesions, such as metastatic disease to the skull and hyperostotic changes associated with meningiomas. Detailed anatomy of the base of the skull, provided by CT imaging, can provide precious information in specific cases, such as intracranial extension of nasopharyngeal tumors and metastatic disease. Currently, CT is not routinely used in the evaluation of patients with brain tumors either pre- or postoperatively, with few exceptions.

Magnetic Resonance Imaging

Magnetic resonance imaging has become the mainstay of diagnosis in the evaluation of primary and metastatic brain tumors. Unfortunately, MRI is very sensitive but not very specific. Although it provides excellent anatomic detail, MRI remains incapable of accurately grading tumors. Extension of T₂ signal abnormalities, involvement of the corpus callosum, enhancement pattern, cortical involvement, intra- versus extraaxial localization, mass effect, and the age of the patient are some of the factors that allow the radiologist to narrow the differential diagnosis of a brain lesion.

New techniques are constantly being developed to increase the specificity of MRI. Among the most promising of those new techniques are fast fluid-attenuated inversion recovery (FLAIR) imaging, diffusion-weighted imaging (DWI), perfusion imaging, and magnetic resonance spectroscopy (MRS). Functional MRI (fMRI), diffusion tensor imaging, magnetization transfer (MT) imaging, and perfusion imaging with arterial spin labeling are applied clinically only infrequently.

Fast Fluid-Attenuated Inversion Recovery (FLAIR) Imaging

FLAIR is an MRI sequence that produces heavily T₂-weighted images with cerebrospinal fluid (CSF) signal suppression by employing a specific inversion pulse placed at the CSF null point.² Suppression of the CSF signal leads to better lesion-to-CSF contrast, allowing better delineation of masses adja-

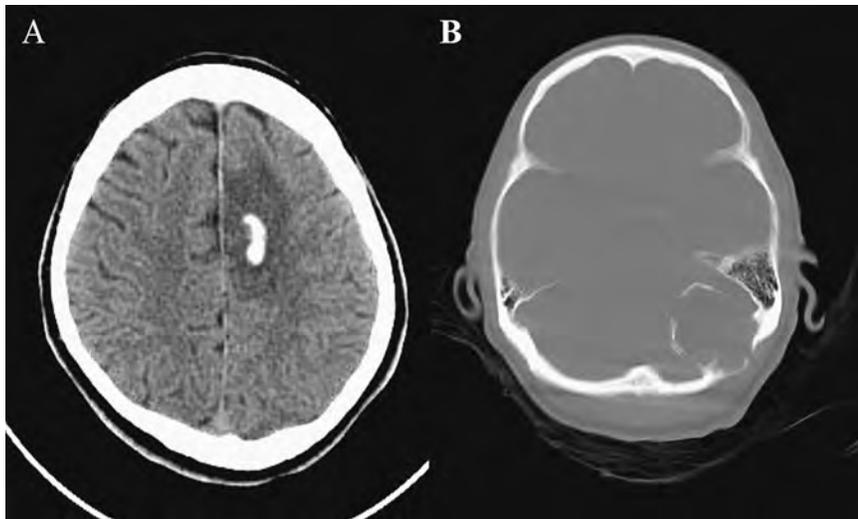

FIGURE 27.1. (A) Oligodendroglioma: nonenhanced computed tomography (CT) scan showing left frontal hypodense mass with calcifications. (B) Intradiploic epidermoid cyst: nonenhanced CT scan showing bony erosion and expansion.

cent to ventricles and sulci (Figure 27.2); however, that is true only for relatively large lesions, as small tumors may be lost among the periventricular gliosis that appears bright on FLAIR.³ Based on multiple studies, FLAIR was found to be superior to both proton density (PD)- and T_2 -weighted images in delineating intraparenchymal lesions. In a large prospective, blinded analysis, Maubon et al. evaluated 102 patients with a multitude of neurologic presentations, including brain tumors, using turbo spin echo (TSE), turbo FLAIR, and gradient and SE (GRASE) images. They found that FLAIR was significantly superior to both GRASE and turbo SE for white matter disease (P less than 0.05), superior only to TSE (P less than 0.05) for vascular disease, but not superior to either gradient SE or TSE for tumors.⁴ Multiple descriptive studies with smaller numbers of patients showed more encouraging results: increased sensitivity of detection and better conspicuity of lesions using FLAIR sequences compared to T_2 -weighted images,⁵ better appreciation of peritumoral edema, and better definition between edema and tumor than T_2 -weighted and proton density-weighted images.⁶ In a retro-

spective analysis including only 18 patients, Bynevelt et al. found FLAIR to be superior for appreciation of the lesion (91% of studies) and for demonstration of its margin (92%) and suggested that FLAIR can replace PD- and T_2 -weighted spin-echo imaging in radiologic follow-up of low-grade glioma.⁷ All three studies, however, relied on the subjective evaluation of the quality of images by different readers.

FLAIR imaging has also been used in the differentiation of intracranial epidermoid from other pathologies, related mostly to the incomplete signal suppression due to the presence of keratin and cholesterol crystals in epidermoids (Figure 27.3B). In a series of eight patients with a surgically confirmed diagnosis of epidermoid, Chen et al. compared conventional MR sequences with fast fluid-attenuated inversion recovery (fast-FLAIR) and echo-planar diffusion-weighted (DW) MR imaging. On fast-FLAIR imaging, the mean signal intensity of epidermoid tumors was significantly higher than that of CSF but significantly lower than that of the brain. The authors concluded that fast-FLAIR imaging is superior to conventional MR imaging in depicting intracranial epidermoid

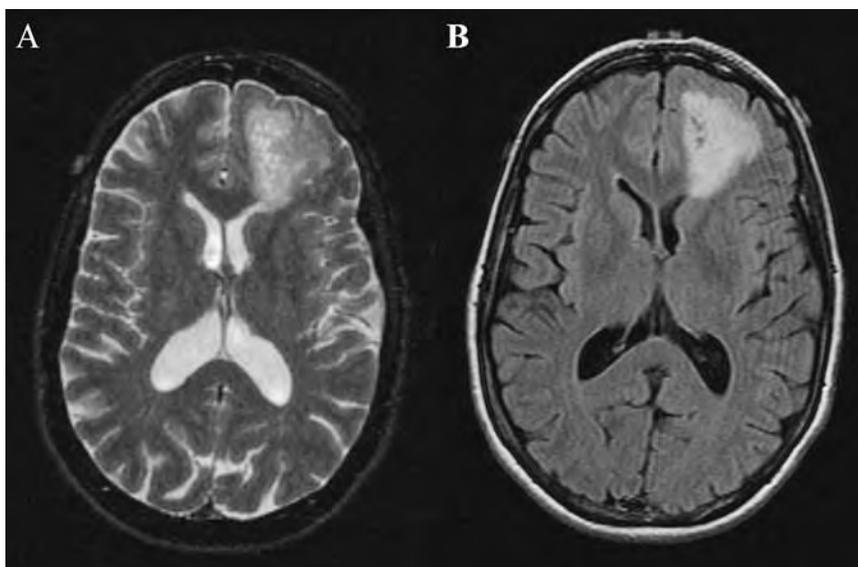

FIGURE 27.2. (A) T_2 -weighted and (B) fast fluid-attenuated inversion recovery (FLAIR) image of left frontal lobe anaplastic astrocytoma. FLAIR delineates the tumor border more clearly as a result of inherent cerebrospinal fluid (CSF) signal suppression.

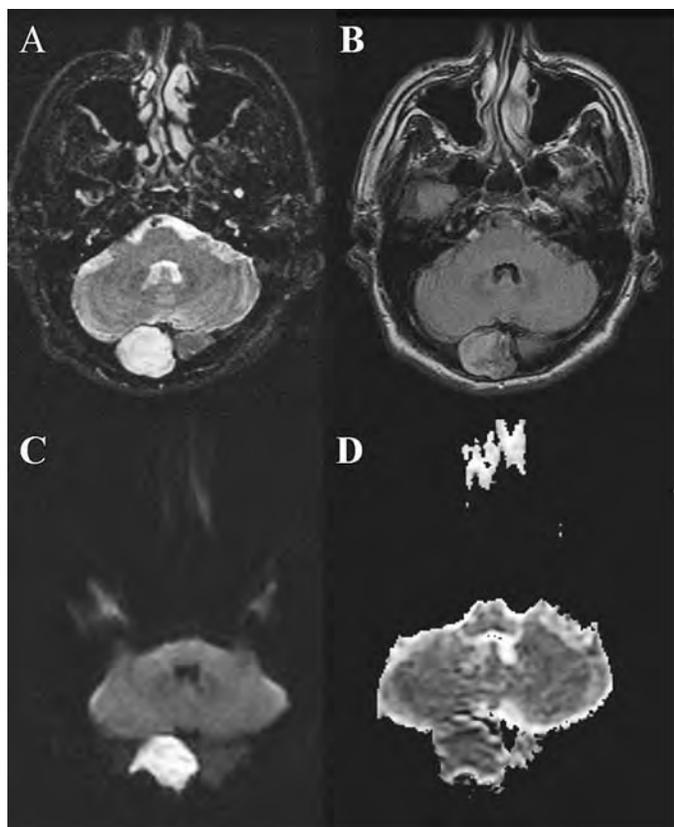

FIGURE 27.3. (A) T₂-weighted images, (B) FLAIR images, (C) diffusion-weighted image (DWI), and (D) apparent diffusion coefficient (ADC) maps of posterior fossa epidermoid cyst eroding the bone. Note incomplete suppression of signal on FLAIR images and restricted diffusion on DWI and corresponding ADC maps.

cysts.⁸ Similar results confirming the superiority of FLAIR to other sequences in the evaluation of epidermoid cysts were reached by Ikushima et al.⁹

A recent application of FLAIR imaging is the evaluation of leptomeningeal spread of tumors, whether primary or metastatic. High signal intensity in the sulci and fissures is suggestive of tumor involvement (Figure 27.4A). In one

study evaluating 70 patients with cytologically proven leptomeningeal metastases, FLAIR imaging was found to have a sensitivity of only 34% for disease detection, compared to 66% for gadolinium-enhanced MR¹⁰ (Figure 27.4B). So, although FLAIR can help support the diagnosis, it alone cannot be used for the exclusion of leptomeningeal metastases, and contrast-enhanced T₁-weighted imaging remains essential for that diagnosis. Contrast-enhanced FLAIR imaging, on the other hand, can improve detection of leptomeningeal disease in pediatric patients when compared to routine contrast-enhanced T₁-weighted imaging, partly because of suppression of signal intensity from normal vascular structures on the surface of the brain, allowing easier visualization of abnormal leptomeninges.¹¹ That study, however, was limited by the small number of patients with a history of medulloblastoma ($n = 6$).

The lack of definite proof of the usefulness of enhanced FLAIR images has hampered the routine implementation of this sequence in the clinical evaluation of brain tumor patients.

Diffusion-Weighted Imaging

Diffusion-weighted imaging (DWI) relies on the detection of the Brownian motion of water molecules between the intracellular and extracellular spaces in the brain. Such motion through tissue is a random event, the speed and direction of which is dictated by the presence of barriers such as macromolecules, cell membranes, and cellular organelles. Contrast is generated on DWI through background suppression and changes in signal intensity between images obtained at different gradient strengths (b values) that are sensitive to diffusion. Apparent diffusion coefficient (ADC) maps are then generated as the slopes of the lines derived from plotting the natural log of the signal intensity (SI) versus gradient strength. These apparent diffusion coefficient maps are essential for the visual evaluation of diffusion because the signal intensity (SI) of DWI is prone to T₂ shine-through effects from heavy T₂ weighting. ADC maps are independent of T₁ and T₂ effects, with decreased ADC values indicative of decreased diffusion.³

DWI has been evaluated for its potential in the differentiation of necrotic brain tumors from abscesses, of infiltrat-

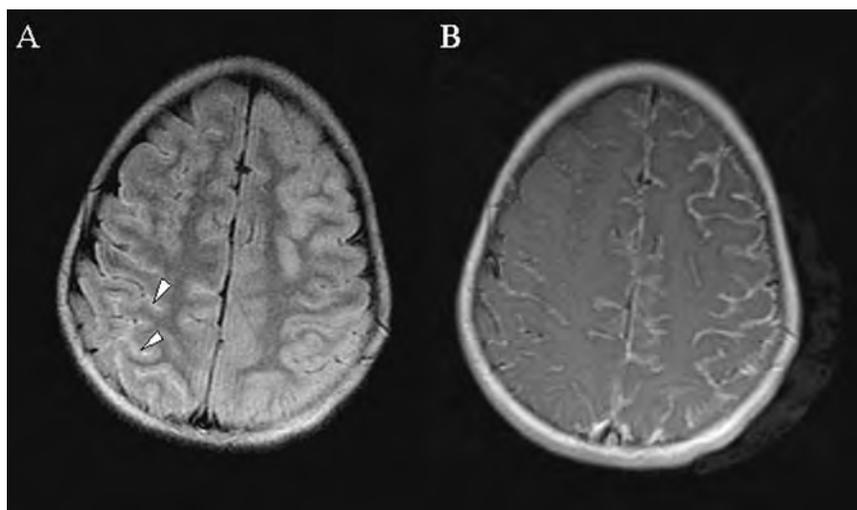

FIGURE 27.4. 10 year-old patient with leukemic meningeal infiltration. (A) FLAIR shows increased signal in the sulci at the brain convexity, more on the right side (arrowheads). (B) Corresponding enhanced T₁-weighted images show marked meningeal enhancement compatible with the diagnosis of diffuse leukemic involvement.

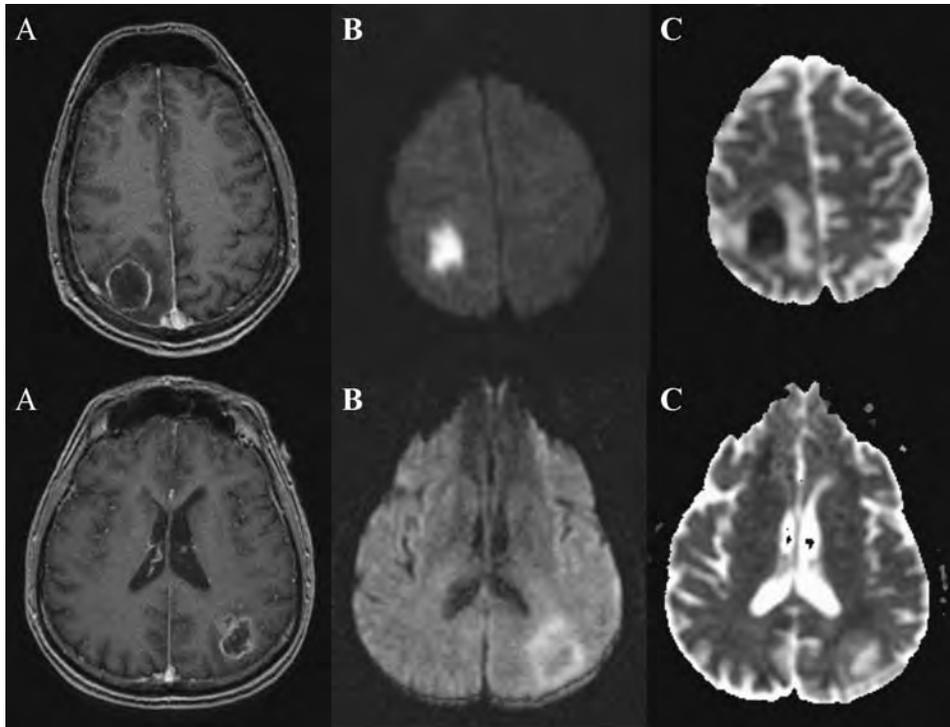

FIGURE 27.5. Enhanced T₁-weighted images, DWI images, and ADC maps of (A) right parietal abscess and (B) left parietooccipital glioblastoma multiforme (GBM). Note restricted diffusion in the abscess cavity (increased signal on DWI and decreased signal on ADC maps) in A compared to nonrestricted diffusion of the necrotic tumor (decreased signal on DWI and increased signal on ADC maps) in B.

ing tumor from vasogenic edema, and in tumor grading. Resembling free water, necrotic or cystic portions of tumors display high ADCs whereas abscess cavities, consisting of necrotic debris, neutrophils, and bacteria, which impede free water diffusion, tend to have low ADCs¹² (Figure 27.5). However, although Dorenbeck et al. found overlapping ADC values between tumors and abscesses,¹³ multiple other studies demonstrated the opposite. In a case-control designed study, Guzman et al. found that the ADC values in patients with brain abscesses were significantly lower than those in patients with neoplastic lesions (*P* less than 0.05).¹⁴ Similar confirmatory results were reached by other investigators.^{15–17}

Besides the differences seen within the cystic/necrotic portions, Chan et al. found that the tumor wall of cystic or necrotic brain tumors had significantly lower ADCs relative to those of the abscess wall (*P* less than 0.005).¹⁸

In a more quantitative study in which the authors calculated ADC values based on eight gradient (*b*) values, the specificity of DWI in differentiating tumor from abscess was 100% using a threshold ADC value of $1.10 \times 10^{-3} \text{ mm}^2/\text{s}$. Unfortunately, those results cannot currently be applied clinically because most available commercial systems calculate ADC based on two *b* values only.¹⁹

Another application of DWI is the differentiation of epidermoid tumors from arachnoid cysts, a classic diagnostic problem on conventional MRI sequences. Because cysts contain more free water than solid masses, they tend to have more restricted diffusion and higher ADC values (see Figure 27.3C,D), which proved to be the case for arachnoid cyst versus epidermoid, as proven in two preliminary studies.^{20,21} DWI was found to provide the best lesion conspicuity of epidermoid in comparison to FLAIR and conventional sequences.⁸ By implementing both FLAIR (see foregoing) and DWI, epidermoid and arachnoid cysts can be fairly easily dif-

ferentiated without cisternography, the previous clinical standard, in the majority of cases.³

The ability of DWI to differentiate between high- and low-grade tumors has been evaluated by several groups. Sugahara et al. found that the cellularity of a variety of histologically verified gliomas correlated well with the minimum calculated ADC value of these tumors (*P* = 0.007) but not with the signal intensity on T₂-weighted images.²² They hypothesized that the highly cellular (higher-grade) gliomas would have smaller intercellular space than tumors of lower cellularity and consequently would display lower ADCs; this is similar to the case for lymphoma and medulloblastoma, both being highly cellular CNS tumors and known to display low ADC values.²³ Further support for the utility of DWI in tumor grading comes from the work of Bulakbasi et al., who evaluated 49 patients with malignant tumors. They found that ADCs were effective for grading malignant tumors (*P* less than 0.001) but not for distinguishing different tumor types with the same grade. In this study, high-grade malignant tumors had significantly lower ADC values than did low-grade malignant and benign tumors.²⁴ Two more studies further supported the previous results, showing that ADC values are significantly higher in low-grade than in high-grade tumors.^{25,26} As far as tumor extension is concerned, however, DWI provided no clear advantage over the conventional methods. ADC values could not separate high-grade gliomas from surrounding edema.^{25,27,28}

Perfusion Imaging

The most common MR perfusion imaging techniques exploit the spin dephasing (T₂^{*}) effect from the passage of contrast through the parenchymal capillary bed. The SI loss engendered by the passage of gadolinium-based contrast enables cal-

ulation of contrast concentration within each pixel over time, which in turn provides relative measurements of regional cerebral blood volume (rCBV). Rapid imaging is necessary to gather as much data as possible from the entire brain during the first-pass of a bolus injection of gadolinium.³

Perfusion imaging likely reflects tumor angiogenesis, a strong indicator of tumor grade. Studies employing perfusion techniques with histologic correlation agree that high rCBVs mean higher tumor grade (Figure 27.6). Specifically, rCBV correlated with areas highest in mitotic activity and vascularity but not with areas of cellular atypia or high cellularity.²⁹ Sugahara et al. found a significant correlation between rCBV ratios of gliomas and vascularity of the tumors determined both by angiography and histology (P less than 0.001).³⁰ In a series of 160 patients, Law et al. demonstrated increased sensitivity of detection of high-grade gliomas with rCBV values when compared to conventional imaging only. They also demonstrated a significant difference in the values of rCBV between high-grade and low-grade gliomas (P less than 0.0001).³¹ Similar results were reached in three other studies.³²⁻³⁴

Perfusion imaging has proved helpful in the preoperative diagnosis of and differentiation between different brain lesions. Recently, Hartmann et al. found significantly lower rCBVs in primary CNS lymphoma (PCNSL) compared to glioblastoma multiforme (GBM) (P less than 0.0001).³⁵ Similarly, low rCBV measurements were found in 17 patients with gliomatosis cerebri, which is in concordance with the lack of vascular hyperplasia found at histopathologic examination in those tumors. The authors concluded that perfusion MR imaging provides useful adjunctive information to conventional MR imaging techniques in the evaluation of this relatively rare but important entity.³² In the classic problem of differentiating toxoplasmosis from lymphoma in patients with acquired immunodeficiency syndrome (AIDS), rCBV was decreased throughout the toxoplasmosis lesions whereas all active lymphomas displayed areas of increased rCBV. The difference in rCBV between those two entities was significant (P less than 0.005). Reduced rCBV in toxoplasmosis lesions is probably due to a lack of vasculature within the abscess

compared to the hypervascularity of lymphomas, especially within foci of active tumor growth.³⁶

Finally, in a series of 51 patients, Law et al. found that peritumoral rCBV values in high-grade gliomas were significantly higher than in metastases (P less than 0.001). Mean maximum rCBV in high-grade gliomas was also significantly higher than in low-grade gliomas in a study by Yang et al.³² Whether perfusion imaging can be used to define tumor borders remains an attractive concept to be investigated.

Magnetic Resonance Spectroscopy

Chemists have relied on nuclear magnetic resonance (NMR) spectroscopy for 50 years for molecular structure elucidation; magnetic resonance spectroscopy (MRS) is an *in vivo* extension of NMR. More than for structure determination, however, MRS is applied in medicine to determine the concentrations of a relatively few metabolites that are altered in disease. In MRS, the high-resolution morphologic imaging capabilities of MR are sacrificed to provide metabolic data that, in many cases, precede structural abnormality.³

Proton MRS is the most commonly applied technique for brain tumors because of the high natural abundance of protons in tissue. For brain tumor proton spectroscopy, the metabolites of interest include *N*-acetylaspartate (NAA), choline (Cho), creatine (Cr), lactate, lipids, and certain amino acids, such as alanine and succinate.³⁷ MRS imaging (MRSI) and chemical shift imaging (CSI) provide phase encoding of spatial information and generate metabolite maps. Multislice MRSI competes with single-voxel MRS, in which a small portion of the lesion is interrogated rather than the whole tumor volume, which is more easily implemented, with brief imaging times (less than 10 min/volume element, or voxel) and commercially available software. Nevertheless MRSI, with its smaller voxel size (less than 1 cm³) and superior brain coverage, is necessary for complete characterization of heterogeneous brain tumors.

The key metabolite in brain tumor MRSI is choline (Cho), the underlying causes for the alteration of which remain controversial. The majority of choline in the brain is, in normal

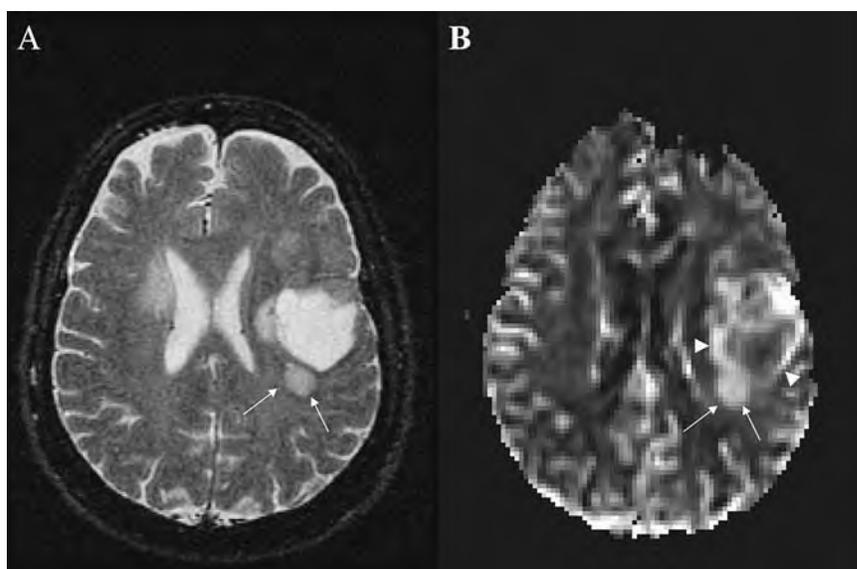

FIGURE 27.6. (A) T₂-weighted image of glioblastoma multiforme showing necrotic changes with well-defined areas of abnormal signal intensity, compatible with tumor, anterior, medial and posterior to the cystic component as well as in the right centrum semiovale. (B) Corresponding regional cerebral blood volume (rCBV) maps show marked increased values in the posterior component (arrows) and in the wall of the necrotic tumor (small arrowheads), suggestive of a higher-grade component of the tumor.

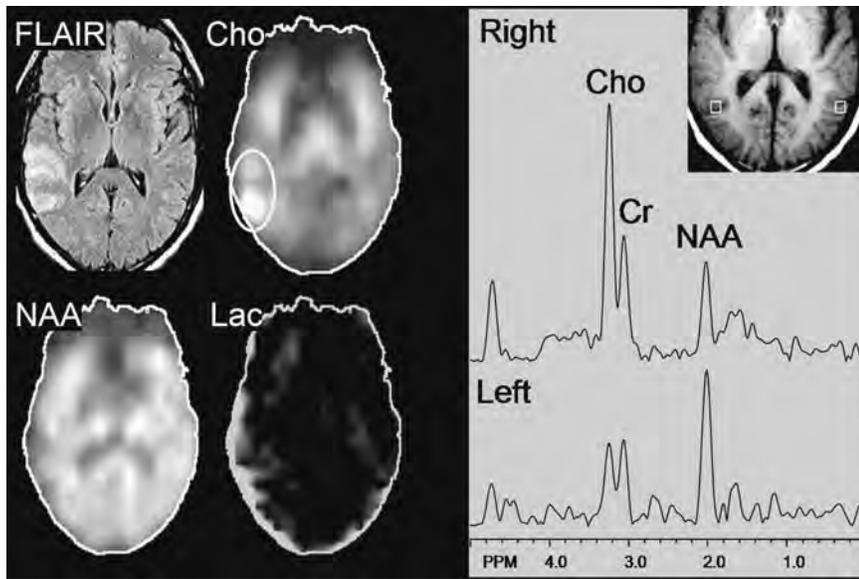

FIGURE 27.7. Patient with right temporal lobe glioblastoma multiforme. Metabolite maps on the right side are notable for increased choline (Cho) in the lesion (*circle*). Note decreased *N*-acetylaspartate (NAA) peak and marked increased Cho peak in the right temporal lobe (*upper spectrum*) when compared to the normal contralateral temporal lobe (*lower spectrum*).

conditions, bound to cell membranes, myelin, and complex brain lipids. In pathologic conditions, Cho is thought to reflect cell membrane, myelin, and lipid turnover, leading to release of MRS-visible Cho.³⁸ Cho is present primarily within glia.³⁹ Because malignant brain tumors are glial neoplasms, it seems reasonable that Cho would be elevated within them, as is usually reported (Figure 27.7). In fact, in one study by Gupta et al., a statistically significant linear correlation between tumor to contralateral normalized Cho signal ratio (nCho) and cell density was found, although nCho did not significantly correlate with proliferative index.⁴⁰

Low NAA levels in brain tumors are believed to be the result of the lack of neurons in what are essentially glial neoplasms (Figure 27.7). Increased lactate and lipids are found in brain tumors, the former believed to be associated with high tumor glycolytic rates and the latter caused by cellular breakdown and necrosis.³

Originally, MRSI was evaluated in the differentiation of normal from neoplastic tissue and its impact on decision making and surgical planning. Rand et al. found that the prospective accuracy of MRSI in the nonblinded and retrospective accuracy in the blinded discrimination of neoplastic from nonneoplastic disease were 0.96 and 0.83, respectively.⁴¹

However, preoperative diagnosis and grading remain the goals of brain tumor MRSI. Despite the stunning results obtained in one study in which Preul et al. accurately graded 90 of 91 brain tumors,⁴² most studies report such overlap as to make spectroscopy of marginal utility for tumor grading. In a study by Bulakbasi et al., MR spectroscopy could differentiate benign from malignant tumors but was not useful in grading malignant tumors. However, in the same study, ADC values were effective for grading malignant tumors (P less than 0.001) but not for distinguishing different tumor types with the same grade, as previously mentioned. The authors concluded that the two modalities can have a complementary effect in the differentiation and grading of brain tumors.²⁴

Law et al. proved that the combination of rCBV, Cho/Cr, and Cho/NAA resulted in increased specificity for the detection of high-grade gliomas from 57.5% with rCBV alone to 60.0% with both modalities. No increased sensitivity, posi-

tive predictive value (PPV), or negative predictive value (NPV) was achieved, however, when the MRS findings were combined with perfusion.³¹ In a series of 176 patients, however, Moller-Hartmann et al. were able to establish that the additive information of proton MRSI led to a 15.4% higher number of correct diagnoses, 6.2% fewer incorrect, and 16% fewer equivocal diagnoses than with structural MRI data alone, in a multitude of pathologies, including brain tumors.⁴³

Perhaps more clinically useful than tumor grading is the role of MRS in the planning of guided biopsies. In 29 patients in whom the preoperative metabolite levels were correlated with the histologic findings, it was found that with abnormally increased Cho and decreased NAA, biopsy invariably was positive for tumor.⁴⁴ Similar results were reached by Martin et al.⁴⁵

In the evaluation of tumor borders in 31 patients with diffusely infiltrating gliomas, Croteau et al. tried to determine a correlation between different proton MRS/I metabolic ratios and the degree of tumor infiltration. They correlated the metabolite ratios with the histopathologic analyses of biopsies obtained at the same location and found that the Cho to normal contralateral Cr and Cho to normal contralateral Cho ratios (Cho/nCr and Cho/nCho) were positively correlated with the degree of tumor infiltration, whereas the NAA to normal contralateral Cr ratio (NAA/nCr) was negatively correlated, for all tumor grades combined.⁴⁶ The strength of this study resides in the coregistration of the biopsy sites with the metabolite values obtained from the same voxels. The potential of MRSI in the accurate delineation of tumor borders requires further investigation.

Another use for MRSI is in the differentiation of primary from metastatic brain tumors. In a recent study, a significant increase in Cho concentration was found in both the peritumoral and tumoral regions of malignant gliomas, compared with metastases. Similarly, a prominent difference in the Cho/Cr ratio between gliomas and metastases (P less than 0.05) and elevated myo-inositol levels (MI/Cr) within the enhancing foci of gliomas but not in the metastases were also found (P less than 0.05). That study, however, was limited by the small number of patients (22).⁴⁷

Functional Magnetic Resonance Imaging

The main use for functional magnetic resonance imaging (fMRI) in neuroimaging has been for the noninvasive study of brain activation. The most common fMRI method detects signals based on the blood oxygen level dependence (BOLD) effect. During brain activation, there is increased blood flow to the area of activation, which appears to be a direct consequence of neurotransmitter activity. Blood flow increases over a wider volume and to a greater extent than is necessary simply to provide oxygen and glucose for increased metabolism, so oxygen extraction decreases with greater neuronal activity. Consequently, the ratio of oxygenated (diamagnetic oxyhemoglobin) to deoxygenated (paramagnetic deoxyhemoglobin) blood near the corresponding areas of neuronal activation will increase, resulting in lower T_2^* (dephasing) effect and increased signal.⁴⁸ Statistical techniques are employed or baseline images are subtracted from images obtained during activation to generate activation maps that are superimposed on MR images.

In brain tumor imaging, fMRI is generally used for the preoperative localization of sensorimotor cortex, hemispheric language dominance, and other eloquent (essential) regions, locations that can be perturbed in the presence of a tumor. Cerebral reorganization (plasticity) is defined as the capacity of ipsilateral and contralateral brain regions to assume functions that are normally assumed by the damaged brain. That

reorganization puts critical motor regions at risk if the standard anatomic techniques are used to locate motor cortex preoperatively. Functional MRI can preemptively locate that reorganized cortex (Figure 27.8).

Neurosurgeons routinely perform cortical mapping intraoperatively. Cortical mapping is just that; that is, it determines function only in the cortex, which is a peripheral brain structure. Functional MRI can evaluate subcortical structures in areas far removed from the limited amount of cortex that is exposed and therefore available for intraoperative mapping.³

Functional MRI, however, is incompletely validated. Good, but not perfect, correlation between fMRI and cortical electrical stimulation has been demonstrated in several studies.^{49,50} Studies comparing PET and fMRI have shown much lower degrees of correlation, usually around 50%, with some patients showing no correlation of activation between the two techniques.^{51,52} Additionally, it remains unclear whether nonactivated brain regions may be safely resected, in part because of that spatial and temporal dispersion of blood oxygen level changes. Schreiber et al. found that the BOLD contrast can be reduced in the proximity of gliomas, but not affected by nonglial space-occupying lesions, such as vascular malformations, leading to overinterpretation of the interhemispheric reorganization in gliomas.⁵³ Similar results were reached by Holodny et al., who suggested that this could result from loss of autoregulation in the tumor vasculature of glioblastomas and venous compression.⁵⁴

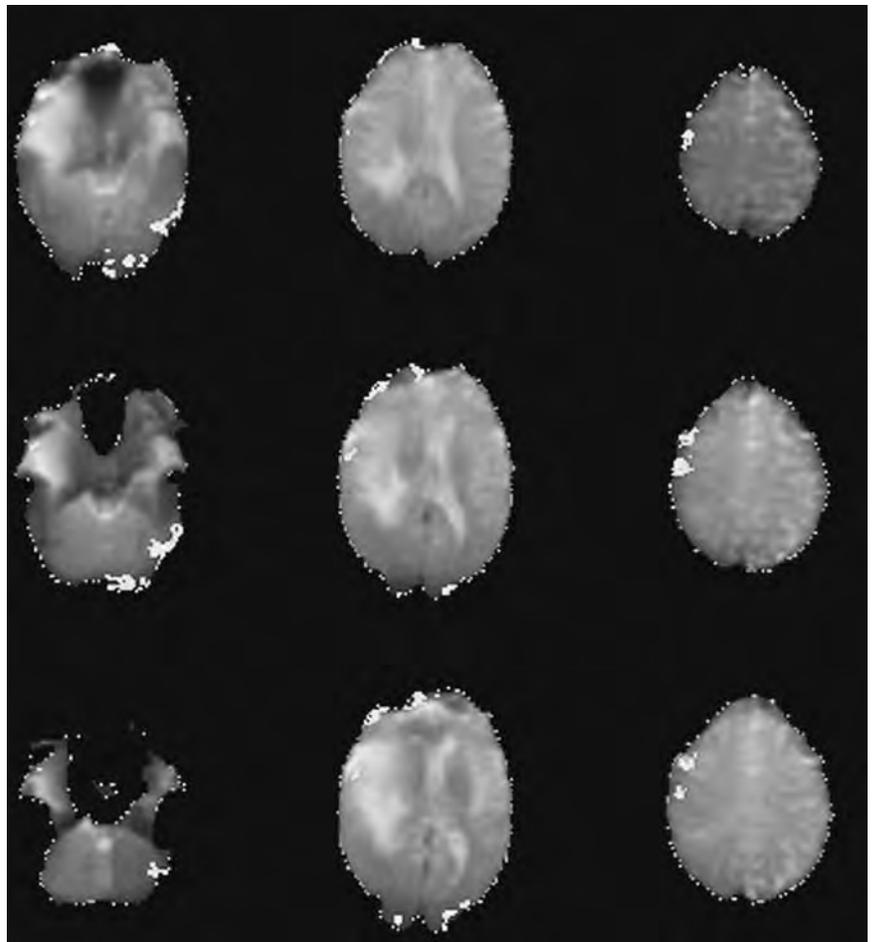

FIGURE 27.8. Cerebral reorganization in right-handed patient with right paracavernous meningioma. Functional magnetic resonance imaging (fMRI) demonstrates that the task of reading words activates superiorly displaced speech areas in the right hemisphere. The patient was informed of the risk of losing speech postoperatively.

Although fMRI is a noninvasive technique with high spatial and temporal resolution, short examination time, and wide availability, it will likely not replace intraoperative cortical mapping.

Diffusion Tensor Imaging

Diffusion tensor imaging (DTI) is a magnetic resonance technique that is sensitive to the diffusion of water in brain tissue, thus revealing the anisotropy and orientation of white matter tracts in the brain. Myelin or protein fibers likely account for diffusion anisotropy. Measurement of ADCs along six independent axes of the tensor provides the shape of the diffusion ellipsoid, that is, fully characterizes diffusion in three dimensions. Mean diffusivity (MD) and fractional anisotropy (FA) can be calculated for each pixel, representing the magnitude and directionality of water diffusion within that pixel. Once fiber direction is known in each pixel, a three-dimensional (3-D) map can be generated that depicts patterns of connectivity throughout the brain. Display of the effects of mass lesions on large nerve fiber tracts by DTI can be used for preoperative planning. Specifically, fiber mapping enables visualization of subcortical fiber tracts that are important in motor function.

Although many studies have demonstrated the usefulness of diffusion tensor imaging in the delineation of tumor infiltration, vascularity, and cellularity⁵⁵⁻⁵⁷ (Figure 27.9), in the differentiation between peritumoral edema and tumor infiltration,⁵⁸ and in the differentiation between metastasis and primary brain tumors,⁵⁹ more studies and well-organized clinical trials need to be performed before fiber tracking can

be integrated into a neurosurgical planning system. Newer techniques decreasing the time of acquisition and minimizing image distortion are being investigated⁶⁰ and could help in making diffusion tensor imaging applicable for routine clinical practice.

Positron Emission Tomography and Single-Photon Emission Tomography

Positron emission tomography (PET) exploits the annihilation of positrons and electrons into photons to achieve the nuclear imaging analog of X-ray computed tomography (CT). In the decay of a positron-emitting radionuclide, the positron interacts with an electron, yielding two photons that travel in (nearly) opposite directions. By detecting those photons in coincidence, the projection data required for tomographic reconstruction are obtained. ¹⁸F-Fluorodeoxyglucose (FDG) is the most commonly used tracer in the clinic. Similar to glucose, FDG is transported into cells by a glucose transporter, but remains trapped within the cell, thus reflecting the energy metabolism within tissues. Highly malignant brain tumors usually show increased FDG uptake in comparison to the surrounding brain parenchyma (Figure 27.10). However, because of inherent limitations, such as low resolution and high background glucose metabolism of normal gray matter structures, ¹⁸F-fluorodeoxyglucose positron emission tomography (FDG-PET) use is not a part of the routine diagnostic evaluation of brain tumor patients. Other potential uses for PET in brain tumor evaluation include grading, localization for biopsy, differentiating radiation necrosis from tumor

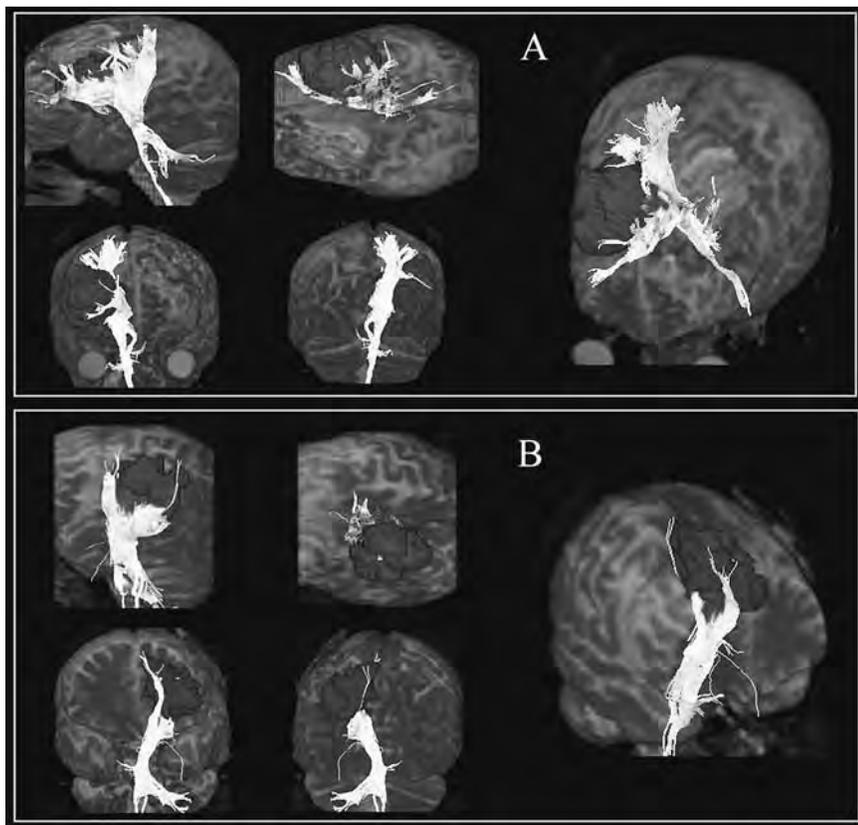

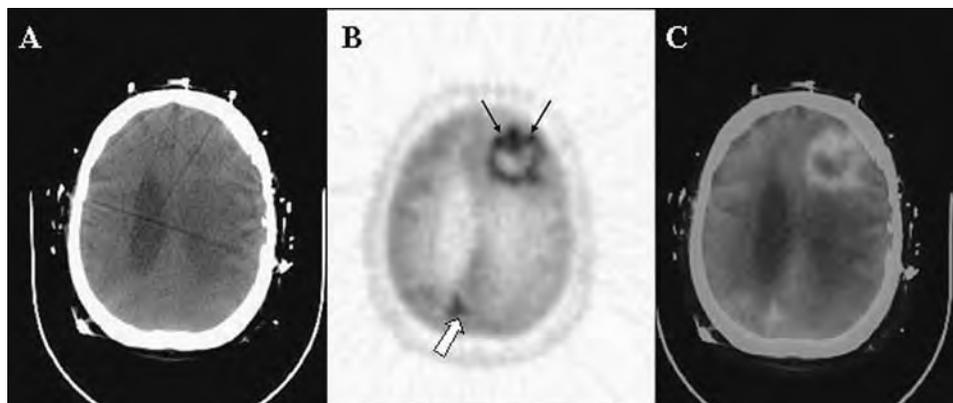

FIGURE 27.9. Fiber tracking in brain tumors with diffusion tensor imaging (DTI). The three-dimensional (3-D) relationship of the corona radiata with the tumor can be clearly appreciated. The corona radiata of the first patient (A) surrounds the surface of the tumor because of mechanical compression rather than infiltration. In the second patient's case (B), the trajectory of the corona radiata was not changed. Instead, it projected into the core of the infiltrative tumor. (From Mori et al.,⁵⁷ by permission of *Annals of Neurology*.)

FIGURE 27.10. (A) CT scan, (B) ^{18}F -fluorodeoxyglucose positron emission tomography (FDG-PET) scan, and (C) fused CT and PET scan images of left frontal lobe recurrent GBM. Note increased FDG uptake in the periphery of the necrotic mass (*black arrows*), compatible with tumor recurrence rather than radiation necrosis. Note the presence of another focus of increased uptake (*white arrow*) in the right parietal region consistent with the diagnosis of multifocal GBM.

necrosis, assessing response to therapy, predicting survival, and assessing malignant transformation of low-grade gliomas. In 47 patients with different brain tumors, the sensitivity of FDG-PET for differentiating tumor from radiation necrosis was 75% and the specificity was 81%.⁶¹ In another study yielding even lower sensitivity and specificity values, the authors concluded that the ability of ^{18}F -fluorodeoxyglucose positron emission tomography (FDG-PET) to differentiate recurrent tumor from radiation necrosis is limited.⁶² FDG-PET was found to be of prognostic importance in multiple studies.^{63,64} However, in the assessment of response to chemotherapy or radiotherapy, the role of FDG-PET remains of limited clinical utility.⁶⁵

Newer tracers such as methyl- ^{11}C -L-methionine (MET) for measurement of amino acid transport and incorporation and ^{18}F -3-deoxy-3-fluorothymidine (FLT) for evaluation of DNA synthesis, among others, seem to be promising in further characterization of brain tumors; however, they remain of limited clinical use currently.

The use of single-photon emission tomography (SPECT) in brain tumors is limited. Thallium (Tl) is the most studied radiotracer with the longest track record. Some studies have shown a relationship between ^{201}Tl uptake and tumor grade.⁶⁶ Due to the overlap between tumor uptake and histologic grades, ^{201}Tl cannot be used as the sole noninvasive diagnostic or prognostic tool in brain tumor patients.^{67,68} However, it may help in differentiating a high-grade tumor recurrence from radiation necrosis. $^{99\text{m}}\text{Tc}$ -Sestamibi is theoretically a better imaging agent than ^{201}Tl , but it has not convincingly been shown to differentiate tumors according to grade.⁶⁸

Intraoperative Imaging and Navigation

Stereotactic Navigation

Rapid 3-D MR techniques that provide thin sections (1.5 mm) can be merged with a frameless stereotactic system to improve the safety and accuracy of neurosurgical procedures. Using this technique, the surgeon's "view" is expanded to include structures deep to the region that he or she is resecting in real time. Accurate delineation of the boundaries of the lesion is the goal with this technique, as the completeness of resection is highly correlated with survival for both low- and high-grade tumors. The usefulness and reliability of the

method was immediately recognized and allowed its widespread use. In a large series of 325 cases, the use of the frameless stereotactic viewing system was associated with minimal additional effort or time spent in setting up the procedure. The system was found to be reliable, achieving a useful registration in 95.4% of cases.⁶⁹ In another case-control study, the impact of neuronavigation on glioblastoma surgery regarding time consumption, extent of tumor removal, and survival was evaluated, with and without the use of neuronavigation, in 52 cases and in 52 corresponding controls. Radical tumor resection based on radiologic evaluation was achieved in 31% of navigation cases versus 19% in conventional operations. The absolute and relative residual tumor volumes were significantly lower with neuronavigation. Radical tumor resection was associated with a highly significant prolongation in survival (P less than 0.0001). Survival was longer in patients who underwent surgery using neuronavigation (median, 13.4 versus 11.1 months).⁷⁰

Similarly, stereotactic techniques have improved the efficiency of postoperative radiation of brain tumors. In stereotactic conformal radiotherapy, a computer-generated plan guides the use of a variable collimator to distribute the radiation field in such a way that the tumor may receive a very large dose, a surrounding area a moderate dose, and radiosensitive structures a minimal dose of radiation.⁷¹

Problems arise with techniques that use preoperative image coregistration, however, because the brain tends to move during the procedure due to swelling or to the introduction of air. Intraoperative acquisition of data sets eliminates the problem of brain shift in conventional navigational systems.

Intraoperative MRI Techniques

Intraoperative MR devices, either with an upright double doughnut configuration or that require the patient to be moved to a magnet adjacent to the operating suite, have been developed to avoid potential image misregistration. Intraoperative MR techniques enable continual, near real-time visual feedback during the procedure.³ In one study evaluating 38 patients with high-grade gliomas, intraoperative MR imaging significantly increased the rate of complete tumor removal.⁷² Other uses for intraoperative MR, besides guidance to the site of an abnormality, include minimization of the size of the craniotomy, identification of adjacent structures, thus maximizing preservation of normal tissue, determination of the

completeness of tumor resection, and surveillance for intraoperative complications.^{73,74-76}

Postoperative Evaluation

The differentiation of tumor recurrence from radiation necrosis in patients with malignant gliomas who have been treated previously remains a challenge. Multiple imaging modalities were evaluated to address the problem, including FDG-PET, MRS, and perfusion imaging, in view of the limitations of conventional MRI in these cases. FDG-PET has been traditionally used in the differentiation of recurrence from radionecrosis. Sensitivities for detection of recurrent tumor ranged from as low as 43% to as high as 86%.^{61,62,77,78} Lower specificity values, however, were found, and most investigators considered the modality insufficient for the evaluation of tumor recurrence.^{62,77}

MRS/I is finding a niche in therapeutic monitoring and has recently been applied with success to the classic problem of differentiating recurrent tumor from radiation injury. In one study ($n = 56$), a significant difference in metabolite ratios (Cho/Cr and Cho/NAA) emerged between neoplastic and nonneoplastic lesions after stereotactic radiotherapy.⁷⁹ In another prospective study involving 27 patients, MRSI spectral patterns allowed reliable differential diagnostic statements to be made when the tissues are composed of either pure tumor or pure necrosis; however, these were less definitive in tissues composed of varying degrees of mixed tumor and necrosis.⁸⁰ Perfusion imaging is also helpful in the prognostic evaluation and postoperative follow-up of patients with brain tumors. Although tumors that recur after radiation therapy tend toward lower rCBV values than native lesions, earlier diagnosis of recurrent tumor has been suggested using perfusion imaging than with serial MR imaging or with nuclear imaging techniques. In a series of 59 patients, perfusion imaging (rCBV maps) was found to predict tumor progression earlier than MR imaging in 32%, earlier than ²⁰¹Tl-SPECT in 63%, and earlier than clinical assessment in 55% of the studies.⁸¹ Sugahara et al. evaluated 20 patients with the diagnosis of recurrent tumor versus radionecrosis by a combination of perfusion imaging and thallium single-photon emission tomography (²⁰¹Tl-SPECT). The rCBV values overlapped between neoplastic and nonneoplastic lesions, and the authors suggested that ²⁰¹Tl-SPECT may be useful in making the differentiation.⁸² In view of an improved spatial resolution in comparison to SPECT and PET,⁸³ perfusion MRI is a promising technique that needs to be evaluated further in clinical studies.

Conclusion

Clinical neuroimaging is undergoing a transformation from the purely anatomic techniques of CT and MRI to those that are functional, such as perfusion imaging and BOLD fMRI, as well as to molecular imaging techniques including MRSI and PET. Complementing the already widely available MR-based methods, the advent of PET-CT and the likely emergence of PET-MR suggest a prominent role for PET in functional brain imaging in the near future. The ultimate goal of this work is to combine multimodality and multiparametric imaging to

gain the most relevant physiologic information for diagnosis, prognosis, and therapeutic monitoring of patients with CNS-related cancer. An early goal is to define the true extent of tumor infiltration within the brain, that is, that which extends beyond that seen on conventional contrast-enhanced MR images. The rational combination of the parameters discussed here will likely enable that definition in the short term, with the potential to affect positively the way brain tumors are currently treated, and ultimately survival, from this now uniformly devastating disease.

Breast Imaging

Wendie A. Berg

In this chapter, the current status of breast imaging for both screening and diagnosis is reviewed. Mammography remains the standard for screening; however, moderate evidence supports the use of ultrasound (US) or magnetic resonance imaging (MRI) for supplemental screening of certain subgroups of women. Evaluation of a lump is highly accurate when both mammography and US are used. For the patient with nipple discharge, US appears to be an acceptable, non-invasive alternative to ductography.

MRI and US also play a role in evaluating disease extent in both ipsilateral and contralateral breasts. No imaging test is sufficiently accurate compared to sentinel lymphadenectomy to preoperatively identify metastatic nodes, although US-guided fine-needle aspiration can confirm metastatic adenopathy. Positron emission tomography plays a role in restaging recurrent breast cancer.

Screening

The goal of screening is early detection that will alter the natural history of the disease without harming healthy individuals. Such an intervention should also be cost-effective and practical to implement. Tabar et al.¹ retrospectively examined the prognosis of breast cancers by histologic type, grade, size, and node status in the Swedish Two-County trial. Cancers were divided into those with good, intermediate, and poor prognosis. Those with good prognosis showed 20-year survival of 91%, compared to 72% for those of intermediate prognosis and 40% for those with poor prognosis. "Good" prognosis cancers had more than 90% 20-year survival and included all ductal carcinoma in situ (DCIS) as well as node-negative invasive cancers of small size: less than 20 mm if grade I invasive ductal, less than 15 mm if grade II, less than 10 mm if grade III, and less than 10 mm invasive lobular.¹ All tubular cancers had good or intermediate prognosis.¹ "Poor" prognosis cancers were larger in size and node positive but fundamentally of the same histology as those of good prognosis. Mammographic screening shifts the distribution of cancers toward those with better prognosis. In the Swedish Two-County trial,¹ 50% of mammographic screen-detected cancers had good prognosis and 18% had poor prognosis, whereas 19% of clinically detected cancers had good prognosis and 47% poor prognosis.

A report commissioned by the United States Preventive Services Task Force² reviewed eight randomized, controlled trials of mammography and two of breast self-examination

(BSE). The Edinburgh trial was excluded for reasons of lower socioeconomic status and higher all-cause mortality in the control group and the lack of masking when evaluating cause of death. Across the seven remaining trials, in women 50 years or older, a 22% reduction in breast cancer mortality was found among women screened [95% confidence interval (CI), 13%–30%] at 14 years of observation.² In women 40 to 49 years of age, the summary risk reduction was 15% (95% CI, 1%–27%) at 14 years of observation.²

Cancer is detected in 5 to 7 of every 1,000 women on the initial mammogram and in 2 to 3 per 1,000 on each incidence (annual) screen,^{3–5} with the incidence increasing with advancing age.⁴ In one practice, cancer detection rates on screening mammography were 6 per 1,000 when breast imaging specialists performed the interpretation and only 3.4 per 1,000 when interpreted by generalists.⁶

Some of the reduction in breast cancer mortality after the introduction of mammographic screening is attributable to improved treatments. In an analysis of population-based service screening in Sweden, Tabar et al.⁷ reported a 16% reduction in breast cancer mortality in the period 1978–1997 compared to the period 1958–1977 among women not screened, by 44% in all women 40 to 69 years of age who were screened with mammography, and by 48% in women 40 to 49 years of age who were not screened.

Randomized controlled trials have not demonstrated a mortality reduction from breast self-examination (BSE). The Shanghai trial of 133,000 Chinese women randomized to receive instruction in BSE or not, found no difference in mortality; indeed, women in the BSE group were 84% more likely to undergo an unnecessary benign breast biopsy.⁸ Importantly, the combination of clinical breast examination (CBE, by the woman's care provider) and mammography is more effective in lowering breast cancer mortality than mammography alone.⁹

Despite its effectiveness in reducing mortality from breast cancer, mammography is less sensitive when the breast tissue is dense. Breast density is classified into four categories¹⁰: fatty (less than 25% dense); minimal scattered fibroglandular density (25%–49% dense); heterogeneously dense (50%–74% dense); and extremely dense (75% or more dense). Dense tissue is especially common in younger women. Stomper et al.¹¹ reviewed mammograms from 1,353 women and reported that approximately 62% of women in their thirties, 56% of women in their forties, 37% of women in their fifties, and 27% of women in their sixties had at least 50% parenchymal density on mammography. Kerlikowske et al.¹² reported

results on 27,281 screening mammograms and found the sensitivity to cancer was 98.4% in women 50 years of age or older with fatty breasts and 83.7% in dense breasts ($P = 0.01$). In women under 50, the sensitivity was 81.8% in fatty breasts and 85.4% in dense breasts (NS), although the numbers of cancers were small.¹² In women under 50 with a family history of breast cancer, sensitivity decreased to 68.8%.¹² Mandelson et al.¹³ reported sensitivity as low as 30% among women with extremely dense breasts in a Seattle screening mammography program. Among women with mutations in BRCA-1 or -2, mammography depicts fewer than half of cancers.¹⁴⁻¹⁷ Thus, in women with dense breasts, and particularly those at increased risk because of a family or personal history of breast cancer or atypia, methods to supplement mammography are sought.

Screening does not assure a benefit to all women.¹⁸ The most aggressive cancers are often not detectable at screening but have metastasized by the time they are clinically detected. Detecting breast cancer when it is small and node negative does not assure improved survival; some of these cancers will still metastasize. Tabar¹ noted that cancers manifested as branching, casting calcifications were often lethal even when less than 15 mm in size at detection. Women treated for breast cancer may still die of other causes; treatment can be unnecessary, particularly in older women as competing risks of death increase. Such "overtreatment" may even increase all-cause mortality.^{19,20} Without treatment, the majority of DCIS will progress to invasive carcinoma, but this may occur over a period of 20 years or more.^{21,22} Yen et al.²³ analyzed the results of the Swedish Two-County trial and estimate that at the first (prevalent) baseline screen, 37% of DCIS is nonprogressive,

but at subsequent (incidence) screens, only 4% of new DCIS would not progress. This finding suggests that "overtreatment" may occur at the first (prevalent) screen with any given screening test but would be uncommon if the test were performed annually. In other words, cancers that are new on subsequent (incidence) screens are almost always biologically relevant. Randomized controlled trials with death as the endpoint are considered the gold standard for assessing the impact of any screening modality on survival.²⁴ Mammography is the only screening test to date that has been shown to reduce deaths due to breast cancer.

Supplemental screening with ultrasound (US) and magnetic resonance imaging (MRI), in addition to mammography, are being considered, particularly in women with heterogeneously dense or extremely dense (hereafter referred to as dense) breast tissue who are at high risk. Indeed, dense breast tissue itself is an indicator of elevated risk of 1.8- to 6-fold, averaging 4-fold across multiple series.²⁵ As recently reviewed,²⁶ in single-center studies of screening US totaling 42,838 examinations in average-risk women,²⁷⁻³² 150 cancers had been identified (3.5 per 1,000 exams) only sonographically in 126 women (Table 28.1). Of 126 women with sonographically depicted cancers, 114 (90.5%) had dense or heterogeneously dense parenchyma. Of the 150 cancers, 141 (94%) were invasive, and 99 (70%) were 1 cm or smaller in size. More than 90% were node negative. Although these results are encouraging, these studies were not blinded to results of mammography, and variable equipment, performance, and interpretive criteria were used. Publication of minimum equipment standards for breast US,³³ as well as a standardized lexicon for description of lesions and reporting

TABLE 28.1. Summary of studies of screening breast ultrasound, biopsies prompted by US, positive predictive value of biopsy, and prevalence of cancers seen only sonographically.

^aBiopsies or aspirations prompted by screening sonography.

^bRefers to cancers seen only on breast sonography, expressed as percent of biopsies (PPV).

^cAll women had clinical or mammographic abnormalities. Diagnosis was by fine-needle aspiration biopsy. Numbers refer to solid masses. Sixteen cancers were found in 15 women with ipsilateral cancer.

^dIn this series, 867 women were evaluated because of palpable or mammographic abnormalities; 5 cancers seen only on sonography were in patients with another mammographically or clinically evident cancer.

^eCancer was found only on sonography in 0.54% of women with a personal history of cancer compared to 0.26% of women with no personal history of cancer.

^fNS, not stated.

^gIncludes patients described in 1998 series.⁹ Number of studies, not women, as some women had more than one study. Cancer was found only on sonography in 0.48% of high-risk women compared to 0.16% of normal risk women.

^hCancer was found only on sonography in 4/318 (1.3%) women with first-degree family history or personal history of breast cancer and 3/1,199 (0.25%) women of average risk; biopsies includes 17 aspirations of which 13 yielded clear fluid.

ⁱ1,016 had a personal history of breast cancer and 136 a palpable lesion (with the palpable lesions themselves excluded), although the number of cancers seen in women at high risk was not specified. Sixteen cancers were identified, but the number of biopsies induced by sonography was not specified: results of this study were not included in calculating the biopsy rate or the malignancy rate of biopsies.

*Results of MRI and mammography were blinded to each other. Not stated in Leach et al.¹⁴¹

^aBiopsies prompted by MRI per number of screenings.

^bPPV, positive predictive value; number of malignancies of total number of biopsies.

^cOf cancers seen only on MRI, number (%) that were ductal carcinoma in situ (DCIS).

^dMRI and mammographic sensitivity reported only when results of MRI and other imaging modalities and clinical follow-up are described.

^eNA, not applicable; all participants had negative mammography and clinical breast examination; NS, not stated.

^fA total of 4,169 rounds of screening were performed. Of 6 DCIS lesions in this patient population, 5 were seen on mammography and only 1 on MRI.

^g41 cancers were classified as BI-RADS category 3 or higher on either mammography or MRI, with 3 cancers classified as BI-RADS 3 on each, but overlap not specified. Sensitivity numbers for each of MRI and mammography do not include category 3 lesions.

criteria,³⁴ will help decrease variability in this technique, although there remains a shortage of highly qualified radiologists and technologists. To better assess the generalizability of breast US, a 3-year multicenter trial of screening sonography in high-risk women, blinded to the results of mammography, opened in April 2004, funded by the Avon Foundation and National Cancer Institute through the American College of Radiology Imaging Network (ACRIN Protocol 6666; www.acrin.org).³⁵ The ACRIN protocol provides training materials for investigators, and standardizes equipment and interpretive criteria, to better assess generalizability of screening US. Sonography is widely available and inexpensive, and it is easy to accurately biopsy lesions seen only on sonography with core biopsy technique.³⁶

Importantly, DCIS is not well seen on US: it should be seen as complementary to mammography. When results of mammography were also reported,^{28,30,31} across 26,753 examinations another 56 cancers were seen only mammographically, of which 42 (75%) were DCIS and 14 (25%) were invasive.

Across eight published series (Table 28.2), 4,293 very high risk women have been screened with MRI, with 77 (1.8%) of women having cancer depicted only on MRI. The median size of cancers was 7 to 20 mm, and in all but one series, more than 80% of MRI-only depicted cancers had negative nodes.³⁷ Where detailed, 15 of 62 (24%) of the cancers seen only on MRI were DCIS (see Table 28.2). In the largest single series of MRI screening to date,³⁸ mammographic and MRI interpretations were blinded to each other, and 51 cancers were detected in 1,909 women. Sensitivity to invasive cancer was 33% for mammography and 80% for MRI, with specificities of 95% and 90%, respectively;

sensitivity to DCIS was 83% for mammography and 17% for MRI.³⁸

When both US and MRI have been performed in the same high-risk patients, MRI has shown superior sensitivity.³⁹⁻⁴¹ Liberman⁴² summarized results across these series, which found 7 of 24 (29%) of cancers on mammography, 7 of 23 (30%) on US, and 23 of 24 (91%) on MRI. MRI is limited, however, by high cost, relative lack of availability, variable patient tolerance, the requirement for contrast injection, and relative lack of availability and expertise to biopsy lesions found only on MRI.

False Positives

False positives are a risk of any screening test. For mammography, Elmore et al.⁴³ estimated that after 10 annual screening mammograms, nearly 24% of women had had a false-positive result at least once, with a cumulative risk of a false-positive mammogram of 49.1%. Of women who did not have breast cancer, 18.6% underwent biopsy after 10 mammograms.⁴³ Short-interval follow-up of specific lesions, such as nonpalpable circumscribed masses and focal asymmetries has been validated,⁴⁴⁻⁴⁶ with risk of malignancy less than 2% among appropriately classified lesions. Importantly, the prognosis is not adversely affected by short-interval follow-up in this setting.

Biopsy of benign lesions seen only sonographically, and induced short-interval follow-up, are risks of screening ultrasound. Across the five series where specifics are detailed,^{27-30,32} after 38,602 screening sonograms, 1,137 (2.9%) resulted in biopsy and 134 (11.8%) biopsies showed malignancy. In the four series with details,^{27,29,30,32} short-interval

follow-up was recommended in another 6.6% of women. Criteria for classifying a lesion seen only sonographically as probably benign have been proposed^{47,48} but require broader validation. Follow-up is generally performed only for nonpalpable lesions, although one recent study suggests the combination of benign-appearing features on both mammography and sonography may allow follow-up of even palpable lesions⁴⁹; further validation of such an approach is required. It should be noted that in all but one series³⁰ only a single prevalence screen was performed: these rates of false positives are likely higher than would be seen on annual incidence screens.

With MRI, from 2% to 17% of women screened were recommended for biopsy based on MRI, and 24% to 89% of MRI-prompted biopsies proved malignant (see Table 28.2). Short-interval follow-up was recommended in 5% to 24% of women on the first screening round where specified^{138,39,50-52} and decreased to 3% to 7% when results of subsequent screening rounds were detailed.^{39,52} With MRI, the criteria for follow-up and risk of malignancy in lesions followed have not been widely studied. Liberman et al.⁵¹ report 7% of lesions seen only on MRI that were followed proved malignant, and another 3% of patients developed cancer elsewhere in their breasts during short-interval follow-up. It is encouraging that, in the series of Kriege et al.,³⁸ 275 of 4,169 (6.6%) of examinations were recommended for short-interval follow-up, with only 3 of 275 (1.1%) of those proving malignant. MRI-guided core and vacuum-assisted biopsy are becoming more widely available^{53,54} but require availability of scanner time and personnel. A facility that offers breast MRI should observe standardized technique and interpretive criteria⁵⁵ and offer MRI-guided biopsy.

Screening Guidelines

There is persuasive evidence that greater reductions in mortality result from annual screening compared with screening every 2 years, particularly in younger women.^{2,56,57} Modeling data also suggest that shorter screening intervals are associated with fewer cases diagnosed with distant metastases⁵⁸ and smaller tumor size at detection. Further, smaller tumor size is highly correlated with survival time, independent of method of detection.⁵⁹ Annual mammography is therefore recommended for women beginning at age 40.^{60,61} Screening should be continued as long as a woman is in good health, with at least 5-year life expectancy,⁶² and as long as she would be a candidate for treatment.^{60,61,63-65} If there is a first-degree relative with premenopausal breast cancer, annual screening should begin 10 years before the age of diagnosis of the relative.⁶⁶ Any woman with a personal history of cancer, atypia, or lobular carcinoma in situ should begin annual screening. Women who have had mantle irradiation to the chest, as for Hodgkin's disease, are at increased risk of breast cancer if the radiation was received before age 31, with increased rates of breast cancer beginning 8 years after the radiation treatment⁶⁷⁻⁶⁹; annual screening should begin 8 years after treatment if the radiation was before age 31.

As already discussed, there is moderate supporting evidence for supplemental screening with US or MRI in certain situations, although further study is warranted. Using MRI to screen women at high genetic risk of breast cancer is approved

by the Blue Cross-Blue Shield Technology Evaluation Center (www.bluecares.com/tec/vol18/18_15.html). No data support the use of MRI to screen women at normal risk. US is more widely available and less expensive and has been shown to increase detection of cancers in women of average risk with dense breast tissue in single-center studies. Insurance does not generally cover screening US, and not all centers have the appropriate equipment or personnel to offer this service. A woman needs to understand the risk of false positives with any screening test. The detection of early breast cancer is critical in reducing mortality due to breast cancer, and both US and MRI depict early invasive breast cancers. Some DCIS is depicted on US and more on MRI, but mammography remains the standard for detection of DCIS. While the natural history of breast cancer should be independent of the method of detection, a survival benefit has not been proven for any screening test other than mammography.

Lump

Ultrasound is the initial test of choice in evaluating a lump in a young woman (under 30 years old).⁷⁰ The most common cause of a palpable mass in a woman under age 30 is a fibroadenoma.⁷¹ A palpable, circumscribed, oval mass with no posterior features or minimal posterior enhancement is most likely a fibroadenoma. If such a mass, in a woman under 30 years of age, has clinically been known to the patient and stable for a period of at least 6 to 12 months, then follow-up is a reasonable alternative to biopsy. Because 15% of fibroadenomas are multiple, bilateral whole breast ultrasound is reasonable in initial imaging evaluation. Many women prefer excision of a palpable lump, and direct excision of a probable fibroadenoma is reasonable in a young woman. The finding of a sonographically suspicious mass should prompt bilateral mammographic evaluation to better define the extent of presumed malignancy. A clinically suspicious mass without a sonographic correlate merits further evaluation with mammography.

At age 30 and over, breast cancer is increasingly common, and mammography is the initial test of choice for symptomatic women. When a lump appears highly suggestive of malignancy on mammography, US is useful in guiding biopsy, with 95% sensitivity on initial core biopsy and no delayed false negatives.^{36,72,73} A spot compression tangential mammographic view over a palpable mass can improve visibility of the mass and demonstrate overlying skin thickening or retraction.⁷⁴ Moderate evidence supports the use of US in addition to mammography in the evaluation of women with palpable masses or thickening (Table 28.3). In the multiinstitutional study of Georgian-Smith et al.,⁷⁵ 616 palpable lesions were evaluated sonographically and all 293 palpable cancers were depicted sonographically. Across several series (see Table 28.3), of 545 cancers in women with symptoms, 529 (97.1%) were depicted with the combination of mammography and US. A negative result after both mammographic and sonographic evaluation of a palpable abnormality is highly predictive of benign outcome, with 98.6% negative predictive value across these series.⁷⁵⁻⁷⁹ Nevertheless, final management of a clinically suspicious mass must be based on clinical grounds.

^bIn the series of Houssami et al.,⁷⁹ 157 women with cancer had a lump and 114 without cancer had a lump.

Nipple Discharge

Bloody nipple discharge and spontaneous unilateral clear nipple discharge merit imaging and clinical evaluation, with malignancy found in 13% of patients on average (range, 1% to 23%) across multiple series.⁸⁰ Papilloma is the most common cause of nipple discharge, found in 44% to 45% of patients,^{80,81} with fibrocystic changes accounting for the rest. Milky discharge is almost always physiologic or due to hyperprolactinemia⁸⁰ and does not warrant imaging workup. Injection of contrast into the discharging duct, followed by magnification craniocaudal and true lateral mammographic views (galactography), has been the standard for imaging evaluation of nipple discharge.⁸² US is an alternative method for evaluating nipple discharge and has the advantage of being noninvasive. A few studies have compared US and galactography (Table 28.4), with promising but limited evidence for the utility of US in this setting. The visualization of intraductal masses on US is facilitated by distension of the duct. Whether the full extent of multiple intraductal lesions is well depicted on US has not been systematically studied. MRI has also been used to evaluate nipple discharge with some success,⁸³ and further study is warranted.

Extent of Disease

From 73% to 98% of DCIS evident mammographically is manifest as microcalcifications.⁸⁴⁻⁸⁶ The extent of calcifications on mammography can underestimate the area involved by DCIS, although Holland and Hendriks⁸⁷ showed this dis-

crepancy was less than 2 cm in 80% to 85% of cases. When the original tumor is manifest as calcifications mammographically, a postlumpectomy mammogram is advocated before radiation therapy, even when clear margins have been achieved.⁸⁸ Residual calcifications on postoperative mammograms do predict residual tumor, with 10 (71%) of 14 patients having residual DCIS in the series of Gluck et al.⁸⁹

Several series have demonstrated a detection benefit of sonography after mammography and clinical examination in evaluating the preoperative extent of breast cancer (Table 28.5), particularly in dense breasts.⁹⁰ On average, 48% of breasts with cancer will have additional tumor foci not depicted on mammography or clinical examination.⁹¹ If US is being used to guide biopsy, there is an advantage to at least scanning the quadrant containing the cancer, because 93% of additional tumor foci are within the same quadrant as the index lesion,⁹² and more than 90% of malignant foci will be detected by combined mammography and US in this setting. When considering extent of disease, imaging of the contralateral breast should always be performed; 4% to 6% of patients are found to have unsuspected contralateral cancer on supplemental US or MRI.^{90,93-95}

As with screening, MRI depicts additional tumor foci not seen on US, mammography, or clinical breast examination. Fischer et al.⁹³ reported results in a series of 463 patients, including 405 cancers, where preoperative mammography, clinical breast examination, sonography, and MR imaging had been performed: multifocality in 30 of 42 patients, multicentricity in 24 of 50 patients, and additional contralateral carcinomas in 15 of 19 patients were depicted with MR imaging alone. As a result of the MR imaging findings, therapy was

^aDCIS, ductal carcinoma in situ; ILC, invasive lobular carcinoma; IDC, invasive ductal carcinoma; NOS, not otherwise specified.

^bOf 105 index lesions, 96 were identified on mammography and 9 only on US. Of 27 breasts with multifocal or multicentric tumor, 48% were identified on mammography, 63% with combined mammography + ultrasound (US), and 81% via magnetic resonance imaging (MRI).

^cIncludes clinical breast examination.

changed in 66 of 463 (14%) of patients.⁹³ In the series of Berg et al.,⁹⁰ of 96 breasts anticipating conservation after mammography and CBE, 30 (31%) were found to have additional tumor: 17 (57%) of those with greater extent were identified by supplemental US and 29 (97%) by MRI; however, disease was then overestimated by at least 2 cm or additional foci in 12 of 96 (13%) of breasts by US and 20 of 96 (21%) of breasts by MRI. After combined mammography, CBE, and US, MRI depicted additional tumor in another 12 of 96 (13%) of breasts and overestimated extent in another 6 (6%); US showed no detection benefit after MRI.⁹⁰ The impact of supplemental US or MRI in evaluating disease extent increases with increasing breast density.⁹⁰ In a study of 104 patients with cancer by Hlawatsch et al.,⁹⁶ US depicted additional tumor in 13 and produced 2 false positives; MRI depicted additional tumor in another 7 and produced 8 false positives.

In particular, an extensive intraductal component (EIC) is often underestimated without MRI.⁹⁰ The presence of an EIC correlates with increased risk of positive margins⁹⁷ and increased risk of recurrence.⁹⁸ Importantly, if clear margins are achieved, even when an EIC is present, Hurd et al.⁹⁹ failed to show an adverse effect on disease-free or overall survival or local control.

Initial detection and extent of invasive lobular carcinoma are also especially problematic on mammography as the single file cells typically infiltrate without associated calcifications or discrete mass. In the series of Butler et al.,¹⁰⁰ 81 of 208 (39%) of invasive lobular carcinomas were mammographically subtle or occult and 71 of 81 (88%) were well depicted sonographically. In several series,^{91,101–103} MRI has been shown to be significantly more accurate than mammography, CBE, or US in determining the extent of invasive lobular carcinoma.

Although the frequency of residual tumor at pathology averages 48%,⁹¹ the risk of recurrence after lumpectomy and radiation is generally 1% to 2% per year for the first 5 years, averaging 5% to 13% at 5 years.^{104–106} Approximately half of this discrepancy may be attributed to cases that would have positive margins if lumpectomy were based on mammography and CBE⁹⁰: supplemental imaging with MRI or US will decrease the need for reexcision. Of the other half with resid-

ual tumor, representing 20% to 25% of patients, roughly half of the residual tumor will be successfully treated with radiation and/or chemotherapy.¹⁰⁷ Distinction of those who will benefit from preoperative additional imaging with US or MRI from those who will undergo unnecessary additional surgery and even mastectomy for tumor that would have resolved in conventional treatment, is not clear at this time, although those with invasive lobular cancer, an EIC, and/or dense breasts appear to be more likely to benefit.

US is insensitive to DCIS, as described, as DCIS is often manifest as microcalcifications. US is not particularly sensitive to lesions manifest solely as calcifications due to their small size and similarity to speckle artifact present in tissue. Nevertheless, US can help identify the invasive component of malignant calcifications. Soo et al.¹⁰⁸ evaluated 111 cases of suspicious calcifications and only 26 (23%) could be seen sonographically. Of those seen on US, 69% were malignant compared to only 21% of those not seen on US.¹⁰⁸ Those cancers seen on US were more likely invasive (72% versus 28%), and underestimation of disease was less common when biopsies were performed with US guidance than stereotactic guidance. Similarly, Moon et al.¹⁰⁹ showed 45 of 100 (45%) of suspicious microcalcifications were sonographically visible, including 31 of 38 (82%) of malignant calcifications and 14 of 62 (23%) of benign calcifications.

MRI is particularly indicated in cases of breast cancer presenting as an axillary metastasis.^{110,111} Identification of the primary usually allows breast conservation. In patients with positive margins at initial excision, MRI is also appropriate to assess for residual tumor.^{112,113} There is no need to delay imaging in this setting, as was suggested by Frei et al.,¹¹⁴ as excision of the area immediately around the lumpectomy site will be performed in any event and false positives due to granulation tissue at the lumpectomy site are not of particular clinical import. The purpose of MRI in the setting of positive margins is to evaluate the rest of the breast(s) and determine the possible need for mastectomy versus wider excision.

In patients with locally advanced breast cancer, in whom neoadjuvant chemotherapy is planned, strong evidence supports the use of MRI in accurately sizing and evaluating the

extent of tumor before and after treatment to assess response and plan appropriate surgery.¹¹⁵⁻¹¹⁷ A multicenter trial is currently under way to further evaluate the use of MRI in this setting (ACRIN Protocol 6652, www.acrin.org). Chest wall invasion can accurately be determined by MRI.¹¹⁸

Positron emission tomography (PET) using ¹⁸F-deoxyglucose (FDG) can predict response to treatment within as little as 8 days.¹¹⁹ After a single course of treatment, Schelling et al.¹²⁰ correctly identified all responders by a decrease in the standardized uptake value to below 55% of baseline. At that threshold, histopathologic response was predicted with an accuracy of 88% after the first course of treatment and 91% after the second course. It has been suggested, therefore, that ineffective chemotherapy as determined by PET might be discontinued and new treatments instituted.¹²⁰ Further study of PET in this context is warranted.

Axillary Node Status

Unfortunately, no reliable noninvasive imaging method has been developed that accurately predicts axillary or internal mammary nodal status. Most lymph nodes are not included on mammographic imaging. In the setting of a known breast cancer, loss of the fatty hilum or indistinct borders to a node seen mammographically can suggest metastatic nodal involvement.¹²¹ Mammographically spiculated borders of axillary nodes in the patient with breast cancer predict extranodal extension and poor prognosis.¹²² Isolated nodal enlargement without a known cancer is usually due to benign, reactive conditions.¹²¹ When a metastatic node is identified and the primary cannot be found clinically or mammographically, MR imaging has been shown to be highly efficacious, depicting the occult primary in 70% to 75% of patients^{110,123,124} and thereby facilitating breast conservation.¹²⁵

On sonography, loss of the fatty hilum, an irregularly thickened cortex, indistinct margins, and a long-to-short-axis ratio less than 1.5 suggest metastatic involvement,¹²⁶ although the accuracy of this approach is not well established.

Enhancement of lymph nodes in the axilla and internal mammary chains is frequently seen on MR imaging. Using a threshold of greater than 100% increase in signal intensity on the first postcontrast series, Kvistad et al.¹²⁷ showed a sensitivity of 83% to axillary metastases, specificity of 90%, and accuracy of 88%. Similar results were found by Yoshimura et al.¹²⁸: using morphologic parameters of long-axis dimension greater than 1 cm and long-to-short-axis ratio less than 1.6, they found a sensitivity of 79%, specificity of 93%, and accuracy of 88% in identifying metastatic axillary nodes on MR imaging. When a suspicious node is identified on MRI or US, fine-needle aspiration can confirm the presence of metastatic adenopathy preoperatively, allowing full axillary dissection at the time of treatment surgery.¹²⁹

Current staging of breast cancer includes identification of the presence of micrometastases (less than 2 mm) in the sentinel node (first draining lymph node). As such, the challenge of imaging is to equal that level of sensitivity and to detect foci of metastatic disease ranging from 2 mm down to even a few cells. This is below the threshold of morphologic imaging. Uptake of FDG in axillary lymph nodes can be used to identify metastatic disease. When the status of the axilla

as a whole is considered, across seven single-center studies,¹³⁰ whole-body PET with FDG successfully predicted the status in 113 of 132 (86%) of axillae with metastatic disease by hematoxylin and eosin (H&E) staining. Another 143 of 174 (82%) of negative axillae were correctly predicted.

Results from a prospective multicenter study were recently published¹³¹ evaluating PET in axillary nodal staging in 308 assessable axillae, 109 (35%) of which had tumor involvement. The mean sensitivity was 61% (range, 54% to 67%), positive predictive value (PPV) 62% (range, 60% to 64%), and negative predictive value (NPV) 79% (range, 76% to 81%).¹³¹ The average sensitivity was lower when there was only one tumor-involved node in the axilla (46%) than when more than one node was involved (64%, $P = 0.005$).¹³¹ Lower sensitivity was seen for metastases from invasive lobular carcinoma (25%) than from invasive ductal carcinoma (64%, P less than 0.005).¹³¹ At this time, PET does not appear to be sufficiently accurate to triage patients to full axillary dissection versus sentinel lymph node biopsy.^{132,133}

Metastatic Disease and Recurrence

The differentiation of scar from recurrent tumor can be problematic on mammography and US. MRI may be helpful in this setting, although further study is warranted. Heywang-Kobrunner et al.¹³⁴ found that in 30 of 32 (94%) cases post-surgical scar did not enhance beyond 18 months after surgery, although delayed development of enhancement in fat necrosis can occur.¹³⁵

PET is approved for restaging breast cancer and evaluating for recurrence. Bender et al.¹³⁶ found all 16 local recurrences and 28 axillary nodal recurrences in their series using FDG-PET. Further study of this issue is needed. Moon et al.¹³⁷ assessed the accuracy of whole-body PET for detection of recurrent or metastatic breast cancer in 57 patients. Sensitivity for individual lesions was 85% and specificity was 79%.¹³⁷ Muscle uptake and inflammation were sources of false positives. Bone metastases are a common source of false negatives.¹³⁷ Indeed, FDG-PET and bone scintigraphy have been shown to be complementary in the detection of bone metastases, with lytic metastases well depicted by PET and blastic metastases by bone scintigraphy.¹³⁸ FDG-PET has no role in detection of brain metastases because of the high normal uptake of FDG in the brain.

Summary

Screening mammography remains the standard. In high-risk women, supplemental screening with MRI is being considered, and further study is warranted. In women of average risk with dense breast tissue, single-center studies support elective supplemental screening with ultrasound, and further study is both needed and ongoing.

At this time, indications for ultrasound include the following:

Initial evaluation of a breast lump in a woman less than 30 years of age. (Note: Mammography should also be performed if the sonogram is suspicious or if there is strong clinical suspicion and the sonogram is negative.)

Evaluation and biopsy guidance of a clinically suspicious lump in a woman of any age.

Evaluation and biopsy guidance of lesions manifest as highly suspicious microcalcifications over a large (greater than 2 cm) area, to identify any associated mass that may represent an invasive component.

Evaluation of bloody or spontaneous clear nipple discharge.

Evaluation of both breasts in women with newly diagnosed breast cancer and dense breast tissue.

Indications for contrast-enhanced breast MRI include the following:

Metastatic axillary node with unknown primary.

Evaluation of the local extent of breast cancer bilaterally, particularly if the breasts are dense, tumor is invasive lobular, or there is suspicion for extensive intraductal component.

Positive margins after lumpectomy.

Initial sizing and assessment of response to neoadjuvant chemotherapy

Suspicious abnormality on mammography, one view only, not able to be localized for biopsy after full workup with additional views and ultrasound.¹³⁹

Imaging of Thoracic Malignancies

Caroline Chiles and Suzanne L. Aquino

Radiologic imaging of malignancy has evolved over the past 20 years. It not only provides better detection with superior anatomic resolution through computed tomography (CT) and magnetic resonance (MR) imaging, but it also provides physiologic information through positron emission tomography (PET). Today's technology incorporates the use of image modality fusion for even better disease localization and characterization. By fusing data from PET and CT studies, radiologic imaging brings together the superior resolution of CT with the low resolution of PET, thereby providing important information on tumor metabolism and replication. Tumor imaging is at the forefront of this technology explosion and is the focus of most cutting-edge research, as well as clinical applications. This chapter reviews current imaging of primary and metastatic malignancies of the thorax.

Tumors of the Bronchus

Bronchogenic Carcinoma

NON-SMALL CELL LUNG CANCER

DETECTION

A patient with bronchogenic carcinoma may report symptoms including cough, sputum production, or hemoptysis at first presentation for evaluation by a physician. Other patients have advanced disease and nonspecific systemic symptoms, including weight loss and weakness, at initial examination. Chest radiographs may show findings that suggest lung cancer. Still other patients report no symptoms related to lung cancer, and abnormal results on chest radiographs prompt further workup. In almost 40% of patients with lung cancer, the disease has spread outside the thorax.¹

Whether earlier detection of lung cancer improves outcomes remains controversial. Randomized, controlled lung cancer screening studies performed in the 1970s did not show a reduction in the number of deaths from lung cancer in patients screened with chest radiography and sputum cytology when compared with controls who received either less-frequent chest radiography or advice that chest radiography and sputum cytology be performed once a year.²⁻⁴ This failure to demonstrate a reduction in lung cancer mortality occurred despite an increase in the detection of early-stage, resectable lung cancers and improved lung cancer survival in the experimental group screened every 4 months. Criticisms of these

studies included insufficient statistical power, contamination of the control group, and a 25% noncompliance rate among the screened group.⁵ In the Mayo Lung Project and the Czechoslovak screening studies, the incidence of lung cancer in the experimental groups was significantly higher than in the control population, suggesting that the two groups were not balanced with regard to important variables that affect lung cancer risk.⁶ This discrepancy in incidence adversely affected calculated lung cancer mortality. The failure of screening chest radiography to improve the outcome in lung cancer occurred in multiple studies. A meta-analysis of screening studies enrolling a total of 245,610 subjects showed an 11% higher mortality from lung cancer when compared with less-frequent radiographic screening.⁷

A newer approach to lung cancer screening is low-dose helical CT, rather than conventional chest radiography. The Early Lung Cancer Action Project (ELCAP) recruited 1,000 high-risk individuals for baseline and annual repeat screening with low-dose helical CT.^{8,9} In 1999, Henschke et al. reported the results of 1,000 baseline screening CT examinations.⁸ Bronchogenic carcinoma was diagnosed in 27 individuals. Twenty-three of these patients had stage I disease; only 1 patient had unresectable disease. In 1,184 annual repeat screening examinations, malignancy was diagnosed in 7 individuals: 5 stage IA, 1 stage IIIA, and 1 small cell carcinoma.⁹

The conflicting analyses of earlier lung cancer screening trials and the advent of new technology capable of detecting early-stage lung cancer prompted the National Cancer Institute to fund a large-scale randomized, controlled lung cancer screening trial, the National Lung Screening Trial (NLST). In this trial, low-dose helical CT was compared with chest radiography in 50,000 participants at increased risk for lung cancer. Inclusion criteria required that participants be 55 to 74 years old and have at least a 30-pack/year cigarette-smoking history. Enrollment and incidence screening occurred between 2002 and 2004. Participants were randomized to either CT (experimental arm) or chest radiography (control arm) and received screening examinations once a year for 3 years. Follow-up will continue through 2009. In a subset of 10,000 participants, samples of blood, urine, and sputum were collected and archived to be available for further study using biomarkers for early detection of lung cancer.

IMAGING APPEARANCE

Bronchogenic carcinomas have a variety of appearances on imaging studies, ranging from a solitary pulmonary nodule to

lobar consolidation. Some of these appearances strongly suggest specific cell types, despite considerable overlap.

SOLITARY PULMONARY NODULE

A solitary pulmonary nodule is defined radiographically as an opacity measuring less than 3 cm in diameter and surrounded by air-containing lung. Opacities that are larger than 3 cm in diameter are considered masses. The solitary pulmonary nodule presents a diagnostic challenge. Although most such nodules are benign, each must be further evaluated as a possible neoplasm. The interface between malignant nodules and the surrounding lung may appear smooth, lobulated, irregular, or spiculated. The margins of the solitary pulmonary nodule have been correlated with the incidence of malignancy.¹⁰ A nodule with spiculated margins has a higher likelihood of malignancy than does the smoothly marginated nodule. A peripheral solitary pulmonary nodule is a common presentation for adenocarcinoma of the lung. The nodule may be round or oval, with smooth, lobulated, or irregular margins (Figure 29.1). The nodule may cause distortion of the surrounding pulmonary architecture and retraction of the overlying pleura. The concept of *scar carcinoma* suggests that some lung cancers, particularly adenocarcinomas, may arise in preexisting lung scars. Fibrosis observed microscopically, however, may represent a desmoplastic reaction of the host tissue to the neoplasm.

CT screening for lung cancer has helped to clarify the early appearances and growth rates of malignant primary tumors in the lung.¹¹ Nodules seen on high-resolution CT (HRCT), with 1.0- to 1.25-mm slice thicknesses, can be categorized on the basis of their CT attenuation as ground-glass opacity, mixed ground-glass and solid attenuation, and solid (Figure 29.2).^{12,13} Volume-doubling rates have been calculated as fastest for solid nodules at 149 days, intermediate for mixed

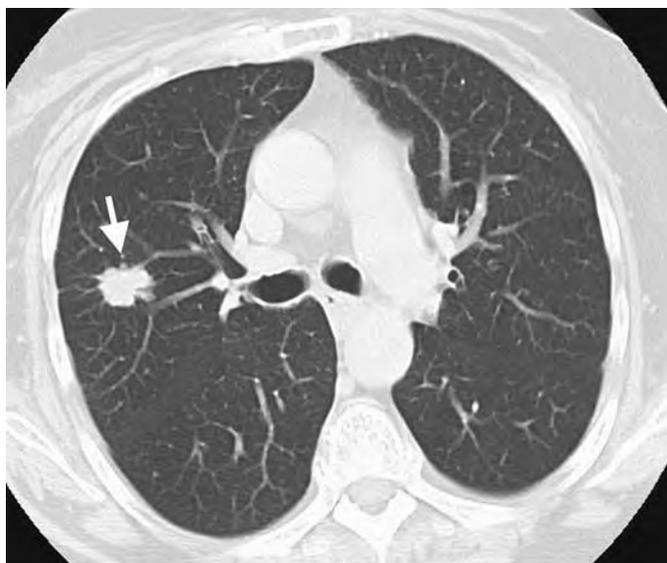

FIGURE 29.1. Axial computed tomography (CT) image (lung window setting) in a 69-year-old woman shows a spiculated, solid attenuation nodule (*arrow*) in the right upper lobe, typical for non-small cell bronchogenic carcinoma.

ground-glass/solid nodules at 457 days, and prolonged for ground-glass opacities at 813 days.¹¹

Henschke et al. report a higher malignancy rate in nodules of mixed or ground-glass attenuation than in solid nodules found with screening CT.¹⁴ Ground-glass attenuation correlates with bronchioloalveolar cell carcinoma histology and with a more favorable prognosis.¹⁵ For this reason, some authorities recommend limited (wedge) resection for nodules of ground-glass attenuation and lobectomy for solid nodules.¹⁶

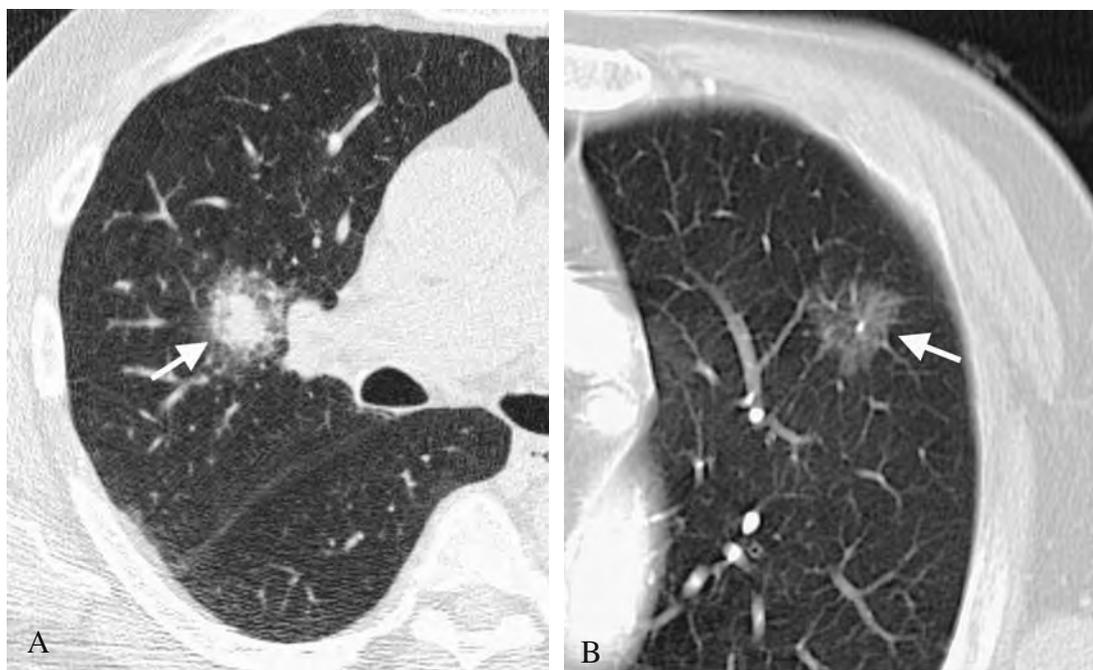

FIGURE 29.2. Axial CT images (lung window settings) show solitary pulmonary nodules in two different patients. (A) The solitary pulmonary nodule (*arrow*) in the right upper lobe demonstrates a mixed ground-glass and solid attenuation. (B) The solitary pulmonary

nodule (*arrow*) in the left upper lobe of a different patient shows a ground-glass attenuation nodule. The ground-glass attenuation is suggestive of a bronchioloalveolar cell histology.

ATELECTASIS AND POSTOBSTRUCTIVE PNEUMONITIS

Atelectasis results from endobronchial obstruction or extrinsic compression of a bronchus. Atelectasis is a common presenting appearance of squamous cell carcinoma.¹⁷ Two-thirds of squamous cell carcinomas arise within main, lobar, or segmental bronchi.¹⁸ Although the atelectasis is most often segmental, it may be lobar or may involve the entire lung.¹⁷ The chest radiograph may demonstrate secondary signs of volume loss, with shift of the mediastinum to the involved side and elevation of the diaphragm. The central mass is often obscured by the collapsed lung.

When the upper lobe is collapsed, the trachea is deviated to the affected side, and the ipsilateral hilum is retracted superiorly. In atelectasis of the right upper lobe resulting from bronchogenic carcinoma, the minor fissure is classically distorted into a reverse S, the "S" sign of Golden.¹⁹ The lateral aspect of the minor fissure migrates cephalad, whereas the medial aspect of the fissure is tethered beneath the central neoplasm.

In some patients, the obstructed lobe is filled with inflammatory debris, and the classic signs of volume loss are not present. In these patients, the opacified lobe represents postobstructive pneumonitis, in which air bronchograms are typically absent. This radiographic finding can help to differentiate postobstructive pneumonitis from infectious pneumonia.¹⁷ All cases of pneumonia occurring in adults should be followed radiographically to confirm resolution after antibiotic therapy and to exclude the presence of an underlying endobronchial lesion. Although squamous cell carcinoma is the neoplasm typically associated with lobar atelectasis, adenocarcinoma may also arise centrally. Enlarged hilar or mediastinal lymph nodes from any of the bronchogenic carcinomas, including both small cell and non-small cell, can extrinsically compress the bronchi and produce obstructive pneumonitis and atelectasis.

AIRSPACE OPACIFICATION

The radiographic appearance of airspace opacification, mimicking pneumonia, can be caused by bronchioloalveolar cell carcinoma (BAC), a subtype of adenocarcinoma. BAC may be either focal (nodular) or diffuse disease. The diffuse form includes lobar or segmental consolidation, as well as multiple poorly defined pulmonary nodules. The pneumonic appearance of BAC is unique to this neoplasm. A diagnosis of BAC should be considered when a peripheral pneumonia seen on chest radiographs fails to clear after antibiotic therapy.

The consolidative form of BAC is seen on CT images as peripheral, segmental, or lobar airspace opacification with air bronchograms (Figure 29.3). The CT angiogram sign was first described with BAC and was initially thought to be useful in the distinction of BAC from pneumonia.²⁰ The CT angiogram sign describes the CT appearance of enhancing pulmonary vessels within an area of homogeneously hypoattenuating pulmonary consolidation. Subsequent reports determined that the CT angiogram sign occurred in postobstructive pneumonitis and pneumonia as well and therefore, was not a useful discriminator for the consolidative form of BAC.^{21,22} Aquino et al. and Jung et al. determined several CT features that were significant in the differentiation of pneumonic-type BAC from pneumonia.^{23,24} Features that suggest BAC include

peripheral distribution, coexisting nodules, elongation and narrowing of the bronchi, widening of the bronchial angle, and bulging of the interlobar fissure.

PANCOAST TUMOR

Pancoast tumors make up less than 5% of all lung cancers. Their radiographic appearance and clinical presentation are unique. The tumor arises in the lung apex and typically involves, through direct extension, the parietal pleura and chest wall.²⁵ The clinical syndrome described by Pancoast results from invasion of the tumor into the lower trunks of the brachial plexus and sympathetic chain. Patients experience shoulder pain, which may radiate down the arm, with eventual numbness and weakness in the C8 and T1 distribution, and atrophy of the muscles of the hand. Horner syndrome occurs in 20% of patients with Pancoast tumors and is caused by invasion of the paravertebral sympathetic chain by the tumor.²⁵ The tumor may also invade the vertebral body and ribs.

A Pancoast tumor is suggested radiographically by a thickening of the pleura of at least 5 mm at the lung apex or by asymmetry of the apical caps of more than 5 mm.^{26,27} The tumor is sometimes detected when the lung apex is seen on images of the shoulder or cervical spine obtained to investigate a complaint of shoulder pain. Although Pancoast tumors can be visualized on axial CT images, MR imaging is the preferred modality.^{28,29} The coronal and sagittal planes of MR provide more accurate information for determining the extent of tumor invasion into the chest wall, including involvement of the brachial plexus, vertebral body, and neural foramen (Figure 29.4). MR angiography is complementary to MR imaging and can demonstrate displacement and encasement of the subclavian and brachiocephalic artery and vein.³⁰

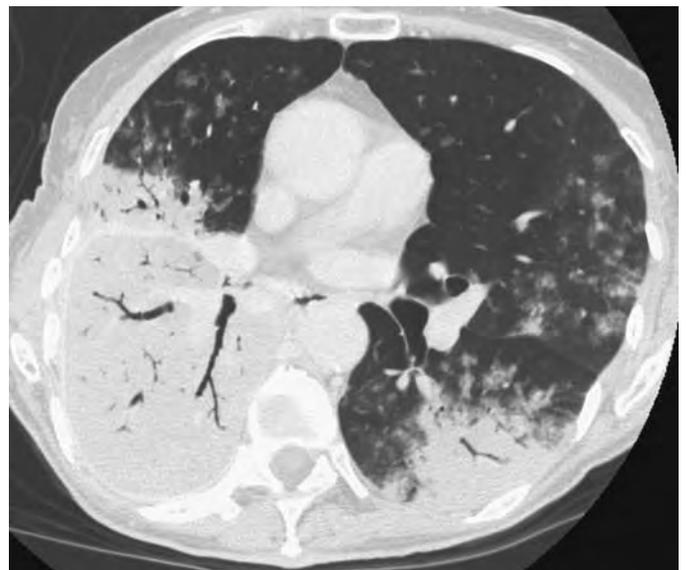

FIGURE 29.3. Axial CT (lung window settings) in a 63-year-old woman with the consolidative form of bronchioloalveolar cell carcinoma shows consolidation of the right lower lobe. The air bronchograms in the right lower lobe appear stretched. Focal areas of consolidation and ground-glass attenuation are also present in the right middle lobe, lingula, and left lower lobe.

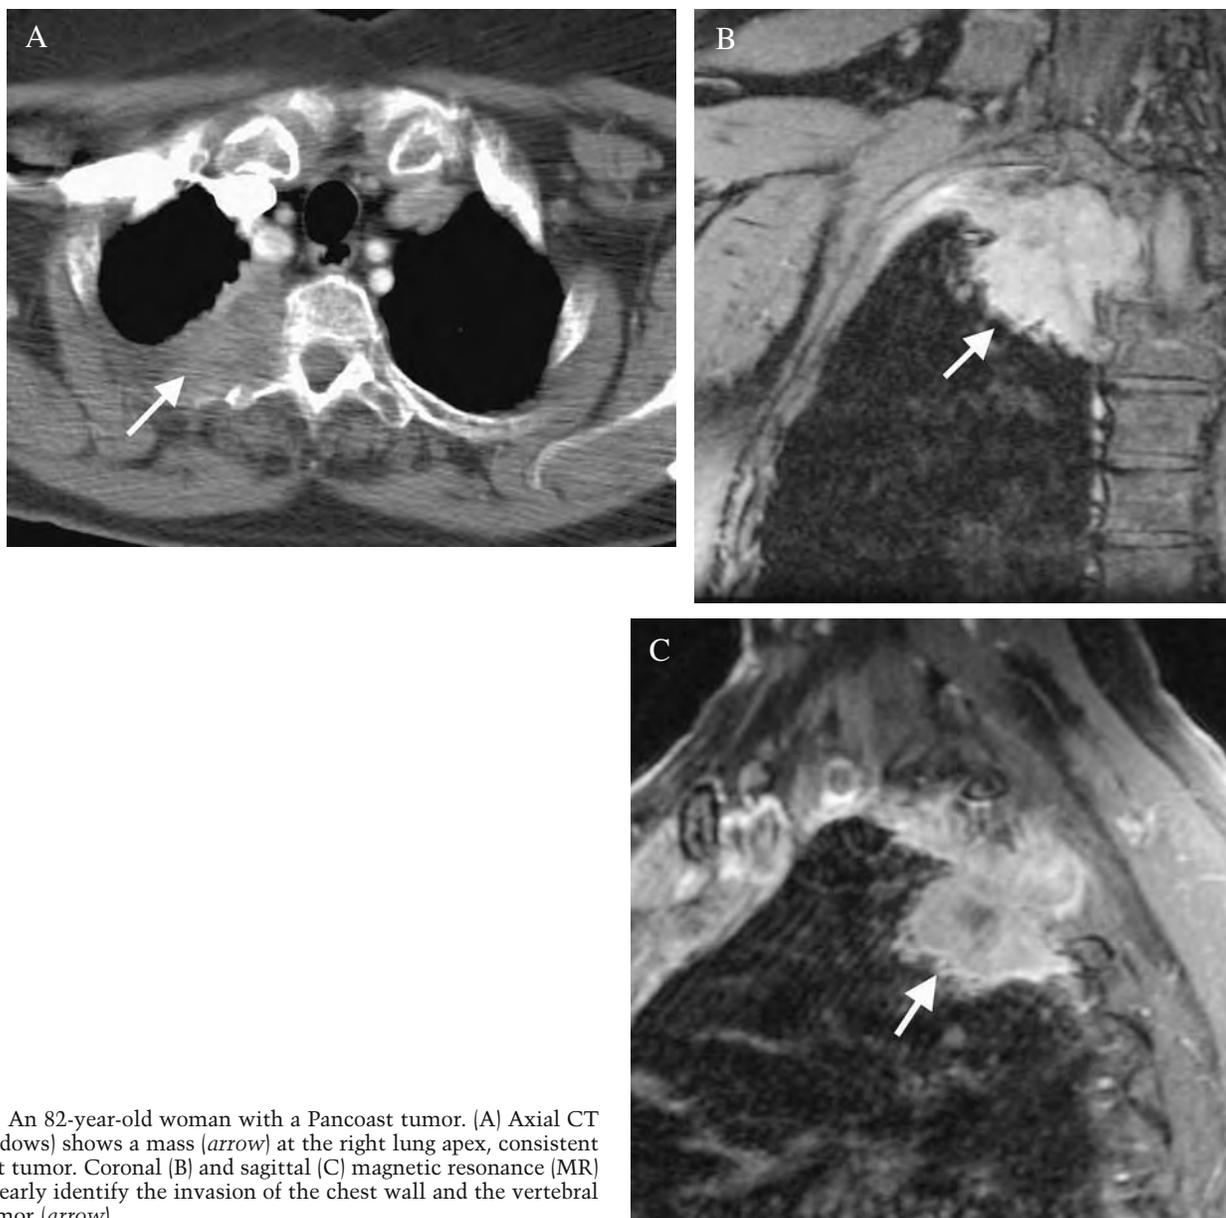

FIGURE 29.4. An 82-year-old woman with a Pancoast tumor. (A) Axial CT (soft tissue windows) shows a mass (*arrow*) at the right lung apex, consistent with a Pancoast tumor. Coronal (B) and sagittal (C) magnetic resonance (MR) images more clearly identify the invasion of the chest wall and the vertebral body by the tumor (*arrow*).

STAGING

IMAGING MODALITIES

Chest radiography remains the most frequently ordered radiographic examination. Its relatively low cost and widespread availability make it a very useful tool in the detection and diagnosis of thoracic disease. A chest radiograph with abnormal findings suggesting bronchogenic carcinoma typically prompts CT examination of the chest. The anatomic detail visible on CT images makes CT the examination of choice in such situations, as well as for patients with strong clinical evidence of thoracic disease despite normal chest radiographic results. CT is also useful to guide percutaneous transthoracic needle aspiration of thoracic masses. Although lacking the spatial resolution of CT, MR imaging allows imaging in coronal and sagittal planes and therefore is especially useful in the evaluation of patients with suspected invasion of the chest wall or diaphragm. In addition, MR

imaging can be helpful in evaluating mediastinal invasion and vascular involvement by tumor.

Positron emission tomography (PET) with fluorodeoxyglucose (FDG) uses the higher glucose consumption of hypermetabolic tumors to assist in differentiating between benign and malignant lesions and to determine the extent of disease. Because it relies on increased metabolism, FDG-PET imaging has improved the radiologic staging of lung cancer.³¹ Some of the limitations of PET, including spatial resolution and visual correlation with CT anatomy, are addressed in the newer dual PET/CT scanners. The addition of fusion imaging shows even better sensitivity and specificity for the detection of lymph node metastases and recurrent tumor.^{32,33}

PRIMARY TUMOR (T)

The high spatial resolution of CT makes it an excellent modality for assessing the size and extent of the primary

TABLE 29.1. TNM definitions.

T = primary tumor	
T1	Tumor less than or equal to 3 cm in greatest diameter, surrounded by lung or visceral pleura without bronchoscopic evidence of invasion more proximal than the lobar bronchus
T2	Tumor with any of the following: greatest diameter more than 3 cm; involvement of main bronchus, at least 2 cm distal to the carina; invasion of visceral pleura; atelectasis or obstructive pneumonitis extending to the hilum but without involvement of entire lung
T3	Tumor of any size that directly invades any of the following: chest wall (includes superior sulcus tumors), diaphragm, mediastinal pleura, parietal pericardium; Tumor in the main bronchus less than 2 cm distal to the carina but without involvement of the carina; Tumor with associated atelectasis or obstructive pneumonitis of the entire lung
T4	Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, esophagus, vertebral body, or carina; Tumor with a malignant pleural or pericardial effusion; Tumor with satellite tumor nodules in the ipsilateral primary-tumor lobe of the lung
N = regional lymph nodes	
N0	No regional lymph node metastasis
N1	Metastasis to ipsilateral peribronchial and/or hilar lymph nodes
N2	Metastasis to ipsilateral mediastinal and/or subcarinal lymph nodes
N3	Metastasis to contralateral mediastinal or hilar lymph nodes; metastasis to ipsilateral or contralateral scalene or supraclavicular lymph nodes
M = distant metastasis	
M0	No distant metastasis
M1	Distant metastasis present

tumor (T). The diameter of the tumor determines its categorization as T1 and T2 (Tables 29.1, 29.2). Nodules 3 cm or smaller in greatest dimension are classified as T1 tumors. Masses larger than 3 cm are considered T2 tumors. A lesion that measures 3 cm or smaller and involves a bronchus is classified as T1 if it does not extend more centrally than the lobar bronchus. T2 tumors can involve a main bronchus but must be at least 2 cm distal to the carina. The 2-cm distance allows a surgeon to clamp the bronchus at the time of lobectomy. A T1 tumor must be surrounded by lung or visceral pleura without invasion of the visceral pleura; a T2 tumor may invade the visceral pleura. Involvement of the visceral pleura is a difficult determination with any imaging modality, as the visceral and parietal pleurae are not readily distinguishable in the absence of pleural effusion or pneumothorax. Visceral pleural invasion is associated with a higher frequency of mediastinal nodal involvement and a poorer prognosis.^{34,35} T2 tumors may also be characterized by lobar collapse or post-obstructive pneumonitis extending to the hilum. T3 tumors are those that invade, by direct extension, the chest wall, diaphragm, mediastinal pleura, or pericardium. Endo-

bronchial tumors within 2 cm of the carina, but without involvement of the carina, are also classified as T3 tumors. Invasion of the chest wall can be evaluated with CT or MR imaging, although the patient's description of chest wall pain may be just as accurate as an indicator of chest wall invasion.^{36,37} CT criteria for chest wall invasion include rib destruction, contact of 5 cm or more with the chest wall, obtuse (greater than 90°) angle of the mass with the chest wall, increase in attenuation of the subpleural fat plane, and visualization of tumor in the intercostal space or deeper chest wall tissue.^{36,38-41} When chest wall invasion is suggested on CT images, thin-section CT or MR imaging may be helpful. Uhrmeister et al. acquired 1-mm collimation CT images to evaluate 39 patients who had tumor contact with the chest wall and who underwent surgical exploration. Soft tissue invasion and abnormalities in the fat plane were more accurately identified on 1-mm CT images reconstructed by means of a standard soft tissue algorithm than with 10-mm collimation.⁴²

On MR images, the most accurate indicator of parietal pleura invasion is signal intensity within the parietal pleura that is identical to that of tumor on T₁-weighted images.³⁷ This sign was present in 17 of 20 patients with chest wall invasion, with no false-positive errors, for an overall accuracy of 91%. In this series, Padovani et al. found that T₂-weighted images and gadolinium-enhanced T₁-weighted images provided no additional information.³⁷ Shiotani et al. recommended breathing dynamic echoplanar MR imaging of the thorax to look for movement of the tumor against the pleura or fixation of the tumor to the chest wall.⁴³ Sakai et al. pointed out, however, that benign pleural adhesions cannot be distinguished from chest wall invasion on MR images.⁴⁴

T4 tumors are the most extensive, invading the mediastinum, heart, great vessels, trachea, esophagus, vertebral body, or carina. The presence of a malignant pleural effusion indicates a T4 tumor. Satellite tumor nodules within the same lobe as the primary lesion are also categorized as T4

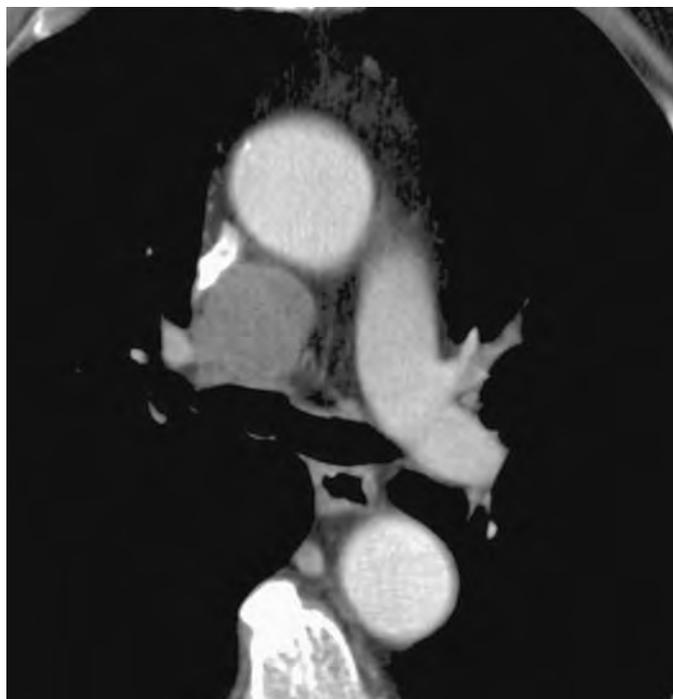

FIGURE 29.5. Axial CT (soft tissue window). A right lower paratracheal node is greater than 1.0 cm in short axis, meeting the CT criterion for abnormality.

disease. Surgical treatment is not appropriate for T4 tumors, which are considered stage IIIB or stage IV disease, depending on the presence or absence of distant metastases.

NODAL INVOLVEMENT (N)

The most widely used CT criterion for the evaluation of hilar and mediastinal lymph nodes is the short-axis diameter. Lymph nodes larger than 1 cm in the short axis on axial CT images are considered abnormal; lymph nodes with diameters up to and including 1 cm are considered normal (Figure 29.5). Because normal-sized lymph nodes can harbor microscopic metastases, CT results can be falsely negative. Conversely, lymph nodes that are enlarged because of inflammatory disease can lead to a false-positive interpretation. In 2003, Toloza et al. published a meta-analysis of 20 studies comparing CT with mediastinoscopy in the staging of lung cancer. The data pooled from a total of 3,438 patients suggest that CT for staging mediastinal disease has a sensitivity of 57%, specificity of 82%, positive predictive value of 56%, and negative predictive value of 83%.⁴⁵ These investigators concluded that, despite a decade of advances in CT technology, the accuracy of CT scanning for staging mediastinal disease was not significantly better than results reported in a meta-analysis by Dales et al. in 1990.^{45,46} These limitations notwithstanding, CT remains valuable in that it can guide the selection of nodes for mediastinoscopy or transbronchial needle aspiration.

In 2003, Gould et al. published a meta-analysis of 39 studies that were reported between 1994 and 2003, evaluating FDG-PET for mediastinal lymph node staging in patients with known or suspected non-small cell lung cancer. They determined that PET with 18-FDG was more accurate than CT for mediastinal staging.⁴⁷ The median sensitivity and specificity of CT for identifying mediastinal nodal (N2 and

N3) disease were 61% and 79%, respectively, whereas median sensitivity and specificity were 85% and 90%, respectively, for PET. When CT showed enlarged lymph nodes, PET was more likely to yield both true positives and false positives. False-positive PET interpretations most commonly occur when acute inflammation is present within lymph nodes, particularly in patients with sarcoidosis, silicosis, and tuberculosis.⁴⁸⁻⁵⁰ False-positive PET results can also occur when there is direct extension of the primary tumor into the mediastinum, as nodal glucose uptake contiguous with the primary lesion may not be distinguishable from direct tumor extension into the node.⁵¹ False-negative interpretations of PET scans can occur as a result of misalignment of the PET findings to the American Thoracic Society (ATS) nodal map, so that FDG uptake is not localized correctly.^{49,52} Other false negatives with PET scan interpretation are due to small malignant lymph nodes that are below the spatial resolution limits of the scanner or enlarged lymph nodes with subtotal tumor replacement.^{49,51} Cerfolio et al. reported that false-negative FDG-PET results were most common in evaluating the subcarinal (ATS station 7) and aortopulmonary window (ATS stations 5 and 6) nodal stations.⁵³

Positive findings on PET studies should be confirmed by biopsy. Some authors believe that negative findings on PET studies should be considered in light of the patient's pretest probability of mediastinal metastasis and whether enlarged mediastinal nodes are demonstrated by CT.⁴⁷ Graeter et al. reported a negative predictive value of 98.4% in their series and suggested that the negative predictive value of PET is sufficient to omit mediastinoscopy.⁴⁸ The American Society of Clinical Oncology (ASCO) recommends biopsy of lymph nodes that are either greater than 1.0 cm in short axis on CT or positive on PET scanning (Figure 29.6). Their 2003 recom-

FIGURE 29.6. A 60-year-old man with non-small cell lung cancer. Coronal reconstruction of a positron emission tomography (PET) scan shows increased uptake within the primary tumor (*arrow*) as well as ipsilateral hilar and mediastinal lymph nodes (*curved arrow*).

recommendations are that a lymph node that is enlarged on CT should still undergo biopsy even if the FDG-PET scan is negative.⁵⁴

Staging is also more accurate with PET than with CT for predicting the likelihood of long-term survival.^{55,56} Dunagan et al. suggested that staging with PET may prove especially worthwhile in patients with comorbid illnesses or poor functional status, in whom the risk from invasive diagnostic procedures or surgery is accelerated.⁵⁵

Some of the errors encountered in visual correlation of PET and CT images can be altered with coregistration of CT and PET data sets.^{32,57,58} A dual PET/CT scanner allows precise coregistration of the functional images of PET with the anatomic images of CT.⁵⁹ Antoch et al. reported a slight, but not statistically significant, improvement in the assessment of lymph node involvement with dual PET/CT when compared with PET.⁶⁰ The positive and negative predictive values were 89% and 94%, respectively, for dual PET/CT, 80% and 94% for PET, and 50% and 77% for CT. Lardinois et al. found that nodal staging with integrated PET/CT was significantly more accurate than with PET alone. Integrated CT-PET provided additional information in 20 (41%) of 49 patients with non-small cell bronchogenic carcinoma beyond that provided by conventional visual correlation of PET and CT.³²

SMALL CELL LUNG CANCER

Because of its rapid growth and early metastatic spread, small cell lung carcinoma is considered separately from non-small cell carcinoma. One in seven patients with lung cancer has small cell lung cancer. In 2000, the age-adjusted incidence of small cell lung cancer in the United States was 8.6 cases per 100,000 population, whereas the incidence of non-small cell lung cancer was 53.8 cases per 100,000.⁶¹ The typical radiographic appearance of small cell lung cancer is that of a hilar or perihilar mass, which may represent a combination of the primary tumor and lymphadenopathy, and bulky mediastinal lymphadenopathy. Tracheobronchial and vascular compression are often present. Bronchial compression is frequently associated with obstructive atelectasis, which is demonstrated radiographically in 22% of patients.⁶² Although chest radiography and CT suggest complete compression of the bronchus, bronchoscopy usually demonstrates a detectable lumen.⁶² Small cell lung cancer is the most common primary tumor to cause superior vena cava syndrome, which results from mass effect on the superior vena cava, brachiocephalic veins, or both. The enlarged lymph nodes may also compress the pulmonary artery, producing oligemia in the involved lung.

The Veterans Administration Lung Cancer Study Group recommended a two-stage system for lung cancer: limited stage, which includes tumor that is confined to the thorax and can be encompassed in a tolerable radiation field, and extensive stage, which extends beyond those confines. A majority of patients (65% to 90%) have extensive-stage disease at presentation. Use of the TNM system has been recommended for those few patients with small cell lung cancer that is potentially surgically resectable. The clinical staging of small cell lung cancer focuses on the most common sites of metastatic disease: the liver, adrenal glands, retroperitoneal lymph nodes, brain, skeleton, and bone marrow. Staging with MR imaging or CT of the brain and abdomen, radionuclide bone scan, and bone marrow aspiration is routine, as patients

may have distant metastases without clinical signs or symptoms. PET scanning may prove to be a worthwhile replacement for this combination of studies. FDG-PET imaging was compared with the sum of other staging procedures in 30 patients with histologically proven small cell lung cancer.⁶³ FDG-PET and the conventional staging system showed identical results in 23 of 36 examinations. Discordant results were observed in the examinations of 5 patients, but the overall staging of limited versus extensive disease was not affected. A retrospective analysis of PET in 46 patients with both treated and untreated small cell lung cancer demonstrated that PET had prognostic value.⁶⁴ Overall survival rates were significantly lower in patients with positive PET results than in those with negative PET results. Survival also showed a significant negative correlation with the maximum standardized uptake value (SUV).

Small cell lung cancer is somewhat unusual in its rapid response to therapy. Within 1 month of initiation of therapy, follow-up chest radiographs show a decrease in mediastinal and hilar lymphadenopathy and often return to their normal baseline appearance. In patients with obstructive atelectasis at presentation, partial or complete reexpansion of the lung is evident radiographically in 85% of patients within 1 month of initiation of therapy.⁶² Contrast enhancement of the mediastinal lymph nodes on CT images has been suggested as predictive of response to chemotherapy. Enhancement of the nodes by 30 Hounsfield units (HU) or more predicted a reduction of at least 80% in tumor volume.⁶⁵ PET may also provide prognostic information in follow-up of treated patients with small cell lung cancer.⁶⁴ Routine radiographic follow-up is not currently recommended, however, to detect recurrence in these patients. Recurrences are signaled by clinical histories in 71% of patients and by chest radiographs in only 12%.⁶⁶

CARCINOID

Bronchial carcinoid is a neuroendocrine neoplasm with behavior that can vary from that of a low-grade typical carcinoid to a more aggressive atypical carcinoid. Pulmonary carcinoid tumors account for 1% to 2% of all lung neoplasms. The patient with carcinoid tumor is usually symptomatic, typically in the fifth decade of life, and likely to describe symptoms related to bronchial obstruction such as cough, hemoptysis, dyspnea, or recurrent pneumonia.^{67,68} Chest radiographs may show signs related to the bronchial obstruction, including lobar atelectasis, or postobstructive pneumonitis.^{69,70} Bronchial obstruction may also produce hypoxic vasoconstriction of the affected lung, resulting in a hyperlucent, oligemic appearance.⁶⁹ A hilar or perihilar mass may also be visible radiographically. With CT, the tumor can be localized within a lobar, segmental, or large subsegmental bronchus. Volume loss of the lobe or lung segment is characterized by displacement of fissures and crowding of the bronchi and pulmonary vessels. In many patients, post-obstructive pneumonitis predominates, with consolidation of the lung and little evidence of volume loss. The presence of air-trapping can facilitate recognition of an endobronchial lesion. Air-trapping is usually visible on inspiratory images but is more marked on images obtained in expiration. Mucoid impaction may also be seen distal to the endobronchial obstruction, signaled by the gloved-finger appearance of mucus-filled bronchi. On noncontrast-enhanced CT images, calcification may be seen within the carcinoid tumor. CT

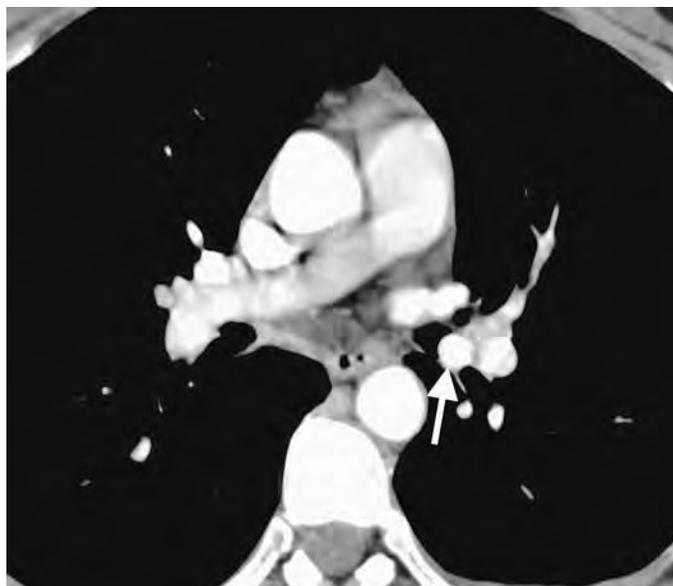

FIGURE 29.7. A 44-year-old woman with atypical chest pain and cough. Axial chest CT (soft tissue window) shows an intensely enhancing nodule in the left lower lobe bronchus (*arrow*) that proved to be typical carcinoid at resection.

demonstrates calcification in 43% of central carcinoids but in only 10% of peripheral carcinoids.^{71,72} Because of their vascular nature, carcinoid tumors often enhance intensely after the intravenous administration of contrast material. The enhancement can be so intense that the tumor is mistaken for a vascular abnormality, such as a pulmonary varix or an arteriovenous malformation (Figure 29.7).⁷³

One third of patients with carcinoid tumors are asymptomatic, and a solitary peripheral pulmonary nodule or mass is discovered incidentally on a chest radiograph. These patients are typically a decade older than symptomatic patients with a central carcinoid tumor. Peripheral carcinoids are usually round or ovoid, with smooth, lobulated margins. The size of these tumors ranges from 1 to 10 cm.⁷⁴ Peripheral

carcinoids are occasionally multiple; a larger tumor may be accompanied by one or more tumorlets. The peripheral carcinoid is likely to be found in the right upper lobe, right middle lobe, or lingula. On CT images, the peripheral carcinoid is of homogeneous attenuation. On MR images, bronchial carcinoids have high signal intensity on T₂-weighted images and short-inversion-time inversion recovery images.⁷⁵

Erasmus et al. reported PET imaging of seven carcinoid tumors, including three central endobronchial lesions, three peripheral pulmonary nodules (1.5–3.0 cm), and one 10-cm lung mass.⁷⁶ The endobronchial lesions had SUV measurements of 1.6 to 2.3 and were indistinguishable from mediastinal activity. SUVs were 2.2 to 2.4 in the peripheral nodules and 6.6 in the large lung mass. Currently, PET imaging is not useful in distinguishing carcinoid tumors from benign nodules.

Although the histologic distinction between typical and atypical carcinoid is important for therapeutic decisions and prognosis, no radiographic features distinguish the two.⁷⁷ Both typical and atypical carcinoid tumors can metastasize to regional lymph nodes or to distant sites, including liver, bone, and skin. Hilar and mediastinal lymph node enlargement can be readily identified with CT. CT is also superior to imaging with radiolabeled somatostatin analogues (¹²³I-Tyr-3-octreotide) in the detection of metastases from carcinoid tumors.⁷⁸

Tumors of the Pleura

Malignant Mesothelioma

According to Kawahima and Libshitz, who evaluated the CT scans of 50 patients with malignant pleural mesothelioma (MPM), the most common finding on CT is pleural thickening (92%), followed by tumor involvement of the interlobar fissures (86%) and pleural fluid (74%) (Figure 29.8).⁷⁹ Similar findings were reported by Metintas et al., who found a rind-

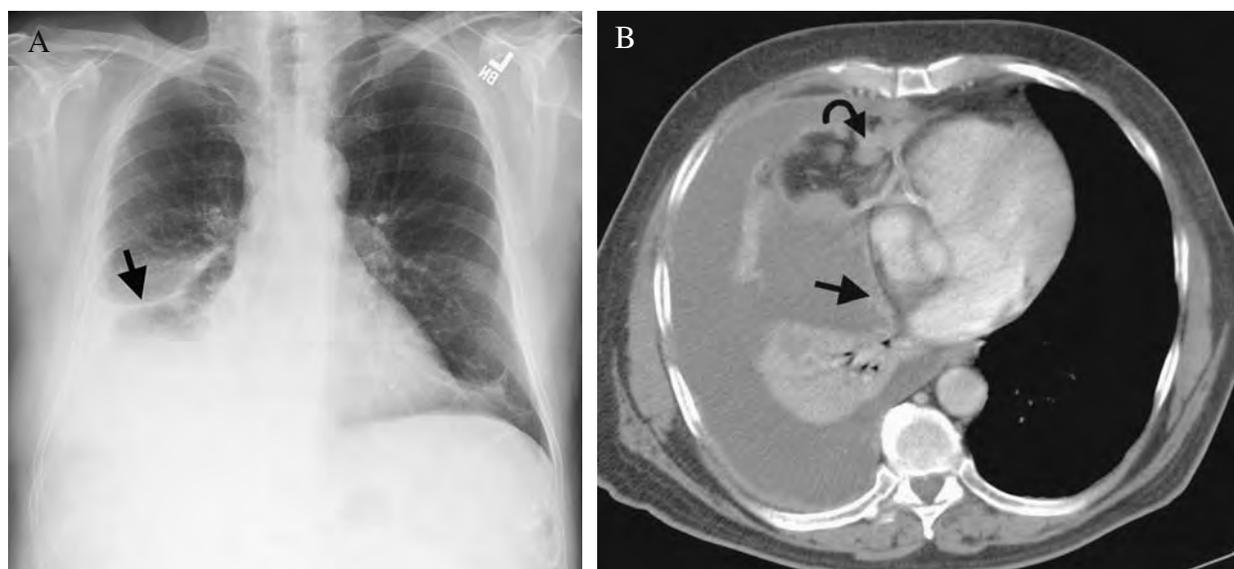

FIGURE 29.8. A 70-year-old man with malignant mesothelioma. (A) Initial chest radiograph shows an asymmetric right pleural effusion that extends into the minor fissure (*arrow*). (B) CT scan shows

irregular thickening and enhancement of the parietal pleura (*arrow*), including the mediastinal pleura. The lymph nodes in the paradiaphragmatic fat are enlarged (*curved arrow*).

like extension tumor on the pleura in 70% of the 99 patients they imaged with MPM.⁸⁰ Other findings suggesting MPM were multiple nodules encasing the lung, pleural thickening with an irregular pleuropulmonary margin, and pleural thickening with superimposed separate nodules. However, these findings were also seen with metastatic pleural disease, which was frequently indistinguishable. Rindlike thickening and thickness greater than 1 cm strongly suggested MPM, but other sources for pleural malignancy should be considered.

Knuutila et al. reported that MR imaging was superior to CT in evaluating MPM. They found that MR imaging improved the detection of tumor involvement in the interlo-

bar fissures, diaphragm, peritoneum, and bony structures (Figure 29.9). The two modalities were equal, however, in detecting invasion of the chest wall, mediastinum, and adjacent lung.⁸¹ In a separate report, Knuutila et al. found that contrast-enhanced T₁ fat-suppression was the most useful sequence for displaying invasion of adjacent anatomic structures, including the diaphragm, lung, mediastinum, pericardium, chest wall, and skeleton by mesothelioma, as well as pleural metastases.⁸²

Heelan et al. also found MR imaging superior to CT in displaying tumor involvement in the diaphragm and chest wall (as extension through endothoracic fascia or solitary

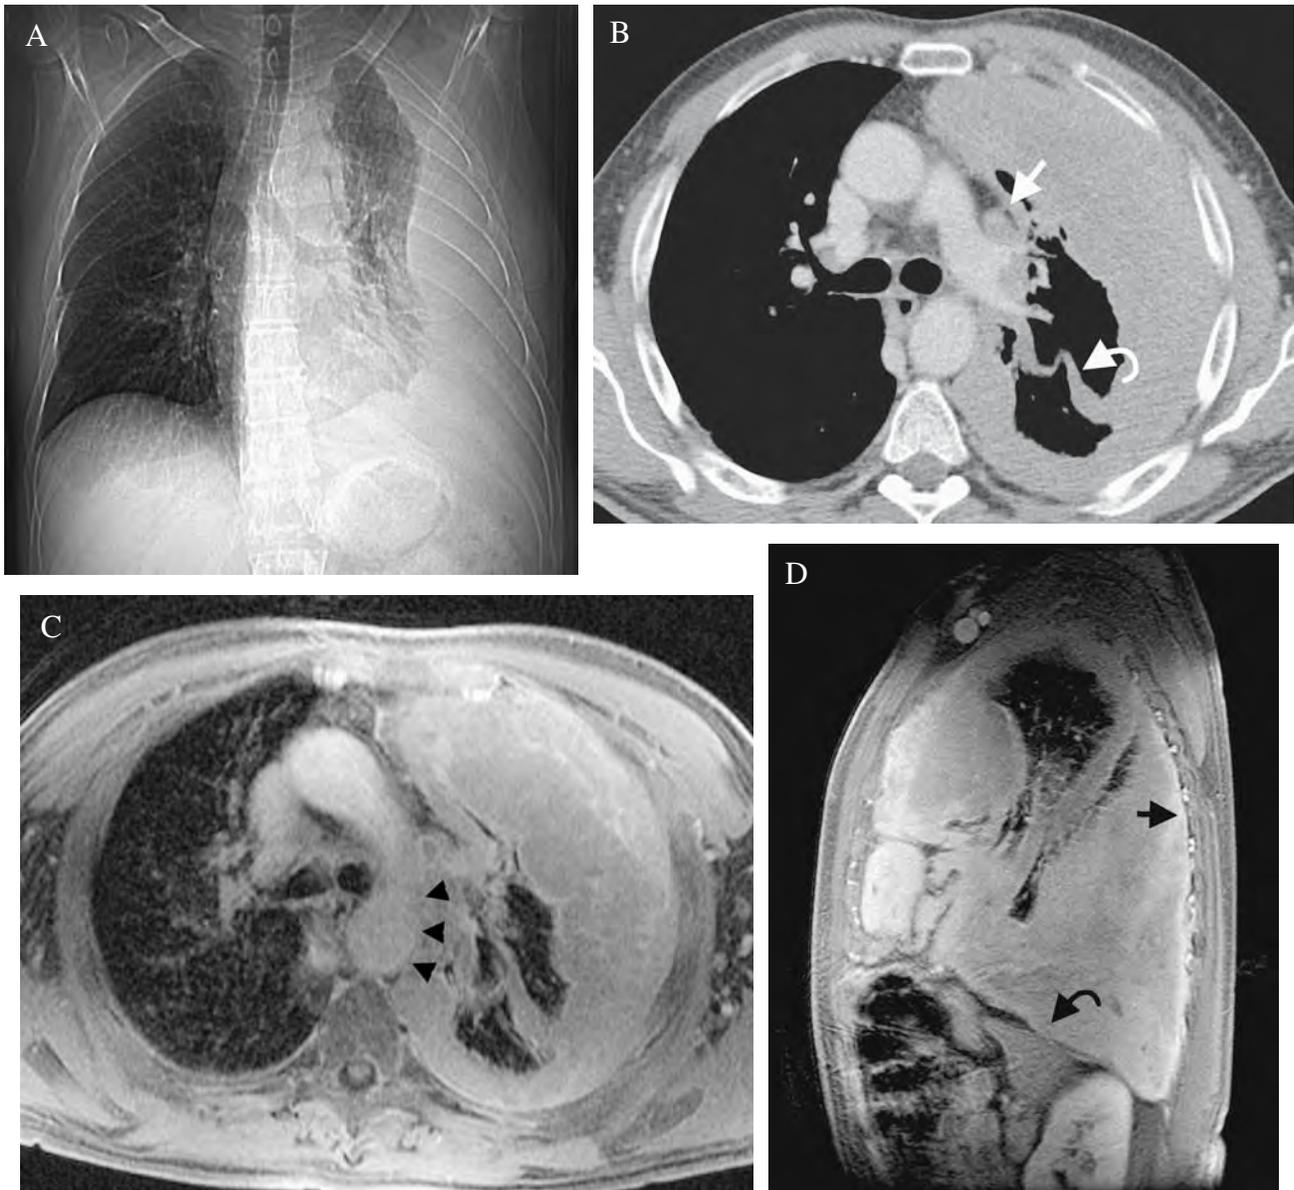

FIGURE 29.9. A 52-year-old man with malignant mesothelioma. (A) Chest radiograph shows loculated pleural effusion in left pleural space with compression of the left lung medially. (B) CT scan of the thorax with intravenous contrast shows large soft tissue mass in the pleural space that involves the pleura along the mediastinum (*arrow*) and fissure (*curved arrow*). (C) T₁-weighted MR image with fat saturation

following gadolinium administration shows no evidence for chest wall invasion, although mediastinal fat planes are obliterated (*arrowheads*). (D) Sagittal image of same sequence shows diffuse pleural tumor that involves the pleura (*arrow*). The mass displaces the diaphragm inferiorly without invasion (*curved arrow*).

chest wall foci).⁸³ The difference between CT and MR imaging in detecting visceral pleural tumor, invasion of lung, and mediastinal and pericardial involvement was not statistically significant. Therefore, CT is recommended as the standard diagnostic choice and MR imaging as an additional study in patients for whom diaphragmatic and chest wall invasion is highly probable.

As with most malignant diseases in the thorax, FDG-PET has shown improved sensitivity in detecting MPM; however, limitations arise with the false detection of tumor in patients with benign inflammatory pleural disease and infection.^{84,85} Sensitivity in the detection of tumor as areas of increased uptake in pleural thickening and nodules identified on CT ranges from 91% to 100%. Although PET is sensitive in detecting tumor, Flores et al. found PET limited in specific tumor and local nodal staging; sensitivities were 19% and 11%, respectively.⁸⁶ However, they concluded, as did Gerbaudo et al., that FDG-PET is very helpful in detecting distant metastases in supraclavicular lymph nodes and abdomen that were not identified with CT.^{85,86}

Metastatic Disease to the Thorax

PULMONARY METASTASES

Radiologic applications for imaging of metastases are useful in initial staging as well as assessment of a patient's response to neoadjuvant therapy for restaging before planned definitive surgical treatment and follow-up imaging for tumor recurrence. CT has evolved as the routine choice in staging, restaging, and detection of recurrence. Its superior anatomic resolution, combined with widespread availability and applications, contributes to its popularity. CT is superior to chest radiography for the detection of pulmonary metastases, although with limitations. Because of its excellent spatial resolution, CT demonstrates small lesions that mimic metastatic foci but are frequently benign. Limitations come into play especially in the initial diagnosis of patients with extrathoracic malignancies and no prior radiographic studies to document preexisting parenchymal disease.⁸⁷ For instance, although Chalmers and Best found pulmonary nodules on CT in 20% of patients with extrathoracic malignancies and normal chest radiographs, 80% of these nodules were benign.⁸⁸ Similar results were found by Kronawitter et al., who found, in routine preoperative workup for liver metastectomy in patients with colon cancer, that the majority of nodules seen on chest CT images were benign.⁸⁹ Only 5% of patients had true metastases. Pivoski et al. reported that CT demonstrated pulmonary metastases in 4 of 100 patients with colon cancer whose results on chest radiographs before hepatectomy were normal.⁹⁰ Picci et al. reported that, in 51 children with osteosarcoma, CT was sensitive but not specific in detecting pulmonary metastases.⁹¹ They found, however, that the likelihood of metastases increased with the number of nodules detected. Four of 13 patients with a single nodule had a true metastasis. All patients with more than seven nodules had metastases.

Other reports have demonstrated that the stage of an extrathoracic malignancy should be considered when determining whether CT should be included in the workup.⁹²⁻⁹⁴ Lim and Carter found that the detection of metastases from renal cell carcinoma with CT was low, especially with small

primary tumors.⁹³ With increasing tumor stage or with the demonstration of a nodule on a radiograph, however, they found CT more useful in detecting pulmonary metastases. Similarly, Heaston et al. reported that CT improved the detection of metastases in patients with locally advanced melanoma, as well as helping to identify extrapulmonary metastases.⁹⁵ Reiner et al. found that routine chest CT was essential in the management of newly diagnosed squamous cell carcinoma of the head and neck.⁹⁶ In 66 of 189 patients, CT demonstrated significant abnormalities, whereas only 23% were detected on chest radiographs. Thirty-six patients had 41 tumors, of which 13 were additional primaries and 28 were metastases. Conventional radiographs showed only 12 (29%) of these tumors. Reiner and colleagues therefore recommended routine thoracic CT before treatment for this patient population, which has a significant cigarette-smoking history and risk for bronchogenic carcinoma.

In the follow-up management of patients who have been treated for cancer and who undergo surveillance for recurrence, CT is very useful for detecting new pulmonary metastases.⁸⁹ Follow-up CT imaging to detect early metastases can improve survival rates for patients with certain malignancies, such as sarcomas and colon cancer.^{91,97,98}

Most pulmonary metastases reach the lungs through the pulmonary arterial system.⁹⁹⁻¹⁰¹ The most common manifestation of pulmonary metastases is multiple nodules.^{99,100,102,103} Association of a nodule with a pulmonary vessel, the "mass-vessel sign" on high-resolution CT (HRCT), has been correlated with a hematogeneous origin.¹⁰¹ Although pulmonary metastases are generally multiple, a few tumors can manifest with a single pulmonary metastasis.^{95,104} Metastatic nodules can range from miliary to several centimeters in size. Miliary nodules are more likely to occur in association with tumors, such as thyroid carcinoma, renal cell carcinoma, and melanoma.^{105,106} Their distribution with respect to the interstitial compartments is typically random.^{107,108} Larger nodules are more likely to be seen with sarcomas and tumors from the colon and kidney. Metastases can be characterized not only by size but also by density and composition. For instance, metastases may have a solid, ground-glass, or mixed solid and ground-glass appearance. Others can calcify or cavitate.

Ground-glass nodules or nodules with surrounding ground-glass opacities are consistent with either hemorrhage or airspace disease into the adjacent lung (Figure 29.10). Metastatic nodules with surrounding hemorrhage have been described with choriocarcinoma, melanoma, renal cell carcinoma, angiosarcoma, and Kaposi's sarcoma.¹⁰⁹⁻¹¹¹ Bronchioloalveolar cell carcinoma nodules may have a ground-glass appearance or may have a surrounding ground-glass pattern.¹¹² This pattern has been attributed to lining of adjacent airspaces by tumor through a lepidic growth pattern or to filling of airspaces with mucinous material.¹¹³ Nonmalignant processes with similar patterns may mimic metastases and should be included in the differential diagnosis. Infections, such as viral pneumonias, tuberculosis, fungal infections including invasive aspergillosis, arteriovenous malformations, and Wegener granulomatosis with local hemorrhage, can be very similar in appearance.^{109,112}

The diagnosis of calcified metastases is straightforward when new nodules develop in a patient with osteosarcoma (Figure 29.11) or chondrosarcoma. However, in the absence of

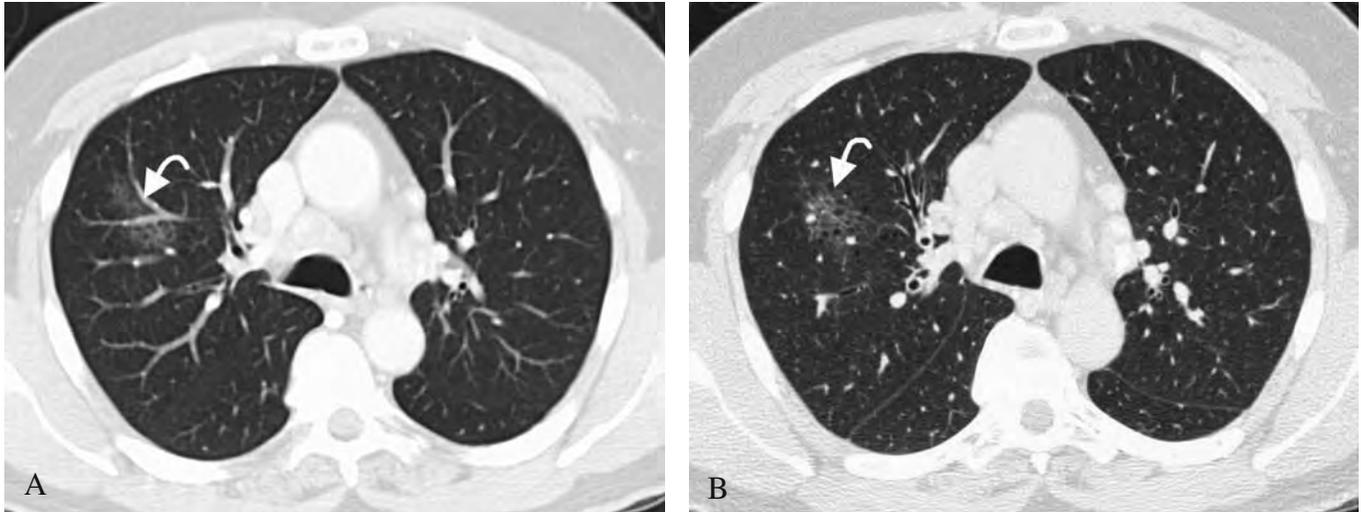

FIGURE 29.10. A 72-year-old man with history of metastatic melanoma involving the lungs. (A) CT scan image in lung windows at 5-mm slice thickness shows one of multiple ground-glass foci in

the lungs (*curved arrow*). (B) High-resolution image at 1.25-mm slice thickness better displays the ground-glass (*curved arrow*) and associated thickened interlobular septa.

prior radiographs to show that a nodule is new, other considerations should include granuloma, amyloid, or hamartoma. Metastatic mucinous adenocarcinoma originating from the pancreas, small bowel, or ovary; thyroid carcinoma; and on rare occasions soft tissue sarcomas and choriocarcinoma may also contain calcifications.¹¹⁴⁻¹¹⁹

Multiple cavitary metastases are more likely to result from squamous cell carcinoma but may also be seen with transitional cell carcinoma, adenocarcinoma, sarcoma, and lymphoma.¹²⁰⁻¹²⁵ Cavitation of metastases may be seen before therapy but may also reflect response after chemotherapy (Figure 29.12).^{122,126} The initial finding of multiple cavitary

nodules does not necessarily suggest tumor.¹²⁷⁻¹²⁹ Inflammatory disease, such as Wegener granulomatosis, rheumatoid arthritis, eosinophilic granulomatosis, and amyloid, may be characterized by numerous cavitary nodules. Pulmonary infections, such as fungal infection, mycobacterial disease, septic emboli, and tracheobronchial papillomatosis, should also be considered.

Tumor emboli are the result of hematogenous metastases that occlude and enlarge within the pulmonary arteries. On CT images they appear as branching lobulated enlargement of the small- to medium-sized vessels (Figure 29.13).¹³⁰ This unusual pattern of metastasis is seen with tumors that spread hematogenously, such as sarcoma, renal cell carcinoma, hepatoma, and melanoma. Distal infarction may result, with distal ground-glass pattern or consolidation.^{130,131} Microscopic emboli, which may manifest as idiopathic cor pulmonale, are rare complications associated with tumors from the breast, liver, and gastrointestinal tract. Frequently, the lungs are clear on chest radiographs and CT images.¹⁰⁸ On rare occasions, CT may show evidence of interstitial disease consistent with associated lymphangitic involvement.¹³² Angiography results may be normal or may show delayed vessel filling.¹³³ Ventilation-perfusion scanning may demonstrate multiple subsegmental perfusion defects.^{133,134}

ENDOBONCHIAL METASTASES

Endobronchial obstruction of an airway by metastasis is rare; the reported incidence is 2%.¹³⁵ The most common tumor to metastasize to the airways is renal cell carcinoma.^{125,136,137} Other tumors that spread to the airways include melanoma, lymphoma, and tumors of the breast, larynx, thyroid, and colon.^{125,135-138} Patients with tumor involving the airways frequently have metastases to other areas of the thorax, including the lymph nodes and pulmonary parenchyma.¹³⁶ The proximal airways, rather than the small airways, are generally involved. Complete occlusion results in mucous filling of the distal occluded airways. On CT images, these occluded airways appear as arborizing opaque structures that are separate from the vasculature. Called the *finger-in-glove sign* on

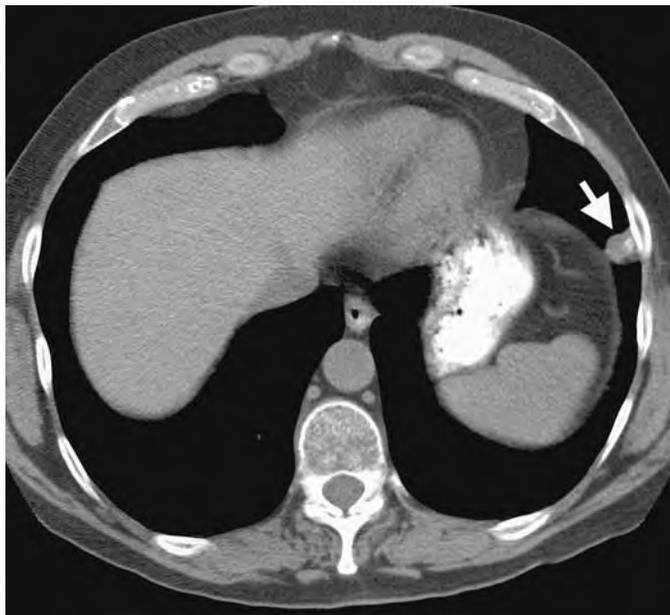

FIGURE 29.11. A 19-year-old man with history of osteosarcoma of the femur. CT scan of the thorax in soft tissue windows shows a pulmonary nodule (*arrow*) with central calcification that was a metastasis on resection.

FIGURE 29.12. A 55-year-old man with pharyngeal carcinoma of the lungs. (A) CT scan in lung windows demonstrates multiple pul-

monary metastases (arrows). (B) Following chemotherapy, CT scan shows interval decrease in size of the nodules with cavitation (arrow).

chest radiographs, the branching plugged airways resemble white-gloved fingers. If airway plugging extends into the subpleural distribution, a tree-in-bud pattern can be seen.

LYMPHANGITIC CARCINOMATOSIS

Lymphangitic tumor involvement of the lungs predominantly affects the pulmonary lymphatics and the investing perilymphatic connective tissue. The patterns most frequently described on HRCT are thickened interlobular septae and bronchovascular interstitium, reticular lines, and polygonal structures.^{139,140} Thickened interstitial compartments can be smooth or nodular.^{140,141} A smooth pattern may be the result of direct tumor infiltration in the interstitium and lymphat-

ics or of interstitial edema from a more proximal tumor of the lymphatics (i.e., with hilar or mediastinal lymphadenopathy).^{142,143} Nodular lymphangitic disease is more indicative of direct tumor deposition in the interstitium (Figure 29.14). Malignancies commonly associated with a lymphangitic carcinomatosis pattern in the lungs include adenocarcinoma from lung, breast, and gastrointestinal tract, melanoma, lymphoma, and leukemia.^{108,142-145} Disease may initially reach the lungs by either embolic spread or direct extension from hilar lymphatic disease.^{132,146} On chest radiographs the pattern frequently resembles edema, with thickening of the perihilar bronchovascularity and subpleural Kerley B lines (see Figure 29.14). Frequently, however, the distribution is asymmetric and therefore suggestive of neoplasm. Alternatively, if a patient appears febrile, a lobar or segmental pattern may mimic pneumonia.

CT and HRCT are more sensitive and specific in identifying lymphangitic involvement. However, Hirakata et al. showed that detection of pulmonary involvement with HRCT is limited in comparison to that of histopathology.¹⁰⁸ Interstitial involvement can extend from the perihilar axial interstitium to the subpleural interlobular septa and also may involve the subpleural interstitium leading to thickened fissures.^{143,147} Johkoh et al. correlated HRCT findings to those of histopathology and found that the distribution in most patients with lymphangitic carcinomatosis was in the perihilar axial interstitium.¹⁴⁷ Other interstitial diseases may resemble lymphangitic carcinomatosis, including sarcoidosis and lymphoma. The distribution of disease and pattern of associated nodules may help to distinguish between disorders. Honda et al. found that lymphangitic carcinomatosis tended to involve the subpleural interstitial spaces, whereas sarcoidosis tended to be more symmetric and to occur in the upper lungs.¹⁴⁸

METASTASES OF MIXED PARENCHYMAL PATTERNS

Lymphoma involvement of the lungs may be mixed, manifesting as a combination of consolidative, nodular, or interstitial involvement (Figure 29.15).¹⁴⁴ The latter form

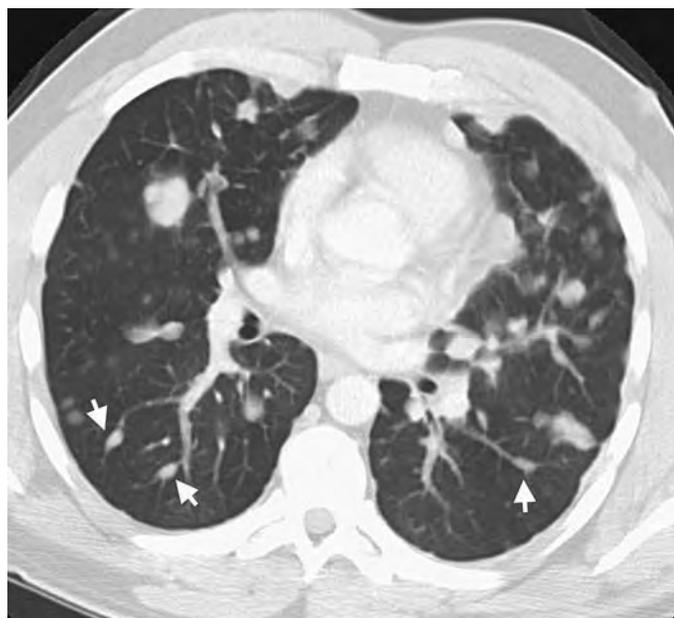

FIGURE 29.13. A 24-year-old man with metastatic soft tissue sarcoma, axial chest CT (lung windows). Some of the nodules appear as focal symmetric enlargement of the small pulmonary arteries (arrows) consistent with tumor emboli.

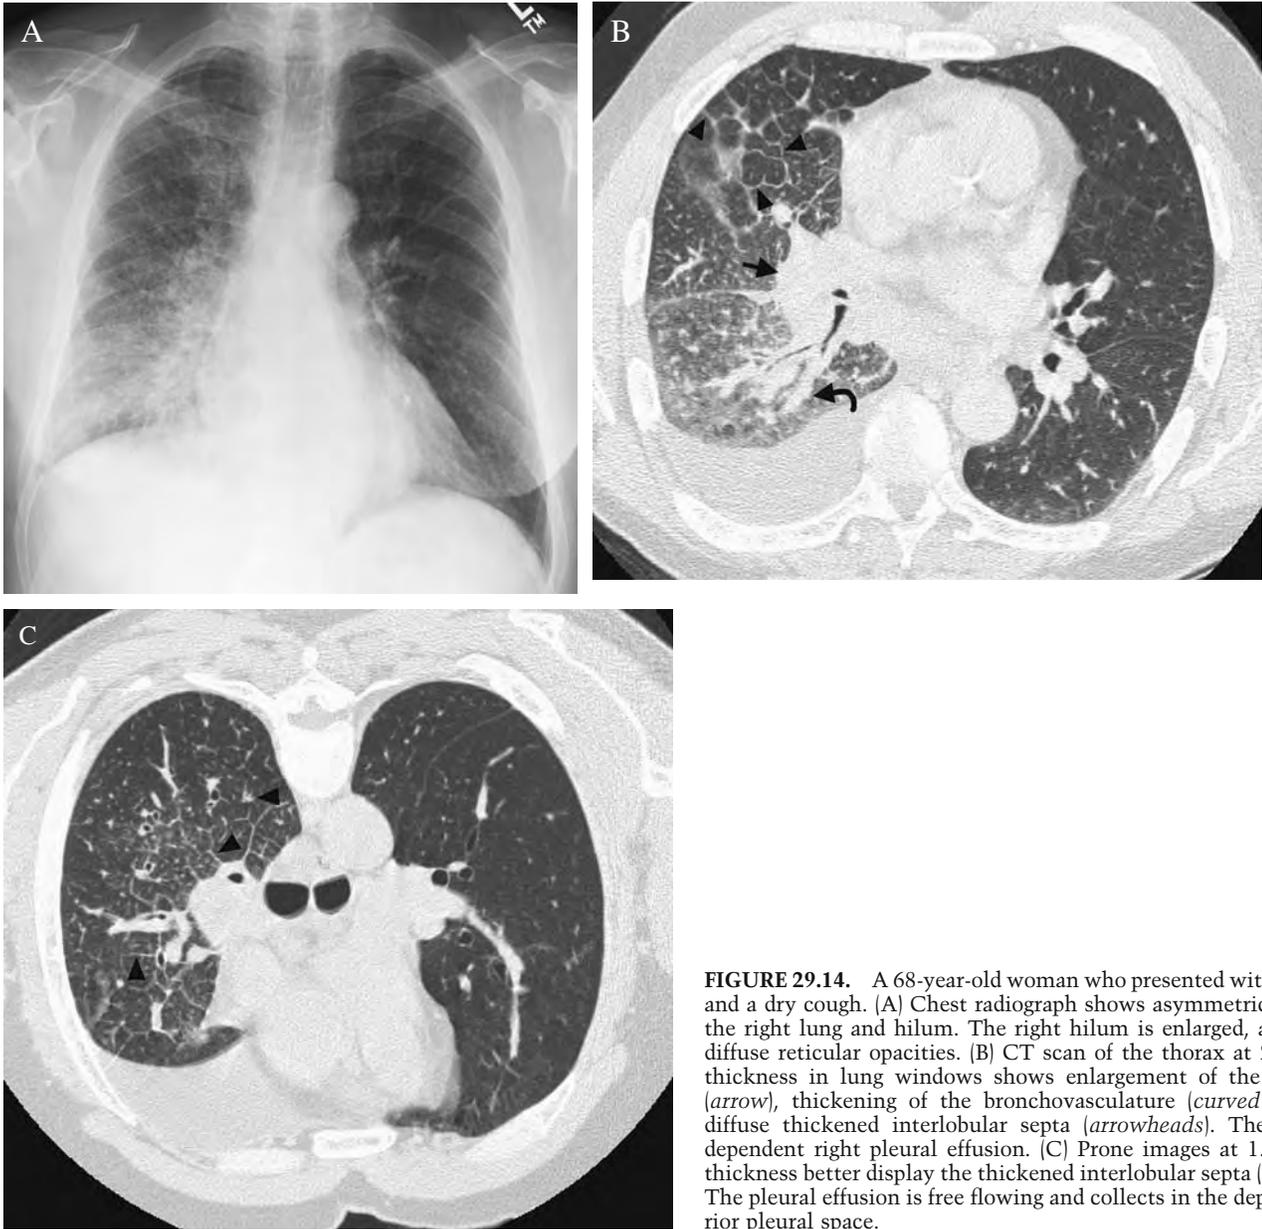

FIGURE 29.14. A 68-year-old woman who presented with weight loss and a dry cough. (A) Chest radiograph shows asymmetric opacities in the right lung and hilum. The right hilum is enlarged, and there are diffuse reticular opacities. (B) CT scan of the thorax at 2.5-mm slice thickness in lung windows shows enlargement of the right hilum (*arrow*), thickening of the bronchovascularity (*curved arrow*), and diffuse thickened interlobular septa (*arrowheads*). There is also a dependent right pleural effusion. (C) Prone images at 1.25-mm slice thickness better display the thickened interlobular septa (*arrowheads*). The pleural effusion is free flowing and collects in the dependent anterior pleural space.

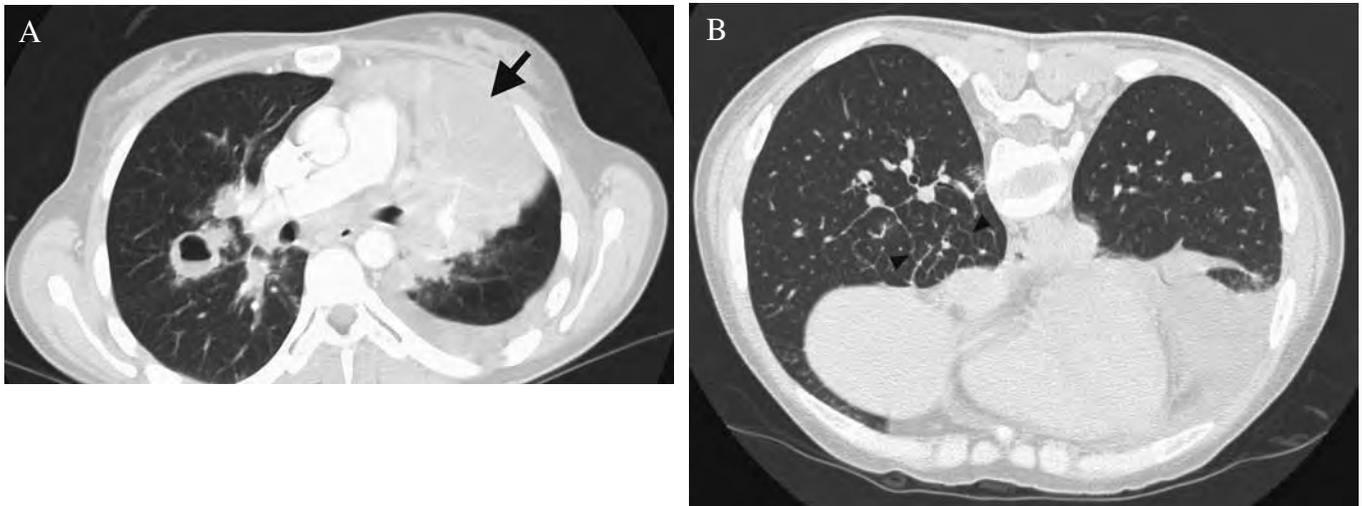

FIGURE 29.15. A 19-year-old woman with recurrent Hodgkin's lymphoma in the thorax. (A) CT scan in lung windows demonstrated a consolidative mass (*large arrow*) in the left upper lobe and left pleural effusion. In the right thorax, there is perihilar lymph-

adenopathy (*curved arrow*) and cavitary nodules (*arrow*). (B) High-resolution CT, 1.25-mm slice thickness, prone images show thickened interlobular septa (*arrowheads*) consistent with lymphangitic spread.

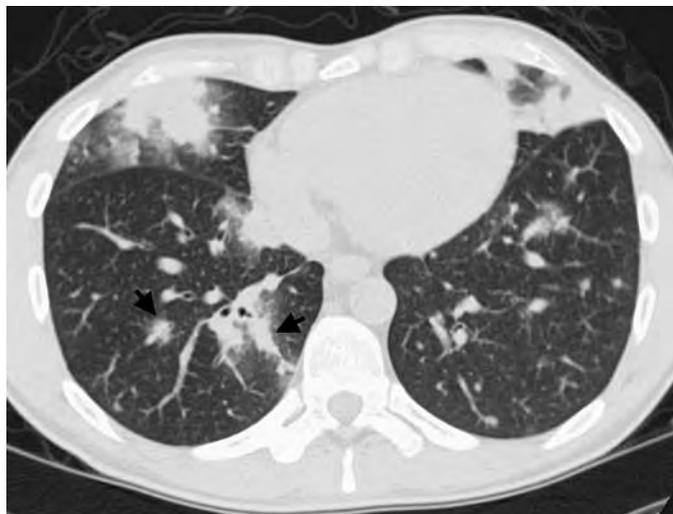

FIGURE 29.16. A 36-year-old man with Kaposi's sarcoma of the lungs. CT scan in lung windows shows multiple airspace nodules and masses with surrounding ground-glass appearance. The nodules in the right lower lobe are distributed along the bronchovascularity (arrows).

commonly is seen as an extension of tumor along the axial bronchovascular interstitium from hilar lymphatic disease or from an adjacent pulmonary mass. An air bronchogram is commonly seen in consolidative and nodular forms. Nodules also may cavitate. The presence of lymphadenopathy may help in the differential diagnosis, especially in patients with Hodgkin disease. However, lymphadenopathy is not necessarily present in involvement of the lungs by primary non-Hodgkin lymphoma.^{144,149}

The consolidative form of adenocarcinoma and its subtype, bronchoalveolar cell carcinoma, are often initially misdiagnosed as lobar pneumonia. Presenting symptoms include fever, cough, and systemic symptoms consistent with infection that may accompany tumor.²³ Coexisting pulmonary findings, such as associated subcentimeter nodules (possibly with a ground-glass appearance, and cavitory) or scattered areas of ground-glass pattern should signal possible malignancy. On rare occasions, cystlike changes in the consolidation may develop.¹⁵⁰ These changes may be mistaken for bronchiectasis or cavitation from necrosis. A ground-glass appearance with septal thickening mimicking a crazy-paving pattern is unusual for metastatic adenocarcinoma but is well described.^{23,151}

Involvement of the lungs by Kaposi's sarcoma commonly includes mediastinal and hilar lymphadenopathy. Tumor tends to extend along the bronchovascularity into the parenchyma (Figure 29.16). Multiple flame-shaped lesions or nodules with poorly defined borders or ground-glass pattern develop in the same distribution and commonly contain an air bronchogram.^{109,152} Other manifestations, however, include a single pulmonary nodule, pleural effusion, or tracheal and bronchial lesions.¹⁵²

FDG-PET DETECTION OF PULMONARY METASTASES

The detection of thoracic metastases from all tumor sources with FDG-PET has not been completely evaluated in the current literature. However, available results show that PET

can be useful in the detection of thoracic metastases for melanoma and tumors of the colon and breast. The major weakness of PET imaging is the nodule size threshold for detection. Limitations exist with metastases smaller than 1 cm. Therefore, PET imaging should be accompanied by an imaging modality with excellent anatomic resolution, such as CT.

LYMPH NODE METASTASES IN THE THORAX

The detection of unsuspected distant lymph node disease has a significant impact on tumor staging and patient prognosis. On chest radiographs, multiple pulmonary nodules are the most common manifestation of intrathoracic metastases; lymph node disease is second.^{124,153-155} Tumors that most frequently have metastases identifiable on chest radiographs include renal and other genitourinary tumors, melanoma, breast tumors, and head and neck tumors (Figure 29.17). Distribution of lymphadenopathy most commonly identified on radiographs is in the mediastinal, especially the right paratracheal, region.¹⁵³

Numerous studies of lung cancer imaging have demonstrated that CT is superior to chest radiography in detecting lymph node metastases. Williams et al.¹⁵⁶ demonstrated that CT is superior to chest radiography in the detection of metastatic testicular seminoma. With chest radiography, metastases were found in 25 of 200 patients. These results included mediastinal lymph nodes in 17 patients, pulmonary metastases in 7, pleural effusions in 5, and pleural masses in 2. With CT, however, metastases were found in 30 patients, including 21 with mediastinal nodes, 12 with lung metastases, 6 with pleural effusions, and 2 with pleural masses. CT showed disease in 5 patients whose chest radiography results were normal and revealed additional metastases in 4 patients with abnormal findings on chest radiographs.

The characterization of lymph node disease by means of CT is limited by the size threshold for detecting abnormal nodes. Lymph nodes are generally interpreted as abnormal if their short-axis diameter exceeds 1 cm. For this reason, lymph node enlargement due to inflammatory or infectious disease

FIGURE 29.17. A 52-year-old man with esophageal carcinoma. Dual fluorodeoxyglucose-positron emission tomography (FDG-PET)/CT scan of the thorax shows increased uptake in paraesophageal lymph node (white arrow). Subcarinal lymph node (black arrow) of the same caliber shows no evidence of FDG uptake, suggesting the absence of metastases.

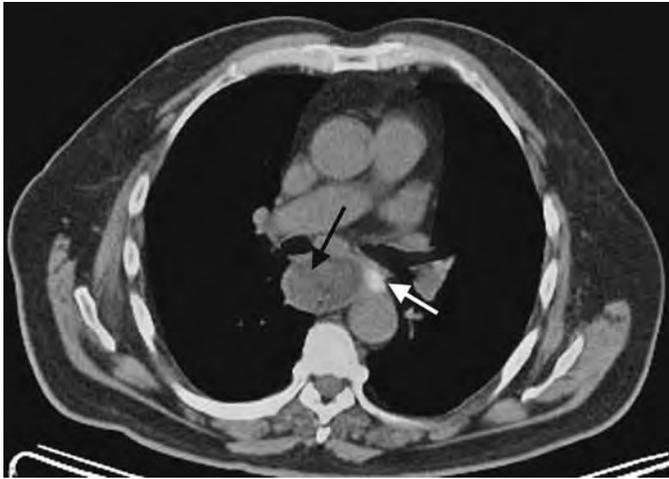

FIGURE 29.18. A 56-year-old woman with previous left mastectomy for breast cancer. Dual FDG-PET/CT scan images show increased uptake of FDG in small subpectoral lymph nodes (*arrow*), indicating metastatic nodal disease. These lymph nodes are normal in size by CT criteria.

is frequently misinterpreted as neoplastic. Early metastases to small nodes are often overlooked. FDG-PET improves specificity by better identifying lymph node disease on the basis of tumor glycolysis rather than visual size criteria (Figure 29.18). Eubank et al. found PET more accurate than CT (88% and 73%, respectively) for detecting metastatic breast cancer to the mediastinum and internal mammary lymph nodes.³² Other studies have demonstrated the usefulness of PET in detecting metastases from the abdomen and lung.¹⁵⁷ However, PET also has limitations with regard to lymph node size. The size threshold for tumor detection in metastatic foci is limited with PET because of camera resolution constraints. Lymph nodes with metastases that measure 5 mm or less can be missed.³² For instance, although FDG-PET is useful for detecting distant metastases in patients with breast cancer, it should not be the study of choice for axillary lymph node staging. Numerous studies have shown the sensitivity of PET for the detection of sentinel node disease to be as low as 20%.^{158,159}

PLEURAL METASTATIC DISEASE

In adult patients, 22% of newly diagnosed pleural effusions identified on chest radiographs are caused by malignancy.¹⁶⁰ The likelihood that a newly diagnosed unilateral pleural effusion is malignant increases with a patient's age and the size of the effusion.^{160,161} Even the presence of bilateral pleural effusions should warrant further evaluation, especially if the patient's heart is of normal size. According to Blackman et al., 50% of patients with such findings have a malignancy.¹⁶² Metastatic adenocarcinoma is responsible for 80% of malignant pleural effusions; however, in 7% to 10%, the primary site remains unknown.¹⁶³⁻¹⁶⁵ Overall, bronchogenic cancer accounts for 36% to 43% of malignant pleural effusions, followed by breast cancer at 9% to 25% and lymphoma at 7% to 10%.^{164,165}

The upright chest radiograph is of limited value in detecting small volumes of fluid in the pleural space. According to Blackmore et al., the smallest amount of fluid detected is 50 mL when a meniscus sign at the costophrenic angle is identified on a lateral chest film.¹⁶⁶ The approximate volume of fluid identified on a posteranterior radiograph is 200 mL when a meniscus sign is present. At a volume of 500 mL, fluid typically obscures the diaphragm. Lateral decubitus films can reveal as little as 5 mL fluid; however, this technique can be limited by soft tissues, bedding, and clothing that may overlie the dependent thorax.¹⁶⁷

As determined with chest radiographs, the incidence of pleural effusion in patients with primary Hodgkin disease is 7% to 13%.¹⁶⁸⁻¹⁷⁰ It is approximately 10% in patients with primary non-Hodgkin lymphoma.^{169,171} With the use of cross-sectional imaging modalities, such as CT, the sensitivity for detecting additional metastases in the thorax increases. Filly et al. reported that 80% of patients with primary Hodgkin disease and pleural effusion had lymphadenopathy that was demonstrated on chest radiographs.¹⁶⁹ However, Castellino et al. reported a higher incidence (100%) on the basis of CT results.¹⁷⁰

Ultrasonography is sensitive in the detection and quantification of pleural effusions.^{172,173} Yang et al. found ultrasound useful in characterizing the nature of pleural effusions.¹⁷⁴ Transudates were usually anechoic. Although exudative effusions could also appear anechoic, fluid that was complex, homogeneously echogenic, or that contained complex septations was specific for an exudate. Associated findings, including a thickened pleura or underlying pulmonary lesions, also indicated an exudate. Only the presence of pleural nodules was useful in detecting malignancy in the pleural space (Figure 29.19). Similar results were reported by Gorg et al., who also reported that only the presence of pleural masses was specific for malignancy.¹⁷⁵ According to Bradley et al., imaging of the pleura with ultrasonography was useful in evaluating malignant effusions to distinguish benign from

FIGURE 29.19. A 55-year-old man with metastatic adenocarcinoma and a pleural effusion. Ultrasound image shows lobulated soft tissue tumor (*curved arrow*) in the pleural space consistent with malignancy.

FIGURE 29.20. A 75-year-old woman with lung cancer. CT scan of the thorax (soft tissue windows) demonstrates an enhancing pleural nodule (arrow) consistent with tumor deposit.

malignant pleural masses and to provide real-time guidance for needle placement during percutaneous biopsy.¹⁷⁶ Vascular abnormalities and other benign masses were readily identified as anechoic and pulsatile. Malignant tumors showed varied echogenicity indicating soft tissue, interruption of the pleural line (90%), and decreased motion with respiration.

Although the spatial resolution of CT is excellent, small tumor deposits on the pleura can be missed.¹⁷⁷ According to Akaogi et al., small nodules in the interlobar fissures in a patient with lung cancer without an effusion may be the only indication of pleural involvement.¹⁷⁸ Malignant effusions frequently do not demonstrate any pleural changes on contrast-enhanced CT studies. Approximately 50% of malignant effusions resemble simple transudative effusions without pleural changes.^{177,179} Therefore, the absence of associated pleural thickening or nodularity does not preclude a malignant effusion. Several studies have evaluated the use of CT in establishing criteria for detecting malignant pleural disease.^{177,179-182} Arenas-Jimenez et al. found that pleural nodules and nodular pleural thickening were the most sensitive and specific findings for malignant pleural effusion (Figure 29.20).¹⁷⁷ The finding of mediastinal and circumferential pleural thickening was also more frequent in malignant disease but could be seen with an empyema. Associated findings such as a pulmonary mass or nodules, enlarged mediastinal lymph nodes, a chest wall mass, or liver nodules helped to confirm radiologic evidence. In patients with lymphoma, ancillary findings of extrapleural tumor or enlarged lymph nodes in the extrapleural space demonstrated with CT may also help to explain the source of pleural disease. Aquino et al. found that 41% of patients with lymphoma and pleural effusion had abnormal pleural or extrapleural disease or both. Ninety-five percent of patients with extrapleural tumors had adja-

cent paraspinal and posterior mediastinal lymph node disease.¹⁸³

MR imaging is useful in the detection of pleural malignancy; however, because of the duration of scan time, limitations in whole-body imaging due to the need for varying sequences for specific organs, limited fields of view, and high costs, this modality is the second choice, after CT. Falaschi et al. found that MR imaging was equal to CT in the detection of morphologic changes suggesting malignant pleural disease.¹⁸⁴ They also found that MR imaging provided additional information as a result of changes in signal intensity with malignancy. In six patients, CT results were equivocal, whereas benign disease was distinguishable from malignant disease on the basis of MR imaging information. The most useful findings on MR images were high signal intensity on proton-density-weighted and T₂-weighted studies and the use of lesion-to-muscle ratio in each sequence. Similar results were found by Hierholzer et al.¹⁸⁵ Both CT and MR imaging were sensitive (93% and 96%, respectively) in detecting morphologic changes of malignant pleural disease (i.e., mediastinal pleural thickening, nodularity, irregular pleural contour, and infiltration of the chest wall or diaphragm). MR images displayed increased signal indicating malignancy in T₂-weighted and contrast-enhanced T₁-weighted series, with sensitivities of 91% and 93%, respectively. No significant features were found on noncontrast-enhanced T₁-weighted images.

As a general imaging tool for routine pretreatment evaluation of thoracic malignancy, CT is more practical and cost-effective. However MR imaging is more sensitive in detecting tumor involvement of the chest wall and diaphragm. As mentioned earlier in the chapter, MR imaging is superior to CT in the assessment of chest wall and mediastinal involvement by superior sulcus tumors. Carlsen et al. also found MR imaging useful in the pretreatment assessment of patients with mediastinal lymphoma and suspected involvement of the chest wall and pleura.¹⁸⁶ MR imaging detected chest wall or pleural malignancy or both in 22 of 57 patients; by comparison, with CT, disease was detected in only 2 patients.

FDG-PET is more sensitive than CT for the detection of malignant pleural disease. Bury et al. described an increase in FDG uptake in the pleura in all 16 patients with malignant pleural disease in their study group.¹⁸⁷ As in most FDG-PET studies, infection could mimic malignancy. In the study by Bury and colleagues, two patients with pleural empyema also showed abnormal uptake, which mimicked tumor. Gupta et al. reported a sensitivity and specificity of 88.8% and 94.1%, respectively, for FDG-PET in correctly distinguishing benign from malignant pleural disease in patients with lung cancer.¹⁸⁸ Extra care should be taken when interpreting any FDG-PET image of a patient with malignant pleural disease who was previously treated by means of talc pleurodesis. Talc, which causes a chronic granulomatous response in the pleural space, appears intensely hot on FDG-PET images and mimics tumor.¹⁸⁹ Careful correlation of PET findings with those of CT is necessary to distinguish abnormal foci of increased attenuation on PET from true neoplasm (Figure 29.21). This abnormal uptake will not resolve over time; therefore, areas of new increased FDG uptake suggest recurrent disease.

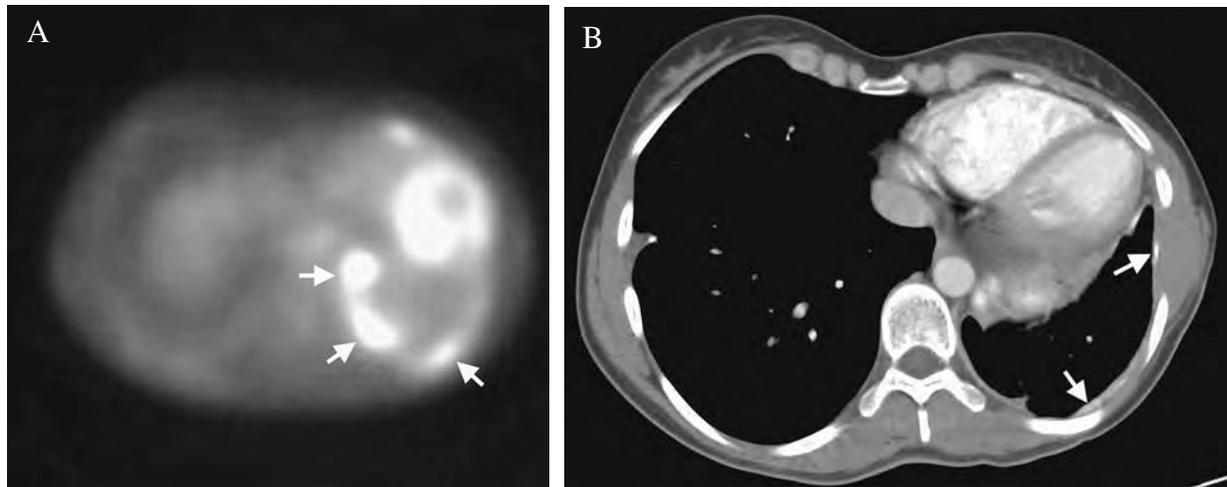

FIGURE 29.21. A 26-year-old woman with previous history of talc pleurodesis for malignant pleural effusion. (A) FDG-PET scan shows areas of increased uptake in the pleural space (arrows). (B) Correlative CT scan (soft tissue windows) shows increased attenuation

(arrows) in the pleural space consistent with talc deposits. The patient had no clinical evidence for recurrence, and her PET and CT scans were stable over 3 years.

Imaging of Gastrointestinal Stromal Tumor

Ihab R. Kamel and Elliot K. Fishman

Gastrointestinal stromal tumor (GIST) is a rare stromal neoplasm that accounts for 5% of all soft tissue sarcomas.¹ It is the most common mesenchymal neoplasm of the gastrointestinal tract.^{2,3} Before the advent of immunohistologic methods, most spindle cell sarcomas of the gastrointestinal tract were considered to be leiomyomas or leiomyosarcomas, with occasional examples of neurogenic tumors. GIST defines a distinct group of gastrointestinal tumors that originate from the intestinal cells of Cajal. These cells act as regulators of bowel peristalsis and therefore are also called *pacemaker cells*.⁴⁻⁶ Cajal cells normally express cKIT (CD 117), which is a tyrosine kinase growth factor receptor. This cKIT immunoreactivity is the best defining feature of GISTs, distinguishing them from true smooth muscle tumors (i.e., leiomyomas and leiomyosarcomas) and tumors arising from neural crest derivatives (i.e., schwannomas and neurofibromas)^{6,7}; this is considered the most specific criterion for the diagnosis of GIST. In addition, targeting the cKIT receptor with a cKIT tyrosine kinase inhibitor [STI-571, imatinib (gleevec); Novartis, Basel, Switzerland] has been successfully utilized in treating patients with GIST.^{8,9}

General Features

GISTs may occur anywhere throughout the gastrointestinal tract, from the esophagus to the anus. They may also occur in the mesentery, omentum, and retroperitoneum. The estimated prevalence of GISTs is 10 to 20 cases per million population.¹⁰ Up to 70% of GISTs arise in the stomach and approximately 20% to 30% arise from the small bowel. Incidence in the esophagus, colon, and rectum is rare.^{11,12} In the esophagus, leiomyomas are more common than GIST, accounting for approximately 75% of mesenchymal tumors.¹³ However, in the stomach, small bowel, colon, and anorectum, GISTs account for almost all mesenchymal tumors because other tumors, such as leiomyoma and leiomyosarcoma in these sites are rare.^{10,14,15} Most GISTs exhibit an exophytic growth pattern, growing along the bowel wall. For small lesions, the overlying mucosa is typically intact, but mucosal ulceration may occur in large and aggressive tumors. Surrounding organ invasion may occur in approximately one-third of cases.¹⁶ Metastatic disease is common and was reported in nearly 50% of patients in one study.¹ The liver

is the most common site of metastases (65%), followed by the peritoneum (21%). Metastases to the lymph nodes, lungs, and bones are considered rare. Most patients eventually develop recurrence after complete surgical resection. The liver and peritoneum are the two most common sites for recurrence.¹⁷

Most GISTs are sporadic, and the majority of cases present with a solitary lesion. However, patients with type I neurofibromatosis have an increased prevalence of GIST. Typically, these patients are children or young adults with multiple small intestinal GISTs.^{18,19} Gastric GISTs may rarely occur in association with pulmonary chondromata and extraadrenal paraganglioma in Carney's syndrome,^{20,21} which has a predilection for young women.

Clinical Presentation

At presentation, most patients are in their fifth and sixth decade of life, and GISTs are rarely seen in patients younger than 40 years of age.¹¹ No gender predilection has been established,^{22,23} although some data showed male predominance.^{1,24} There is no association between race, ethnicity, occupation, or geographic location.²⁵

The clinical manifestation of GIST is widely variable, depending on tumor location and size. The most frequent location for GIST is in the stomach (70%), followed by the small bowel (20% to 30%).¹⁰ Tumor size is extremely variable, ranging from small lesions to large masses. Small tumors are usually asymptomatic and are diagnosed incidentally during imaging, endoscopy, or surgery. GISTs may remain clinically silent because of their submucosal origin and tendency to grow exophytically. Symptomatic GISTs are usually large and may present with gastrointestinal bleeding from mucosal ulceration.²⁶ Patients may present with hematemesis, melena, or symptoms and signs of anemia resulting from occult bleeding.²⁷ Other symptoms include abdominal fullness and pain. A palpable mass may also be present. The submucosal location of the tumor may cause obstruction or perforation, especially those arising from the esophagus or small intestine. Tumors in the esophagus may present with dysphagia, and those arising in the duodenum may compress the adjacent pancreatic head, resulting in fever and jaundice. Rectal GISTs may present with symptoms of

mass effect such as frequency, hesitancy, or poor urinary stream due to invasion of the urinary bladder.²⁶

Pathologic, Histologic, and Immunohistochemical Features

GISTs usually involve the outer muscular layer and therefore, are predominantly exophytic. They usually project into the abdominal cavity. Mucosal ulceration may be seen in up to 50% of cases.²⁸ Tumor size ranges from several millimeters to larger than 30 cm. Typically, tumors are well circumscribed but lack a true capsule. They may result in significant mass effect on surrounding organs. Cut sections are pink, tan, or gray with focal areas of hemorrhage, cystic degeneration, and necrosis, especially if large. Extensive hemorrhage and necrosis may result in cavity formation, which may communicate with the gastrointestinal lumen.

GISTs usually present with moderate to high cellularity, and tumor cells vary from spindle (70% to 80%) to epithelioid (20% to 30%).^{16,27} Spindle cell GISTs exhibit spindle cells that have elongated nuclei with tapered, blunt, or rounded ends and eosinophilic or basophilic cytoplasm. Epithelioid GISTs are composed of round or polygonal cells with central or slightly eccentric nuclei; they may show mitosis, but typically, they have a more benign clinical course than spindle cell GISTs. Histologically, GISTs with spindle-shaped cells may simulate smooth muscle tumors or nerve sheath tumors. They may also have prominent vascularity, hemorrhage, extensive hyalinization, or myxoid degeneration.

The biologic behavior of GISTs ranges between benign and malignant, and the differentiation is based on size, location, cellularity, and the degree of mitotic activity. Generally, malignant GISTs are large and more cellular than benign GISTs. However, the critical size is not agreed upon. Tumor behavior varies significantly by location, and the cutoff tumor size also varies by location. GISTs arising from the stomach are more likely to be benign than malignant.¹⁰ Gastric GISTs that are smaller than 5 cm in maximum diameter, with five or fewer mitoses per 50 consecutive high-power fields, have a low risk for metastasis, and are considered benign. Gastric GISTs that are larger than 10 cm and with more than five mitoses per 50 high-power fields are considered malignant. Tumors that fall between these two categories have indeterminate malignant potential. Tumors with high mitotic activity (more than 50 mitoses per 50 high-power fields) are considered aggressive with high-grade malignant potential.²⁹ GISTs that arise from the small intestine tend to be more aggressive than those arising from the stomach. Most esophageal, colonic, and anorectal GISTs are malignant. Because benign-appearing GISTs may recur or metastasize, it has been recently suggested to classify GISTs into very low, low-, intermediate-, and high-risk categories rather than as benign or malignant.³⁰ Careful clinical and imaging follow-up is therefore advised for all patients.^{30,31}

The diagnosis of GIST requires confirmation with immunostaining for CD 117, which is expressed by all GIST, both spindle and epithelioid type,⁶ regardless of their anatomic site or clinical behavior. The presence and expression of CD 117 is also found in the interstitial cells of Cajal,

which are the pacemaker cells of the gastrointestinal tract. This association suggests that these cells are the common origin of GISTs.⁴ The expression of CD 117 is the most specific marker for GIST.³⁰ However, it is not pathognomonic, as other malignant neoplasms, including malignant melanoma, seminoma, sarcoma, and some leukemias, may also express CD 117.⁶ Fortunately, the distinction between GISTs and other tumors that express CD 117 can be made histologically. Approximately 70% to 80% of GISTs also express CD34, which is a hemopoietic progenitor cell antigen. GIST may also express smooth muscle antigen in approximately one-third of cases, but it is rarely reactive to desmin, present in true smooth muscle tumors, and S-100 immunostaining, present in schwannoma.

Computed Tomography Protocol and Image Processing Technique

Many cross-sectional imaging modalities are available for the evaluation of patients with GISTs, including ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET). CT is the mainstay of abdominal imaging. It is widely available and highly accurate, particularly in assessing liver metastases.^{32,33} If properly performed, CT will adequately address most clinical concerns in patients with GISTs. CT features provide information that may help in differentiating GISTs from lymphoma and epithelial gastrointestinal tumors. With the introduction of new targeted medical therapy for GISTs, CT is increasingly utilized to assess tumor response and to evaluate for disease recurrence. In addition, CT is currently the first imaging modality requested in patients with suspected bowel obstruction, which is reported in up to 30% of GISTs.^{34–36} Occasionally a small bowel neoplasm may be detected in these cases. CT may also be utilized to guide tissue biopsy.

The recent introduction of multidetector row CT, combined with multiplanar reconstructions and high-fidelity volume rendering, can provide comprehensive evaluation of the abdomen, particularly the vascular anatomy^{37–39}; this is particularly useful in determining the origin of large exophytic GISTs, which may be difficult to determine in an axial plane. Multiplanar volume rendering and maximum intensity projection techniques are also used to accurately delineate small mucosal lesions, to better characterize the morphology of the lesion, and to detect hepatic and peritoneal metastases.

Although CT may detect an incidental GIST, patients are more commonly referred for accurate tumor localization, characterization, staging, and surveillance for metastases or recurrence after surgery. For routine scanning of the abdomen and pelvis, a detector configuration of 4 × 2.5 mm, table speed of 15 mm, and pitch of 6:1 allow for adequate coverage in a single breath-hold of 20–25 seconds. Image reconstruction of 5 mm, with optional 2.5-mm overlap, can be performed in such cases. Newer 16-slice multidetector CT scanners allow the use of 1.5-mm detectors with 2-mm-thick slices at 1-mm intervals. Contrast enhancement is typically achieved using 120 mL (2 mL/kg) nonionic contrast media injected intravenously, with a power injector, at a rate of 3 mL/s. Depend-

ing on the clinical indication, arterial and/or portal venous imaging is performed using a 25-second and 60- to 65-second scan delay, respectively. In patients undergoing dual-phase CT of the liver, in addition to CT of the chest, abdomen, and pelvis, arterial-phase images of the liver should be obtained in the first breath-hold at 25 seconds, followed by scans through the chest, abdomen, and pelvis in the second breath-hold at 65 seconds. For the evaluation of the abdominal vascular anatomy before possible resection, a detector configuration of 16×0.75 -mm collimation and 0.5-mm intervals will result in superior three-dimensional image reconstruction and volume rendering techniques.

Positive oral contrast is not administered when imaging GIST because it may degrade image reconstruction and obscure small mucosal lesions. Positive oral contrast agents may also mix unevenly with gastric and intestinal fluid, resulting in pseudotumor.^{40,41} When imaging the stomach and small bowel, 750 mL water is recommended as a negative contrast agent, given to the patient approximately 15 minutes before imaging. Patients also receive an additional 250 mL immediately before the study to ensure adequate distention of the stomach. Water is well tolerated and results in good gastric and proximal small bowel distension as well as excellent visualization of the enhancing gastric wall.⁴² One disadvantage of using water as oral contrast is the suboptimal distension of the distal small bowel. Some authors have advocated using positive contrast initially, followed by water to allow adequate distension of the stomach and small bowel.⁴³ Alternatively, oral metoclopramide can be administered to improve ileal distension and reduce bowel peristalsis.⁴⁴ GISTs that are detected incidentally may be seen on a routine CT scan of the abdomen, which is usually performed with high-density oral contrast.

At our institution, CT scanning is performed using a multislice variable detector array (Sensation 16; Siemens Medical Solutions, Malvern, PA). Multidetector row CT images are acquired as a volume data set during a single breath-hold. All CT imaging data, in the original resolution of 512×512 , are sent from the scanner to a freestanding workstation for postprocessing (Leonardo with In Space software; Siemens). Volume rendering allows the best approach to visualize the stomach and small bowel compared to other rendering algorithms.^{42,45} Volume rendering utilizes all the attenuation information in any given slab of tissue, and real-time adjustments can be performed to accentuate the stomach and small bowel. Histograms of the relative density values are manipulated through trapezoid control of variables, such as width, level, opacity, and brightness. This function assigns opacity and color to each voxel and can be instantaneously adjusted to alter the final display. It is often helpful to start with two-dimensional multiplanar reconstructions and then proceed to the three-dimensional volume rendering. Initial two-dimensional multiplanar reconstructions allow for quick assessment of the abdomen in the axial, coronal, and sagittal planes. The main advantage of three-dimensional volume rendering is the enhanced depth perception, which improves visualization of a complex mass or tortuous vessels. Interactive application of different orientations and cut planes enhance the visualization of the bowel and the display of tumor in any plane that is necessary for the surgeon or referring physician.

General CT Features

General features of GISTs depend on the organ of origin and tumor size. Most tumors arise from the muscularis propria of the stomach or small intestine, and the submucosal origin of these tumors explains their typical CT features. They commonly manifest as a dominant exophytic mass. Less common CT findings include dominant intramural and intraluminal masses. Small tumors are typically homogeneous, well defined, and sharply marginated. Contrast enhancement is usually moderate. Large tumors tend to have central necrosis and mucosal ulceration. Enhancement of large tumors is typically heterogeneous, although this feature cannot reliably predict tumor behavior or malignant potential.²⁷ Peripheral contrast enhancement indicates viable tumor, whereas central areas of low attenuation may appear due to hemorrhage, necrosis, or cystic degeneration. Cavitary lesions may develop, which often communicate with the bowel lumen. They may contain air, air–fluid level, or food residue. Calcification is unusual and may be mottled or extensive. Ascites has rarely been reported in patients with GISTs, suggesting that these tumors do not incite local inflammatory reaction. Vessels are often stretched over large tumors, but vascular encasement of the mesenteric and retroperitoneal vessels is rare.²⁴

Regardless of the site of GIST, differentiation of benign tumors from their malignant counterparts is difficult on CT. Distinguishing between low-grade and high-grade malignant GISTs by CT has been recently reported.⁴⁶ CT features favoring a diagnosis of high-grade GIST and, associated with poor survival, included large tumor size (larger than 11.1 cm), irregular surface, unclear boundary, mesenteric or bowel wall invasion, heterogeneous enhancement, distant metastases, and peritoneal dissemination.

CT is the most common technique in evaluating hepatic metastases.^{32,33} These are typically hypodense on unenhanced CT, with occasional hyperdensities resulting from hemorrhage or proteinaceous material. Contrast-enhanced CT metastases are heterogeneous in enhancement, likely because of cystic degeneration. Following treatment with imatinib, metastases to the liver commonly become hypodense, appearing cystlike with a well-defined margin.^{47,48} Decrease in attenuation of the treated lesions may be due to myxomatous change resulting in small pyknotic nuclei in an eosinophilic myxoid background.⁴⁹

Stomach

Most GISTs arise from the stomach, accounting for 2% to 3% of all gastric tumors. According to a recently published study, 28 of 64 GISTs (44%) were located in the stomach.²⁷ At CT, most tumors are large with an exogastric extension into the gastrohepatic ligament, gastrosplenic ligament, or the lesser sac.²⁷ Most tumors have rim enhancement, with central areas of low attenuation due to hemorrhage, necrosis, or cystic degeneration (Figures 30.1–30.3). These findings have no correlation with malignant potential. Large tumors may also cavitate, and the cavities may communicate with the gastric lumen and become filled with food residue, fluid, or air–fluid

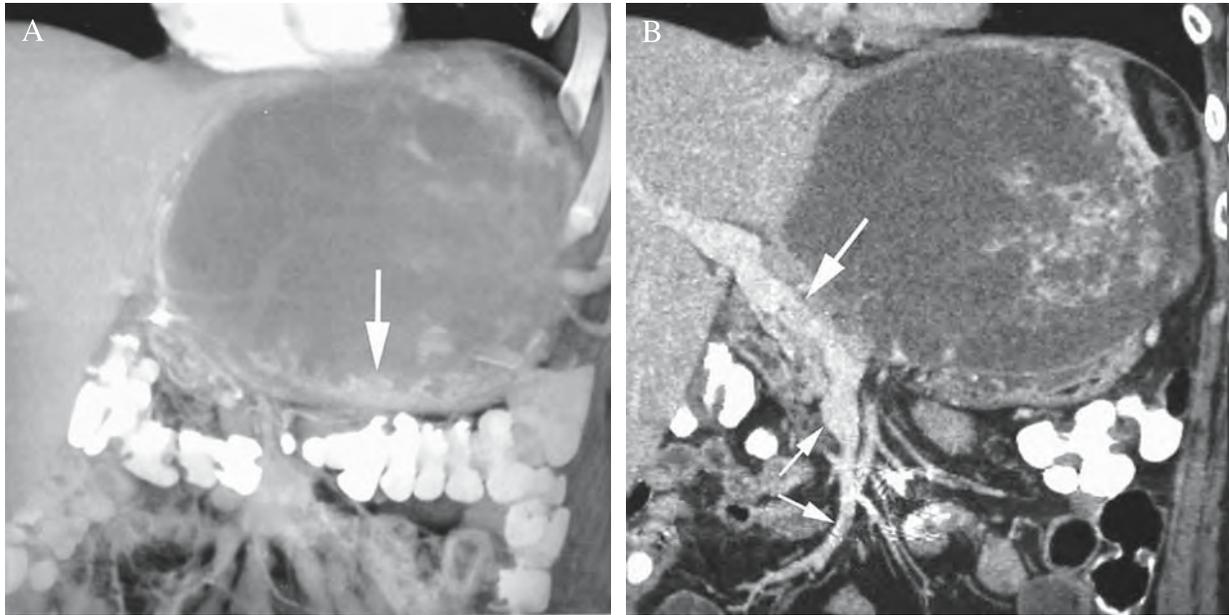

FIGURE 30.1. Large gastric gastrointestinal stromal tumor (GIST) in a 45-year-old man with history of abdominal pain and weight loss. (A) Coronal volume-rendered image through the upper abdomen reveals a large heterogeneous cystic and/or necrotic mass in the left upper quadrant that is inseparable from the stomach. Notice peripheral solid component with heterogeneous enhancement (*arrow*). The

mass abuts the liver without evidence of invasion. Oral contrast is seen in the large bowel from a prior computed tomography (CT) scan. (B) Coronal reconstruction reveals patency of portal vein (*arrow*) and superior mesenteric vein (*small arrows*). These findings are important for surgical planning.

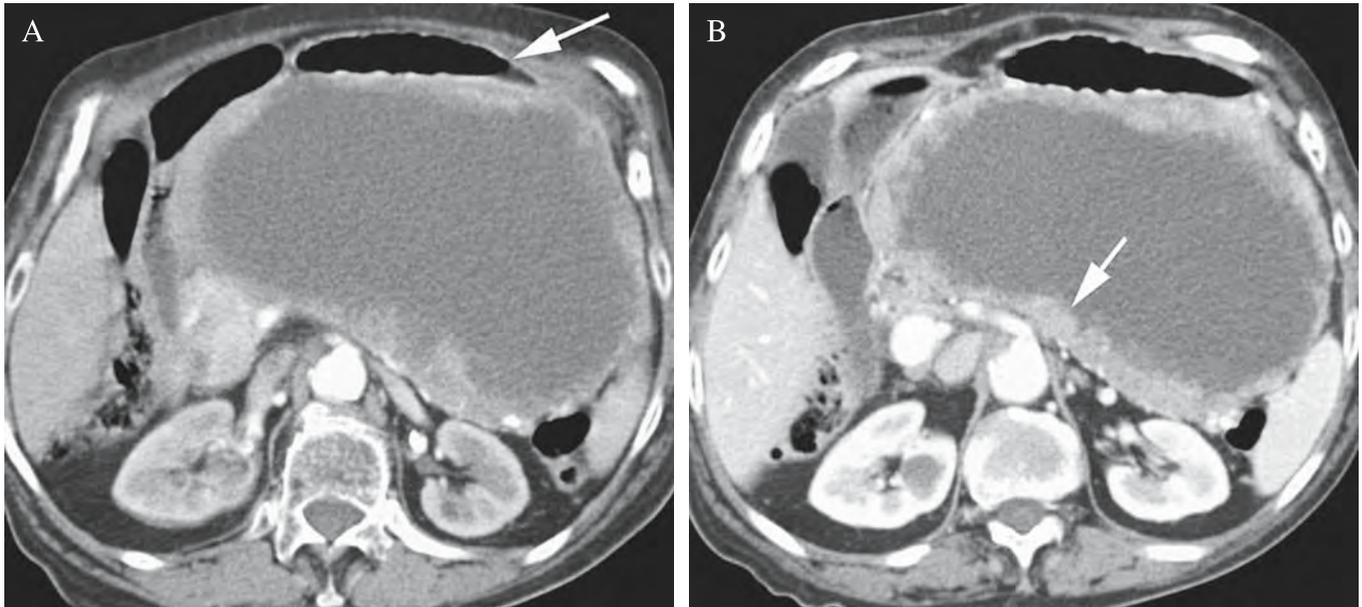

FIGURE 30.2. Gastric GIST in a 92-year-old woman with early satiety, abdominal pain, and anemia. (A) Axial CT of the abdomen in the arterial phase reveals a large cystic/necrotic mass in the left upper quadrant, extending into the gastrosplenic ligament. The mass appears to arise from the posterior aspect of the stomach, which is displaced anteriorly (*arrow*). (B) Axial CT at the same level as (A) in

the portal venous phase shows irregular enhancing peripheral solid components (*arrow*) and central necrosis. (C) Coronal volume-rendered image demonstrates the craniocaudal extension of the mass to the pelvis. (D) Sagittal reconstruction better reveals the extraluminal nature of the mass. The mass is related to the posterior aspect of the stomach (*arrow*), which contains an air-fluid level.

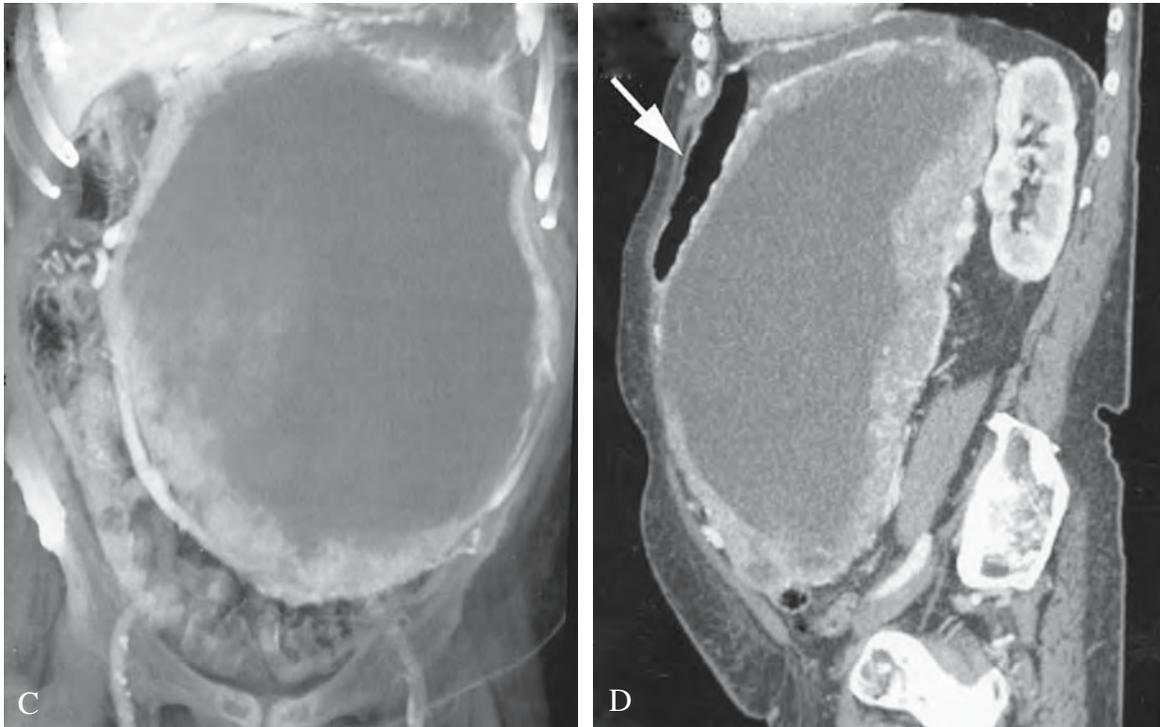

FIGURE 30.2. (continued)

level (Figure 30.4). Homogeneous enhancement of the tumor is uncommon, accounting for 8% of cases according to one study.²⁷ Calcifications are unusual and were reported in 3% of cases. Multidetector row CT with volume rendering allows for accurate delineation of the tumor outline and subtle gastric wall thickening at the site of tumor attachment to the gastric wall. These features help in determining the organ of origin in large tumors and their relationship to surrounding organs. CT may also demonstrate extragastric extension into

the gastrohepatic ligament, gastrosplenic ligament, and lesser sac. It can demonstrate invasion of surrounding organs, ascites, or peritoneal carcinomatosis. Liver metastases may also be detected; these are usually hypovascular and best seen in the portal venous phase. Metastatic lymph node involvement is not observed in patients with GIST.

The differential diagnosis for gastric GISTs includes other mesenchymal neoplasms that arise in the gastric wall, including leiomyomas (Figure 30.5), leiomyosarcomas, schwanno-

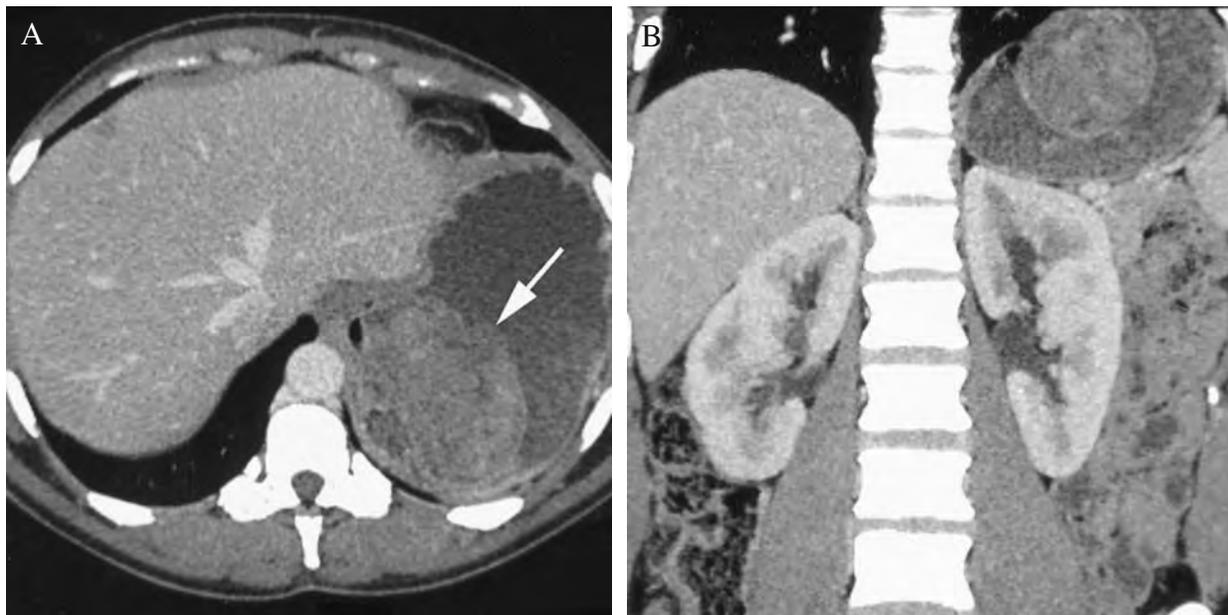

FIGURE 30.3. Gastric GIST in a 48-year-old woman presenting with upper gastrointestinal bleeding. (A) Axial CT of the abdomen reveals a large mass (*arrow*) in the fundus of the stomach. The mass is entirely projecting into the gastric lumen, with no exophytic com-

ponents. This finding is somewhat atypical because most GISTs have an exophytic component. (B) Coronal reconstruction confirms the intraluminal nature of the mass. No extragastric extension was seen.

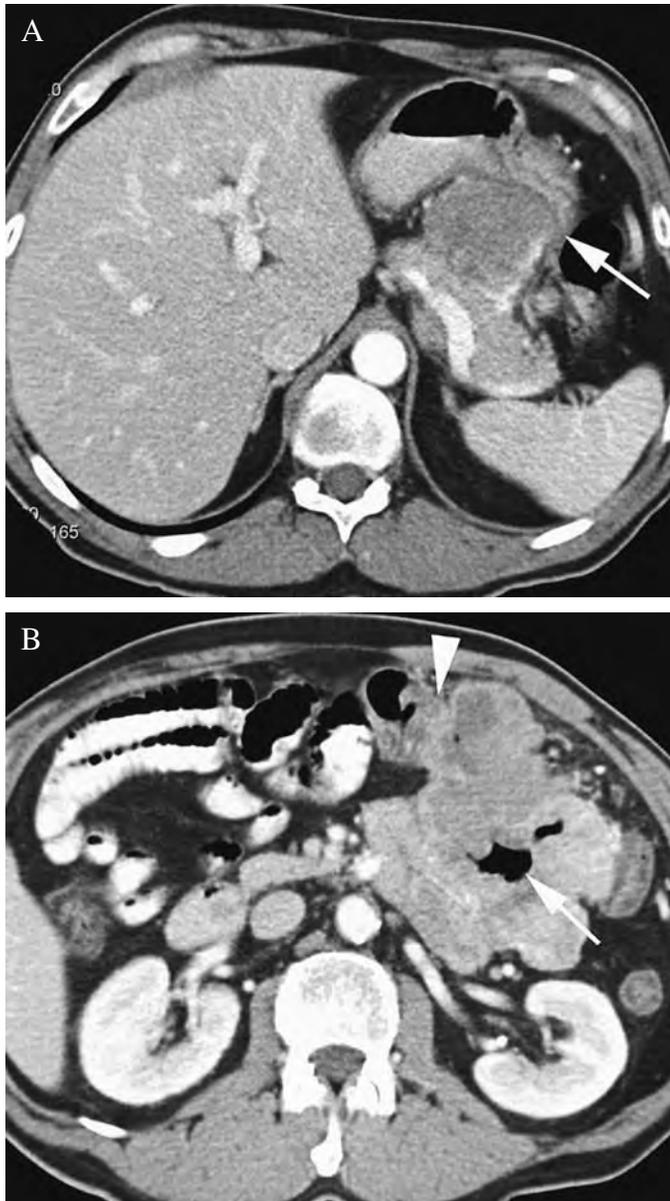

FIGURE 30.4. Malignant gastric GIST in a 49-year-old man. (A) Axial CT of the abdomen with oral and intravenous contrast reveals an exophytic mass arising from the posterior aspect of the stomach (*arrow*) and extending along the gastrosplenic ligament. Note marked thickening of the gastric mucosal folds posteriorly. (B) Axial CT of the abdomen at a level lower than (A) reveals extensive central necrosis and a cavity (*arrow*) that is air filled. The mass invades the wall of the transverse colon (*arrowhead*).

mas, and neurofibromas. The imaging features of these tumors may be similar to GISTs. Gastric adenocarcinoma and lymphoma may also have a radiologic appearance similar to GISTs. However, they rarely demonstrate large exophytic growth, and when advanced are commonly associated with bulky adenopathy, a feature that is not seen in malignant GISTs.

Small Intestine

GIST may occur anywhere throughout the small intestine, and these patients usually present with signs and symptoms of bowel obstruction. At CT, GISTs may appear as an intra-

mural polyp or intraluminal mass. Tumor margins are typically well defined, unless they have mucosal ulcerations. Tumors may also cavitate and form fistulous communication with surrounding bowel loops. Similar to gastric GISTs, tumors typically enhance with central areas of low attenuation due to hemorrhage, necrosis, or cyst formation (Figure 30.6). Homogeneous pattern of enhancement is less common. Tumors may encase or invade surrounding small bowel, colon, urinary bladder, or ureter. Patients may also present

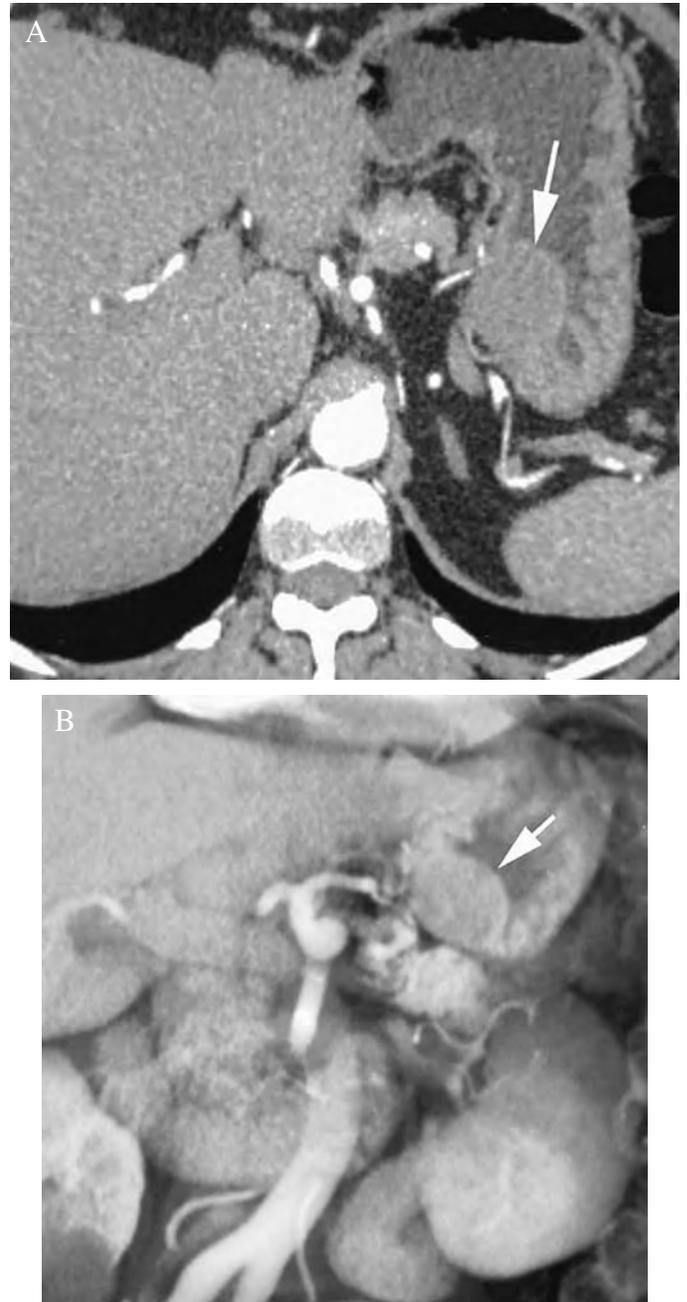

FIGURE 30.5. Incidental submucosal gastric leiomyoma simulating GIST in a 56-year-old man. (A) Axial contrast-enhanced CT of the abdomen reveals a small submucosal soft tissue mass in the fundus of the stomach (*arrow*). The homogeneous enhancement and lack of exophytic component favor the diagnosis of leiomyoma over GIST. (B) Coronal volume-rendered image better demonstrates the smooth contour of the lesion (*arrow*) and the intact overlying mucosa.

FIGURE 30.6. Duodenal malignant GIST in a 56-year-old male patient presenting with a palpable abdominal mass. (A) Coronal volume-rendered image reveals a large mass (*arrow*) with peripheral enhancement and central necrosis, arising from the second portion of the duodenum. Interactive volume rendering helps in confirming the duodenal origin of the mass, which should not be mistaken for pancreatic neoplasm. (B) Coronal maximum intensity projection image better reveals the superior mesenteric artery (*arrow*) and its branches draped around the mass. No vascular encasement was seen; this was confirmed at pathology. (C) Sagittal reconstruction demonstrates the craniocaudal and anteroposterior extent of the mass (*arrow*) and the relation to the surrounding organs, including the liver (*L*), gallbladder (*G*), and right kidney (*K*). These findings are important for surgical planning.

with metastases to the liver, peritoneum, or omentum. Ascites may occur but is uncommon. Patients with neurofibromatosis (type I) may have multiple small intestinal GISTs^{18,19} (Figure 30.7).

Differential diagnosis for small intestinal GISTs includes adenocarcinoma, which is the most common primary malignancy of the proximal small bowel. However, adenocarcinoma typically manifests as an annular lesion in the proximal small bowel, which is not a feature of GISTs. Lymphoma may be indistinguishable from GISTs, especially when it produces large masses that may cavitate, ulcerate, and extend into the mesentery. However, the presence of lymphadenopathy favors the diagnosis of lymphoma. Tumors of the duodenum and proximal small bowel may cause a significant mass effect

on the pancreas or simulate a pancreatic primary^{50,51} (Figure 30.8). Judicious application of image postprocessing may help in avoiding this pitfall.

Anorectum

Anorectal GISTs account for 9% of 64 GISTs, according to a recently published series.²⁷ Unlike GISTs in other locations, a male predominance has been reported.^{14,52} Clinical presentation includes rectal pain, bleeding, and rectal mass. Anorectal GISTs present as eccentric mural masses that invade the rectal wall. The most common finding at CT is a focal well-circumscribed mural mass, which expands the rectal wall and

FIGURE 30.7. Multiple GISTs in a 42-year-old man with history of neurofibromatosis (type I) and lower gastrointestinal bleeding. Axial CT of the lower abdomen in the arterial phase reveals multiple pedunculated skin lesions (*arrowhead*) and within the abdomen (*small arrows*) compatible with neurofibromas. In addition, there is an enhancing soft tissue mass in the distal jejunum (*arrow*), which was proven to be a GIST at small bowel resection.

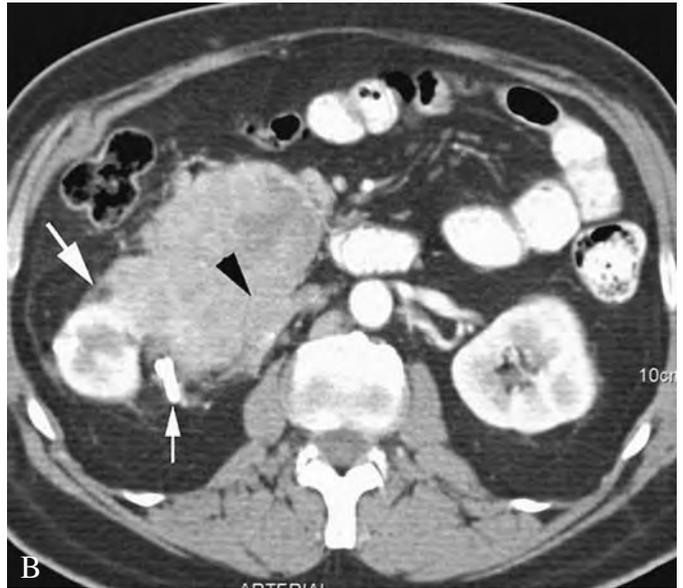

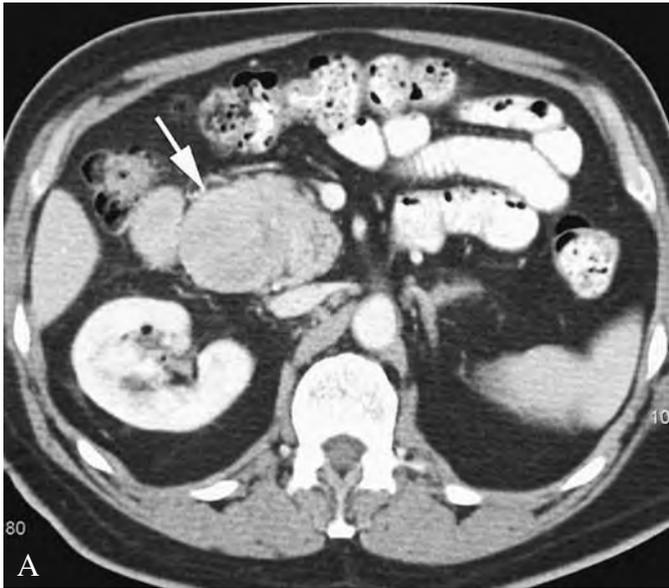

FIGURE 30.8. Poorly differentiated high-grade duodenal sarcoma in a 61-year-old man. (A) Axial CT of the abdomen with oral and intravenous contrast reveals a soft tissue mass in the region of the pancreatic head (*arrow*), involving the descending portion of the duodenum. This mass could be mistaken for pancreatic neoplasm. (B) Axial CT of the abdomen at a level lower than (A) shows invasion of the right renal hilum (*arrow*) and the inferior vena cava (*arrowhead*). A ureteric stent is seen in place (*small arrow*). (C) Coronal volume-rendered image shows the epicenter of the lobulated mass along the descending portion of the duodenal mass, with surrounding mesenteric fat stranding (*arrow*) indicating peritumoral spread of disease. The pancreas is well visualized (*arrowheads*) and is normal.

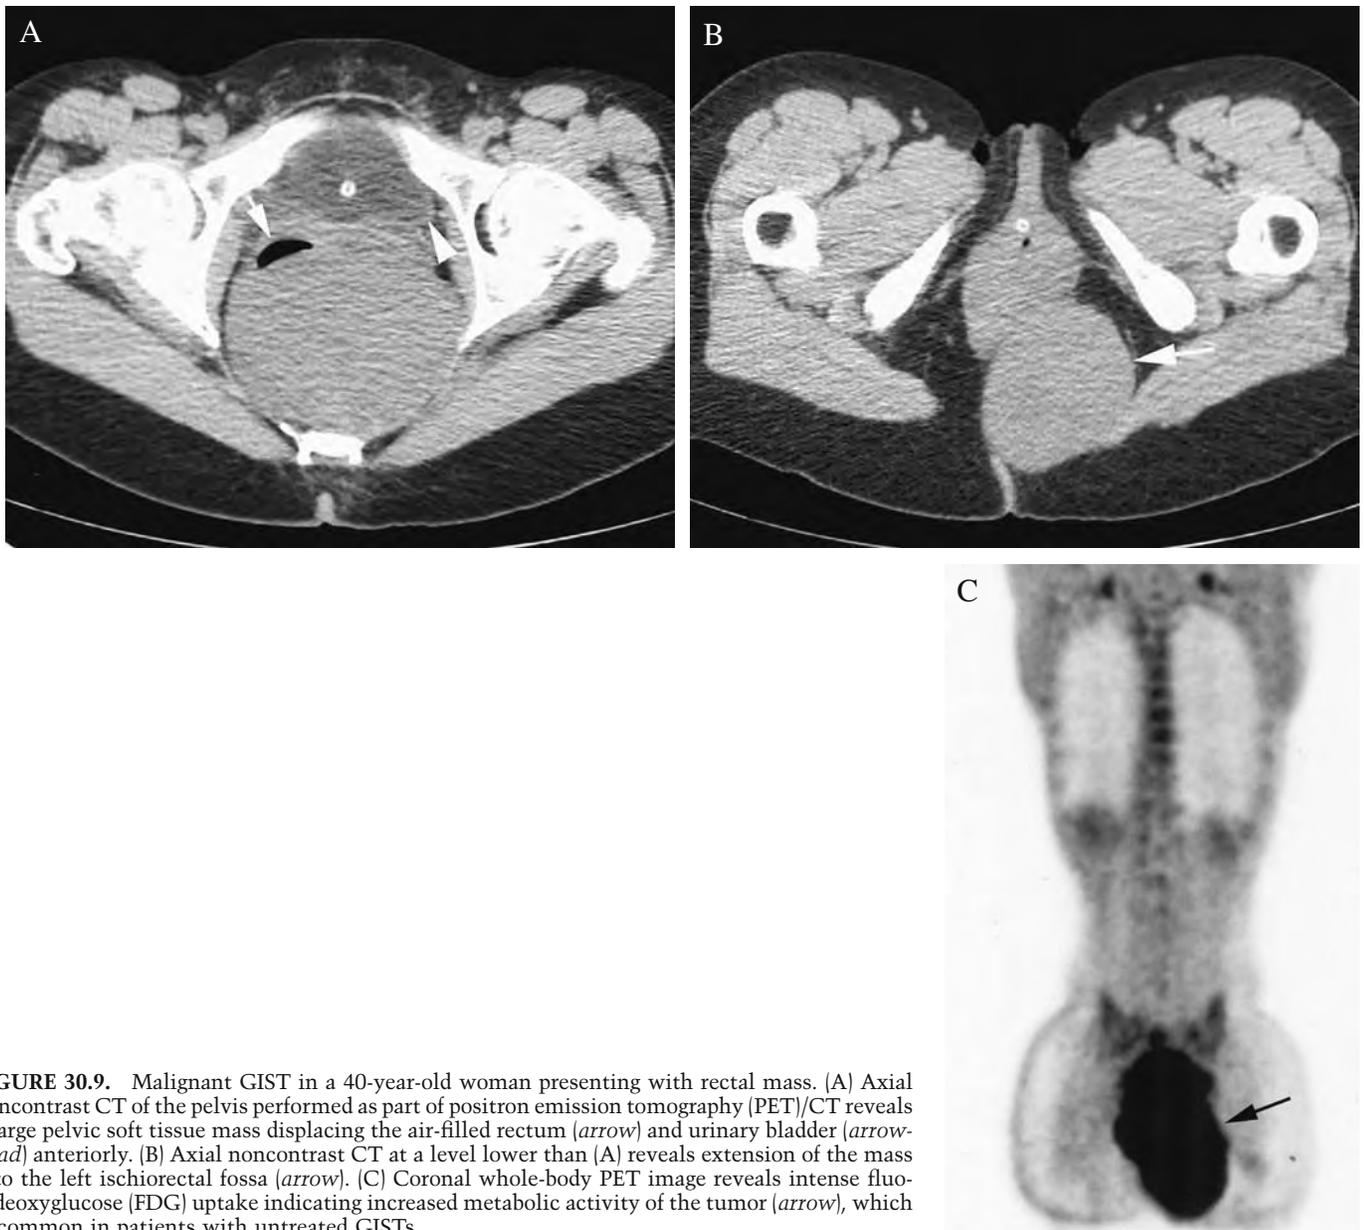

FIGURE 30.9. Malignant GIST in a 40-year-old woman presenting with rectal mass. (A) Axial noncontrast CT of the pelvis performed as part of positron emission tomography (PET)/CT reveals a large pelvic soft tissue mass displacing the air-filled rectum (*arrow*) and urinary bladder (*arrow-head*) anteriorly. (B) Axial noncontrast CT at a level lower than (A) reveals extension of the mass into the left ischiorectal fossa (*arrow*). (C) Coronal whole-body PET image reveals intense fluorodeoxyglucose (FDG) uptake indicating increased metabolic activity of the tumor (*arrow*), which is common in patients with untreated GISTs.

may ulcerate (Figure 30.9). The mass may extend into the ischiorectal fossa and may invade surrounding pelvic organs, including the vagina, prostate, or urinary bladder. These findings may result in difficulty identifying the organ of origin on cross-sectional imaging. Similar to GISTs in other locations of the gastrointestinal tract, enhancement is heterogeneous with areas of low attenuation from hemorrhage or necrosis. Calcification and adenopathy are rare. GISTs in the anorectal region show malignant behavior even when small (less than 2 cm in maximum dimension) and have no more than five mitoses per 50 high-power fields. These tumors are also associated with significant mortality rates.⁵³

Rectal adenocarcinoma, anal squamous cell carcinoma, leiomyoma, leiomyosarcoma, lymphoma, and malignant melanoma may have a CT appearance similar to anorectal GIST and are in the differential diagnosis. Leiomyosarcoma may have a dominant polypoid mass while adenocarcinoma may have an irregular margin, soft tissue invasion into

ischiorectal fossa, and perirectal adenopathy.¹⁴ Primary anorectal lymphoma may be seen in patients with acquired immunodeficiency syndrome and may be associated with mucosal ulceration or perianal fistula. Other features that may be seen in primary anorectal lymphoma, include tumor heterogeneity, concentric wall thickening, intraluminal polypoid masses, and thickening of adjacent levator ani muscle.²⁷

Colon

Primary colonic GISTs are much less common than gastric, small bowel, and anorectal GISTs. These transmural tumors may involve the intraluminal and extraserosal surfaces of the colon.¹⁵ They are smooth or multinodular in contour with areas of low attenuation due to hemorrhage, necrosis, or cystic degeneration. Circumferential involvement of the

colon with aneurysmal dilatation of the involved segment of the colon has been described.¹⁵

At CT, small lesions are confined to the wall of the colon and appear as mural or submucosal masses, which may ulcerate. Differential diagnosis includes adenocarcinoma, lymphoma, leiomyosarcoma, and metastatic melanoma. Tumors arising adjacent to the colon, such as retroperitoneal sarcomas, may involve the colon and may be mistaken for GISTs.

Esophagus

The most common neoplasm of the esophagus is leiomyoma, accounting for 75% of tumors. They occur in a younger population (median age, 35 years) compared to GISTs, which are relatively uncommon in the esophagus and occur in older patients (median age, 63 years).¹⁵ Esophageal GISTs are most commonly located in the distal third of the esophagus and may extend into the stomach. These lesions may be homogeneous or heterogeneous with central areas of low attenuation due to hemorrhage, necrosis, or cystic degeneration. Most esophageal GISTs are benign, unlike the trend seen elsewhere in the gastrointestinal tract where most GISTs are malignant.

The differential diagnosis of esophageal GISTs include leiomyoma, duplication cysts, lipoma, neurofibroma, schwannoma, and hemangioma. GISTs may also simulate other lesions that have a polypoid appearance such as papilloma, adenoma, fibrovascular polyp, and inflammatory polyp. Large GISTs may invade the mediastinum, simulating advanced carcinoma, lymphoma, leiomyosarcoma, and malignant melanoma.

Omentum and Mesentery

Primary GISTs rarely may arise from the omentum or mesentery⁵⁴; these are usually large multilobulated masses with areas of low attenuation due to hemorrhage, necrosis, or cystic degeneration. Trace amount of free fluid in the abdomen may be present.⁵⁵ CT findings of GISTs arising in these locations are not characteristic, and they are indistinguishable from other sarcomas including liposarcoma, fibrosarcoma, leiomyosarcoma, inflammatory pseudopolyp, and mesenteric fibromatosis. Therefore, presumptive diagnosis before biopsy or surgery may be difficult.

GISTs from the gastrointestinal tract may metastasize to the omentum and mesentery, resulting in multiple peritoneal masses (Figure 30.10). Patients may also develop peritonitis secondary to tumor rupture. In these cases, the differential diagnosis includes peritoneal carcinomatosis and lymphoma.

Treatment and Prognosis

Surgical resection of the primary disease followed by observation is the conventional treatment for patients with GISTs and offers the best cure rate.^{48,56} For resectable GISTs, preoperative histologic confirmation is usually not necessary as these tumors may bleed, rupture, or disseminate as a result of biopsy.¹⁷ For the same reasons, the tumor should be removed en bloc during surgery.⁵⁷ A safety margin of normal surrounding soft tissue or bowel should be included if pos-

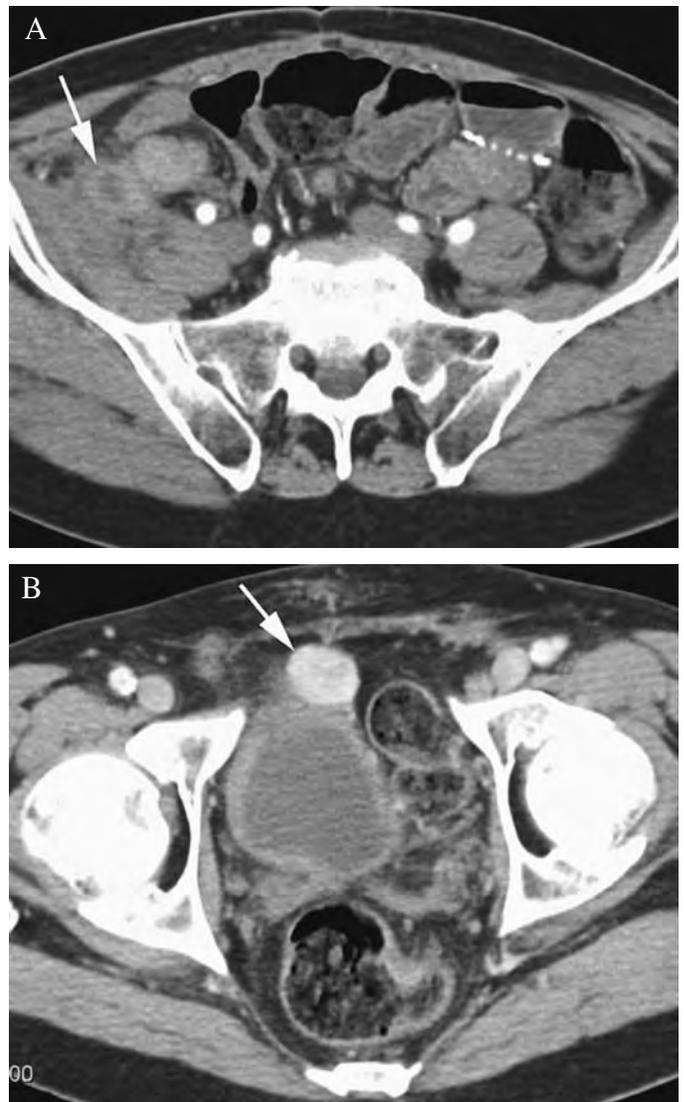

FIGURE 30.10. Tumor recurrence in a 75-year-old man 14 months after resection of malignant mesenteric GIST. (A) Axial CT of the pelvis reveals a rim-enhancing soft tissue mass along the right ilio-pectus muscle (*arrow*) suspicious for tumor recurrence. Surgical sutures from prior bowel resection are identified in the left lower quadrant. (B) Axial CT of the pelvis at a level more inferior than (A) reveals a hypervascular mass (*arrow*) anterior to the urinary bladder compatible with tumor recurrence.

sible to reduce the risk of recurrence.^{48,58} Because lymph node metastases are rare, extensive lymphadenectomy is not routinely performed.

Because of the unpredictable behavior of GIST, follow-up by imaging is performed to assess for disease recurrence, even though there is no proof that early detection of recurrent GIST results in survival benefit.³¹ Disease recurrence has been reported in up to 80% of cases despite complete resection with pathologically proven negative margins.⁵⁷ Although most recurrences occur within 2 years, tumors with low mitotic index may take more than 10 years to metastasize.³⁵ Recurrence is commonly local and peritoneal, often associated with liver metastases (Figure 30.11). Lymph node involvement is unusual. Most metastatic GISTs are confined to the abdomen, unlike other soft tissue sarcomas, which metastasize to the lungs.⁵⁹

Patients with recurrence have a poor prognosis.³⁰ Arterial embolization, surgery, and irradiation have been ineffective in treating patients with metastases and recurrent disease. Until recently, drug therapy for patients with GISTs has also been ineffective. However, a promising new drug, STI 571 (imatinib mesylate, gleevec) has been recently introduced. This new drug inhibits tyrosine kinase and was first reported in a case of recurrent metastatic GIST that failed extensive surgery and chemotherapy.⁵⁶ The authors reported favorable response to therapy after 1 month of treatment, using MRI and PET. The safety and effectiveness of this new therapy were subsequently demonstrated in patients with advanced unresectable or metastatic disease.^{60,61} Current studies demonstrate up to 69% of patients showing favorable response to therapy.⁶¹ However, it is still unclear how long the response to therapy will last and whether maintenance therapy is required.

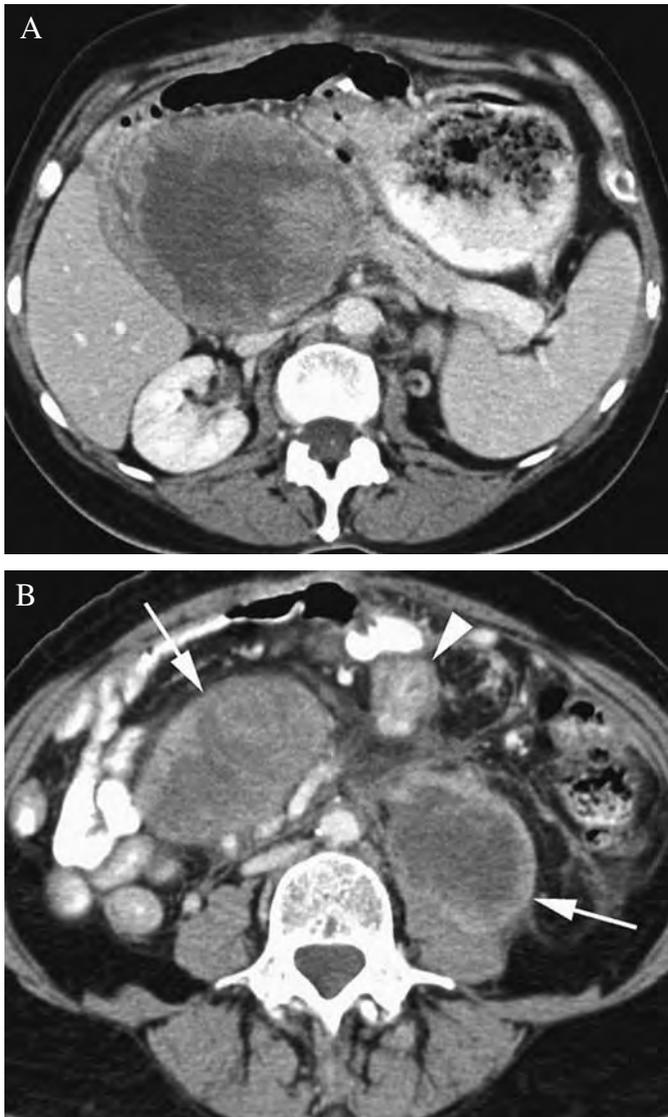

FIGURE 30.11. Recurrent malignant GIST of the small bowel in a 62-year-old woman. (A) Axial CT of the upper abdomen in the portal venous phase reveals a large partially necrotic liver mass, with peripheral enhancement and central low attenuation. (B) Axial CT at a level lower than (A) reveals additional enhancing paraaortic (*arrows*) and mesenteric root (*arrowhead*) masses, with central necrosis. These findings are consistent with peritoneal recurrence.

Kidney

Renal Cell Carcinoma

With the increased availability of abdominal ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI), many renal cell carcinomas are now incidentally discovered, which has resulted in detection of such tumors at an early stage in asymptomatic patients.

CT is currently the method of choice for evaluation of suspected renal masses and for preoperative staging of renal cell carcinoma (Figure 31.1).¹⁻³ The advent of spiral CT has had a significant impact on evaluation of renal masses. With the use of spiral CT, the sensitivity of CT in detecting renal cell carcinoma approaches 100% and specificity is 88% to 95%,^{4,5} or evaluation of known or suspected renal masses, both pre- and postcontrast images with intravenous contrast medium, should be obtained because small renal cell carcinomas are difficult to diagnose without intravenous contrast and diagnosis of masses requires assessment of enhancement.^{1,6} Spiral CT allows a high-quality scan dedicated to the kidneys during various phases of contrast enhancement after a rapid bolus of intravenous contrast material.^{4,7,8} In addition, reformatted and three-dimensional images created from volumetric data sets obtained by spiral CT, particularly with recently introduced multidetector CT, can help assessment of the tumor extent and accurate staging (Figure 31.2).⁹ For detection of renal masses, nephrographic phase images obtained with scan delay, at least 90 seconds after the start of intravenous contrast medium injection, are important because of a higher sensitivity than corticomedullary phase images to detect renal masses.^{6-8,10}

MRI can also be used as an alternative imaging modality to CT for patients allergic to iodine or patients with an inconclusive CT study.¹¹ Gadolinium (Gd)-containing contrast material has been shown to be remarkably safe and is well tolerated in patients with a history of iodinated contrast allergy. Recent studies showed MRI is considered equivalent to CT in accuracy for the detection and characterization of renal masses.¹²⁻¹⁴ A high-quality MR examination can be performed with torso phased-array coils and a variety of breath-hold sequences. Imaging protocols generally include T₁-weighted images obtained with spin-echo and/or breath-hold spoiled gradient echo images and T₂-weighted images obtained with fat-suppressed fast spin-echo images or breath-hold half Fourier single-shot fast spin-echo images. Gadolinium-containing intravenous contrast material is necessary to detect and characterize small lesions (Figure

31.3).^{15,16} An advantage of MRI gadolinium contrast (as opposed to CT contrast) is lack of nephrotoxicity.

Staging of the tumor by radiologic examination is relevant because prognosis and surgical planning largely depends on preoperative imaging delineation of disease extent. Reported accuracy of CT and MRI for staging of renal cell carcinoma is similar, ranging from 67% to 95% for CT and from 67% to 96% for MRI.^{9,11-13} It may be difficult to distinguish stage I (confined within the renal capsule) from stage II (extending into the perinephric fat) disease. Thickening of the renal fascia and dilated tortuous vessels in the perinephric space are not reliable signs of tumor extension into the perinephric fat and may be caused by edema, inflammation, or engorgement of vessels due to increased blood flow through a vascular tumor. Perinephric fat stranding has been detected in up to 50% of stage I tumors on CT (see Figure 31.1). The presence of an enhancing nodule of 1 cm or greater in the perinephric space has been reported to be highly specific (98%) but only 46% sensitive on CT. MRI has been reported to be slightly more accurate compared to CT to predict invasion of perirenal fat.^{11,12}

Tumor thrombus within the renal vein, inferior vena cava (IVC), or right atrium can be directly visualized by CT or MRI. Using spiral CT and electron beam CT, sensitivity and specificity of tumor thrombus in the renal vein were 85% and 98%.¹⁷ In a recent study using multidetector CT with dedicated protocol and thin collimation, 100% accuracy of tumor thrombus in the renal vein and IVC has been reported.⁹ MRI and MR angiography also achieved high sensitivity of 89% to 100%, with specificity of 96% to 100%, in assessment of tumor thrombus in the renal vein and IVC.^{16,18,19} A recent study showed tumor invasion of the IVC wall was imaged by MRI with three-dimensional (3-D) gadolinium-enhanced MR angiography and venography with sensitivity and specificity of 100% and 89%, respectively.²⁰

Distinction between metastatic and hyperplastic lymph nodes is limited for both CT and MRI because size remains the only criterion for diagnosis of lymph node metastasis. Studer et al. reported that CT is sensitive for the detection of enlarged lymph nodes in patients with renal cell carcinoma (95%), but more than 50% of enlarged nodes were caused by benign inflammatory changes, probably the result of tumoral necrosis or venous thrombosis.²¹ They also reported that when using a size criteria of 1 cm or greater for regional lymph node metastasis there is a 4% false-negative rate for lymph node staging.²¹

A variety of complex or complicated cystic masses occur in the kidney. Bosniak has described a classification system

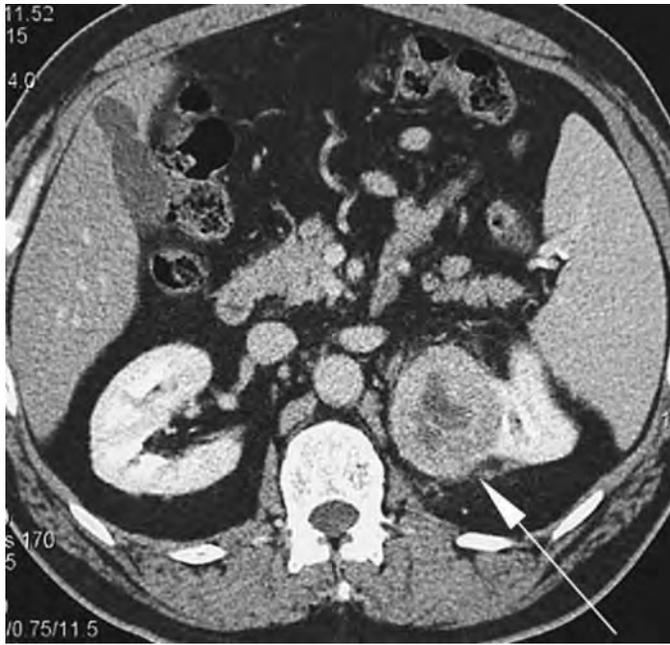

FIGURE 31.1. Renal cell carcinoma. Contrast-enhanced computed tomography (CT) scan shows heterogeneous mass in the left kidney (arrow). There is stranding around the mass, which is caused by peritumoral inflammation found by pathologic specimen. There was no capsular invasion. The pathologic stage was T2 Nx Mx.

in which CT features are used to classify cystic masses into four types to determine the likelihood of malignancy and aid in the management of complicated cystic lesions.²² CT and MRI with intravenous contrast material are equivalent for distinguishing cysts from neoplasms.¹ Image subtraction is commonly used for MRI and aids in complex cases. Images without gadolinium are subtracted from those obtained after gadolinium contrast agent. Complex cystic lesions that may otherwise appear to enhance are subtracted from the resulting image. The method is particularly important for patients with polycystic kidneys.

With increased detection of renal tumors at an earlier stage, more limited or less invasive surgical procedures, such as nephron-sparing and laparoscopic surgery, have evolved as effective alternatives to radical nephrectomy.²³ Nephron-sparing surgery is increasing in frequency because excellent preliminary results have been reported with small, low-stage renal cell carcinoma. More recently, less invasive nephron-sparing procedures have been applied to the treatment of renal cell carcinoma including laparoscopic surgery, radiofrequency ablation, and cryoablation. CT and MRI can play an important role to assess the precise location of the tumor in relation to the major vessels and the renal collecting system and to determine whether nephron-sparing surgery can be performed (see Figure 31.2).²⁴⁻²⁷

Other solid renal masses include oncocytoma, lymphoma, angiomyolipoma, pseudotumor, and metastatic tumor to the kidney (Figure 31.4). Oncocytoma requires surgical resection because it is not radiographically distinguished from renal cell carcinoma, but other tumors are generally not treated by surgery. Percutaneous renal biopsy may be useful in several clinical situations: (a) lesions that do not have the typical

radiologic features of renal cell carcinoma, (b) lesions that are unresectable, (c) lesions that are of uncertain histology, (d) possibly metastatic lesions, (e) lesions for which lymphoma is a diagnostic consideration, and (f) lesions for which treatment may be altered by histologic diagnosis.²⁸ In these populations, the accuracy of biopsy of 87% to 89% without significant complications has been reported.^{28,29}

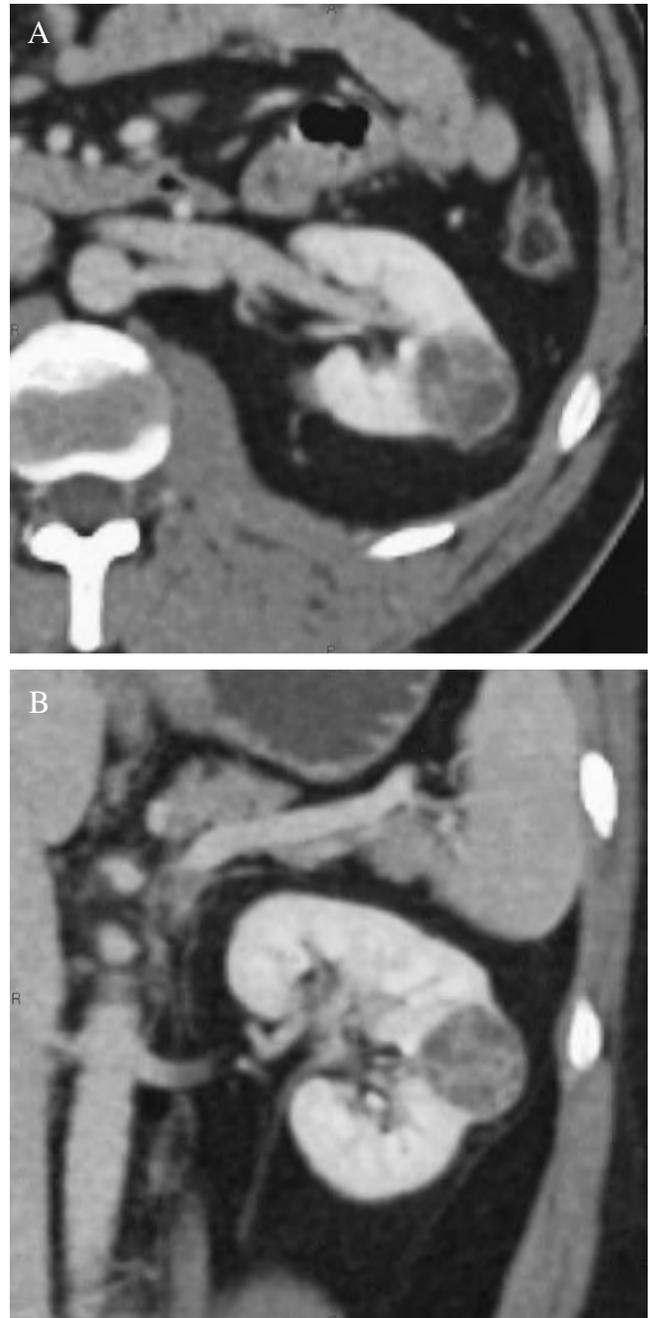

FIGURE 31.2. Renal cell carcinoma. (A) Contrast-enhanced CT scan obtained during nephrographic phase shows a 3-cm mass in the left kidney. (B) Coronal reformatted CT image shows the mass is located in the periphery and is partially exophytic. There is no evidence of vascular or collecting system involvement. The patient underwent nephron-sparing nephrectomy. The pathologic stage was T1 Nx Mx.

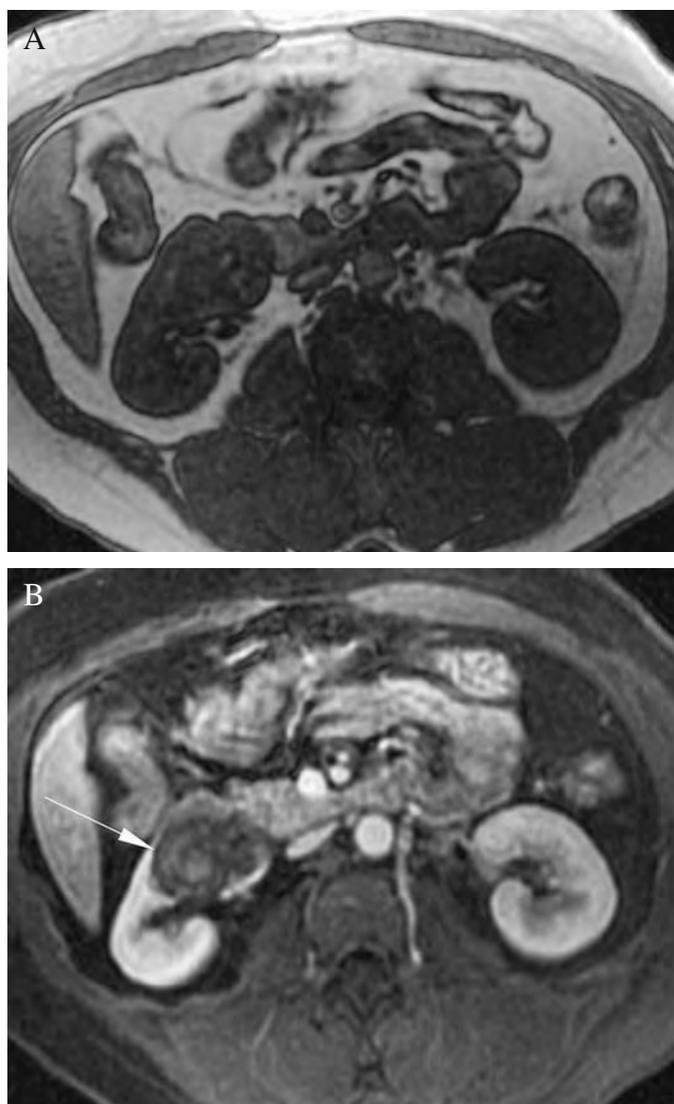

FIGURE 31.3. Renal cell carcinoma. (A) Axial T₁-weighted image shows right renal mass isointense to the kidney, which is difficult to appreciate without contrast enhancement. (B) Postcontrast T₁-weighted image with fat suppression shows the minimal enhancement of the mass, which is much less than the adjacent renal cortex. The mass abuts the pancreatic head (*arrow*). The patient underwent right nephrectomy. Pathologically, it was papillary renal cell carcinoma with the pathologic stage of T1 Nx Mx.

Urothelial Carcinoma

Collecting System and Ureter

Transitional cell carcinoma (TCC) of the renal pelvis accounts for approximately 7% of primary malignancies of the kidney. TCC is often multifocal. Two percent to 4% of patients with TCC of the bladder develop upper urinary tract tumors, and metachronous upper tract tumors develop in 19% of upper tract TCC. Urography, sonography, or retrograde pyelography is often the initial study for suspected upper tract urothelial tumors.¹ The most sensitive imaging modality for detecting and delineating tumors in the upper urinary tract is retrograde pyelography,³⁰ with sensitivity of 72% and specificity of 85%.³¹

Transitional carcinoma of the upper urinary tract may be seen on CT as an intraluminal soft tissue mass (Figure 31.5), diffuse or eccentric thickening or irregularity of the wall, or with obstruction of the collecting system proximal to a soft tissue mass.^{32,33} On noncontrast CT, it is seen as soft tissue density of 10 to 40 Hounsfield units (HU), and there is minimal increase in density after intravenous contrast medium administration.¹ With multidetector CT, a ureteral mass as small as 5 mm can be detected. It may displace and compress the renal sinus fat or infiltrate the renal parenchyma (Figure 31.6).^{32,33} A focal obstructive nephrogram may be seen with a delayed and late persistent dense nephro-

FIGURE 31.4. Malignant lymphoma of the kidney. (A) Contrast-enhanced CT obtained during corticomedullary phase shows large soft tissue mass involving the left kidney. Lymphadenopathy is also seen along the left renal vein (*arrow*). (B) Contrast-enhanced CT obtained during excretory phase shows minimal, homogeneous contrast enhancement of the mass. The patient underwent ultrasound-guided percutaneous biopsy, which revealed malignant lymphoma.

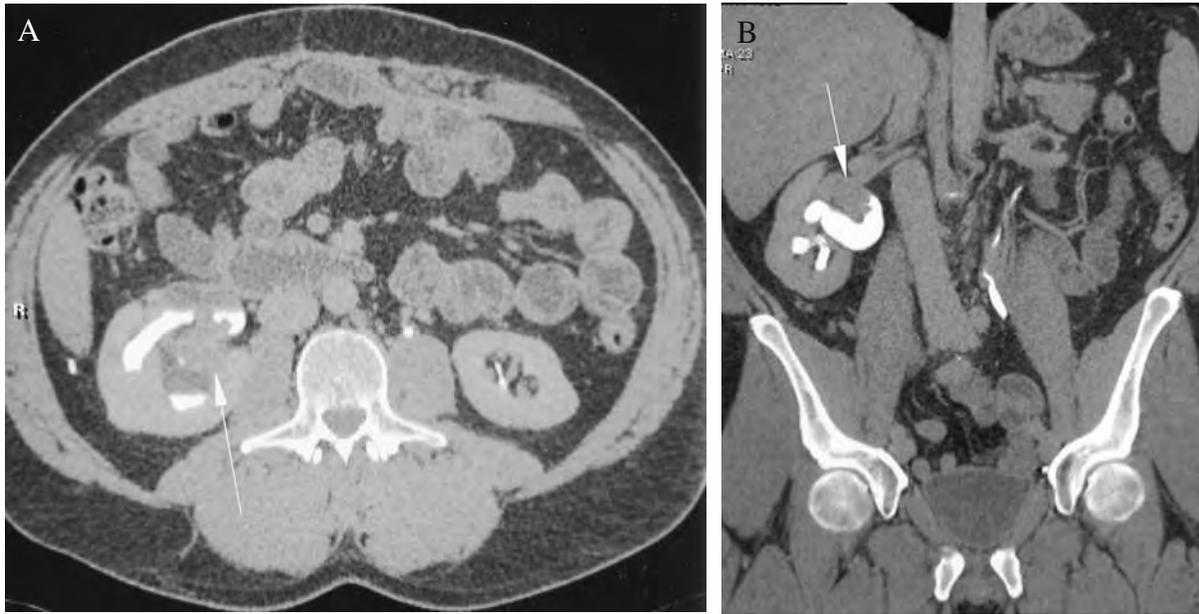

FIGURE 31.5. Transitional cell carcinoma of the right renal pelvis. (A) Contrast-enhanced CT scan obtained during excretory phase. There is a soft tissue mass within the right renal pelvis. Right hydronephrosis is caused by the accessory right renal artery crossing the ureterovesical junction seen on arterial phase images (not shown).

(B) Coronal reformatted CT image obtained during excretory phase. Soft tissue mass causes filling defect within the dilated right renal pelvis. The patient underwent laparoscopic nephrectomy. Pathologically, it was superficially invasive low-grade transitional cell carcinoma, and the pathologic stage was T1 Nx Mx.

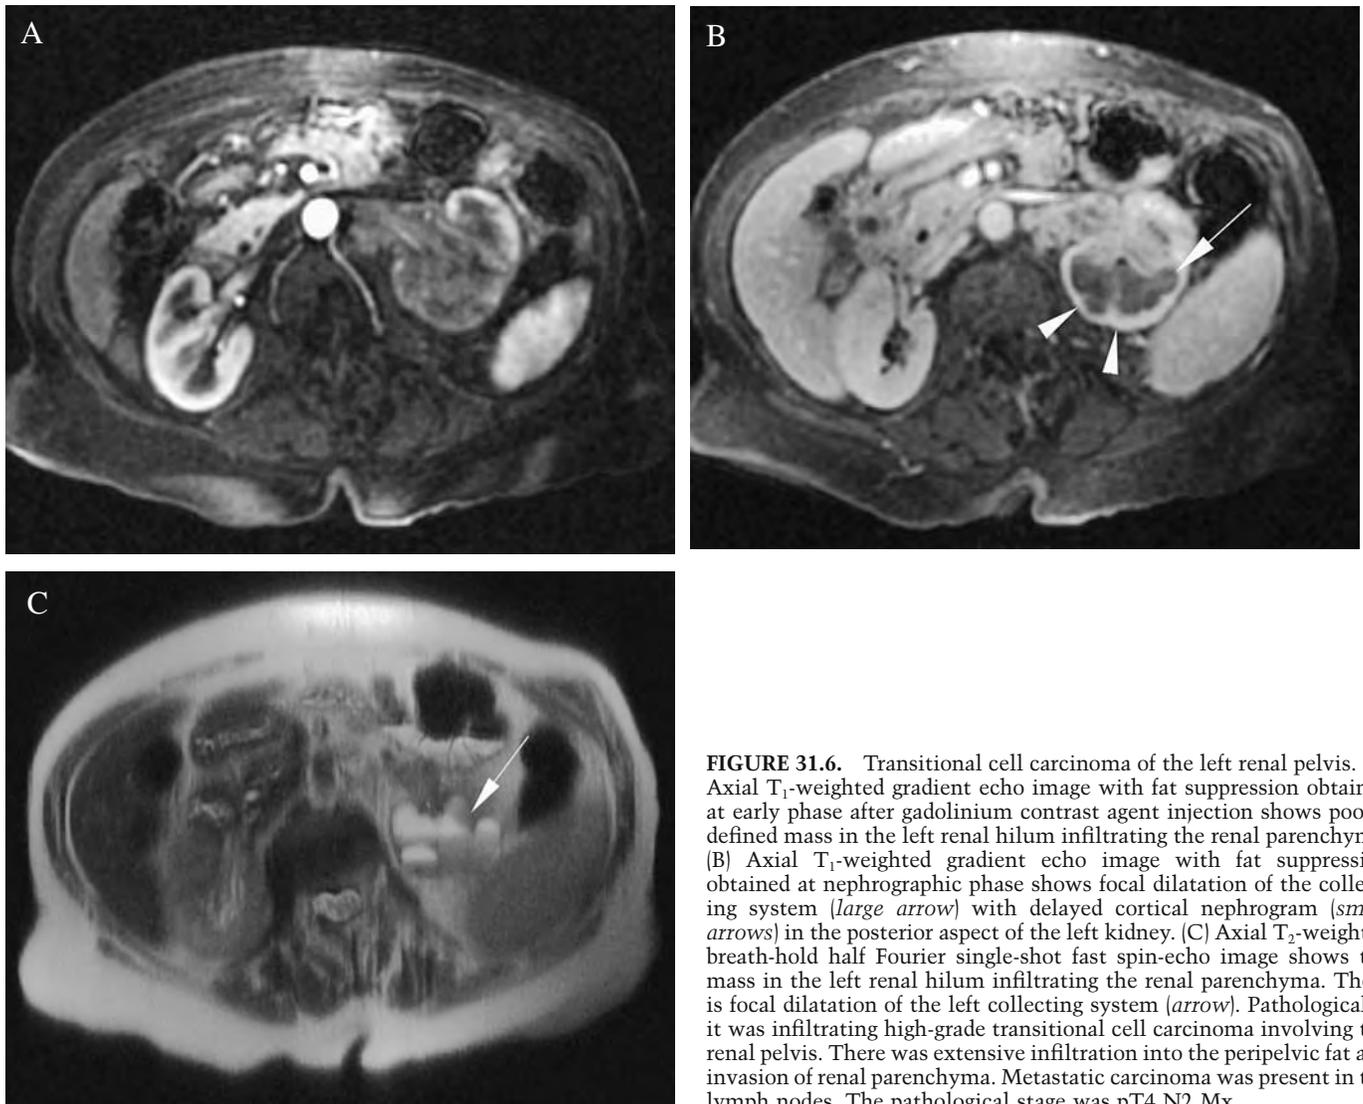

FIGURE 31.6. Transitional cell carcinoma of the left renal pelvis. (A) Axial T₁-weighted gradient echo image with fat suppression obtained at early phase after gadolinium contrast agent injection shows poorly defined mass in the left renal hilum infiltrating the renal parenchyma. (B) Axial T₁-weighted gradient echo image with fat suppression obtained at nephrographic phase shows focal dilatation of the collecting system (*large arrow*) with delayed cortical nephrogram (*small arrows*) in the posterior aspect of the left kidney. (C) Axial T₂-weighted breath-hold half Fourier single-shot fast spin-echo image shows the mass in the left renal hilum infiltrating the renal parenchyma. There is focal dilatation of the left collecting system (*arrow*). Pathologically, it was infiltrating high-grade transitional cell carcinoma involving the renal pelvis. There was extensive infiltration into the peripelvic fat and invasion of renal parenchyma. Metastatic carcinoma was present in the lymph nodes. The pathological stage was pT4 N2 Mx.

gram.³⁴ CT can differentiate tumor from other causes of filling defects such as stone or blood clot by measurements of density.³⁵

Although CT is the most accurate imaging procedure available for staging of urothelial tumors,¹ it is generally agreed that CT cannot distinguish Ta to T2 lesions (Ta, limited to mucosa; T1, tumor involves the submucosa; T2, muscle invasive tumor).³⁶ Overstaging localized disease as T3 (deep invasion into the renal parenchyma or peripelvic soft tissue) is common, particularly when hydronephrosis is present. However, to detect invasion beyond the pelvic wall or metastatic disease, conventional CT has 85% accuracy,³⁷ and CT plays an important role in defining adjacent organ invasion.³⁸ In the detection of lymph node involvement, CT has specificity of 94% to 100% but variable sensitivity of 47% to 88%.³⁸⁻⁴⁰ With use of spiral CT, improved T staging is expected due to better resolution, but no publications are available to date.

MRI is not commonly used for diagnosis and staging of the upper tract TCC. However, MRI is useful for patients who cannot tolerate iodinated contrast material (see Figure 31.6).³³ In a study of MRI with nine patients with upper urinary tract transitional cell carcinoma, including gadolinium-enhanced sequences, MRI achieved accuracy of 89% for staging.⁴¹ There was understaging of direct tumor invasion into the renal parenchyma in one case.⁴¹

Bladder Carcinoma

Cystoscopy is the primary diagnostic procedure for diagnosis and follow-up of bladder carcinomas and is very sensitive in detecting small bladder neoplasms. The stage of tumor at diagnosis determines management and is an important prognostic factor. Clinical staging by cystoscopy, biopsy, and bimanual examination under anesthesia is accurate for superficial tumors (T1 and lower), but a significant error has been shown in staging muscle-invasive tumors (T2a and higher).^{42,43}

CT and MRI are performed for tumor staging once the diagnosis of bladder carcinoma has been established. Bladder tumors are seen as focal or diffuse wall thickening, or a sessile or pedunculated soft tissue mass protruding into the bladder lumen on CT and MR imaging (Figures 31.7, 31.8). Transitional cell carcinoma of the bladder enhances immediately and intensely after bolus injection of iodinated contrast material compared to uninvolved bladder wall on CT or MRI (Figures 31.7, 31.8). In some instances, MRI can differentiate superficial (T2a) and deep muscle invasion (T2b). MRI also allows detection of extravesical spread more readily than with other imaging modalities because of its superior soft tissue differentiation and multiplanar imaging capability. On MRI, transitional cell carcinoma tends to have an intermediate signal intensity, greater than normal muscle on T₂-weighted images, and is significantly more intense than muscle on gadolinium-enhanced T₁-weighted images. If the inner aspect of the low-intensity bladder wall is irregular, superficial muscle invasion is suspected. If the low-intensity bladder line is disrupted, deep muscle invasion is diagnosed.⁴⁴⁻⁴⁷ Reported overall accuracy of MR imaging in staging of bladder cancer ranges from 73% to 96%, which is 10% to 33% higher than that obtained with CT.⁴⁷ With the use of gadolinium-containing contrast material, improved detection of small

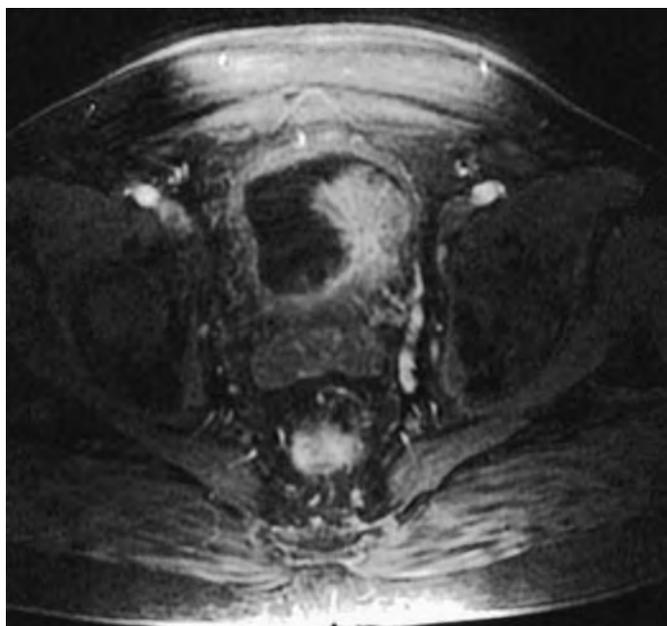

FIGURE 31.7. Bladder cancer. Axial T₁-weighted magnetic resonance (MR) image with fat suppression obtained after gadolinium contrast agent injection shows a large papillary mass arising from the left posterior wall projecting into the bladder lumen. There is contrast enhancement in the central portion of the tumor.

tumors and an increase in accuracy of local staging were reported.⁴⁶ Therefore, MRI is the staging modality of choice for invasive tumors. The use of phased-array external surface coils or endorectal surface coils allows higher signal-to-noise ratio and higher spatial resolution images of the bladder, and these are successfully applied to the imaging of bladder cancer.⁴⁸

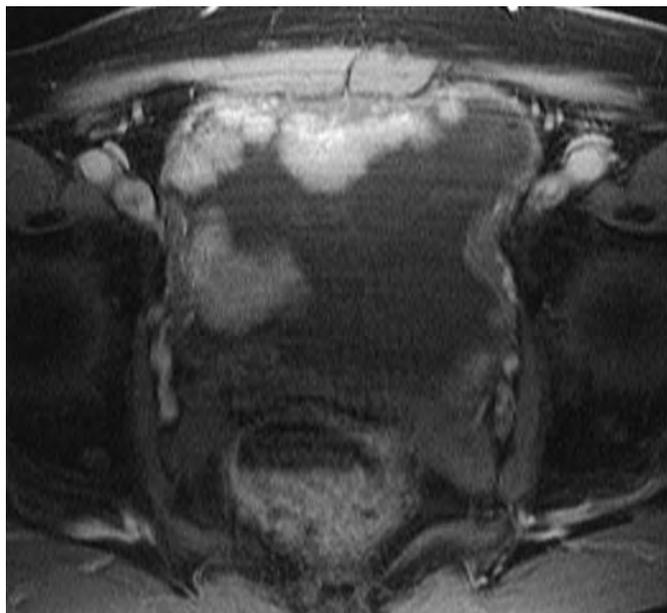

FIGURE 31.8. Bladder cancer. Axial T₁-weighted MR image with fat suppression obtained after gadolinium contrast agent injection shows multifocal masses arising from the anterior and right lateral wall of the bladder projecting into the bladder lumen.

Patients with bladder cancer and lymph node metastases have a worse prognosis than those without metastatic nodes. Reported accuracy of CT and MRI in detecting lymph node metastasis is similar, ranging from 70% to 98%.⁴⁹ Three-dimensional magnetization prepared rapid acquisition gradient echo (MP-RAGE) images have improved the detection of suspicious lymph nodes.^{50,51} Lymphotropic contrast agents, such as ultrasmall superparamagnetic iron oxide (USPIO) may improve distinguishing between benign and malignant lymph nodes.⁵²

Inflammation of the bladder wall after radiotherapy or other causes may be indistinguishable from neoplastic infiltration as both may enhance substantially. A study showed that early-phase dynamic gadolinium-enhanced imaging improved distinction of tumor and postbiopsy changes of the bladder wall because bladder cancer enhanced earlier (6.5 seconds) than postbiopsy inflammation and granulation tissue (13.6 seconds) after gadolinium contrast administration.⁵³

Virtual cystoscopy created with CT or MR data has recently been used to detect bladder cancer. Recent studies of virtual cystoscopy created with CT data showed a sensitivity of 89% to 100% compared with fiberoptic cystoscopy.⁵⁴⁻⁵⁶ Most tumors not detected by virtual cystoscopy were reported to be less than 1 cm.

Adrenal Gland

Adrenal Adenoma and Differentiation from Other Adrenal Masses

Incidental discovery of adrenal masses is a common clinical problem as a result of the widespread use of imaging procedures, occurring in up to 5% of patients who have undergone

abdominal CT.⁵⁷ Most adrenal masses are benign nonhyperfunctioning adenomas even in patients with a known extra-adrenal malignancy (Figure 31.9).⁵⁷ Primary adrenal carcinoma is rare, with a reported incidence of 2 cases per million (Figure 31.10). Differentiation of benign and malignant adrenal masses is critical to determine appropriate treatment. With advances in CT and MR imaging with dedicated imaging protocols, characterization of these adrenal masses has greatly increased in accuracy.

CT is generally considered the modality of choice for initial characterization of the adrenal mass. A noncontrast scan should be first performed, and a contrast-enhanced CT scan may be necessary if the noncontrast scan is not conclusive.⁵⁸ MRI is reserved for cases that have indeterminate findings on CT.^{58,59}

Generally, larger adrenal lesions have a greater likelihood of being malignant (see Figure 31.10). In 39 patients with extraadrenal malignancy, 87% of lesions smaller than 3 cm were benign and 95% of lesions greater than 3 cm were malignant.⁶⁰ In another study, among 45 adrenal masses greater than 5 cm found by imaging studies, 33% were malignant.⁶¹ Because of significant overlap of benign and malignant lesions based on size criteria alone, most authorities recommend that masses greater than 4 or 5 cm should be biopsied or surgically excised. Increase in size of the lesion during follow-up can be helpful in predicting malignancy. Adenomas tend to have smooth margins and a homogeneous density, whereas metastases can be heterogeneous and have an irregular shape. However, these are not specific signs of malignancy.⁵⁸

The presence and amount of lipid in many adrenal adenomas accounts for their low attenuation on unenhanced CT scans and their loss in relative signal intensity on chemical shift MR images (see Figure 31.9). There is an inverse linear relationship between the percentage of lipid-rich cortical cells

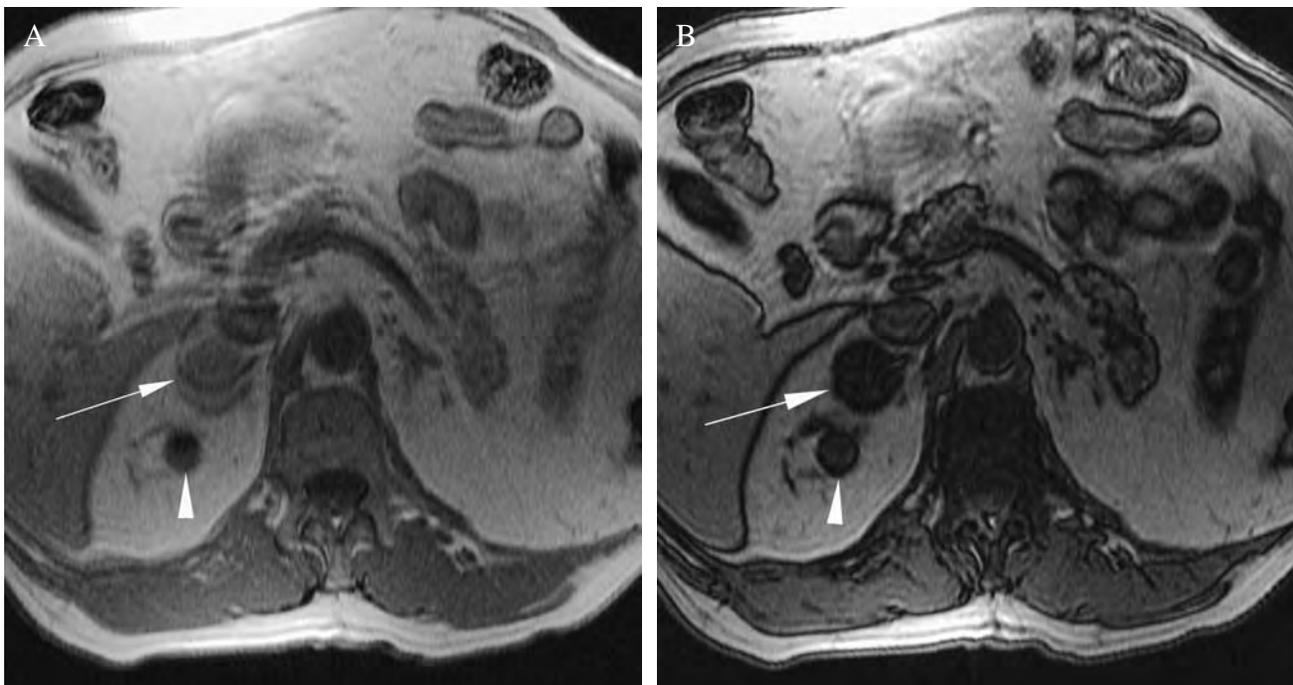

FIGURE 31.9. Adrenal adenoma. (A) Axial T₁-weighted in-phase MR image shows right adrenal mass (*large arrow*). There is a small cyst in the upper pole of the right kidney (*small arrow*). (B) Axial T₁-

weighted out-of phase image shows significant signal dropoff in the lesion (*large arrow*), which is diagnostic of an adenoma.

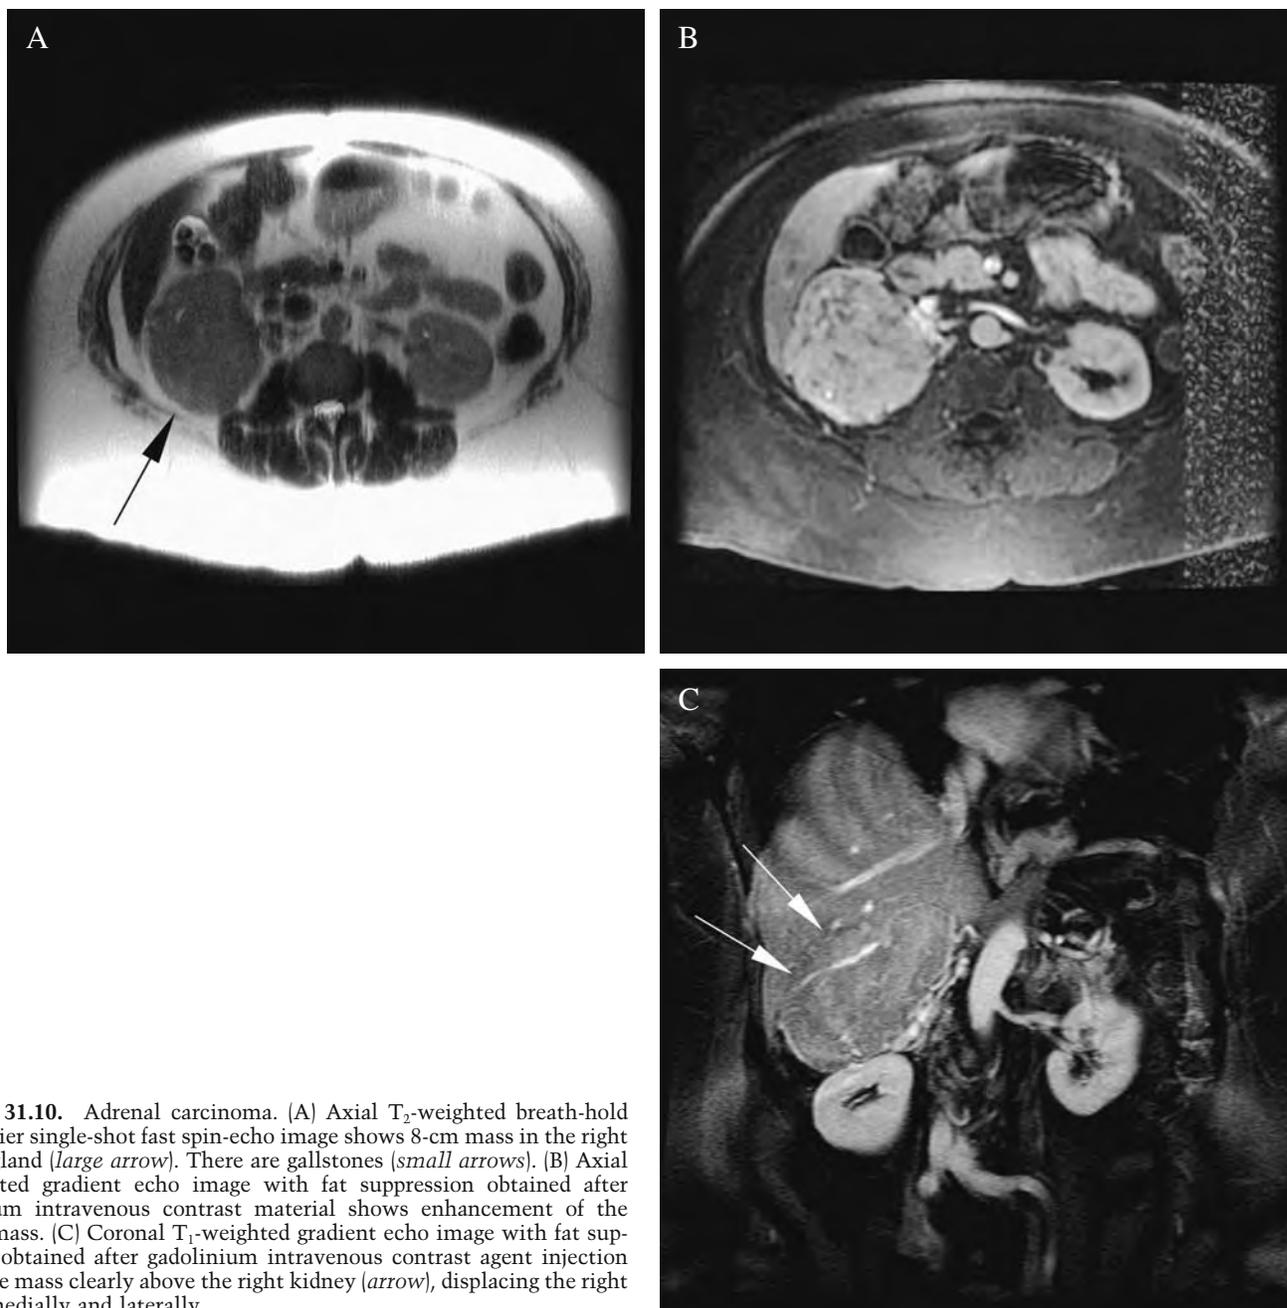

FIGURE 31.10. Adrenal carcinoma. (A) Axial T₂-weighted breath-hold half Fourier single-shot fast spin-echo image shows 8-cm mass in the right adrenal gland (*large arrow*). There are gallstones (*small arrows*). (B) Axial T₁-weighted gradient echo image with fat suppression obtained after gadolinium intravenous contrast material shows enhancement of the adrenal mass. (C) Coronal T₁-weighted gradient echo image with fat suppression obtained after gadolinium intravenous contrast agent injection shows the mass clearly above the right kidney (*arrow*), displacing the right kidney medially and laterally.

in adrenal adenomas and the unenhanced CT attenuation number and a similar inverse linear relationship to the relative change in MR signal intensity on chemical shift images. Metastases, on the other hand, have little intracytoplasmic fat and therefore do not have low attenuation at nonenhanced CT.⁵⁸ Similarly, metastases do not lose signal on chemical shift MR images.

Studies have been performed to determine an adequate threshold to differentiate benign versus malignant adrenal masses on nonenhanced CT. Boland et al. performed a meta-analysis of 10 studies to determine an optimal density threshold to differentiate benign from malignant lesions, and reported that using 10HU as a threshold, noncontrast CT has 71% sensitivity and 98% specificity for characterizing adrenal masses.⁶²

If the adrenal mass is more than 10HU at noncontrast CT, CT with intravenous contrast material should be performed to evaluate enhancement washout characteristics. Adenomas lose enhancement more rapidly than nonadenomas, and delayed CT attenuation value was used to differentiate adenomas from nonadenomas. Using an attenuation measurement of less than 30 to 40HU at 10 to 30 minutes after contrast injection, the adrenal mass is almost always an adenoma.⁶³ A relative percentage enhancement washout of greater than 50% calculated by $(1 - \text{delayed enhanced HU value} / \text{initial enhanced HU value}) \times 100$ has a sensitivity of 98% and specificity of 100% for benign disease.⁶⁴ Other investigators used percentage enhancement washout calculated by $(\text{initial enhanced HU value} - \text{delayed enhanced HU value}) / (\text{initial enhanced HU value} - \text{unenhanced HU value})$ with a

threshold of 60% at 50 to 80 seconds after administration of contrast material for the initial scan and 15 minutes for the delayed scan, and achieved 86% to 98% sensitivity and 92% to 96% specificity.^{65,66}

When CT with intravenous contrast is equivocal, chemical shift MR imaging should be performed as chemical shift MR imaging is the most sensitive technique for differentiating adenomas from metastases of the adrenal gland.⁵⁸ With the chemical shift MR technique, the sensitivity and specificity for differentiating adenomas from metastasis ranges from 81% to 100% and 94% to 100%, respectively.⁶⁷⁻⁷⁰ Reported cases of nonadenomas that met these CT or MRI criteria for adenoma, included pheochromocytoma,⁷¹ metastasis from renal cell carcinoma, and adrenocortical carcinoma.^{66,72}

Pheochromocytoma

Pheochromocytoma is usually benign, but approximately 10% of these lesions are malignant. CT is the study of choice to confirm the diagnosis when a pheochromocytoma is suspected on clinical and laboratory grounds.⁵⁸ On CT, pheochromocytoma appears as a well-defined mass with marked enhancement after intravenous contrast administration. MR findings may enable characterization of pheochromocytoma because the signal intensity of these tumors may be very high on T₂-weighted images, probably caused by cystic components. However, there is considerable overlap between the MR appearance of pheochromocytoma and other adrenal lesions. The sensitivity and specificity of MR imaging for diagnosing pheochromocytoma were 64.7% and 88.0%, respectively.⁷³

Adrenal Biopsy

Adrenal biopsy is required when imaging studies cannot accurately characterize an adrenal mass. Harisinghani et al. analyzed 225 oncologic patients who had undergone CT-guided biopsies of an adrenal mass that were indeterminate at CT or MRI and reported that a negative or benign pathology can be regarded as a true-negative evaluation with no necessity to repeat the biopsy.⁵⁹

Prostate Cancer

Accurate staging of prostate cancer is essential for the prognosis and treatment planning. In particular, it is crucial to determine the local extent of prostate cancer (extracapsular extension and seminal vesicle infiltration) and the presence of metastatic disease (lymphatic or hematogenous), because radical prostatectomy is the preferred method of treatment for patients with disease confined to the capsule. Patients with disease outside the prostate are generally not surgical candidates and may be offered an alternative therapy. Clinical staging based on digital rectal examination, transrectal ultrasound, Gleason score, sextant biopsy, and prostate-specific antigen (PSA) has limited accuracy and may underestimate the extent of disease. Previous studies indicated that digital rectal examination underestimates the local extent of cancer in 40% to 60% of the cases.⁷⁴ The purpose of preoper-

ative imaging evaluation is to increase the accuracy of the assigned clinical stage.⁴⁹

The current major clinical role of MRI is to detect disease outside the capsule, including extracapsular extension, seminal vesicle infiltration, nodal metastasis, and bone marrow metastasis once cancer has been diagnosed (Figure 31.11).⁷⁴ Detection of such extracapsular disease eliminates unnecessary surgical procedures.^{49,74} A decision analysis model suggested that preoperative MRI was cost-effective for men with moderate or high probability of extracapsular disease.⁷⁵

On T₂-weighted images, prostate cancer is typically seen as an area of decreased signal intensity within the normally high-signal-intensity peripheral zone. The presence of decreased T₂ signal intensity in the peripheral zone is of limited sensitivity as some tumors are isointense and of limited specificity because other causes, such as hemorrhage, prostatitis, scarring, radiotherapy, cryosurgery, and hormonal therapy can cause low T₂ signal intensity. Overall, the sensitivity of MRI for detecting prostate cancer is approximately 60%.⁷⁶ A more-recent study indicated that in patients with an elevated PSA and negative transurethral sonography-guided quadrant or sextant biopsy results, MRI had a sensitivity of 83% and a positive predictive value of 50% for detection of prostate cancer.⁷⁶ Extracapsular tumor extension is seen as asymmetry or invasion of the neurovascular bundle, obliteration of the rectoprostatic angle, and bulging of the prostate capsule, which may be irregular with a square or rectangular edge or, less commonly, a smooth curvilinear bulge. Accuracy of staging extracapsular extension with MRI ranges

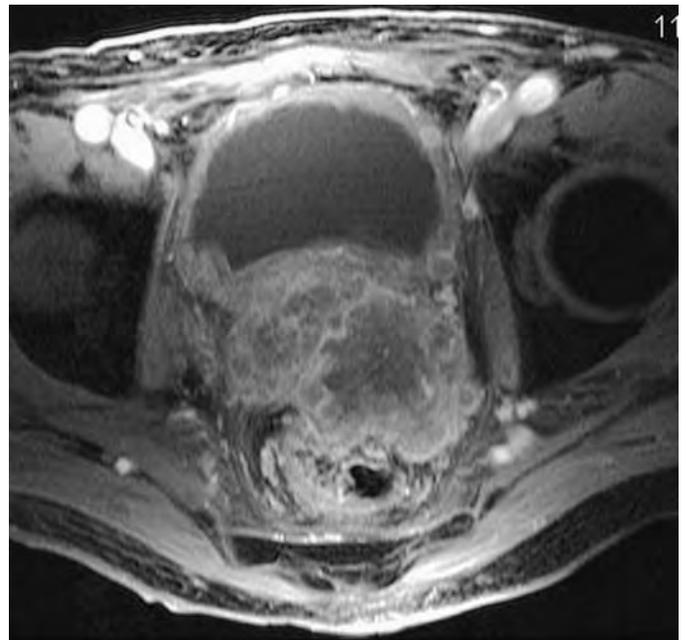

FIGURE 31.11. Prostate cancer. Axial T₁-weighted gradient echo image with fat suppression obtained after gadolinium contrast agent injection. There is a large heterogeneously enhancing mass involving the prostate gland, with involvement of the bladder wall and rectal wall. Pathologically, it was poorly differentiated carcinoma with small cell neuroendocrine features.

from 51% to 92%. It remains impossible to detect microscopic extracapsular extension.⁷⁴ Seminal vesicle invasion is seen as enlargement of one seminal vesicle with abnormal asymmetric low signal intensity within the lumen on T₂-weighted images, although low signal intensity of the seminal vesicles can be caused by other reasons including hemorrhage, radiation, hormonal therapy, and amyloid deposits.⁴⁹ The accuracy of detection of seminal vesicle invasion with endorectal coil ranges between 54% and 96%.^{77–80} A meta-analysis suggested that turbo spin echo, endorectal coil, and multiple imaging planes improve staging performance by MRI.⁸¹

By combining diagnostic variables (age, PSA level, and Gleason tumor grade) with MRI findings, the accuracy of staging can be increased.⁸² It has been shown that the addition of MRI improves the prediction of seminal vesicle invasion and extracapsular extension in patients with intermediate risk, as indicated by PSA levels of 10 to 20 ng/mL and Gleason scores of 5 to 7.⁸³

CT is not recommended for local staging because of its inability to differentiate among normal, hyperplastic, and cancerous glands.⁴⁹ Sensitivity in detection of extracapsular extension of prostate carcinoma is low, especially in early clinical stages. However, it provides useful information for clinically suspected advanced disease with apparent extracapsular extension and extrapelvic involvement.⁴⁹ Guidelines for the use of CT in patients with PSA greater than 20 ng/mL have been reported and are in clinical use.⁸⁴

CT and MRI are useful to detect nodal metastasis in a select group of patients with high risk for nodal metastasis, predicted by digital rectal examination, serum PSA, and biopsy Gleason score.⁷⁴ A study showed that identification of enlarged lymph nodes with subsequent biopsy using CT guidance was shown to identify lymph nodes metastases and thus prevent unnecessary surgery in more than 10% of patients.⁸⁵ In this study, nodes 6 mm or greater in cross-sectional diameter were considered pathologic and were biopsied. CT-guided aspiration biopsy improved the specificity and accuracy of CT in diagnosing lymph node metastases from 96.7% and 93.7% to 100% and 96.5%, respectively. The overall accuracy of CT in detecting pelvic lymph node metastases from prostate cancer is in the range of 67% to 93%.⁴⁹ MRI with a three-dimensional technique has revealed an accuracy of 90% in the detection of nodal metastasis in bladder and prostate cancer.⁵¹ Use of ultrasmall superparamagnetic iron oxide particles (USPIO) was investigated to detect clinically occult lymph node metastases in prostate cancer and significantly improved the detection of small and otherwise undetectable lymph node metastasis compared to conventional MRI. It increased sensitivity and specificity of nodal metastasis from 35.4% and 90.4% to 90.5% and 97.8%, respectively.⁸⁶

MR spectroscopic imaging (¹H-MRSI) is a method that demonstrates normal and altered tissue metabolism. It has been shown that prostate cancer is characterized at MRSI by increased choline and/or decreased levels of citrate.⁸⁷ The addition of MRSI to MRI has been shown to increase staging accuracy⁸⁸ and have potential for more accurate tumor localization.⁸⁹ MRSI, interventional MRI-guided biopsy, and therapy are currently under investigation^{90,91} and not considered to be routine.

Uterus

Cervical Cancer

Cervical carcinoma is staged according to the International Federation of Gynecology and Obstetrics (FIGO) staging system. Accurate staging of cervical cancer is crucial in determining the mode of treatment. Routine clinical staging incorporates gynecologic pelvic examination under anesthesia, chest X-ray, lesion biopsies, cystoscopy, and, if indicated, renal sonography for detection of hydronephrosis.⁹² In most centers, stage IB (confined to the cervix) and stage IIA (extends beyond the cervix but within upper two-thirds of the cervix, no parametrial invasion) disease are treated with hysterectomy with pelvic lymph node dissection. Radiation therapy is the treatment of choice with parametrial involvement (stage IIB or higher).⁴⁹ However, clinical staging was shown to be inaccurate, and discrepancy between clinical staging and surgical staging, ranging from 34% to 39%, has been reported.⁹²

MRI is the modality of choice to image cervical masses that are greater than 1.5 cm or presumed to extend beyond the cervix.⁹³ On MRI, cervical carcinoma most often appears as an intermediate signal or high-signal-intensity mass distorting or disrupting the normal cervical zonal anatomy of the cervix (Figure 31.12). The size of the tumor measured by MRI correlates well with surgical measurement of the tumor size. When the hypointense ring of the cervical stroma is preserved on MRI, parametrial extension can be virtually excluded.⁹³ Parametrial extension is suggested when there is full-thickness invasion of the cervical stroma associated with irregularity or asymmetry of the lateral cervical margin, parametrial mass, or stranding within the parametrial fat (Figure 31.12). However, when full-thickness stromal invasion occurs, microscopic parametrial extension may be present despite a smooth lateral cervical margin and the absence of abnormality in the parametrial fat.

Boss et al. performed meta-analysis of 12 studies published between 1986 and 1995 describing the staging accuracy of MRI in cervical carcinoma.⁹² The mean percentage of overall staging accuracy of MRI without use of contrast agents was 79% (range, 47%–90%), in comparison with the accuracy of the clinical examination of 72% (range, 55%–85%) and that of CT of 62% (range, 32%–80%). The mean percentage of accuracy in detecting parametrial invasion with MRI was 88%, with clinical examination 86%, and with CT 72%. Some studies indicated higher staging accuracy of gadolinium-enhanced T₁-weighted⁹⁴ or dynamic enhancement studies.^{95–97} Another meta-analysis study including 57 articles from 1985 to 2002 showed higher sensitivity and specificity in evaluating bladder invasion by MRI (75% and 91%) compared to CT (64% and 73%), but the specificity of rectal invasion was comparable between MRI and CT.⁹⁸

CT has been used to assess patients with tumors of advanced cervical cancer and evaluating patients for recurrence.⁴⁹ The use of CT in early disease has been limited due to prior reports of low sensitivity and specificity for local invasion.⁹⁹ However, major advances in CT technology during the past few years may broaden the use of CT.⁹⁹ Accuracy of

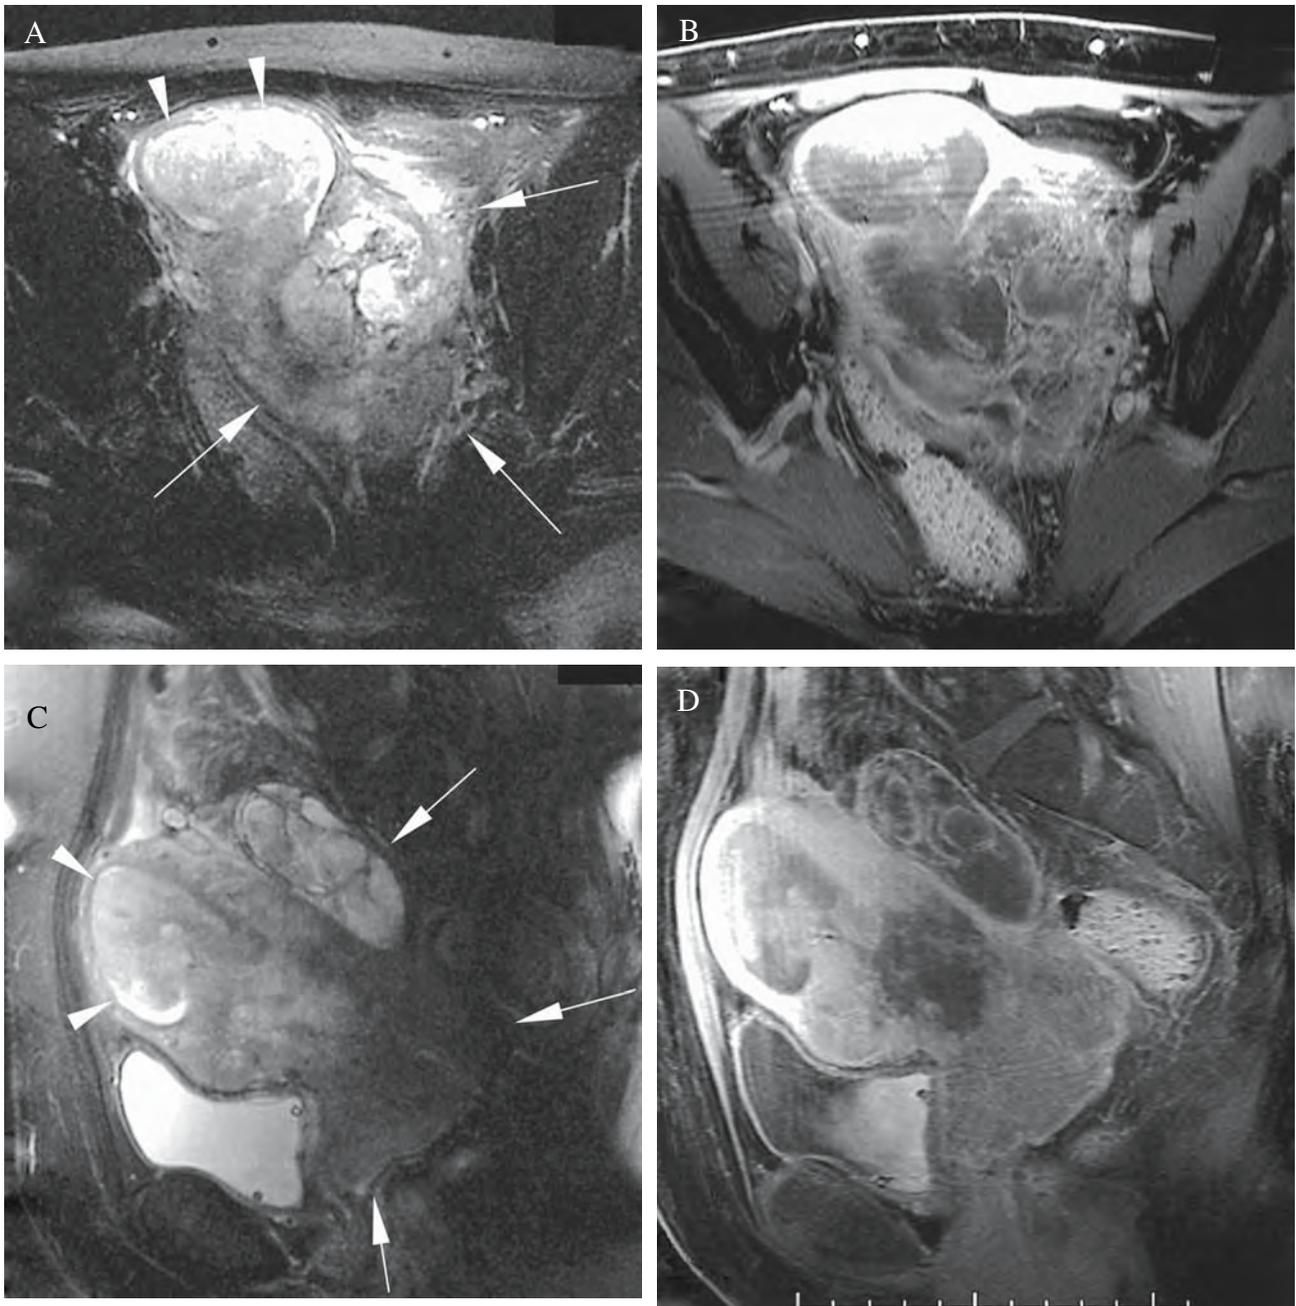

FIGURE 31.12. Cervical cancer. (A) Axial T₂-weighted image with fat suppression shows a large mass obliterating the entire cervix, extending anteriorly into the myometrium and the left pelvic side wall (*large arrow*). The mass obstructs the endometrial canal, which is dilated and filled with secretion and debris (*small arrows*). (B) Axial T₁-weighted gradient echo image with fat suppression obtained after gadolinium contrast agent injection. There is heterogeneous contrast enhancement of the mass. The central area is not enhanced, representing necrosis. (C) Sagittal T₂-weighted image with fat suppression

shows large mass arising from the cervix, extending superiorly into the myometrium (*large arrow*). The mass obstructs the endometrial canal, which is dilated and filled with secretion and debris (*small arrows*). (D) Sagittal T₁-weighted gradient echo image with fat suppression obtained after gadolinium contrast agent injection. There is heterogeneous contrast enhancement of the mass with areas of necrosis. The International Federation of Gynecology and Obstetrics (FIGO) staging was IIIB.

CT staging is greater with advanced disease and is reported as 92% for stage IIIB to IVB cervical cancers.¹⁰⁰

The presence of pelvic lymph node metastases is not part of the FIGO staging criteria; however, it is the most important prognostic factor and findings may be crucial for treatment planning.⁹² Yang et al. reported that central necrosis of pelvic lymph nodes had a positive predictive value of 100%

in the diagnosis of metastatic adenopathy in patients with cervical cancer.¹⁰¹ They reported that spiral CT and MRI are roughly equivalent with accuracy in detecting metastatic pelvic lymph nodes, with accuracy rate of spiral CT and MRI being 89.5% and 85.5%, respectively, when a node of greater than 10 mm in maximal axial diameter or a node with central necrosis was defined as a metastatic node.¹⁰¹ Meta-analysis

studies also showed similar performance in the detection of lymph node metastasis from cervical cancer,¹⁰² with mean accuracy of detection of lymph node metastasis being 86% with nonenhanced MRI and 81% with CT.⁹²

Local recurrence of cervical cancer occurs centrally in the pelvis or at the side wall. CT is an effective diagnostic tool for detection of recurrent cervical cancer, but it may be difficult to differentiate recurrence from postoperative and postirradiation fibrosis.¹⁰³ Gadolinium-enhanced MRI is useful to detect recurrent tumor, which shows increased signal intensity on T₁-weighted images, whereas radiation fibrosis remains low in signal intensity if imaged more than 12 months after radiation therapy.¹⁰³ Dynamic contrast-enhanced MRI has been reported to be more accurate in depicting postoperative recurrent tumor compared to pre- and postcontrast T₁-weighted images and T₂-weighted images.¹⁰⁴

Endometrial Cancer

Endometrial carcinoma is staged according to the FIGO staging system. The prognosis is related to the histologic tumor grade, depth of myometrial invasion, stage of the tumor, and presence of lymph node metastasis. Metastasis to the paraaortic and paracaval lymph nodes may occur without involvement of pelvic lymph nodes if the tumor spreads along the lymphatics accompanying the ovarian vessels. The probability of extrauterine disease and risk of nodal involvement is related primarily to tumor grade and depth of myometrial invasion.

Endometrial carcinoma often presents with vaginal bleeding in postmenopausal women and is usually diagnosed by a combination of ultrasound and endometrial biopsy, which provides the tumor grade and histologic type. Most women with endometrial carcinoma do not require imaging studies⁹³ as surgical staging with the FIGO staging system is performed. However, knowledge of the extent of endometrial cancer spread before undertaking surgery can be of value because myometrial invasion of more than 50% may require more extensive surgery, including pelvic and paraaortic lymphadenectomy.¹⁰⁵ MRI is recommended when locally advanced disease is expected based on physical examination findings and in patients with a difficult physical examination because of obesity or prior radiation or surgery.¹⁰⁶ Hardesty et al. performed a cost analysis study and reported that staging with MRI has similar cost and accuracy compared to the current method of staging with intraoperative gross dissection of the uterus and that MRI decreases the number of unnecessary lymph node dissections.¹⁰⁷

Kinkel et al. performed a meta-analysis in the preoperative assessment of myometrial invasion and demonstrated that contrast-enhanced MRI of the pelvis performed significantly better than ultrasound, CT, and noncontrast MRI.¹⁰⁸ Because MRI can more clearly demonstrate the primary neoplasm and more accurately determine the depth of myometrial invasion than CT, MRI is often used as the imaging procedure of choice in the preoperative evaluation of patients with high-grade endometrial carcinoma,⁴⁹ although advanced extrauterine disease may be assessed with either MRI or contrast-enhanced CT scan.⁹³

Noninvasive endometrial carcinoma may be identified within the uterine cavity on T₂-weighted MR images and is seen as a signal intensity mass intermediate between that of

normal endometrium and that of myometrium.⁴⁹ In some cases, the endometrial stripe may appear homogeneously widened. Preservation of the low-signal-intensity junctional zone usually implies the absence of myometrial invasion, with negative predictive value close to 100%. When myometrial invasion occurs, the interruption of the low-signal-intensity junctional zone on T₂-weighted images¹⁰⁹ or the interruption of the subendometrial enhancing line on early dynamic T₁-weighted images¹¹⁰ is seen. The depth of myometrial invasion can also be assessed to differentiate stage IB and IC disease. The accuracy of MRI in differentiating noninvasive carcinoma (stage 1A) from invasive carcinoma has been reported to range from 74% to 85%, and in distinguishing deep invasion (stage 1C) from superficial disease (stage 1A and 1B) accuracy ranges from 75% to 95%. Dynamic contrast-enhanced MRI improved the accuracy of assessing myometrial invasion from about 83% to 91%.¹⁰⁸ When patients have thinning of the myometrium due to distension of the endometrial cavity,¹¹¹ when the junctional zone is not entirely visualized, or when the zonal anatomy is distorted by uterine abnormalities, such as leiomyoma or adenomyosis, MRI is less accurate for assessing myometrial invasion.⁴⁹ For patients with a thickened or indistinct junctional zone from adenomyosis or other reasons, dynamic contrast-enhanced MRI improves the accuracy of staging.^{112,113}

Ovarian Cancer

Because of paucity of symptoms in early stages, approximately 60% to 75% of patients with ovarian cancer present with advanced disease.^{93,114} Ovarian cancer is staged surgically according to the FIGO staging system. The FIGO system reflects the three primary mechanisms of disease spreads of ovarian cancer, including local, peritoneal, and lymphatic.

In most centers, endovaginal ultrasound is the primary imaging modality used for screening for ovarian cancer and evaluation of an adnexal mass. Because most patients with ovarian cancer present with adnexal or pelvic masses and the majority of adnexal and pelvic masses are benign, differentiation between benign and malignant ovarian tumor is clinically important.

In patients with ovarian cancer, imaging can be used to determine the extent of primary disease before surgical staging and debulking. Imaging is also used to assess for recurrence, especially in symptomatic patients. The primary disease can be staged with CT or MRI, which are equivalent for detecting peritoneal metastases.¹¹⁵⁻¹¹⁸ In a study of 118 women with pelvic malignancies, the sensitivity for peritoneal disease was 92% for CT and 95% for MRI.¹¹⁸

The major role of MRI in evaluation of adnexal masses includes determining if a mass is truly ovarian in origin, to accurately diagnose certain benign lesions, such as dermoid cyst and endometrial cyst, and to more precisely define the internal architecture of ovarian masses. MRI is reported to be a cost-effective next step when the results of the ultrasound are indeterminate.¹¹⁴

On MRI, the presence of solid components or nodules in a cystic tumor, necrosis in a solid tumor, thick, irregular walls or septations, larger lesion size, enhancement of internal structure as well as presence of ascites, peritoneal disease, or adenopathy increase the possibility of malignancy.¹¹⁹ The

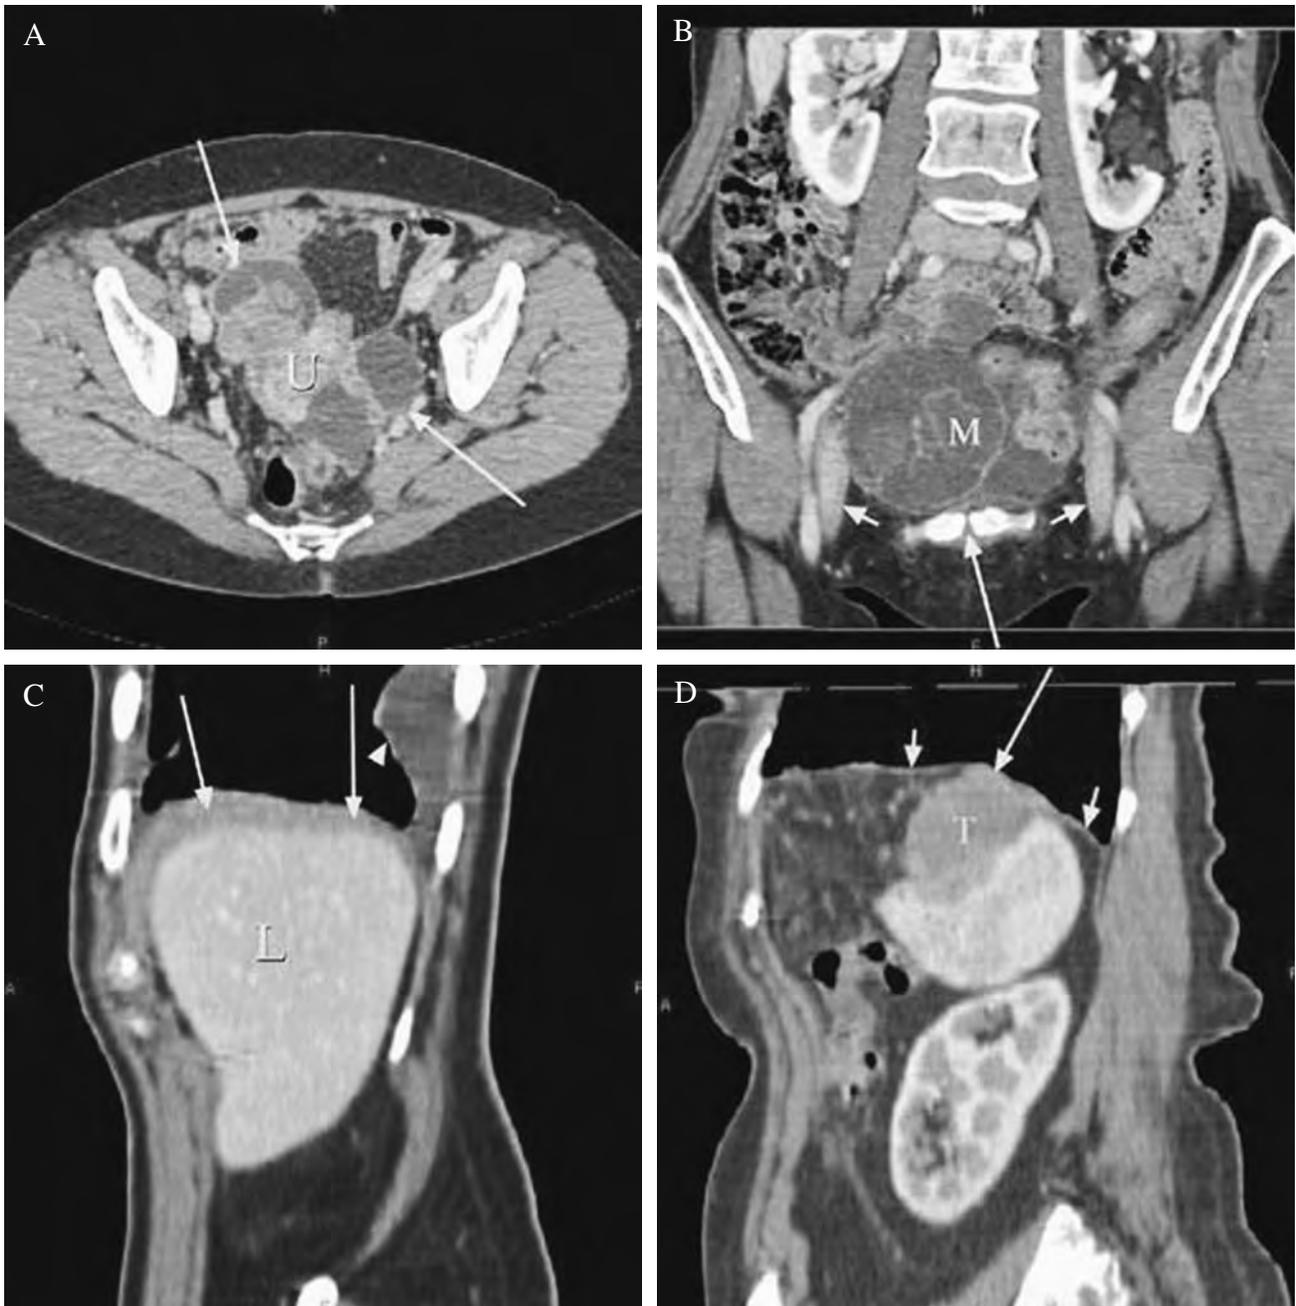

FIGURE 31.13. Ovarian cancer. (A) Axial CT of the pelvis obtained after intravenous contrast material injection shows mixed cystic and solid masses in the bilateral adnexae. *U*, uterus. (B) Coronal reformatted image obtained after intravenous contrast material injection shows cystic ovarian masses abutting the bilateral external iliac veins (*short arrows*). *Large arrow* indicates the pubic symphysis. (C) Sagittal reformatted image of the right upper abdomen obtained after intra-

venous contrast material injection shows thickening of the right hemidiaphragm by tumor deposits along the liver surface (*large arrows*). *Arrowhead* indicates a right pleural effusion. (D) Sagittal reformatted image of the left upper abdomen obtained after intravenous contrast material injection shows tumor (*T*) invading the superior portion of the spleen. *Short arrows* indicate left hemidiaphragm. (From Pannu et al.,¹²⁴ by permission of *RadioGraphics*.)

accuracy of MRI for the diagnosis of malignancy has been reported to range from 83% to 86% without contrast enhancement and from 78% to 95% with contrast enhancement.

CT is usually performed as it is a rapid test and readily available. The peritoneum, retroperitoneum, and viscera are assessed for metastases. Evaluation includes sites that are difficult to evaluate at surgery, such as the diaphragm, splenic hilum, stomach, lesser sac, liver, mesenteric root, and

suprarenal paraaortic nodes (Figure 31.13).^{120,121} Optimal debulking of disease at sites, such as the bowel mesentery and porta hepatis may also be difficult. With a successful debulking procedure, residual tumor implants are subcentimeter in size. Preoperative localization of the sites of peritoneal metastases and retroperitoneal adenopathy aids in surgical planning. Preoperative imaging also helps identify patients who may benefit from neoadjuvant chemotherapy to reduce

disease volume before surgical debulking. CT and clinical parameters have been used to develop scoring systems to predict the success of surgery.^{116,120,122}

A study performed in the late 1990s on 64 patients presenting with ovarian cancer found that the overall sensitivity of single-detector CT for detecting peritoneal metastases was 85% to 93% and the sensitivity for subcentimeter lesions was 25% to 50%.¹²³ There have been significant improvements in CT technology in the past few years with newer multidetector row scanners replacing older single-detector scanners and increasing number of detector rows. These changes allow thin slices of large volumes of anatomy to be obtained in a few seconds. Thin slices optimize visualization of subcentimeter structures and can be used to generate images in multiple planes to evaluate structures, such as the diaphragm and pelvis (see Figure 31.13).^{124,125}

Patients who are suspected to have recurrent disease based on symptoms or biochemical markers can be imaged with CT, MRI, or PET. Detection of lesions on all modalities is dependent on size. For CT, detection is greater for implants greater than 5 to 10 mm than for smaller lesions.^{123,126} Sensitivity of single-detector CT is more than 50% for detecting implants at most sites, except the small bowel and mesentery, where lesions can be difficult to appreciate because of partial volume averaging.¹¹⁶ Implants are easier to visualize when surrounded by ascites. The sensitivity of multidetector row CT for detecting tumor recurrence is not established. The sensitivity of MRI was 91% for detecting recurrence in 64 women with ovarian cancer.¹²⁷ Implants less than 2 cm were present in false-negative cases. Peritoneal, mesenteric, and bowel metastases can be effectively detected with MRI.¹²⁸

Although CT and MRI are usually performed to evaluate patients for recurrence, small implants can be difficult to detect on visceral surfaces by anatomic imaging. The lesions may not be appreciated because of lack of significant contrast difference between tumor and normal viscera. An advantage of functional imaging with PET is that lesions are conspicuous as there is increased uptake in tumor and minimal background activity. The sensitivity of PET for recurrent tumor is higher in patients with suspected relapse compared with those without clinical disease.¹²⁹ Sensitivities ranging from 80% to 100% have been reported in four series with a total of 113 patients.¹²⁹⁻¹³² However, similar to CT and MRI, lesion detection is dependent on size and is less likely for lesions less than 1 to 2 cm in size than for larger masses.^{129,130,133,134} Omental carcinomatosis with subcentimeter lesions may not show sufficient uptake to be detected on PET although it is evident on CT.¹³⁴ In 22 patients with primarily subcentimeter lesions, including microscopic disease, the sensitivity of PET for detecting tumor recurrence was 10%.¹³⁵ In a study of 31 patients with a mean lesion size of 1.1 cm, the patient-based sensitivity of PET for disease recurrence was 81% and lesion-based sensitivity was 45%.¹³⁴ The specificity of PET for recurrent ovarian cancer ranges from 42% to 100%.^{129-132,134,135} Three studies that compared PET findings with surgery found specificities of 93%, 42%, and 50%, respectively.^{130,134,135} High specificities of 83% and 100% were reported in two studies comparing PET with surgical or clinical follow-up.^{129,131} Increased uptake can be seen in postsurgical inflammation and in normal bowel and urinary tract.

However, PET may play a role in assessing patients when CT and MRI are negative and tumor markers are

rising.^{131,136-138} It has been suggested as a complementary test to anatomic imaging.^{131,134,138,139} Sensitivity is improved when both CT and PET are performed.¹⁴⁰ There is also improved correlation with surgical findings if the findings on CT and PET are combined.¹⁴¹ Detection of omental implants and malignant retroperitoneal nodes is improved. PET/CT scanners may play a more significant role in the future in evaluating patients with ovarian cancer. CT images as well as PET images are generated and fused for localization of abnormal activity on PET and characterization of malignant potential in masses seen on CT.^{142,143} However, as currently performed, the CT obtained as part of a PET/CT study is technically limited as the tube current is lower and images are noisier, there is respiratory motion artifact, there is artifact from the patient's arms, and bowel or intravenous contrast are typically not given.

In summary, CT or MRI can be used to detect extraovarian spread of primary tumor and recurrent disease. CT is usually performed due to ease of study and ready availability. Lesion conspicuity is high on PET, and it has been suggested as a complementary test to anatomic imaging for detecting tumor spread. The new fused PET/CT scanners combine the benefits of functional and anatomic imaging and have the potential to more accurately determine disease extent. Subcentimeter lesions are difficult to detect by all imaging modalities.

Musculoskeletal Imaging

Leanne L. Seeger and Kambiz Motamedi

Musculoskeletal tumors often present an imaging dilemma to the clinician. This dilemma occurs not only because primary musculoskeletal malignancies are less common than tumors of other organ systems, such as lung or gastrointestinal, but also because of the vast array of possible pathologies reflecting the many different types of mesenchymal tissue. This chapter concentrates on imaging neoplasia of the extremities (see Chapter 58 for Soft Tissue Sarcoma).

It should be kept in mind that distinguishing between benign neoplasia and low-grade malignancy can be challenging, even for the pathologist¹; this is especially true for tumors composed of cartilage (enchondroma or osteochondroma versus chondrosarcoma)^{2,3} and fat (lipoma versus liposarcoma).⁴ The key to the diagnosis and treatment of musculoskeletal neoplasia is best accomplished by a team approach, with close interaction between the oncologist, oncologic surgeon, radiologist, and pathologist.⁵⁻⁷

Tissue Type

Musculoskeletal tumors may originate from any mesenchymal tissue, including bone (osteoid), cartilage (chondroid), fat (lipoid), connective tissue (fibrous), or vessels (endothelium). The primary cell of origin for some musculoskeletal tumors is unknown; for example, the spectrum of Ewing sarcoma–primitive neuroectodermal tumor (PNET).⁸

Quite often, in cases of benign or low-grade malignant tumors where the principal architectural structure of the underlying cell type is preserved, the tumor origin can be determined with imaging because of the distinct imaging properties of each cell type. In contrast, for the moderate- and higher-grade malignancies, the imaging appearance is generally nonspecific because of alteration of the cells of origin. Plain films show only a mass or a destructive lesion of bone, computed tomography (CT) shows a density similar to muscle, and magnetic resonance imaging (MRI) shows a low to intermediate signal on T₁-weighted images and a high signal on T₂ images.⁹

Tumors that make an osteoid (e.g., osteosarcoma) or chondroid matrix (e.g., chondrosarcoma) are usually mineralized on plain film, and the calcification will almost always show on CT. Osteoid mineralization is amorphous and cloudlike, whereas chondroid mineralization is usually punctate, often in small circles and arcs (Figures 32.1, 32.2).

Osteoid

Calcified lesions can be recognized as such by the high density seen on plain film and CT. On MRI, calcification will be low signal on both T₁- and T₂-weighted images.^{10,11} Ossification, on the other hand, will show a peripheral rim of low signal similar to cortex, representing the calcified surface, and an internal signal characteristic of fat, similar to marrow.^{12,13}

Chondroid

Cartilage lesions are usually lobulated in appearance, with typical chondroid mineralization. As a result of the high inherent water content of hyaline cartilage, the density on CT is greater than that of fat but less than that of muscle. On MRI, cartilage will show low signal on T₁ images and very high signal with T₂ imaging.^{3,14} Chondrosarcomas are often secondary tumors, arising from an underlying benign lesion, such as enchondroma or osteochondroma.^{15,16} Tissue sampling with percutaneous biopsy can be misleading as only a portion of the tumor may contain malignant cells. Thus, imaging plays an important role in evaluating for more aggressive behavior of the lesion, such as cortical thinning (endosteal scalloping), cortical destruction, and a soft tissue mass.¹⁷ The biopsy should then be directed toward these areas. If doubt exists, the entire lesion must be removed.¹⁸

Fat

Low-grade lesions composed of fat will appear as a lucent mass on plain film and show a density equal to subcutaneous fat on CT. The MR appearance will also follow that of subcutaneous fat, appearing high signal (white) on conventional T₁ spin-echo images and low signal (black) with fat suppression.¹⁹

If a soft tissue mass contains both areas of fat and areas that are clearly different by either MR or CT, this is usually a liposarcoma.²⁰ The regions that appear to be muscle on CT or show high signal on T₂ MRI images, should be targeted for biopsy as these are more likely to contain cells of a higher malignant grade. Lipomatous lesions may sometimes display areas of chunky ossification, indicating a nonaggressive behavior.²¹

Fibrous

Fibrous tumors have a density similar to muscle on plain film and CT. With MRI, low-grade fibrous lesions are

FIGURE 32.1. Osteoid matrix in an osteosarcoma of the proximal fibula. The mineralization is amorphous and cloudlike.

characteristically low signal on both T₁- and T₂-weighted images.²² In addition to low-grade fibrous lesions, low T₁ and T₂ signal can also be seen with osteoid and hemosiderin. An osteoid-forming lesion can be excluded by plain film evaluation.

FIGURE 32.2. Chondroid matrix in a chondrosarcoma. The mineralization is punctate and forms circles and arcs.

Vascular

Benign vascular lesions of soft tissue may display phleboliths on plain film or CT (Figure 32.3). With MRI, the vessels can be recognized as serpentine tubular structures that may show signal voids from flowing blood. The mass usually contains fat interspersed between the vessels, another finding suggestive of a low-grade vascular lesion.¹⁰

Although hemangiomas of the skull and vertebra have a classic imaging appearance,²³ vascular tumors of bone in the extremities have no typical appearance, and even benign

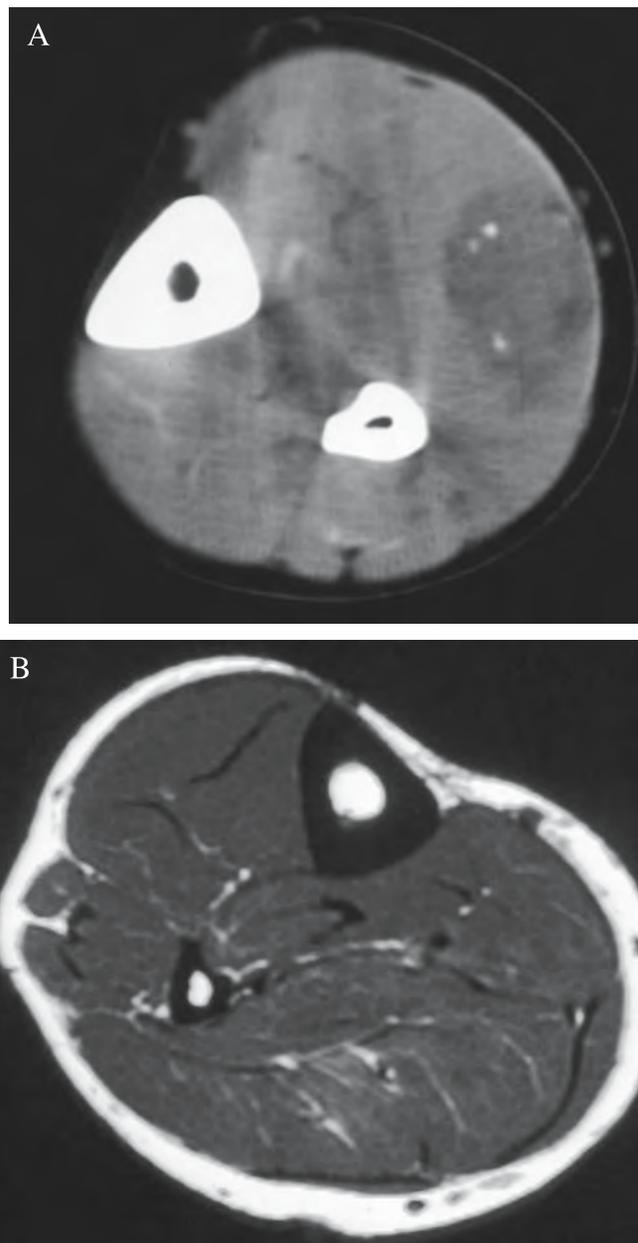

FIGURE 32.3. Soft tissue hemangioma of the calf. (A) Computed tomography (CT) image shows a mass that is lower density than muscle, suggesting the presence of fat. The punctate densities represent phleboliths, a classic finding with benign hemangiomas. (B) T₁-weighted magnetic resonance (MR) scan shows signal intensity equal to subcutaneous fat around and within the mass. Note that the phleboliths are not evident on MR.

hemangioma can look extremely aggressive. Angiosarcomas appear similar to sarcomas of other tissue types, but may be multifocal and cross joints, a behavior unusual for other sarcomas. It is therefore important to image the entire extremity when dealing with this tumor.²⁴

Tumor Location

As indicated, certain bone tumors have a typical appearance with imaging, especially if low grade. Certain tumors also have predilection for specific bones and a specific location along a bone (epiphysis, metaphysis, diaphysis) (Figure 32.4). Most of these are benign.

In the realm of malignancy, the round cell tumors stand out in that they have both favorite locations and a typical appearance^{25,26}; this includes both primary lymphoma of bone and Ewing sarcoma-PNET. These tumors are characteristically found along the shaft (diaphysis) of long bones, or on flat bones including the ilium, scapular body, and ribs. Their appearance is that of a lesion that permeates the cortex circumferentially in a manner similar to a sieve rather than causing focal cortical destruction. These tumors are almost uniformly associated with a large soft tissue mass, another feature not typically seen with other malignant bone tumors.

Imaging Modalities

Many imaging techniques are now at the disposal of the oncologist, not only for diagnosing musculoskeletal tumors but also for evaluating the response to radiation or chemotherapy and for posttreatment follow-up. The choice of modality will reflect the cell of origin for the diagnosis and the type of treatment undertaken for long-term surveillance.

Plain Radiography

Whether a bone or soft tissue neoplasia is the concern, the initial evaluation of a mass should be performed with plain radiography.²⁷ For bone lesions, plain films will show the aggressiveness of the tumor, and these remain the most specific modality for developing a differential diagnosis. For soft tissue masses, plain films can narrow the differential diagnoses by displaying or excluding the presence of mineralization in or around the lesion and detect changes in adjacent bone.²⁸

When evaluating plain films, it is important to search for periosteal new bone and, if present, characterize it (Figure 32.5). This feature, which is often overlooked, can be extremely helpful in determining the behavior of a lesion. Periosteal new bone that is unilaminar or multilaminar but uninterrupted, is associated with benign processes, including low-grade neoplasia, trauma, or indolent infection. Periosteal new bone that is interrupted signifies an aggressive process, which may be either neoplastic or inflammatory.

FIGURE 32.4. Edema around a proximal tibia osteosarcoma. (A) The tumor is confined to the focal low signal area in the medial metaphysis. The heterogeneous marrow signal lateral and distal to the tumor represents edema. (B) With inversion recovery imaging (similar to fat-suppressed T₂), edema in the surrounding marrow becomes high

signal; this could be mistaken for tumor, significantly overestimating the size of the lesion. Note that the soft tissue mass extends further distal than the marrow involvement; this is important to recognize for surgical planning.

FIGURE 32.5. Benign periosteal new bone overlying a hemangioma of the femoral shaft. It is delicate and bilaminar, but continuous. Periosteal new bone associated with a more aggressive process would be interrupted.

Computed Tomography

Following plain films, CT is indicated for imaging primary tumors of bone and soft tissue lesions that are mineralized. For bone lesions, CT is superior to MRI in characterizing changes, including subtle areas of cortical thinning or destruction, and in providing information that may assist in planning an approach for biopsy.^{29,30} CT easily displays the relationship of soft tissue masses to neurovascular structures and joints, assisting in determining the choice of surgical procedure (resection versus amputation) and the surgical approach.

CT is excellent for showing architectural detail in small bones, including ribs. An area where CT remains underutilized is in evaluation of bone scan abnormalities in cases where plain films fail to demonstrate the pathology; this is especially true for focal tracer uptake in ribs in the patient with a known primary malignancy. Thin-section scans targeted to the area of concern can almost always differentiate between a traumatic etiology (often forgotten by the patient) and metastatic disease.

CT guidance is commonly used for percutaneous biopsy.³¹ With skin markers over the area of concern, the exact area of interest can be accurately localized with respect to depth and proximity to vital structures. This method is especially useful for core biopsies where precise needle localization might be essential.³²

One argument for using MRI rather than CT has been the multiplanar imaging capability of MR imaging, allowing scan acquisition in the sagittal, coronal, or oblique plane. This situation is no longer the case. The advent and popularity of

multidetector row CT has placed this technique again in the forefront of diagnostic imaging.³³ Especially for bone tumors, rapid acquisition of slices at submillimeter increments and the ability to reformat in any plane displays anatomy and pathology to an advantage never before possible with CT.^{34,35}

Magnetic Resonance Imaging

Not uncommonly, when a person complains of a new mass or bone pain, an MRI is the first study ordered. Although this is frequently diagnostic for traumatic lesions, the appearance of malignancy with MRI is generally nonspecific.³⁶ Plain films are far superior for characterizing bone lesions. MRI may overestimate the extent of a lesion if it is fractured and will almost uniformly overlook foci of mineralization. The role of MRI is thus primarily one of staging rather than diagnosis.^{29,37,38}

Although the radiology literature initially advocated the use of intravenous gadolinium for imaging musculoskeletal tumors, subsequent work has shown that the contrast agent generally adds nothing to the diagnosis or local staging of musculoskeletal neoplasia. Attempts within the past decade to add specificity to MRI with use of dynamic contrast imaging have been popular overseas but have not added diagnostic information at a clinically significant level.³⁹ The advantage of contrast enhancement, as originated in imaging of the central nervous system, reflects the destruction of the blood-brain barrier by a pathologic process. There is no corollary for such a barrier in the musculoskeletal system. Contrast enhancement thus reflects local vascularity and the size of the extracellular fluid compartment. As these features significantly overlap for benign and malignant processes, the technique adds nothing to tumor conspicuity, diagnosis, or staging.⁴⁰

Technetium 99m medronate (^{99m}Tc-MDP) remains the mainstay for detection of bone metastatic disease. This may, however, not remain the case. Research using total-body MRI has suggested that this modality may not only be more sensitive than bone scintigraphy but also allows simultaneous imaging of solid organs, including the brain and liver.⁴¹ One caveat is that evaluation of ribs with MRI is limited because of both the small size of the bone and respiratory motion. Another possible problem with whole-body MRI is the common detection of incidental lesions in both bone and soft tissues throughout the body. Studies with whole-body CT screening have shown that significant financial resources go into workup of these findings, often with invasive procedures, for confirmation of a benign diagnosis.

There is a recent trend for utilizing molecular imaging in conjunction with cross-sectional imaging, specifically MRI. Recent published research appears very promising, likely opening new chapters specifically in musculoskeletal tumor imaging.^{42,43}

Radionuclide Imaging

Aside from its role in routine screening and detection of metastatic disease, the ^{99m}Tc-MDP bone scan can serve other purposes.^{44,45} Not uncommonly, metastatic disease may present as a solitary symptomatic lesion in an area that is not readily amenable to biopsy for technical reasons.⁴⁶ In this instance, a bone scan may show that the process is actually

multifocal and plain film correlation might display another focus that is more readily approachable. Radionuclide bone scans are also useful for evaluation of primary bone lesions that might be multifocal, such as brown tumors from hyperparathyroidism.⁴⁷ Bone lesions are often incidentally discovered on imaging studies obtained for unrelated reasons. In cases where the diagnosis is in question, a radionuclide scan will show the activity of the lesion. If tracer uptake is normal, the lesion can generally be disregarded. If the area is either photopenic or shows increased activity, further workup is warranted.

Thallium (²⁰¹Tl chloride) single photon emission computed tomography (SPECT) scanning has been used for determining a tumor's response to therapy as well as searching for metastatic disease.⁴⁸ The concept is quite attractive, because CT and MRI show only morphology, not tumor metabolism. Unfortunately, thallium uptake is nonspecific, with activity seen not only in malignancy but also in benign neoplasia and traumatic and inflammatory disorders. Its use has thus declined, being replaced by positron emission tomography (PET).⁴⁹

Positron Emission Tomography

PET imaging is addressed in depth in Chapter 33. Suffice to say here that trials are now under way to define the exact role of PET in diagnosis and screening for a variety of tumors, including various types of sarcoma.⁵⁰ Although relatively recent, the advent of PET/CT has had a great impact on musculoskeletal oncology, as foci of abnormal activity can be precisely localized on the CT image and evaluated for their significance.⁵¹

Ultrasound

Ultrasound plays little role in the routine diagnosis, staging, and follow-up of sarcomas. Although it can be used for image guidance for biopsy,⁵² this is usually more easily accomplished with CT. Ultrasound may be useful for detecting suspected tumor recurrence in the patient with implanted hardware, where artifact precludes other means of cross-sectional imaging.^{53,54}

Occasionally ultrasound may be used for the diagnosis of vascular lesions by using color Doppler imaging mode.⁵⁵ In addition, ultrasound is helpful in differentiating fluid collections from solid masses.

Which Modality to Use When

Primary musculoskeletal malignancies are often treated initially with chemotherapy and/or radiation therapy, followed by surgical resection. Surgical choices include en bloc resection, resection and reconstruction (endoprosthesis, allograft, arthroplasty or arthrodesis), and amputation. The surgical procedure is determined by the histologic type of tumor, its location, and the extent of local involvement.

Preoperative Local Staging

Evaluation of bone tumors should begin with plain films.⁵⁶ If the tumor needs to be further characterized for either diagnosis or biopsy, CT is usually the modality of choice. If there

is a possibility of multifocality in bone, a radionuclide bone scan is in order.⁴⁸ Although marrow involvement can be easily seen with CT, many surgeons prefer MRI to assess the length of marrow disease to determine the level of resection.

Bone tumors should be evaluated for location, length of intramedullary involvement, areas of cortical destruction, and any soft tissue mass. For both bone and soft tissue tumors, the relationship or involvement of major neurovascular structures or joints should be determined.

If endoprosthetic or allograft reconstruction is under consideration, measurements need to be made from the end of the tumor to the proximal and distal joints⁵⁷; this is important not only for determining the level of osteotomy but also for sizing the prosthesis or allograft. This step is most easily accomplished with MRI, where a longitudinal T₁ scan can be acquired that includes both the proximal and distal joint. Accurate measurements may then be made at the console or on a workstation.

For soft tissue neoplasia, either CT or MRI may be used for local staging. Both accurately show the relationship of the mass to neurovascular structures and may be used to determine compartmentalization of the tumor.

Posttreatment Evaluation

Following chemotherapy and/or radiotherapy, one indicator of tumor response is obviously a reduction in size of the mass. This evaluation may be done with equal accuracy with either CT or MRI, where cross-sectional measurements are easily achieved.⁵⁸

Long-Term Surveillance

The modality for long-term monitoring will depend on the type of treatment undertaken. If a patient has undergone en bloc resection or amputation, cross-sectional imaging with CT or MRI may be used for follow-up.⁵⁹ In certain cases of postsurgical treatment, intravenous contrast may be useful to differentiate between a residual or recurrent mass and a fluid collection, such as a seroma.⁴⁰ If an endoprosthesis, arthroplasty, or allograft has been placed, artifact from the metal components will render both these modalities basically useless. Plain films are useful to evaluate for mechanical complications but are of limited use for local recurrence unless mineralization is present. If a mass is highly suspected and hardware is present, imaging with ultrasound or PET may be useful. If ultrasound is used and a mass lesion is seen, it could be biopsied under ultrasound guidance at the time of the scan.

When follow-up studies are requested, it is important for the individual responsible for image interpretation to have access to prior examinations, both preoperative and especially, postoperative. Small foci of residual or recurrent disease may be easily overlooked without the advantage of direct comparison for subtle architectural changes.

Conclusion

Imaging plays a crucial role in musculoskeletal oncology. In cooperation with the functions of the other members of the team, it provides for detection and characterization of the

tumor. It is capable of producing a useful list of differential diagnoses for initial workup and approach. It directs the biopsy toward the areas of interest within a lesion. It further assists in staging the disease, planning the therapy and follow-up.

The imaging of musculoskeletal sarcomas of the extremities should commence with plain radiography to evaluate for matrix mineralization and bone erosion/destruction. The next step should include a CT scan (for bone lesions) or MRI to further characterize the imaging characteristics. CT is commonly used for image-guided biopsy. Either CT or MRI may be used for staging of the tumor. The radionuclide bone scan and PET are used as an adjunct to detect polyostotic lesions. Ultrasound plays a limited role, usually for cases with hardware where other modalities are of limited value, and in guidance for biopsies. Both MRI and CT are frequently used for posttherapy follow-up if hardware is not present.

Positron Emission Tomography and Cancer

Daniel N. Chatzifotiadis, Julia W. Buchanan, and
Richard L. Wahl

Positron emission tomography, PET, is a potent imaging tool in the management of a diverse array of cancers. This chapter briefly discusses the rationale for PET imaging and describes how it differs from more typical anatomic imaging, reviews the principles of metabolic targeting with the radiolabeled glucose analogue ^{18}F -fluoro-2-deoxy-D-glucose (FDG), and then describes the clinical results of PET imaging in several types of common cancers. Although there are detailed descriptions of tumor imaging with other modalities in several areas of this textbook, the discussion here focuses on the role of PET.

PET imaging was originally introduced as a functional tool for quantitatively imaging metabolic activity in the brain. PET is a nuclear medicine technique in which positron-emitting radiopharmaceuticals with short half-lives are injected intravenously into patients and then imaged with a PET scanner. The readers are referred to a textbook that describes in detail the chemistry and physics of positron emission tomographic imaging.¹ It should be noted that the most commonly used positron emitter is ^{18}F -fluoride, which is cyclotron produced and has a 109-minute half-life. This radioisotope is most commonly used in clinical PET imaging as ^{18}F -fluoro-2-deoxy-D-glucose (FDG), which traces the early steps of glucose metabolism.

Cancers typically have accelerated glucose metabolism, and FDG traces the initial accumulation of the radiotracer into the cancer via membrane transport, and also its initial phosphorylation by hexokinase to FDG-6-phosphate. This latter substance is polar and typically retained in most cancers.

Glucose utilization is accelerated in most cancers, but some cancers do not have high glucose uptake; these include many prostate cancers, renal cancers (primary), hepatomas and mucinous tumors, and some low-grade lymphomas. Some cancers, such as some brain tumors, that have high glucose uptake may also be difficult to image because the background FDG uptake is high in normal brain. This condition makes defining brain tumors more problematic as the target/background uptake ratios are often lower than elsewhere in the body where there is less normal FDG uptake.

Normal tissues using glucose include the brain, heart, kidneys, testes, exercising skeletal muscle, and the kidneys. FDG is excreted unchanged via the kidneys, which can make detection of lesions in the renal area problematic as well as in the bladder region. PET is a "molecular imaging" tool and,

in contrast to single photon emission computed tomography (SPECT) imaging, is capable of providing quantitative data based on the amount of radioactivity in a tissue in the human body noninvasively. It is highly accurate in such quantitation and is able to detect lesions smaller than 1 cm in size. However, PET is not a microscope tool and can often fail to detect lesions in the subcentimeter range. With current available equipment, PET typically loses considerable sensitivity for lesions in the 5-mm range and smaller, but lesion detectability is dependent on many factors, most importantly, the absolute uptake of radiotracer into the lesion as well as the lesion/background ratio. The higher the lesion uptake and the lower the background, the better the chance of lesion detection.

In general, lesions smaller than 5 mm are not detected well with PET in its current form. As a functional imaging tool, PET quantifies the tracer uptake well and displays it in an anatomically correct manner. Unfortunately, if the lesion/background ratio is high, the PET scan can show a "hot spot" but only provide general information as to the precise lesion location. Thus, there has been a great deal of interest in using PET to provide fused images with anatomy, so-called anatomometabolic images, which combine form and function into a single image. This merge can be done with software fusion methods, fusing PET and CT or PET and magnetic resonance imaging (MRI) images, but the most common approach is to use dedicated PET/CT scanning devices, which are both PET and CT scanners in a single device.

PET/CT imaging is quickly replacing PET imaging alone as the preferred tool for PET imaging in cancer. This approach was developed by Townsend and colleagues and has been rapidly disseminated throughout the world, with PET/CT scanners representing nearly the entire marketplace for PET imaging equipment at this time. Such devices acquire a CT scan and then a PET scan as part of the same imaging procedure. Because the scanners are linked together, they generate PET, CT, and then PET/CT fused image data. This approach is the new standard for PET imaging of cancer, is the routine procedure for clinical PET at the authors' institution, and is quickly replacing PET alone as an imaging tool. Of interest is that PET alone is a superb imaging tool in many cancers, and PET/CT, while often better and more easily interpreted, is not necessarily dramatically more accurate than PET in all cancers. Nonetheless, PET/CT quite consistently has fewer equivocal diagnoses, fewer equivocal lesion localizations, and

greater accuracy than PET. However, much of the evidence for PET is based on the PET literature and is not yet based on PET/CT data. Although only PET/CT images are shown in this chapter, PET imaging represents the foundation for most of the conclusions presented. The use of PET, which has clear advantages over CT or MRI as a functional imaging tool, remains a very valid technique for tumor imaging in clinical practice.

The use of PET has expanded widely in the United States and the world since the approval by the Center for Medicare Services for reimbursement of PET imaging in several common situations. Broadly, Medicare will reimburse for tumor diagnosis, staging, and restaging at present, with more limited reimbursement for PET assessments of early responses to treatment. However, these rules have been in rapid evolution. Currently, the most common uses for PET imaging in our center are for tumor staging, assessment of treatment response, and restaging for recurrence after treatment or with rising serum markers.

The use of PET in several disease types is discussed in detail in the following sections, covering several major types of cancer.

Head and Neck Cancer

FDG-PET, is considered to be a useful technique in the evaluation of primary head and neck small cell carcinoma (HNSCC). The imaging technique can be performed either 50 minutes after the injection of FDG injection or up to 90 minutes after, because of the continuing improved target-to-background ratios. Normal variants of uptake in adenoidal, palatine, and lingual tonsils, in laryngeal and neck musculature (scalene, vocalis, cricoarytenoid), or in glands (salivary and parotids) need to be kept in mind.

Staging of the primary tumor was tried by some investigators,² but CT and physical examination remain the mainstay in tumor staging. FDG-PET has a role in only 5% of patients, but it can identify the unknown primary in about 20% to 50% of these cases.³⁻⁶

Routine panendoscopy can identify the small lesions that may not be seen by PET;⁷ however, FDG-PET seems to predict tumor curability with radiotherapy.⁸

Adams et al.⁹ reported that FDG-PET has a sensitivity of 90% and a specificity of 94%, which are better than MRI (80% and 79%, respectively) and CT (82% and 85%, respectively).

Kau et al.¹⁰ studied 70 patients suspicious for lymph node metastases and found that the sensitivity and specificity of FDG-PET for detecting lymph nodes were 87% and 94%, respectively, compared with those of CT (65% and 47%) and MRI (88% and 41%) (Figure 33.1).

Several studies have compared the sensitivity and the specificity of all imaging modalities (FDG-PET and conventional imaging).¹¹⁻¹⁴ False-negative PET studies are found because of small tumor burden in nodes, cystic degenerations of metastatic nodes that are only surrounded by a small rim of viable tumor, low tracer uptake in a metastatic node, imaging artifacts, and proximity to the primary tumor. Additionally, in distant metastases or in synchronous second primary tumors, which are present in 8% of the cases,¹⁵ the rate of PET detection is very high¹⁶ (Table 33.1).

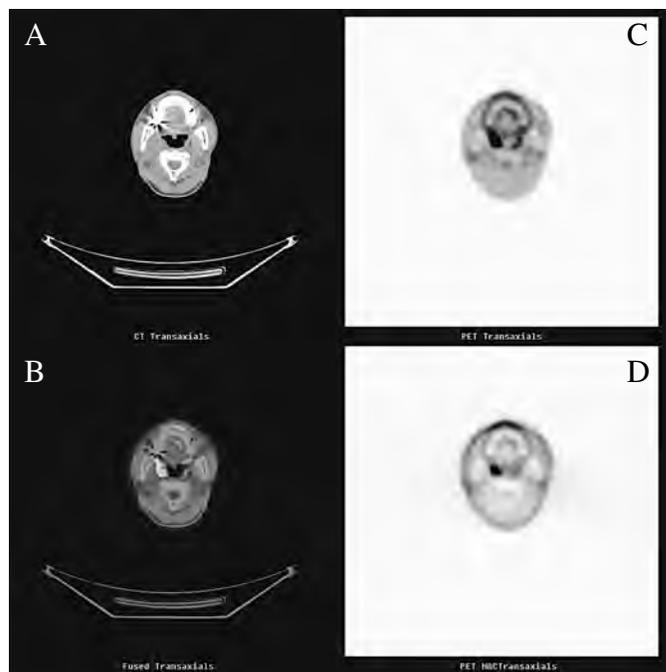

FIGURE 33.1. A transverse ¹⁸F-fluoro-2-deoxy-D-glucose (FDG)-positron emission tomography (PET) scan in a middle-aged patient who had a history of an enlarged right neck lymph node at level 7 that had been excised and demonstrated squamous cell carcinoma. PET/computed tomography (CT) images were obtained with FDG to determine if there was evidence of a primary squamous cell carcinoma. Transverse PET images (with (C) and without (D) attenuation correction) and CT (A), and fused PET/CT (B) images, are displayed. Focal increased FDG is seen in the right palatine tonsil region; this is greater than the normal FDG uptake expected in the lymphocyte-rich tonsils. Biopsy of the right tonsil demonstrated a primary squamous cell carcinoma. PET has been reported to detect between 15% and 35% of unknown primary squamous cell carcinomas in the head and neck.

FDG-PET in Evaluation of Recurrent Head and Neck Cancer

Most recurrences occur in the first 24 months after therapy for HNSCC. Distant recurrences are more common in patients with locally recurrent disease than distant metastases at initial staging, with the lungs the most common site of distant recurrence.¹⁷

Early detection of recurrent head and neck cancer has a crucial role in predicting the clinical outcome, because patients with early-stage HNSCC who undergo salvage surgery have a 70% 2-year relapse-free survival (RFS), whereas those with recurrent advanced-stage disease undergoing salvage surgery have a 22% 2-year RFS.¹⁸

FDG-PET is more sensitive, specific, and accurate in the detection of local recurrent head and neck cancer¹⁹⁻²¹ and in the detection of recurrent HNSCC, regardless of the primary treatment modality (surgery versus radiation therapy)²¹⁻²⁵ than CT or MRI (Table 33.2).

The negative predictive value of FDG-PET is very high, but the positive predictive value is somewhat lower for local recurrence in the region of the primary tumor because of false-positive findings (i.e., laryngeal muscle uptake, adipose tissue uptake, or radioactive saliva in the floor of the mouth, throat, or vallecula).

TABLE 33.1. Studies comparing CT, MRI, US, and PET for nodal staging in head and neck cancer.

Author	Year	No. of patients	CT/MRI/US	Sens	Spec	PET Sens	Spec
Hannah et al. ¹²	2002	40	CT	81	81	82	94
Di Martino et al. ¹³	2000	50	CT US	84 88	96 88	84	90

Kau et al. ¹⁰	1999	70	CT MRI	65 88	47 41	87	94

CT, computed tomography; MRI, magnetic resonance imaging; US, ultrasonography; PET, positron emission tomography; Sens, sensitivity; Spec, specificity.

A positive PET scan requires a biopsy, and if this is not positive, a repeat biopsy or close clinical follow-up may be required 2 to 3 months later. Standard uptake value (SUV) measurements have a wide overlap between disease recurrence versus nontumor-related FDG accumulation (SUV range, 2.1–36.9 versus 1.5–9.3, respectively).

Role of FDG-PET in Monitoring Therapy

Brun et al.²⁶ in a study of 47 patients, with two-thirds of these in stage IV disease, showed that the pretreatment SUV was lower in patients with a complete response (8.0 versus 12.0), the 5-year overall survival (OS) was 72% in those who had low FDG activity after 1 to 3 weeks of treatment, and the 5-year OS was only 35% in those who had high FDG uptake in the same period.

Kitagawa et al.²⁷ studied 15 patients who were treated with neoadjuvant chemotherapy and showed that lesions with a pretreatment SUV greater than 7 had residual viable tumor in 3 of 8 cases, whereas all lesions with SUV less than 7 were treated successfully. All 7 tumors with posttreatment SUV less than 4 did not show residual disease and 3 of the 7 tumors with posttreatment SUV greater than 4 did. The same group calculated the sensitivity, specificity, and accuracy of PET-FDG, MRI, and CT in primary lesions and in neck metastases, finding FDG-PET to be more specific (89%) compared with MRI (41%) and CT (59%) in primary lesions but not in nodal metastases (74% versus 85% and 76%, respectively).²⁸

Goerres et al.²⁹ evaluated the detection of residual disease in 26 patients with stage III–IV HNSCC, and PET was performed 6 weeks after the end of combined chemotherapy and radiation therapy. The sensitivity, specificity, and accuracy were 91%, 93%, and 92%, respectively. They also showed that the PET study at 6 weeks often revealed a second primary tumor or a distant metastasis that had not been detected at the time of initial staging.

Kubota et al.³⁰ also concluded that the high negative predictive value of FDG-PET (91%) may be used to prevent additional invasive procedures for the detection of recurrent head and neck cancers after combined radiochemotherapy in most clinical settings.

Radiation Therapy Alone

Greven et al.³¹ demonstrated, in a study of 45 patients who had FDG-PET before and at 1, 4, 12, and 24 months after high-dose radiation therapy, that imaging at 4 months was more reliable than at 1 month. It seems that an interval of 6 to 8 weeks after radiation treatment is most appropriate, but it must be kept in mind that FDG uptake can be significantly high in regions of radiation therapy up to 12 to 16 months after treatment.³²

Other PET Tracers

Radiolabeled amino acids, ¹¹C-methionine, radiolabeled tyrosine, ¹¹C-choline, ¹⁸F-thymidine, ⁶⁴Cu-ATSM [copper (II)-dia-cetyl-bis (*N*-4-methylthiosemicarbazone)], ¹⁸F-fluoromisonidazole, and ¹⁸F-2-nitroimidazole (EF5), have been studied as potential imaging agents for head and neck tumors.^{33–40} Several of these show promise and may be introduced into clinical practice in the future.

Thyroid

Since the early 1950s, the whole-body scan (WBS) using a tracer dose of iodine-131 (¹³¹I) has been widely used for detection of metastases of differentiated thyroid cancer (DTC). Some studies have investigated the role of FDG-PET in thyroid nodules, based on the hypothesis that malignant lesions would be more FDG avid^{41,42} than the benign ones.

TABLE 33.2. Imaging of recurrent head and neck cancer.

This is clearly not true, as shown by Kresnik et al.,⁴³ who demonstrated that many malignant nodules were not FDG avid, most likely because they were well differentiated. Additionally, other studies have shown that multimodular goiter^{44,45} or thyroiditis,^{46,47} predominantly lymphocytic, may have increased FDG uptake.

In patients who underwent FDG-PET for some other reason, Kang et al.⁴⁸ reported that thyroid incidentalomas were found in 2.2%, and among these, 27% proved to be cancer. In a larger group of patients (4,525) Cohen et al.⁴⁹ reported that incidentalomas were found in 2.3% and 47% were thyroid cancers.

FDG-PET in Evaluation of Differentiated Thyroid Cancer

In a large multicenter study of unselected thyroid cancer patients ($n = 222$), Grunwald et al.⁵⁰ found that the sensitivity of FDG-PET for localizing metastatic disease in patients with DTC was 75% and that it was 85% for the group with a negative WBS ($n = 166$).

Feine et al.⁵¹ noticed that there were tumors that accumulated only FDG, others only ¹³¹I, and some both FDG and iodine. He named this alternating pattern of either ¹³¹I or FDG uptake in thyroid cancer metastases as the “flip-flop” phenomenon. Thus, some thyroid tumors without functional differentiation for iodine (¹²³I or ¹³¹I) uptake showed high glucose metabolism, and many differentiated papillary and follicular thyroid cancers did not have increased FDG uptake.

Wang et al.⁵² reported that progressive dedifferentiation of thyroid cancer cells results in a loss of their ability to concentrate iodine, which results in a negative WBS in 20% of originally differentiated thyroid cancers. Thyroid cancer cells that lose their ability to concentrate radioactive iodine may exhibit increased metabolic activity, which results in enhanced glucose uptake. Many studies showed that FDG-PET is more sensitive than WBS in high-grade tumors, whereas an iodine scan is more commonly positive in low-grade carcinomas.^{53–55} Expression of the GLUT-1 transporter on the cell membrane is closely related to the grade of malignancy in thyroid neoplasms, with anaplastic tumors and widely invasive follicular or metastatic tumors showing a high-level of GLUT-1 glucose transporter expression.⁵⁶

Some studies have reported that increased TSH levels stimulate FDG uptake by thyroid cancer cells.^{57,58} A case report by Sisson demonstrated increased FDG uptake in a thyroid cancer metastasis imaged both before and then after withdrawal from thyroid hormone therapy. Helal et al.⁵⁹ studied 37 patients with DTC who had undergone resection and ablation with radioactive iodine. He found a sensitivity of 76% in these patients and concluded that FDG-PET should be a first-line investigation in patients with elevated thyroglobulin and a negative WBS (Figure 33.2).

Schluter et al.⁶⁰ studied 64 patients with thyroid cancer with either elevated serum thyroglobulin or clinical suspicion of metastases and negative WBS and reported that the positive predictive value (PPV) was 83% whereas the negative predictive value (NPV) was 25%. The true positive FDG-PET findings were correlated positively with increasing thyroglobulin levels. The FDG-PET was true positive in 11%, 50%, and 93% of patients with thyroglobulin levels less than 10, 10 to 20, and more than 100ng/dL, respectively. This

finding suggests that the mass of thyroid cancer tissue is related to detectability, which is not surprising.

The use of recombinant human thyrotropin (rhTSH) has recently been proposed to increase the sensitivity of FDG-PET in the diagnosis of recurrent and metastatic cancer versus the unstimulated setting. Moog et al.⁶¹ compared imaging findings in 10 patients who were either under TSH suppression and were hyperthyroid, or were hypothyroid with stimulated TSH. Increases of 63% in the tumor-to-background ratios were observed in the latter case. Petrich et al.⁶² reported that in 30 patients they found more suspicious lesions for cancer in more patients when they received rhTSH. These observations were also supported by an in vitro culture experiment.⁶³

Wang et al.⁶⁴ evaluated 125 patients with a mean of 41 months of follow-up who had a negative WBS, a positive FDG-PET study, and elevated thyroglobulin. They concluded that the single strongest predictor of survival was the volume of FDG-avid disease. Detection of tumor with FDG-PET is a volume-dependent phenomenon.

In another study, the same authors⁶⁵ evaluated the ability of an ablation dose of ¹³¹I to destroy FDG-avid metastatic lesions in patients with thyroid cancer who had FDG-PET scans pre- and post-¹³¹I treatment. The authors found that the total volume of FDG-avid metastases rose from a mean of 159 mL to 235 mL after ¹³¹I ablation therapy and the post-¹³¹I thyroglobulin level rose 132% above the value at baseline. In patients with a negative FDG-PET scan, the serum thyroglobulin levels decreased to 38% of baseline after ¹³¹I

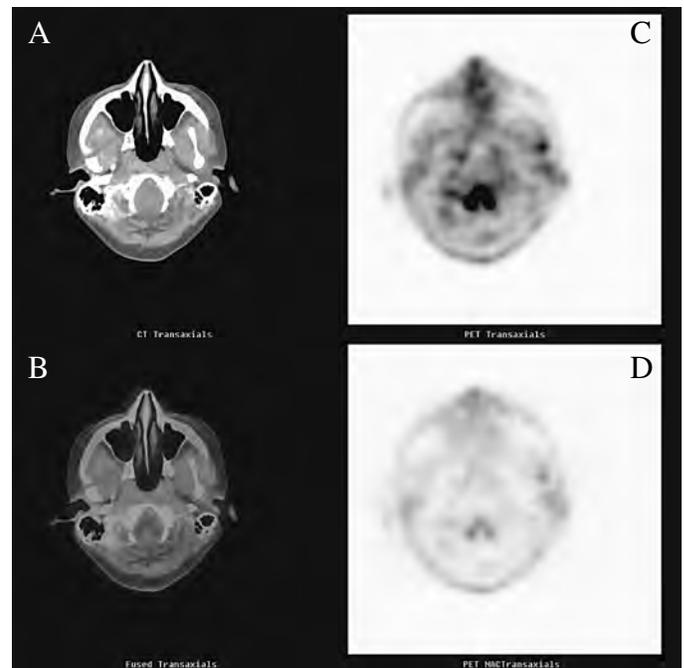

FIGURE 33.2. Transverse FDG-PET scan of a young female who had a history of follicular thyroid carcinoma with lymph node and capsular involvement 3 years before this scan. She had developed an elevated serum thyroglobulin level, and her iodine scan was negative. This PET scan was performed to look for a recurrent noniodine-avid tumor. This scan was performed without recombinant thyroid-stimulation hormone (rhTSH) stimulation and demonstrates increased radiotracer uptake in the left neck in level 2 lymph nodes, which were subsequently proven to be metastatic thyroid cancer (A) CT scan. (B) Fused PET/CT image. (C) Attenuation corrected PET image. (D) Nonattenuation corrected PET image.

therapy. High-dose ¹³¹I therapy does not appear to have a tremendously beneficial effect on the viability of metastatic FDG-avid lesions. Nonresectable regional disease can be treated with external-beam irradiation or, if limited, with surgery, while widespread disease may be amenable to experimental chemotherapy.

Hürthle Cell Carcinoma

Hürthle cell cancer is a histologic subtype of DTC that is clinically more aggressive and has little or no iodine uptake. In a study of 12 patients Lowe et al.⁶⁶ described a sensitivity of 92% for FDG-PET. Plotkin et al.⁶⁷ reported a sensitivity of 92%, a specificity of 80%, a PPV of 92%, a NPV of 80%, and an accuracy of 89% (Table 33.3).

Medullary Thyroid Cancer

Medullary thyroid cancer (MTC) is a rare calcitonin-secreting tumor originating from the parafollicular C cells. At the time of initial diagnosis, most of the patients with this malignancy are noted to have lymph node metastases. The primary treatment modality is surgical resection of all malignant lesions. Brandt-Mainz et al.⁶⁸ studied 20 patients and found the overall sensitivity to be 76%. In another study, Diehl et al.⁶⁹ demonstrated, in 55 cases, that FDG-PET had a sensitivity of 78% and a specificity of 79%, in comparison with ¹³¹I-pentetreotide, 25% and 92%, with dimercaptosuccinic acid (DMSA), 33% and 78%, with ^{99m}Tc-MIBI (hexakis-2-methoxy-2-isobutyl isonitrile), 25% and 100%, with CT, 50% and 20%, and with MRI, 82% and 67%. A reasonable imaging approach in the staging and follow-up of MTC would be a combination of FDG-PET and MRI.

Novel, more-specific PET tracers, such as ¹⁸F-dihydroxyphenylalanine and 6-¹⁸F-DOPAv (dopamine), have been proposed by Hoegerle et al.⁷⁰ and Courgiotis et al.,⁷¹ respectively, with promising results, especially in lymph node staging. Nonetheless, FDG-PET has assumed an increasingly important role in the management of thyroid cancer. The ability of this method to detect many non-iodine-avid tumor foci is of considerable practical utility and is changing the practice of thyroidology. Our own experience suggests that, in patients with thyroid cancer with possible recurrence of non-iodine-avid disease, FDG-PET/CT (ideally under TSH stimulation) is an excellent method to precisely locate recurrent tumors and to direct the surgeon to their precise location if surgical intervention is being considered.

Esophagus

Esophageal cancer is relatively infrequent, with 14,000 new cases reported in the United States in 2003. The 5-year survival rate is not more than 14%.⁷² The incidence of the

disease is much higher in Asia and Northern France and in some regions of the world where esophageal cancer is endemic.

FDG-PET in Staging Esophageal Carcinoma

The accuracy of endoscopic ultrasonography (EUS) is lower for evaluation of T1 and T2 tumor than for T3 and T4, and the CT scan is inaccurate for identifying nonbulky lymphadenopathy. Neither EUS nor CT is able to distinguish tumor from inflammation. The introduction of FDG-PET has greatly improved the staging of esophageal carcinoma. Squamous cell and adenocarcinomas of the esophagus are both generally characterized by high FDG uptake.^{73,74} FDG uptake in esophageal cancer is greater than that in the normal uninfamed esophagus, and the primary tumor can be distinguished easily from background activity in most cases.⁷⁵

FDG-PET false-positive results in the esophagus and nearby tissues can be caused by inflammation (reflux esophagitis), radiation-induced esophagitis, benign tumors, skeletal and adipose tissue uptake, and heterogeneous uptake in the primary, simulating periesophageal nodal metastases.

FDG-PET false-negative results are the result of small tumor volume, well-differentiated tumor, and close proximity to the primary tumor. Histologic confirmation of PET findings is necessary before a patient is denied potentially curative surgery. PET is very useful in identifying a site suitable for biopsy.

FDG-PET has been shown to detect primary esophageal cancer with a higher sensitivity than that of CT (95% to 100% versus 81% to 92%).^{73,76-78} Himeno et al.⁷⁹ reported that FDG-PET has a sensitivity of 100% for the detection of primary tumors extending to the submucosa (T1b) or deeper, but cannot detect lesions confined to the mucosa (T1a). Kato et al.⁸⁰ described that there is a significant relationship between FDG uptake and the depth of tumor invasion; this is most likely a relationship between tumor volume and invasion (Figure 33.3).

Although PET detects most primary esophageal cancers, it is not as sensitive for nodal metastases. Yoon et al.⁸¹ evaluated 82 patients with squamous cell carcinoma and 677 lesions and found the sensitivity for PET was 30% and that for CT was 11%. This result shows the extent of the problem of nodal staging with both methods. Although PET was more sensitive than CT, both techniques failed to detect small nodal metastases that are often under 1 cm in size. There is considerable variability in the literature concerning nodal staging in esophageal cancer.

The 5-year survival without lymph node involvement is 42% to 72% versus only 10% to 12%⁸² for patients with disease that has spread to the lymph nodes. Metastatic lymph

node size was the strongest independent predictor of survival among several prognostic factors, such as primary tumor size, histopathologic type, number of metastatic lymph nodes.⁸³

The combined accuracy of EUS and CT (70% to 90%) in the detection of mediastinal nodal metastases was reported to be greater than that of each modality alone,⁸⁴ but limitations remained because of inability to detect tumor involvement in normal-sized lymph nodes and to differentiate metastatic from inflammatory disease.

Kim et al.⁷⁴ compared FDG-PET with CT and histopathologic results from esophagectomy and extensive lymph node dissection. The sensitivity, specificity, and accuracy for FDG-PET to detect metastatic lymph nodes were 52%, 94%, and 84%, respectively, and those for CT were 15%, 97%, and 77%, respectively. That study showed that FDG-PET had greater sensitivity and accuracy than CT, with equal specificity in nodal staging.

Flamen et al.⁷³ compared FDG-PET (attenuation corrected with spiral CT) and EUS in 74 patients with potentially resectable esophageal cancer and showed that EUS was more sensitive (81% versus 33%) but less specific (67% versus 89%) than PET for detection of regional nodal metastases. Combined EUS and CT were more sensitive (62% versus 33%) and less specific (67% versus 89%) in the same setting. The findings from PET resulted in upstaging in 15% of patients and in downstaging in 7% of patients. PET is a better method for detection of distant metastatic disease than any other method available, but it is not as robust for locoregional disease. PET is routinely recommended before surgery for esophageal carcinoma.

A curative surgical approach is not appropriate in patients with metastases to distant foci. Distant metastatic disease most commonly occurs in distant lymph nodes, liver, and lung. FDG-PET is superior to CT and MRI for detection of distant metastatic disease.^{73,74,85-89} FDG-PET uncovered 3% to 37% of findings that were unsuspected. Kinkel et al.⁸⁷ reported that at the specificity level of 85% the mean sensitivities of FDG-PET, ultrasound, CT, and MRI were 90%, 55%, 63%, and 76%, respectively.

Flamen et al.⁷³ demonstrated that the accuracy of FDG-PET in 74 patients with stage IV disease was 82%, whereas it was only 64% for a combination of CT and EUS (P less than 0.01). The sensitivity and specificity were 74% and 90% for FDG-PET, 41% and 83% for CT, and 42% and 94% for EUS.

Luketich et al.⁸⁸ found, in 35 patients with potentially resectable esophageal cancer, that distant metastatic disease was identified by PET in 20% with an accuracy of 91%. The same group⁸⁹ found that the sensitivity and specificity of FDG-PET for detection of distant disease were 69% and 93% for FDG-PET and 46% and 74% for CT.

PET prevents ineffective radical therapies by detection of occult stage IV disease and identification of the local or distant metastases that are most accessible to confirmation by directed tissue sampling using minimally invasive procedures. Wallace et al.⁹⁰ found that the combination of PET and EUS with fine-needle aspiration biopsy is the most effective strategy for staging.

Table 33.4 summarizes the results of studies evaluating the sensitivity, specificity, and accuracy of CT, EUS, and FDG-PET for detecting local tumor extension (T and N stages) and systemic disease (M).^{73,74,81,89,91-93}

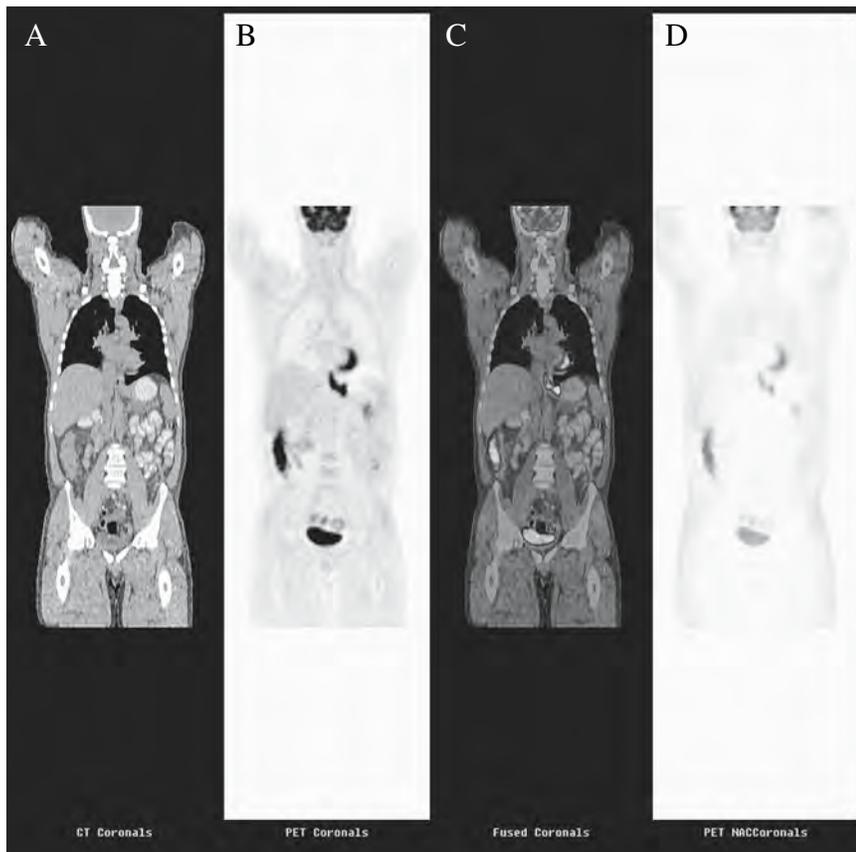

FIGURE 33.3. Coronal PET/CT images obtained from a middle-aged male with a history of gastroesophageal reflux and biopsy-proven esophageal carcinoma. Luketich et al.⁸⁹ also demonstrated the 30-month survival rate was 60% in patients with localized disease on PET, as compared with 20% in patients with PET evidence of distant disease. The same numbers for CT, 52% and 38%, respectively, were not significantly different.

Assessment of Response to Treatment

Complete macroscopic and microscopic resection of the primary tumor is a strong independent prognostic factor. Patients with locally advanced disease (T3–T4) after complete resection have a 20% to 31% chance of 5-year survival, whereas there is essentially no chance of a 5-year survival in those with an incomplete resection.⁸²

Randomized trials compared patients who received preoperative chemotherapy or chemoradiotherapy followed by surgery with patients who received surgical treatment alone. The results were conflicting,⁹⁴ and this was attributed to the fact that the response to chemoradiotherapy was probably not uniform. Nonresponders had a poor prognosis, not only because of their disease but also because of therapy-induced side effects and the delay in surgical treatment. Anatomic imaging modalities cannot differentiate viable tumor from posttherapeutic effects in many instances. The accuracy of EUS for determination of tumor stage after therapy is less than 50%.^{95,96}

Several studies demonstrated the usefulness of FDG-PET to predict response either shortly after initiation of therapy or after its completion. Weber et al.⁹⁷ studied 40 patients with locally advanced adenocarcinomas of the gastroesophageal junction. PET imaging was performed before preoperative chemotherapy and on day 14 of the first chemotherapy cycle. Changes in tumor FDG uptake at these early time points were correlated with the clinical and histopathologic response after 3 months of chemotherapy. In clinical responders, defined as a decrease of tumor length and wall thickness by more than 50%, FDG uptake at day 14 had decreased by 54% ± 17%, compared with nonresponders, at 15% ± 21%.

Using a threshold of a 35% decrease in the SUV from the baseline metabolic activity, FDG uptake predicted subse-

quent clinical response with a sensitivity and specificity of 93% and 95%, respectively. Sensitivity and specificity for predicting histopathologic response were 89% and 75%, respectively. The 2-year survival rate of "PET responders" was 49% whereas it was only 9% for "PET nonresponders."

The same authors studied⁹⁸ 27 patients with locally advanced squamous cell carcinomas of the esophagus before neoadjuvant chemoradiotherapy and 3 to 4 weeks after completion of therapy. Therapy-induced reduction of tumor FDG uptake was significantly higher for histopathologic responders (72% ± 11%) than for nonresponders (42% ± 22%). Using a threshold of a 51% decrease in the SUV from the baseline metabolic activity for prediction of a response to therapy resulted in a sensitivity of 100% and a specificity of 52%. Brucher et al.⁹⁹ and Flamen et al.¹⁰⁰ showed similar results, with the latter using only visual analysis (sensitivity, 71% and specificity, 81%).

Downey et al.¹⁰¹ studied 24 patients with esophageal cancer who received induction therapy before esophagectomy. The 2-year disease-free survival (DFS) was greater when the tumor showed more than a 60% decrease in FDG uptake. Arslan et al.¹⁰² failed to distinguish residual tumor from postchemoradiation esophagitis using SUV measurements in 24 patients 4 weeks after treatment completion. PET appears to have a greater role in assessing early response than it does in assessing residual tumor (Table 33.5).

Detection of Recurrent Disease

Recurrence is common despite a presumed cure after resection because of micrometastatic disease at distant sites, which can then proliferate. Fukunaga et al.¹⁰³ first reported the increased FDG uptake in patients with recurrence. Yeung et al.¹⁰⁴ and Flamen et al.¹⁰⁵ studied recurrent disease. The latter study showed that FDG-PET was comparable to or somewhat inferior to conventional imaging. The sensitivity, specificity, and accuracy for FDG-PET were 100%, 57%, and 74%, respectively, and 100%, 93%, and 96% for conventional imaging. In the detection of regional or distant recurrence, the sensitivity, specificity, and accuracy were 94%, 82%, and

87% for FDG-PET and 81%, 82%, and 81%, respectively, for conventional imaging. In practice PET has been useful for detecting recurrent disease and is complementary to CT.

In summary, PET with FDG is a useful diagnostic tool for esophageal carcinoma. It is generally used at initial diagnosis to perform whole-body staging and to determine the baseline metabolic rate of the tumors. It then can be used to follow the response to locoregional or systemic therapies. Large declines in FDG uptake after therapy are associated with a better response than a modest decline in tracer uptake. PET cannot detect microscopic disease or even disease under a few millimeters in size with current technology. This is a continuing limitation as is the uptake of FDG into inflammatory cells after treatment. Nonetheless, FDG-PET is established as an important tool at several points in the management of patients with esophageal carcinoma. PET/CT is the preferred embodiment of this application at present, but literature to strongly support the superiority of PET/CT over PET is limited at this time.

Lung

Non-small cell lung cancer (NSCLC) is the leading cause of cancer death in men and women in the United States. It has surpassed breast cancer as the number one cancer killer of women. When it is diagnosed early, the prognosis is relatively good, with greater than a 60% 5-year survival for stage I disease compared to only 14% for all patients.¹⁰⁶ The primary treatment of lung cancer is surgery (if it is indicated), but once nodal or distant metastases have developed, the correct type of therapy is adjuvant chemotherapy or radiation therapy. Correct staging is the mainstay of appropriate clinical management.

FDG-PET is a valuable noninvasive imaging test for detecting malignancy in solitary pulmonary nodules (SPNs), for staging or restaging NSCLC, for monitoring therapy, and for detecting residual or recurrent disease, and, finally, it provides prognostic information that is independent of lesion size, clinical stage, and cell type. It contributes to better informed medical decision making and more cost-effective medical care.

Diagnosis of NSCLC and Evaluation of Pulmonary Nodules

In the United States, approximately 150,000 indeterminate pulmonary nodules are discovered each year and between

30% and 50% of these are malignant.^{107,108} The incidence of cancer is not low enough to ignore it, nor is it high enough to decide to resect all nodules.

Chest radiography and CT scan can establish the benign nature of a lesion. Certain patterns of calcification (likelihood ratio, 0.07) or the presence of fat within the nodule or a low growth rate over 2 years (likelihood ratio, 0.01) are diagnostic of a benign etiology.¹⁰⁹ CT provides some assessment of the likelihood of malignancy based on morphology and the presence of secondary findings, such as hilar or mediastinal adenopathy, but the vast majority of SPNs are indeterminate by radiographic or CT criteria.¹¹⁰

Biopsy by CT-guided transthoracic needle aspiration and bronchoscopy are helpful when positive, but because of sampling error, a benign result cannot exclude tumor. On the other hand, more invasive procedures, such as thoracoscopic or surgical biopsy, are associated with increased cost and morbidity.¹¹¹ FDG-PET and contrast-enhanced dynamic CT (dCT) are accurate, noninvasive methods for diagnosing lung cancer.

Lowe et al.¹¹² showed that FDG-PET has an overall sensitivity of 92% and a specificity of 90% in a study of 89 patients with nodules between 0.7 and 4.0 cm in diameter using a SUV cutoff of 2.5 or greater. Another criterion is if nodules are hyperintense compared to the mediastinum. With application of these two criteria, FDG-PET is approximately 96% sensitive and 80% specific for malignancy.

False-positive results may be caused by the increased glycolytic activity within activated macrophages. Active granulomatous diseases can be FDG avid, such as tuberculosis,¹¹³ sarcoidosis,¹¹⁴ aspergillosis,¹¹⁵ histoplasmosis,¹¹⁶ or lipoid pneumonia and talc granulomata after pleurodesis,¹¹⁷ and pneumonitis and necrosis after high-dose radiation therapy.¹¹⁸ False-negative results can occur in some low-grade tumors, including bronchoalveolar carcinoma¹¹⁹ and bronchial carcinoma.¹²⁰ Lesions that are near the limiting spatial resolution of the PET scanner (about 6mm on newer systems) may be falsely negative because of the effect of the volume averaging (partial volume effect).

In a meta-analysis of 40 studies of 1,474 focal pulmonary lesions, Gould et al.¹²¹ reported a sensitivity of FDG-PET of 92% (95% confidence interval, range 89%–93%). They noted that in practice the sensitivity of 97% and a specificity of 78% decrease false-negative results. A nodule less than 1 cm should be considered worrisome for malignancy if any FDG accumulation is seen.

Dynamic CT uses intravenous iodinated contrast material to measure nodule perfusion, and this information provides an estimate of the likelihood of malignancy. A pre-

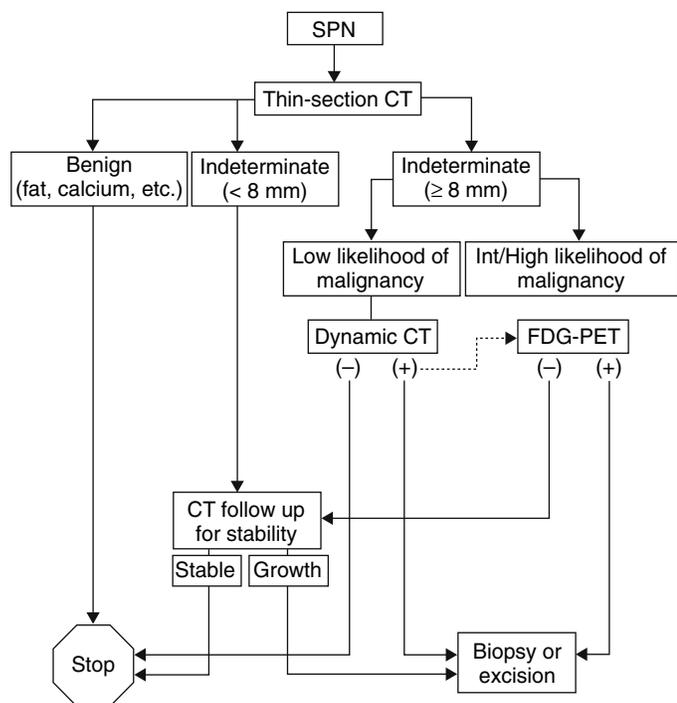

FIGURE 33.4. Diagnostic algorithm for lung nodules.

diagnostic strategies (percutaneous needle biopsy or mediastinoscopy) and to guide appropriate therapy.

One in 10 to 1 in 20 pulmonary nodules that are negative by FDG-PET imaging may, in fact, be malignant. One approach is to follow patients with a negative PET scan with serial CT examinations. A negative PET scan excludes high-grade lung carcinoma, so the risk of following patients over 1 to 2 years for nodule growth is low. Most of them are T1NOMO at the time of surgery.¹²⁵

Zhuang et al.¹²⁶ and Matthies et al.¹²⁷ proposed dual-time PET imaging and thought this was suitable for nodules near the level of the cutoff value of 2.5 for SUV.

Relative FDG uptake in malignant nodules tends to increase between the scans, whereas the relative FDG uptake in benign nodules tends to remain stable or decrease slightly. Using a threshold of a 10% increase in SUV between 1 and 3 hours led to an increase in sensitivity for FDG-PET from 80% to 100%. The specificity, however, declined from 94% to 89% (Table 33.6). Demura et al.¹²⁸ reported the significance of dual time point PET imaging in the staging of disease of the mediastinum.

Staging NSCLC

The most standardized staging system is the TNM system. T denotes features of the primary mass, including size, location, and invasion, N denotes regional lymph node status, and M the presence or absence of metastatic disease.¹²⁴

Because most patients have had a diagnostic CT before referral for FDG-PET, the PET scan is used mainly for assigning T stage (1) for the evaluation of the likelihood of malignancy in additional pulmonary nodules and to direct a confirmatory biopsy to them and (2) for the identification of malignant pleural effusions, which may be reactive or malignant, as CT cannot distinguish them.

In a study of 100 patients with newly diagnosed bronchogenic carcinoma, Marom et al.¹²⁹ compared staging with FDG-PET to staging obtained with a chest CT scan, a bone scan, and contrasted brain CT or MRI. For overall staging FDG-PET had an accuracy of 83%, whereas with conventional imaging it was 65% (*P* less than 0.005) (Table 33.7).

For mediastinal lymph nodes, PET had an accuracy of 85% and for conventional imaging it was 58%. The important point here was that 9% of PET-positive studies were CT negative and 10% of PET-negative studies were CT false positive. In N3 stage disease, the sensitivity and specificity of PET were 92% and 93%, respectively, and for CT they were 25% and 98% (*P* less than 0.005). In M stage, the PET scan

contrast density measurement in Hounsfield units (HU) is obtained after a bolus injection of contrast material, and density measurements are performed at 1, 2, 3, and 4 min. Enhancing nodules are presumed to be malignant and nonenhancing nodules are presumed to be benign. Using a threshold of 15HU, this technique has a sensitivity of 98%, a specificity of 58%, an accuracy of 77%, and a very high negative predictive value (Swensen et al.¹²²).

Nathan et al.,¹²³ in a recent study of 36 patients, evaluated pulmonary nodules larger than 8mm with both FDG-PET and dCT. The overall sensitivity and specificity for FDG-PET were 95% and 80%, respectively (using the criteria referred to above), and for dCT (with a cutoff of 15HU) were 100% and 27%, respectively.

Rohren et al.¹²⁴ suggested a diagnostic algorithm as is shown in Figure 33.4. A negative dCT scan can confidently exclude malignancy, but after a positive dCT the patients should be followed with an FDG-PET study, because one-half of them can be shown to be truly negative with PET imaging. All this staging information can be used to plan subsequent

BS, bone scan; CI, conventional imaging.

was 91% accurate and conventional imaging was 80%. FDG PET also was superior to bone scintigraphy for evaluating osseous metastases from lung cancer: sensitivity, specificity, PPV, and NPV for FDG-PET were 92%, 99%, 92%, and 99%, respectively, and for bone scintigraphy these were 50%, 92%, 50%, and 92%.

Erasmus et al.¹³⁰ showed that FDG-PET was very sensitive and specific for evaluating adrenal metastases.

Metastatic disease to regional lymph nodes is categorized by location in relationship to the tumor. For N0 disease, the 5-year survival is 60%, for N2 it is 20%, and for N3 it is very poor.¹⁰⁶

The "gold standard" method for mediastinal lymph node staging is supposed to be mediastinoscopy. The overall sensitivity of the "gold standard" is approximately 90%, and it has the disadvantage of sampling errors and the technical difficulty of obtaining overall coverage with a single entry port (i.e., inaccessibility in the aortopulmonary window lymph nodes).¹²⁴

On the other hand, CT uses size criteria to assess nodal metastases (1 cm in the short axis dimension). The limitation of this approach is that enlarged nodes may reflect inflammatory changes rather than metastatic involvement and small nodes may contain tumor deposits. Dwamena et al.,¹³¹ in a meta-analysis of 514 patients, reported that the sensitivity, specificity, and accuracy of FDG-PET were 79%, 91%, and 92%, respectively, and those of CT were 60%, 77%, and 75%. The average sensitivity of PET for nodal disease from a variety of studies¹³²⁻¹³⁵ was 88% as compared with 63% for CT, and the average specificity was 91% for PET and 76% for CT.

The most common sites of metastases from lung carcinoma include lung (additional pulmonary lobes or to the contralateral lung), brain, adrenals, bone, and, less commonly, in liver and soft tissue.

Monitoring Therapy and Detection of Residual or Recurrent Disease

FDG-PET provides metabolic rather than anatomic information and allows functional assessment of lung tumors during or shortly after therapy. Patients with a complete resolution of FDG uptake in their tumor following therapy have been

shown to have a good prognosis, as compared to those who have residual FDG uptake in their tumors. After treatment it is not necessary to find visible alterations in gross anatomic structure, but some posttreatment effects do occur. Tissue necrosis and concomitant macrophage-mediated inflammation after radiotherapy usually lead to the delay of a follow-up PET scan for 3 to 6 months. Radiographic findings usually peak within 6 to 12 weeks following completion of therapy and resolve by 6 months. The typical appearance on PET is diffuse low-grade or intermediate-grade FDG activity confined to a geographic field corresponding to the radiation port.

Bury et al.,¹³⁶ in a study of 126 patients with stage I to IIIB NSCLC treated with radiation therapy, showed that in detection of residual or recurrent disease FDG-PET had a sensitivity, specificity, accuracy, PPV, and NPV of 100%, 92%, 96%, 92%, and 100%, respectively, and the values for CT were 72%, 95%, 84%, 93%, and 79%. Because of its high sensitivity and negative predictive value, the investigators concluded that FDG-PET was a useful adjunct to CT in monitoring the effects of radiation therapy.

Prognostic Information and Future Trends in PET Imaging

FDG-PET is used in determining planning target volumes (PTV), target coverage, and critical organ dose for radiotherapy. In one study, inclusion of a PET scan resulted in a change in PTV in approximately 30% of the patients¹³⁷ because of more accurate delineation of metabolically active tumor. In another study, PTV was changed in all patients after inclusion of a PET scan in the preprocedure evaluation.¹³⁸ It has been shown that FDG uptake in NSCLC correlates with the grade of the primary tumor, but it is an independent risk factor.¹³⁹

Ahuja et al.¹⁴⁰ showed that FDG-PET provides prognostic information that is entirely independent of a tumor's size and clinical stage at the time of diagnosis. When the SUV in the primary tumor was less than 10, the median patient survival was 24.6 months. If it was greater than 10, survivals fell to 11.4 months. If the SUV was greater than 10 and the primary lesion was larger than 3 cm, survival was only 5.7 months. Dhital et al.¹⁴¹ reported that the 1-year survival of patients

with tumor SUV_{max} less than 10 was 75% and with SUV_{max} greater than 20 it was only 17%.

Radiolabeled thymidine, a marker of DNA synthesis, choline agents (for the evaluation of membrane synthesis and turnover), and radiolabeled amino acids (for the evaluation of protein catabolism), are many of the agents that are under investigation for potential utility in patients with NSCLC.^{142,143}

Breast

Breast cancer is the most common malignancy in women in the United States and is the second leading cause of cancer death in women. It represents 31% of all cancers in women. It is estimated that nearly 190,000 new cases appear every year and that 40,000 women die of breast cancer yearly.^{144,145} Brown et al.¹⁴⁶ described the marked overexpression of the GLUT-1 glucose transporter in human breast cancer and the correlation between tumor FDG uptake and the number of viable tumor cells. Biochemical imaging using PET offers significant advantages and provides unique information about the physiologic processes associated with cancer.

Early studies¹⁴⁷⁻¹⁴⁹ in patients with locally advanced breast cancer (LABC) or metastatic disease reported that FDG-PET detected the majority of the lesions, but the selection bias of patients with advanced disease did not allow determination of the specificity. Several subsequent clinical studies have shown that FDG-PET has a sensitivity ranging from 63% to 93% and specificity ranging from 73% to 94%.¹⁵⁰⁻¹⁵⁴ (Table 33.8).

Adler et al.¹⁵⁵ reported a sensitivity of 96% in 27 primary lesions. Using a standard uptake value (SUV) threshold of 2 to 2.5, they were able to differentiate malignant from benign lesions with approximately 90% accuracy. Dehdashti et al.¹⁵⁶ found a sensitivity of 88% and specificity of 100% using a SUV of 2.0 as the cutoff number to discriminate malignancy. In a recent meta-analysis¹⁵⁴ of the PET literature, data from 606 patients indicated that FDG-PET had a sensitivity of 88% [95% confidence interval (CI), 83%–92%] and a specificity of 79% (95% CI, 71%–85%) (Figure 33.5).

FDG-PET has limitations in detecting (1) tumors smaller than 1 cm), (2) more well-differentiated histologic subtypes of

tumors (tubular carcinoma and in situ carcinoma), and (3) lobular carcinomas.

Avril et al.¹⁵⁰ demonstrated that the sensitivity for detecting tumors larger than 1 cm using sensitive imaging reading criteria (definite and probable FDG uptake) was 57%, compared with 91% (with conventional image reading) for tumors larger than 1 cm. The sensitivity for detecting carcinoma in situ was even lower at 25%, and there was a significantly higher false-negative rate with infiltrating lobular carcinoma (65%) than with infiltrating ductal carcinoma (24%). In the same study, they showed that the overall sensitivity of FDG-PET for detecting breast cancer was improved by using a more sensitive threshold for image interpretation compared to a conventional threshold (80% versus 64%), although the overall specificity was significantly poorer (75% versus 94%). They also reported a sensitivity of 50% for the identification of multifocal or multicentric breast cancer. Although breast conservation therapy has become standard for treating early breast cancer, it cannot be applied in these subsets of patients because up to 41% of breast cancers are multifocal or multicentric.¹⁵⁷

Schirrmeister et al.¹⁵¹ demonstrated that PET was twofold more sensitive (63%) than combined mammography and ultrasound (32%) to detect multifocal lesions. The specificity was not different between these approaches.

The disadvantages of FDG-PET, such as high expense, modest whole-body radiation exposure, and a low accuracy in general screening, have prompted the development of high-resolution PET scanners dedicated to breast imaging with the capability of coregistering PET and mammographic images.¹⁵⁸⁻¹⁶⁰ The spatial resolution of these scanners is 2.8 mm full width at half maximum, about half that of current whole-body PET instruments, and they can utilize a lower dose of radiotracer and decreased acquisition time.

The level of FDG uptake in an untreated breast cancer has prognostic information that may help to (1) stratify patients according to risk for recurrence or treatment failure and (2) target the aggressiveness of therapy for an individual patient to the aggressiveness of her tumor.

FDG uptake has a strong correlation with the histologic type (higher in ductal versus lobular),¹⁶¹⁻¹⁶³ tumor histologic grade,^{161,164,165} indices of proliferation (higher uptake with higher levels of proliferation),^{162,163} microscopic tumor growth

pattern¹⁶² (nodular versus diffuse), and S phase.^{164,165} A weaker correlation with FDG has been reported for microvessel density, a surrogate of angiogenesis,^{166,167} and tumor cell density.^{162,167}

No correlation was found between FDG uptake and tumor size,^{162,163,168} axillary node status,^{161,162,163} steroid receptor status,^{162,163,168,169} the presence of inflammatory cells,¹⁶² percentage of necrotic, fibrotic, and cystic components,¹⁶² or the thymidine labeling index (LI).¹⁶⁸

Oshida et al.¹⁶⁶ and Mankoff et al.¹⁷¹ found that FDG uptake in the primary tumor is predictive of response to treatment and patient outcome, even when they are treated with a variety of different protocols.

Eubank et al.¹⁷⁰ assumed that FDG uptake may be a marker of tumor cell resistance to apoptosis, and this was supported by other studies.^{172,173} Intermediates in the glycolytic pathway are key factors in initiating apoptosis, and alterations in these pathways limit apoptosis. Overexpression of some genes is associated with high glycolytic rates and resistance to apoptosis. An example is the P13K/Akt pathway.

Lymph Node Staging

The single most important prognostic factor in early stage breast cancer is the status of the axillary lymph nodes. The 10-year survival rate of patients with histologically negative axillary nodes (65% to 80%) is significantly higher than that of those with involvement of one to three nodes (38% to 63%) or more than three axillary nodes (13% to 27%).¹⁷⁴ The extent of axillary disease influences the choice of the therapeutic

regimen for individual patients. Many studies using FDG-PET for axillary staging showed a sensitivity of 40% to 94% and a specificity of 80% to 100%.^{154,175-180}

Because neither physical examination nor conventional imaging can detect axillary nodal metastases, lymph node dissection (either conventional or limited with the use of sentinel node localization) is routinely performed to assess axillary nodal status in all patients with invasive cancers of 20 mm or less (80% or more of these patients have negative axillary lymph nodes). The risk of axillary nodal metastases is reported to be less than 5% in patients with tubular carcinoma less than 1 cm in diameter, grade I tumors less than 5 mm in diameter, or tumors with a single focus of microinvasion.

With the introduction of step sectioning and immunohistochemical staining, micrometastases can be detected in up to 45% of cases.¹⁸¹ Microscopic nodal involvement may be important for prognosis and treatment planning, and FDG-PET will miss this.¹⁸²

Avril et al.¹⁸⁰ found that the sensitivity of FDG-PET for detecting axillary disease in patients with T1 tumors (33%) was significantly less than for patients with tumors larger than 2 cm (94%). The specificity (100%) was the same for both subgroups. It has also been shown that the number of nodes involved with tumor at dissection influenced the sensitivity of PET (Table 33.9).

In preclinical studies of several types of tumors, including rat mammary tumors, Wahl et al.¹⁸³ showed that FDG uptake in lymph nodes involved by metastatic tumor is greater than FDG uptake in normal lymph nodes. In a recent multicenter study involving 308 axilla sites, the same investigators reported a moderate accuracy of FDG-PET and a

mean sensitivity and specificity of 61% and 80%, respectively, when at least one focus of abnormal axillary uptake was detected.¹⁸⁵

A recent meta-analysis found that FDG-PET has a higher sensitivity for predicting lymph node metastases in the axilla of patients with palpable axillary nodes, 90%, than for those having nonpalpable nodes, 69%, but lower specificity, 88% versus 94%.¹⁵⁴ Greco et al.¹⁷⁸ showed that in primary breast cancers, the detection rate for axillary nodal disease by FDG-PET depended on the size of the primary lesion, with an overall sensitivity and specificity of 94% and 86%, respectively.

Sentinel lymph node mapping is now a validated, minimally invasive technique that includes histologic analysis of the primary draining nodes in the axilla identified at surgery after perilesional injection of ^{99m}Tc-sulfur colloid and/or blue dye.¹⁸⁶

FDG-PET has been reported to have a sensitivity in the range of 20% to 50%¹⁸⁵⁻¹⁸⁷ in patients with pathologic results from sentinel lymph node (SLN) biopsy. In more advanced disease, however, especially with palpable axillary nodes, a large volume of disease ("packed" SLN) may not be visualized at mapping because lymph flow is diverted around it, and this may potentially result in a false-negative examination.¹⁸⁸

Lymphatic spread of tumor to the internal mammary (IM) nodes occurs in up to 25% of patients at the time of initial diagnosis and more commonly in recurrence.¹⁸⁹ IM nodes are not as accessible as axillary nodes, and radiotherapy and lymphadenectomy did not seem to improve patient survival.¹⁵⁷ For these reasons, they are not sampled, although the presence of IM-FDG uptake predicts treatment failure.

Detection of Distant Metastatic Disease and Recurrence

The most common sites of locoregional recurrence among patients following mastectomy, axillary node dissection, and radiation therapy are the chest wall and supraclavicular nodes.¹⁹⁰ FDG-PET is a sensitive method for detecting metastases in the brachial plexus in patients with breast cancer.^{191,192} Eubank et al.,¹⁹³ in a study of 73 patients with recurrent or metastatic breast cancer, demonstrated that FDG uptake in mediastinal or IM nodes was two times more prevalent than suspiciously enlarged nodes by CT. The sensitivity of FDG-PET was 85%, much higher than CT (50%), with nearly the same specificity (90% for PET and 83% for CT). Of these, 30% of patients suspected of having only locoregional recurrence by conventional imaging and clinical examination had mediastinal or IM-FDG uptake. Moon et al.¹⁹⁴ reported an overall lesion-by-lesion sensitivity of 85% for FDG-PET and a specificity of 79%.

Gallowitsch et al.¹⁹⁵ reported sensitivity, specificity, PPV, NPV, and accuracy of 97%, 82%, 87%, 96%, and 90%, respectively, for FDG-PET, compared with 84%, 60%, 73%, 75%, and 74%, respectively, for CT. Lonneux et al.,¹⁹⁶ in a study of 39 patients (asymptomatic) with a rise in tumor markers, showed that FDG-PET detected recurrences with 94% sensitivity, whereas conventional imaging had a sensitivity of 18%. Kamel et al.,¹⁹⁷ in a study of 60 similar patients, found an overall sensitivity, specificity, and accuracy of 89%, 84%, and 87%, respectively, for locoregional recurrence and found it more sensitive than the serum tumor marker CA15-3 (Table 33.10). Inoue et al.¹⁹⁸ demonstrated that the patients

with a higher SUV had a significantly poorer prognosis than those patients with lower values.

The skeleton is the most common site of distant metastases in breast cancer. Bone scintigraphy is considered the most sensitive method for detecting and determining the extent of skeletal metastases. However, purely lytic lesions or metastases confined to the marrow cavity may be difficult to detect on a bone scan, due to the lack of a sufficient osteoblastic response.¹⁹⁹ Cook et al.²⁰⁰ reported that the level of FDG uptake in lytic lesions was significantly greater compared with osteoblastic lesions and that the prognosis of patients with predominantly lytic disease was significantly worse.

Osseous metastases are a frequent finding in breast cancer; approximately 70% of patients with advanced disease have an osseous metastasis, which is a major contributor to morbidity and treatment cost.²⁰¹ The median survival for these patients is 24 months and the 5-year survival is 20%. Breast cancer causes osteolytic more often than osteoblastic metastatic lesions, although osteoblastic changes often develop after treatment.

The reported higher sensitivity of FDG-PET for detection of osteolytic lesions likely reflects the ability of FDG-PET to detect metastatic deposits in the bone marrow before the development of a significant reactive bone formation that is necessary for detection by bone scintigraphy. FDG-PET detection of osseous metastatic disease appears to be unrelated to reactive bone formation, but rather is related to detection of the metabolic activity of the tumor cells.

¹⁸F-Fluoride PET may provide improved detection of bone metastases in breast cancer, and in other tumors, because its concentration is approximately twofold greater than that of ^{99m}Tc-methylene diphosphonate (^{99m}Tc-MDP) and its clearance is faster, resulting in a higher bone to background ratio. Schirrmeister et al.²⁰² compared a whole-body ¹⁸F-PET scan with a whole body ^{99m}Tc-MDP scan and demonstrated that the former detected more lesions in more patients than the conventional bone scan. Finally, it was found that FDG-PET changed the clinical stage in 36% of patients with breast cancer and the management in 58%.²⁰³

Monitoring Treatment Response

Neoadjuvant chemotherapy (NACT) is the standard therapy for patients with locally advanced breast cancer (LABC). NACT is associated with a good response rate in more than 70% of the patients, including a complete pathologic remission in about 10% to 15%.²⁰⁴ It has been used to improve primary tumor resectability (including the use of breast-conserving surgery) and to assess chemosensitivity to selected chemotherapeutic agents. It can also be used as an alternative therapy for patients who are unresectable or chemoresistant.

Conventional imaging methods are limited in assessing response to therapy, and often a delay of several weeks after completion of therapy is required before the effectiveness of the treatment can be assessed. Wahl et al.²⁰⁵ reported that metabolic changes could be detected as early as 8 days post-treatment in responders. Persistent FDG uptake is seen in nonresponding patients.

Schelling et al.²⁰⁶ and Smith et al.²⁰⁷ were able to separate responders from nonresponders with sensitivities of 90% and 100% and specificities of 74% and 85% after the first course

of chemotherapy. Their results were similar although they used a different SUV cutoff.

In assessing the response to chemotherapy, Vranjesevic et al.²⁰⁸ noted, in a study of 61 patients using FDG-PET and conventional imaging (CT/MRI/US), that the former was more accurate (90% versus 75%).

Other biologic and physiologic tumor properties may be responsible for clinical prognosis. For example, imaging with ¹⁵O-water can estimate regional blood flow within a tumor. Low perfusion may be responsible for a poor response to intravenous chemotherapy.²⁰⁹ Mankoff et al.²¹⁰ showed that blood flow declined an average of 32% in responders and increased an average of 48% in nonresponders. The posttherapy blood flow measurement was the only statistically significant variable associated with improved disease-free survival. Using PET in this way may help to identify the physiologic manifestations of drug resistance.

Patients with breast cancer undergoing chemotherapy often receive the hematopoietic cytokines, granulocyte colony-stimulating factor (G-CSF) or granulocyte macrophage colony-stimulating factor (GM-CSF). The use of these agents results in an increase in bone marrow uptake of FDG, which may be misinterpreted as diffuse bone marrow involvement by breast cancer. The higher bone marrow background activity after cytokine therapy may make it more difficult to detect osseous metastases.

Sugawara et al.²¹¹ studied the effects of G-CSF and GM-CSF on the biodistribution of FDG in rats and found that SUV_{lean} (SUV corrected for lean body mass) of the bone marrow was greater during G-CSF treatment than the baseline level. Markedly increased FDG uptake is also often seen in the spleen because of extramedullary hematopoiesis in the spleen.^{211,212}

Smith et al.²¹³ and Gennari et al.²¹⁴ showed by quantitative methods that a significant reduction in axillary nodal FDG uptake after neoadjuvant chemotherapy could predict a complete microscopic pathologic response, and that may be an even more important marker for prognosis because nodal disease is thought to reflect the presence of occult disseminated disease.

Stafford et al.²¹⁵ evaluated the response of skeletal metastases to therapy using serial FDG-PET and found a strong correlation between the quantitative change in FDG SUV and the overall clinical assessment of response, assessed with physical examination, conventional imaging, and change in tumor markers.

Mortimer et al.²¹⁶ reported a series of 40 patients who underwent FDG-PET for the evaluation of response to tamoxifen 7 to 10 days after institution of therapy. FDG uptake predicted a subsequent response to therapy consistent with a "metabolic flare."

Other PET Tracers

Energy metabolism is associated not only with tumor growth, but also with a variety of other biologic processes, such as inflammation or tissue repair. Other PET tracers have been used for staging and guiding treatment by identifying therapeutic targets, by identifying factors associated with resistance to therapy, and by making early assessments of therapeutic response.

Decreased tumor proliferation is an early event in response to successful treatment.²¹⁷ Thymidine is incorporated into

DNA but not RNA, so its uptake and retention in the tumor serves as a specific marker of cell growth. Shields et al.²¹⁸ showed that ¹¹C-thymidine could be used in assessing early response to treatment. The ¹⁸F analogue of thymidine (FLT) has been used because its longer half-life is an advantage.^{219–221} FLT has been used to measure the response to treatment in several different tumor types, including breast cancer.

Tumor hypoxia has been established as a resistance factor for radiotherapy, and evolving evidence indicates that it promotes tumor aggressiveness and resistance to a variety of systemic treatment modalities.^{222,223} Hypoxia could not be reliably predicted by FDG uptake,²²⁴ although it contributes to increased rates of glycolysis, as was shown by Clavo et al.²²⁵ The most widely used PET agent for imaging hypoxia is ¹⁸F-fluoromisonidazole.²²⁶ PET imaging of hypoxia holds great promise for identifying the subset of breast cancers with significant hypoxia, where alternative therapeutic strategies that can overcome the resistance associated with hypoxia will likely be needed.

The majority of breast cancers express estrogen receptors (ER) and progesterone receptors (PR), and their expression is an indicator of prognosis and predicts the likelihood of responding to antiestrogen therapy.²²⁷ Most breast cancers are hormone sensitive, requiring estrogen for proliferation. Currently, tumor ERs and PRs are evaluated by in vitro assays, but these assays provide limited information about the functional status of the receptors and the likely responsiveness of the tumor to hormone therapy. Only 55% to 60% of patients with ER(+) disease actually respond to hormonal therapy [versus fewer than 10% of patients with ER(-) disease].^{228,229} Furthermore, ER expression can be heterogeneous in large or metastatic breast cancers, and biopsy can be misleading as a result of sampling error.

The most extensively studied compound is 16 α -¹⁸F-fluoro-17 β -estradiol (FES), which showed an excellent correlation between tumor FES uptake measured on PET images and the ER concentration of the tumor determined by conventional quantitative ligand binding assays²³⁰ or by immunohistochemistry,²³¹ either in the primary tumor or in metastatic lesions. FES-PET has been shown to be highly sensitive (93%) for detection of ER(+) metastatic foci²³² at an acceptable radiation dose to the patient.²³³ Mankoff et al.²³⁴ showed heterogeneous FES uptake within the same tumor and between metastatic lesions, both qualitatively and quantitatively, which can help in establishing prognosis and in guiding treatment selection.

In patients with known metastatic breast cancer, FES uptake decreased after the initial therapeutic dose of tamoxifen, and this is presumably related to the nonavailability of ERs to interact with FES because the receptors were occupied by tamoxifen and its bioactive metabolites. This finding shows that the tumor uptake of FES appears to be a receptor-mediated process.

Dehdashti et al.²³⁵ found no significant relationship between FDG uptake and either ER status or FES uptake. FES-PET and in vitro ER assays agreed in 88% of patients. Mortimer et al.²³⁶ reported that patients with FES(+) disease had longer survival than those with FES(-) tumors. When there is a high degree of ER blockade in the primary tumor (about 50% decrease in SUV from baseline), a good response to therapy is predicted.²³⁷

Within 7 to 10 days after the initiation of hormonal treatment, a small number of patients (5% to 20%) experience a phenomenon known as the hormonal flare reaction, with pain in osseous metastatic lesions, pain and erythema in soft tissue lesions, hypocalcemia, and apparent disease progression on bone scintigraphy.²³⁷

The percent change in FDG uptake and the baseline FES uptake were the best predictors of response to therapy. The PPV for response to tamoxifen with a metabolic flare (an increase in tumor FDG uptake of 10% or more as the cutoff criterion) was 91% and the NPV was 94%. The PPV and NPV for the baseline FES uptake (with a cutoff SUV of 2.0) were 79% and 88%, respectively.²³⁷

The flare reaction is a strong predictor of response because nearly 80% of the patients who develop this reaction respond to hormonal therapy.²³⁸ Hormonal flare is presumed to represent an initial agonist effect of the drug on the tumor before its antagonist effects supervene.²³⁹

PET can be used to guide therapy by showing characteristics of the tumor at the biochemical level before therapy or early during therapy.

Gastric Cancer

Gastric cancer is the second most common cause of cancer death in the world, with an overall 5-year survival rate less than 25%.²⁴⁰ The leading cause for the development of gastric cancer is repeated infection with *Helicobacter pylori*.

There are two different types: the intestinal type, which predominantly involves the distal stomach (most common in Asia), and the diffuse or signet-ring type, which mainly involves the proximal stomach (most common in Western countries).

Tumors consisting of signet-ring cells or with large amounts of mucin are frequently false negative by FDG-PET, probably because of a lower expression of glucose transporters in these types of tumors and a lower tumor cell density.^{241,242} Even large tumors with a diameter of several centimeters can be falsely negative on FDG-PET if the tumor cells demonstrate low metabolic activity.²⁴³

Yeung et al.²⁴⁴ studied 23 patients with gastric cancer and found that FDG-PET had a sensitivity of 93% for detection of gastric cancer, a specificity of 100% for detection of local recurrence, but low sensitivity (22%) and high specificity (97%) for detection of metastatic disease in intraabdominal lymph node stations.

Stahl et al.²⁴¹ reported higher detection rates in the intestinal type (83%) compared with the nonintestinal type (41%). The SUV was greater in the intestinal type (6.7 \pm 3.4) than in the nonintestinal type (4.8 \pm 2.8). Nonmucinous tumors had higher SUVs (7.2 \pm 3.2) than the mucinous ones (3.9 \pm 2.1), and the same was true for grade 2 tumors, which had higher FDG uptake than the grade 3 tumors.

Mochiki et al.²⁴⁵ described the existence of a relationship between the intensity of FDG uptake and survival, which did not agree with the results of Stahl and coworkers.²⁴¹ Yoshioka et al.²⁴⁶ demonstrated the usefulness of FDG-PET in detecting metastatic disease in the liver, lungs, and lymph nodes, but it was not useful for detection of osseous metastases and peritoneal or pleural carcinomatosis. De Potter et al.²⁴³ reported in a study of 33 patients that the sensitivity, speci-

SR, survival rate.

ficity, PPV, and NPV of FDG-PET were 70%, 69%, 78%, and 60%, respectively, in the detection of recurrent disease.

Ott et al.²⁴⁷ have used a 35% decrease from the baseline metabolic activity on day 14 of preoperative chemotherapy to predict tumor response in patients with gastric cancer (Table 33.11). The sensitivity and specificity of FDG-PET for prediction of histopathologic response were 77% and 86%, respectively, and the 2-year overall survival of "responders" compared with that of "nonresponders" was 90% and 25%, respectively.

Colorectal Carcinoma

Colorectal cancer is the third most common cause of cancer in men and women, and it affects 5% of the population in the United States and other Western countries. Approximately 106,000 new cases of colon cancer, 40,570 new cases of rectal cancer, and 57,000 deaths (10% of all cancer deaths) were expected to occur in 2004 in the United States.²⁴⁸ Most patients (70%) diagnosed with colorectal cancer undergo surgery with curative intent, and the overall survival of 5 years is less than 60%.

The recurrence rate is close to 40% within the 5 years following surgery, with up to 80% of the recurrence appearing in the first 2 years. The most common sites of recurrence are in the liver (20%), in the original local site (12.5%), and in the lungs (8%). Only 20% of patients are amenable to a second surgery with curative intent, and long-term survival is expected in only 30% of these.^{249,250}

The diagnosis of colorectal carcinoma is based on colonoscopy and biopsy. Most follow-up strategies include carcinoembryonic antigen (CEA) testing and liver imaging. The use of frequent colonoscopy is still being investigated.

FDG-PET in the Diagnosis and Initial Staging of Colorectal Carcinoma

FDG-PET can usually differentiate benign from malignant lesions (hepatic and pulmonary lesions, indeterminate lymph nodes) and can play an important role in the evaluation of patients with rising tumor markers in the absence of a known source of disease. When these lesions (or metastases) are found with FDG-PET, they may lead to a cancellation of surgery in these patients.

Abdel-Nabi et al.²⁵¹ and Kantorova et al.²⁵² demonstrated that FDG-PET had a high sensitivity for detection of distant metastases, particularly in the liver, but neither FDG-PET nor

CT was sensitive enough to reliably detect local lymph node involvement. FDG-PET was, however, superior to CT for detecting hepatic metastases, with a sensitivity and specificity of 88% and 100%, respectively, compared with 38% and 97% for CT.²⁵¹

Mukai et al.²⁵³ reported that FDG-PET changed the treatment modality in 8% of patients and the extent of surgery in 13%. In a study of 110 patients, Yasuda et al.²⁵⁴ showed that precancerous adenomatous polyps could be detected with a sensitivity of 24% for lesions from 5 to 30 mm in size and of 90% for lesions greater than 13 mm.

Although there are false-positive findings such as abscesses, fistulas, diverticulitis, and adenomas, the identification of focal uptake should not be ignored. However, the impact on patient management is not high because most patients will undergo surgery anyway, and staging is usually performed with preoperative liver ultrasound and during surgery. PET results may have a role in changing the type of surgery (curative versus palliative or concomitant liver metastases resection).

FDG-PET in the Diagnosis and Staging of Recurrent Colorectal Cancer

Early detection of recurrent disease is of primary importance because it may lead to a cure in up to 25% of patients. Surgical or medical treatment with the intent to improve survival and the quality of life should be guided by the accurate staging of disease. The size and number of hepatic metastases and the presence of extrahepatic disease affect the prognosis. The prognosis is poor if extrahepatic metastases are present, and this is believed to be a contraindication to hepatic resection.²⁵⁵

Iterative measurement of CEA is a useful, albeit imperfect, method to monitor the detection of recurrence, with a sensitivity of 59% and specificity of 84%.²⁵⁶ Barium studies have been reported to be only 49% sensitive, 85% specific, and 80% accurate for overall recurrence.²⁵⁷ A strategy in which increased CEA levels trigger the ordering of a PET study is limited by the diagnostic performance of CEA itself, which is far from optimal.

CT has an accuracy of 25% to 73% for localizing recurrence, but it fails to demonstrate hepatic metastases in up to 7% of patients and underestimates the number of lobes involved in up to 33% of patients. Metastases to the peritoneum, mesentery, and lymph nodes are commonly missed on CT, as well as the differentiation of postsurgical changes from local tumor recurrence.^{258,259} CT portography (superior mesenteric arterial portography) is more sensitive (80% to 90%) than CT (70% to 80%) for detection of hepatic metas-

tases, but there are many false-positive findings, which lower the positive predictive value.^{260,261} There are also limitations in accurate operative staging because of adhesions or the site of the surgical incision (transverse upper abdominal for liver resection). Shiepers et al.²⁶² studied 76 patients and found that the accuracy of FDG-PET and CT were 95% and 65%, respectively, for differentiation of scar from local recurrence.

Huebner et al.,²⁶³ in a meta-analysis review of 11 articles, reported that the sensitivity and specificity for detecting recurrent colorectal cancer with FDG-PET were 97% and 76%, respectively, and for liver and local pelvic recurrences FDG-PET had specificities of 99% and 98%. Whiteford et al.²⁶⁴ demonstrated that the sensitivity of FDG-PET imaging for detection of mucinous adenocarcinoma was significantly lower than for nonmucinous adenocarcinoma, 58% and 92%, respectively, mainly because of the relative hypocellularity of these tumors.²⁶⁵

The high diagnostic accuracy of FDG-PET for detecting liver metastases was confirmed by Kinkel et al.,²⁶⁶ who compared noninvasive imaging modalities (US, CT, MRI, and FDG-PET) for the detection of hepatic metastases from colorectal, gastric, and esophageal cancers. They found that FDG-PET had the highest sensitivity (90%), compared with 76% for MRI, 72% for CT, and 55% for US. Delbeke et al.²⁶⁷ reported that FDG-PET had a higher accuracy (92%) than CT (78%) and CT portography (80%) for detection of hepatic metastases. Although the sensitivity of FDG-PET (91%) was lower than that of CT portography (97%), the specificity was much higher, particularly at postsurgical sites.

Ogunbiyi et al.²⁶⁸ compared the sensitivity of FDG-PET and CT in local recurrence (91% versus 52%) and in hepatic lesions (95% versus 74%). Rydzewski et al.²⁶⁹ found that the PPV of FDG-PET for characterizing liver lesions was similar to that of intraoperative ultrasonography (US) (93% and 89%, respectively) and superior to CT and MRI imaging (Table 33.12).

A major advantage of FDG-PET is its ability to detect extrahepatic disease not discovered by the other modalities. Valk et al.²⁷⁰ compared the sensitivity of FDG-PET and CT for specific anatomic locations and found that FDG-PET was more sensitive than CT in all locations except the lung, where the two modalities were equivalent. The largest difference between PET and CT was found in the abdomen, pelvis, and retroperitoneum, where more than one-third of PET-positive lesions were negative by CT. PET was also more specific than CT at all sites except the retroperitoneum.

Delbeke et al.²⁶⁷ concluded that, outside of the liver, FDG-PET was especially helpful in detecting nodal involvement, differentiating local recurrence from postsurgical changes, evaluating the malignancy of indeterminate pulmonary nodules, and detecting distant metastases in the chest, abdomen, or pelvis.

Gambhir et al.,²⁷¹ in a review of 2,244 patient studies, reported that the sensitivity and specificity for FDG-PET were 94% and 87%, respectively, compared with 79% and 73% for CT. Flanagan et al.²⁷² reported the use of FDG-PET in 22 patients with unexplained elevation of CEA serum levels after resection of colorectal carcinoma with no abnormal findings on conventional workup, including CT. The sensitivity of FDG-PET in these patients was 100%, the specificity 71%, and the PPV 89%. Valk et al.²⁷⁰ reported a sensitivity of 93% and a specificity of 92% in a similar group of 18 patients.

Flamen et al.²⁷³ used FDG-PET to study 50 patients with elevated CEA and negative ($n = 31$) or equivocal ($n = 19$) findings on conventional imaging and found a sensitivity of 79% for the patients and 75% for the lesions. Cohade et al.,²⁷⁴ in a study of 45 patients, showed that PET/CT integrated imaging reduced the frequency of equivocal and probable lesion characterization by 50% compared with PET alone. This hybrid modality increased the number of definite locations by 25% and increased the overall correct staging from 78% to 89%.

Impact of FDG-PET on Patient Management

FDG-PET imaging allows the detection of unsuspected metastases in 13% to 36% of patients and has a clinical impact in 14% to 65%.^{267,268,270,272,273,275-279}

In the study by Delbeke et al.,²⁶⁷ PET altered surgical management in 28% of the patients, in one-third by initiating surgery and in two-thirds by avoiding surgery.

Meta et al.²⁸⁰ analyzed the answers to questionnaires that were sent to 60 referring physicians and concluded that PET had an impact on the clinical management in 65% of their patients (80% upstaged and 20% downstaged). In a study of 51 patients Ruers et al.²⁸¹ found that clinical management decisions based on conventional diagnostic methods were changed in 20% of patients based on the findings of FDG-PET imaging, especially by detecting unsuspected extrahepatic disease.

Strasberg et al.²⁸² demonstrated a higher long-term overall survival (OS) at 3 years (70%) and higher disease-free rates in patients selected for curative resection who had a PET study than those who did not have PET included in their workup (30% to 64%).

Current PET/CT fusion images can further affect clinical management²⁸³⁻²⁸⁷ by guiding therapy toward a less invasive and more efficient surgical procedure or by guiding a biopsy to an FDG-avid region of the tumor. Additionally, it can provide better maps than CT alone to modulate the field and dose of radiation therapy.

Monitoring Therapy

The ability of PET to differentiate scar tissue from recurrent tumor in the pelvis was recognized very early.^{288,289} Increased FDG uptake can be present immediately after radiation because of inflammatory changes, and this is not always associated with residual tumor. Moore et al.²⁹⁰ found a sensitivity of 84% and specificity of 88% for the detection of local pelvic recurrence 6 months after external-beam radiation therapy for rectal cancer. In contrast, Schiepers et al.²⁹¹ concluded that there was no correlation between FDG uptake and cell kinetics in patients with primary rectal cancer treated by irradiation. Guillem et al.²⁹² demonstrated in a study of 15 patients treated with combined chemoradiation that FDG-PET added useful information. In a study of 25 patients with rectal cancer, Calvo et al.²⁹³ described SUVs that were significantly decreased after treatment, but no correlation was found between postradiation metabolic activity and the 3-year survival rate.

Hepatic metastases can be treated with either systemic chemotherapy or regional therapy to the liver. A variety of

regional therapies exist, including chemotherapy administered through the hepatic artery using infusion pumps, selective chemoembolization, radiofrequency ablation, cryoablation, alcohol ablation, and radiolabeled ^{90}Y -microspheres.

Findlay et al.²⁹⁴ showed that, in patients with hepatic metastases, responders can be discriminated from nonresponders after 4 to 5 weeks of chemotherapy with fluorouracil by measuring FDG uptake before and during therapy. Some results reported by Vitola et al.,²⁹⁵ Torizuka et al.,²⁹⁶ and Langenhoff et al.,²⁹⁷ showed that 3 weeks after radiofrequency ablation and cryoablation, 51 of the 56 metastatic sites became FDG negative and there was no recurrence during 16 months follow-up.

Wong et al.²⁹⁸ compared FDG-PET imaging, CT, MRI, and serum levels of CEA to monitor the therapeutic response of hepatic metastases to ^{90}Y -glass microspheres. They found that FDG uptake correlated best with the changes in serum levels of CEA.

New PET Tracers for Clinical Use

^{18}F -Fluoride has a mechanism of uptake similar to that for other bone imaging radiopharmaceuticals, but because of the better spatial resolution and routine acquisition of tomographic images, ^{18}F -fluoride PET imaging offers potential advantages over conventional bone scintigraphy for detecting metastases. Schirrmeister et al.²⁹⁹ demonstrated that twice as many benign and malignant lesions were detected with ^{18}F -fluoride PET compared to planar scintigraphy.

Higashi et al.³⁰⁰ demonstrated that the *in vitro* uptake of ^{11}C -thymidine or ^{18}F -fluorothymidine correlates with the tumor proliferation rate and that these radiopharmaceuticals are assessing the rate of DNA synthesis. Dittman et al.³⁰¹ compared FDG with FLT uptake and showed that FLT-PET accurately visualized thoracic tumors and cerebral metastases, but that high physiologic uptake in the liver and bone marrow prevents detection of metastases in these locations.

Summary

FDG-PET is indicated as the initial test for diagnosis and staging of recurrence, for preoperative staging (N and M) of known recurrence, for the differentiation of benign from malignant lesions (indeterminate lymph nodes, hepatic and pulmonary lesions), for the differentiation of posttreatment changes from recurrent tumor, for the evaluation of patients with rising tumor markers in the absence of a known source, for a subgroup of patients at high risk (elevated CEA levels), for patients with a normal CT in whom surgery could be avoided if FDG-PET shows metastases, and for screening for recurrence in patients at high risk. It also affects the clinical management by guiding further procedures (biopsy, surgery, and radiation therapy) and excluding the need for additional procedures.

Lymphoma

Lymphoma is a general term that refers to a group of malignancies originating in the lymphoid tissue, including Hodgkin's disease (HD) and non-Hodgkin's lymphoma

(NHL).³⁰² The first evaluations of PET for staging in large cohorts of patients with lymphoma were performed by Moog et al.^{303,304} (mixed populations with HD and NHL). For nodal staging, Moog et al.³⁰³ evaluated 60 patients with CT and PET and verified discordant results by biopsy whenever possible. A total of 160 nodal regions were positive by both modalities, and 25 were positive by PET alone. Nine of these were verified histologically, and PET was true positive in 7 cases and false positive in 2 cases. Six regions were positive by CT only, and in the 3 in which verification was obtained, the CT result was false positive. There was a change in management in 10% to 15% of the patients.

For extranodal staging, Moog et al.³⁰⁴ also evaluated 81 patients. Forty-two disease sites were detected by both modalities, and PET detected an additional 24 sites, of which 15 were verified pathologically, including 9 sites in bone marrow, 3 in the spleen, and 2 elsewhere, and in 14 sites PET was true positive. Six of 7 lesions detected only by CT were verified, and 5 of these were false positive.

FDG-PET was found to be of value in the diagnosis of HD and aggressive NHL.^{305,306} It is generally accepted that FDG-PET may have a role in diagnosis and staging of low-grade follicular NHL. For other subtypes of low-grade lymphoma (small cell lymphocytic and probably mantle cell lymphoma), it seems that FDG-PET has no value for staging and follow-up.^{305,307} Similar discouraging results have been demonstrated in a small group of patients with follicular lymphoma of the duodenum.³⁰⁸ In contrast, marginal zone B-cell lymphoma, an entity that was initially considered to originate from mucosa-associated lymphoid tissue (MALT) lymphoma, but in recent reports is classified as a distinctive histologic type, was shown to take up FDG only in the involved lymph nodes.

From the studies of Moog et al.³⁰⁹ and Carr et al.,³¹⁰ it appears that both PET and iliac crest biopsy should be performed to stage the bone marrow. It is probable that some patients with diffuse involvement have homogeneous uptake on PET, whereas some patients with focal involvement are missed by random biopsy. FDG-PET can be useful in guiding the biopsy to a site of active disease.

An additional study evaluated FDG-PET as a predictor of prognosis. Aggressive and treatment resistant tumors showed a trend toward higher uptake of FDG, with an inverse relationship between the survival rate of patients and the degree of FDG uptake.³¹¹

The complementary role of FDG-PET to conventional staging of 45 patients with newly diagnosed HD and NHL was investigated by Delbeke et al.³¹² In addition to the positive impact of PET, these authors report that false-negative FDG imaging understaged 3 patients (7%), including 2 patients with low-grade NHL and 1 with HD. They concluded that FDG-PET is an efficient method for staging of lymphoma but should be used in conjunction with conventional staging as a complementary modality.

Recently, Hong et al.³¹³ evaluated the clinical value of FDG-PET for the staging of malignant lymphoma. The sensitivities and specificities for detection of nodal involvement for PET, CT, and ^{67}Ga scanning were determined to be 93.3%, 98.9%, and 25.8%, and 100%, 99.1%, and 99.8%, respectively. In detecting extranodal lymphoma, the sensitivities and specificities of the PET, CT and ^{67}Ga scanning were 87.5%, 87.5%, and 37.5%, and 100%, 100%, and 100%, respectively. Sasaki et al.³¹⁴ showed a specificity of 99% for

both CT and PET, whereas the sensitivity of CT was 65% and that of PET was 92%. An older study including 50 patients compared FDG-PET for staging of HD and NHL to CT.³¹⁵ The sensitivity and specificity of PET were 86% and 96% for HD and 89% and 100% for NHL. The sensitivity and specificity of CT were 81% and 41% for HD and 86% and 67% for NHL.

In comparison to ⁶⁷Ga, PET showed better performance than ⁶⁷Ga, as was reported by Paul et al.³¹⁶ (the first report on FDG uptake in five patients with lymphomas) and Okada et al.³¹⁷ Of course, their mechanism of uptake by malignant tissue is based on different principles. FDG, as mentioned before, is incorporated into malignant cells with a high glycolytic metabolism due to intracellular trapping of FDG phosphate. ⁶⁷Ga is taken up by malignant cells, lymphoma in particular, probably based on an intracellular transferrin-related transport mechanism. Inside the cells, the tracer is incorporated in lysosome-like granules and shows a slower clearance from malignant as compared with normal tissues.

A study comparing PET and ⁶⁷Ga evaluated 111 sites of disease in 25 patients with different types of lymphoma at diagnosis and relapse.³¹⁸ The sensitivity of PET was 96% versus 72% for ⁶⁷Ga. The false-negative ⁶⁷Ga studies were attributed to poor detection of low-grade NHL, bone and bone marrow involvement, and lesions smaller than 12 mm in diameter.

The differences in the performance rate of PET, ⁶⁷Ga, and CT for staging of HD and NHL were evaluated in 50 patients.³¹⁹ On a site-based analysis, PET showed superior values, 82%, as compared with both ⁶⁷Ga, 69%, and CT, 68%.

Diagnosis of splenic involvement is difficult using nuclear medicine techniques, because both ⁶⁷Ga and FDG are physiologically taken up in variable amounts by the normal spleen. Lymphomatous splenic involvement is, as a rule, diffuse, thus increasing the diagnostic challenge. The sensitivity, specificity, and accuracy of PET were 92%, 100%, and 97%, respectively, as compared with 50%, 95%, and 78% for ⁶⁷Ga³²⁰ (Table 33.13).

Buckmann et al.³²¹ found that PET is 10% to 20% more accurate than CT in detecting and staging of malignant lymphoma. They also reported that PET is better than CT in detecting bone marrow involvement and is useful as a guide for bone marrow biopsy.

A change in staging is more likely to result in a change in treatment strategy for lymphoma subtypes in which treatment is given with a curative intent. For example, upstaging from an early (stage I–II) to an advanced stage (III–IV) in HD

or large cell lymphoma will probably result in the selection of a longer course of chemotherapy as the exclusive treatment, as opposed to a shorter course of chemotherapy followed by radiation therapy (Figure 33.6).

A similar upstaging in patients with follicular lymphoma will also influence treatment and follow-up of the disease. Schoder et al.³²² demonstrated that PET findings led to a change in the clinical stage in 44% of 46 patients: in patients with NHL and HD, 21% were upstaged and 23% were downstaged. In a recent prospective study of 88 patients with HD, Naumann et al.³²³ demonstrated a change in staging in 18 patients (20%).

FDG-PET appears to be a noninvasive, efficient, and cost-effective whole-body imaging modality with a high sensitivity, specificity, and accuracy for staging patients with most histologic types of HD and NHL (Figure 33.7). It is generally

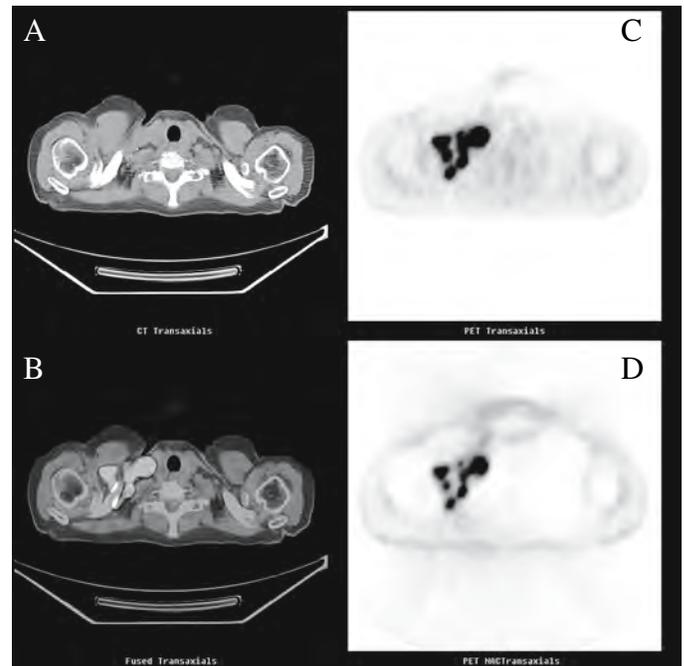

FIGURE 33.6. Transaxial PET/CT images obtained with FDG in a patient in the mid-twenties with a new diagnosis of Hodgkin's lymphoma. accepted today that FDG-PET is a clinically valuable tool that should be added to conventional staging modalities.^{329,330}

FDG-PET for Predicting Treatment Response

Evaluation of PET for assessment of treatment response has been studied more extensively in HD and NHL than in any other tumor. Differentiation of viable tumor from fibrosis in a residual posttreatment mass is a common problem in lymphoma that is seen in more than 85% of patients with HD and approximately 40% of the patients with NHL.

Initial studies have assessed response to treatment in heterogeneous populations including both HD and NHL patients. Cremerius et al.³²⁴ reported better specificity and positive predictive value (PPV) for FDG-PET (92% and 94%, respectively) as compared with that of CT (17% and 60%) in 27 patients.

Zinzani et al.³²⁵ studied 44 patients with HD or aggressive NHL who had residual abdominal disease and showed that the 2-year progression-free survival (PFS) rate was 95% for the PET-negative group and 0% for the PET-positive group.

A PPV of 100% for PET, as compared with 42% for CT, was found in 54 patients with HD and aggressive NHL assessed after therapy by Jerusalem et al.³²⁶ The negative predictive values (NPV) of PET (83%) and CT (87%) were not significantly different. Recurrence was noticed in the same study, with both positive PET and CT in 26% of patients and with negative PET and positive CT in only 10%. The PFS (2-year) rate with negative PET and negative CT was 87%, with positive CT and negative PET only 60%, and finally, with positive PET regardless of the CT, 0%.

Mikhaeel et al.³²⁷ also found in 45 patients with aggressive NHL that the relapse rate was 17% for PET-negative patients and 100% for PET-positive patients compared with 25% for CT-negative patients and 41% for CT-positive patients. The progression-free survival (PFS) for 1 year was 83% for PET-positive and 0% for PET-negative patients.

Spaepen et al.³²⁸ evaluated 93 patients with NHL and reported that all patients who had persistent FDG uptake relapsed, with a 2-year PFS rate of 85% of patients with negative PET findings. The 2-year PFS rate was 4% in patients with positive PET findings. Weihrauch et al.³²⁹ studied the predictive value of PET in 28 patients with HD who had residual masses after treatment. The 1-year PFS was 95% for the PET-negative group as compared with 40% for the positive group. Spaepen et al.³³⁰ evaluated 60 patients with HD with or without masses at the end of first-line treatment; the 2-year disease free survival (DFS) rate was 4% for the PET-positive group and 85% for the PET-negative group.

Kostakoglu et al.³³¹ compared FDG-PET after the first cycle of chemotherapy and after completion of chemotherapy. PET had greater sensitivity and PPV for predicting relapse after the first cycle. PET after the first cycle had a lower false-negative rate (13%) than the posttherapy PET (35%), possibly reflecting the presence of a small but still detectable tumor load of resistant cells early, but not late, in the therapy course (Table 33.14).

In general, in NHL and high-grade HD, a positive PET at the end of first-line therapy is highly suggestive of disease and requires intensive confirmatory investigation. A negative PET does not exclude the presence of minimal residual disease or future relapse and requires close follow-up. However, in early HD, a negative PET can be used to define complete response (CR) with favorable prognosis, even in the presence of residual masses on CT (see Figure 33.7A,B). A positive PET, especially if located in a site different from the residual mass, should be assessed with caution, and benign or inflammatory etiologies should also be considered in the differential diagnosis of persistent disease.³³⁰

Evaluation During Treatment

Many studies have been conducted to evaluate the extent and time course of changes in FDG metabolism in response to chemotherapy. The rapidity of response during treatment

appears to be an accurate predictor of overall response, with early tumor regression indicating higher cure rates.³³² Accurate early assessment of response allows for timely institution of aggressive second-line protocols. If resistant tumor burden is identified, additional treatment-related toxicity might be prevented.

Romer et al.³³³ found that a single PET study performed after two cycles of chemotherapy was predictive of long-term prognosis. Mikhaeel et al.³³⁴ reported the results of 23 patients with NHL who had FDG-PET after two to four cycles of chemotherapy. No relapse was seen in patients with minimal or no FDG uptake, whereas 88% of patients who had persistent FDG uptake relapsed. The same group also found that in 23 patients with HD during treatment, the relapse rate was 100% in the PET-positive group and 8% in the PET-negative group.

Zijlstra et al.³³⁵ studied the prognostic value of FDG-PET in 26 patients with aggressive NHL after two cycles of chemotherapy. At a median follow-up of 16 months, the PFS rate was 64% in patients who had negative FDG-PET findings and was 25% in patients who had positive FDG-PET findings. Spaepen et al.³³⁶ evaluated 70 patients with aggressive NHL and found that visual interpretation of FDG-PET, performed after three to four cycles of first-line chemotherapy, predicted PFS and OS independently from and better than the international prognostic index.

Torizuka et al.³³⁷ reported that FDG-PET may be predictive of clinical outcome and could differentiate short-term responders from nonresponders in a group of 17 patients, most of them with advanced-stage lymphoma.

Prognostic value of FDG-PET Before Stem Cell Transplantation

High-dose chemotherapy (HDT) with autologous stem cell transplantation (ASCT) has been shown to improve survival in patients with relapsed aggressive NHL or HD.³³⁸ A number of studies indicate that FDG-PET performed during or after salvage chemotherapy has a high predictive value for relapse after HDT/ASCT.^{339,340} Schot et al.³⁴¹ evaluated 46 patients with recurrent or persistent NHL/HD lymphoma after HDT/ASCT. The PFS for 2 years was 62% for PET-negative studies versus 32% for PET-positive patients.

Filmont et al.³⁴² showed that PPV (92%) and NPV (88%) in 43 patients with NHL/HD were very similar if the PET study was obtained 2 to 5 weeks after initiation of salvage chemotherapy, before ASCT, or within a median interval of 2.4 months. Spaepen et al.³⁴³ assessed the prognostic value of FDG-PET after salvage chemotherapy before HDT/ASCT in 60 patients with NHL and HD. The 2-year PFS and OS rates for patients with negative FDG-PET scans were 96% and

100%, respectively, as compared with 23% and 55% for those with positive FDG-PET results.

FDG-PET for the Detection of Recurrence

Although early diagnosis of relapse will lead to early administration of salvage therapy, the crucial question is whether a lesion is metabolically active, because two-thirds of patients with HD present with fibrotic or recurrent mass lesions, and 20% of these relapse.³⁴⁴ Fifty percent of patients with high-grade NHL present with a mass lesion and only 25% of them relapse.³⁴⁴ ⁶⁷Ga will not accurately indicate whether a tumor is metabolically active, and it has limitations in detection of intraabdominal and low-grade lymphoma.³⁴⁵

False-positive PET studies may be the result of FDG uptake in a hyperplastic thymus, in the gastrointestinal tract, or in an inflamed lung lesion.³⁴⁶ False-negative results may also arise from the absence of an FDG-avid lesion within small tumor lesions, possibly because of low glucose metabolism after therapy or acquisition problems, such as spatial resolution and partial volume effect.

The value of the sensitivity and specificity of FDG-PET and CT to predict the relapse of malignant lymphoma were described in several studies.^{347,348} Jerusalem et al.³⁴⁹ evaluated the recurrence rate in 45 NHL/HD patients with residual tumor masses and positive FDG-PET results, and it was only 26% in patients with residual tumors and negative FDG-PET results. The 1-year PFS and OS rates were 86% and 92%, respectively, for the PET-negative group, and only 0% and 55%, respectively, for the PET-positive group.

Guay et al.³⁵⁰ compared the diagnostic accuracy of FDG-PET and CT in detecting residual disease or relapse during the posttherapy period in 48 patients with HD. The sensitivity, specificity, PPV, and NPV of FDG-PET for predicting relapse were 79%, 97%, 92%, and 92%, respectively. The accuracy of FDG-PET was 92%, higher than the accuracy of CT (56%). Freudenberg et al.³⁵¹ described the advantages of PET/CT fusion imaging in 27 patients with lymphoma and evaluated the clinical significance of combined PET/CT and compared the staging results of PET/CT with those of FDG-PET and CT alone (Table 33.15).

Summary

FDG-PET provides an excellent tool in the initial staging of lymphomas, in restaging lymphoma after initial treatment, in predicting response during and at the end of therapy, and during follow-up for diagnosis of recurrence.

A pretreatment FDG-PET study is essential for accurate assessment of residual masses and early monitoring of response to the treatment. A baseline PET will help detect

TABLE 33.15. Recent literature of PET findings in recurrence of lymphoma.

Authors	Year	No. of patients	Sens		Spec		PPV		NPV		ACC	
			PET	CT	PET	CT	PET	CT	PET	CT	PET	CT
Freudenberg et al. ³⁵¹	2004	27	86	78	100	54	100	65	87	70	93	67
Guay et al. ³⁵⁰	2003	48	79	—	97	—	92	—	92	—	92	56
Filmont et al. ³⁴²	2003	78	87	94	80	56	95	72	83	67	90	71

relapse or residual disease, because relapse occurs most often in the region of previous disease.³⁵²

Melanoma

Cutaneous melanoma is the seventh most common newly diagnosed cancer in the United States: 55,100 new cases were diagnosed in 2004 and 7,910 patients will have died of systemic disease.³⁵³ Wahl et al.³⁵⁴ and Kern et al.³⁵⁵ demonstrated that radiolabeled glucose analogues were preferentially taken up in murine melanomas and human melanoma xenografts, establishing the rationale for the potential use of FDG in patients with melanoma.

There is no defined role for PET in the initial diagnosis of melanoma, as has been shown by Wagner et al.,³⁵⁶ because the inherent spatial resolution of PET reduces the sensitivity for detection of lesions less than 80mm² and it is unlikely that this technique (as currently performed) will ever be effective in the initial diagnosis of small, surgically curable melanoma in situ.

Initial Staging of Clinically Localized Disease

In intermediate- and high-risk lesions greater than 1 mm in thickness, assessment of the SLN draining the tumor site is very important. Rinne et al.³⁵⁷ studied 52 patients with primary melanoma greater than 1.5 mm in depth who had no evidence of local or distant metastases; they found that the accuracy of PET for identification of regional or distant metastases was 95% per lesion and 94% per patient and that for CT was 68% per lesion and 77% per patient.

Macfarlane et al.³⁵⁸ found that PET accurately predicted regional nodal status in 88% of 23 patients with primary melanoma more than 1.5 mm thick. Wagner et al.³⁵⁹ performed a large prospective trial containing 70 patients with primary thick melanoma (more than 1.0 mm) and 4 patients with recurrent melanoma in or adjacent to the surgical scar who underwent PET and SLN biopsy. They demonstrated a sensitivity of 11% to 17% (depending on reading threshold) and a specificity of 94% to 100%. This is one of the first articles to suggest that PET is not sensitive for staging regional nodes in patients with newly diagnosed thick melanomas.

Acland et al.³⁶⁰ found that FDG-PET failed to identify all 14 positive SLNs found in 50 patients who underwent sentinel node biopsy for primary melanomas more than 1 mm in thickness. Fink et al.³⁶¹ found, in 48 patients with stage I or II disease, that FDG-PET identified only one metastatic node, and they concluded that this result was likely "due to the small size of the metastatic deposits in the sentinel node."

There is now strong evidence that FDG-PET is not useful in the initial staging of primary melanoma when there is no clinical evidence of local or distant metastatic spread. This finding is attributed to the small size of most nodal metastases and the low prevalence of nodal disease in patients with primary melanoma.

Local Recurrence and Satellite or In-Transit Metastases

There are no studies that specifically examine the efficacy of FDG-PET in the evaluation of patients with locally recurrent

primary melanoma tumors, and there are only two studies that evaluated satellite and in-transit metastases. Acland et al.³⁶² studied 9 patients with satellite metastases adjacent to the primary tumor excision site and found a sensitivity of 93% and a specificity of 50% for the ability of FDG-PET to detect locoregional metastatic disease. Stas et al.³⁶³ described a change in clinical management in patients with varying types of recurrent melanoma with adjacent metastases or distant in-transit lesions. These findings suggest a possible role for PET in this population, but very small tumor volume of disease will not be detected.

The sensitivity of FDG-PET may be low in patients with small metastases in adjacent lymph nodes,^{379,380} but patients with suspected regional metastases based on physical examination or other imaging modalities may have greater detectability with PET. The majority of patients (80% or greater) with clinically localized tumors never develop distant disease. Blessing et al.³⁶⁴ found a sensitivity of 74% and a specificity of 93% for the evaluation of 20 clinically suspicious lymph node basins imaged with FDG-PET.

Crippa et al.³⁶⁵ in a study of 38 patients, found the accuracy of FDG PET to be 91% for clinically or radiographically enlarged lymph nodes. Sensitivity dropped off rapidly for lymph nodes less than 5 mm, but was 100% and 83% for nodes that were greater than or equal to 10 mm and 6 to 10 mm, respectively.

Tyler et al.³⁶⁶ attempted to show the utility of FDG-PET in a study of 95 patients with clinically evident stage III lymph node and/or in-transit melanoma. The sensitivity was 87%, the PPV (with the integration of pertinent clinical information) was 91%, the specificity was 44% (although few prophylactic lymph node dissections were performed), and the findings led to a change in clinical management in 15% of the patients. These findings argue that FDG-PET has a useful role in the patient with suspected regional lymph node metastases (Table 33.16).

In the case of confirmed lymph node metastases beyond the SLN, the value of FDG-PET is to localize occult distant metastases that might be amenable to surgical resection or to exclude metastatic disease in patients with equivocal findings on conventional anatomic images. Wagner et al.³⁶⁷ and Acland et al.³⁶² showed that in this group of patients it was unknown distant disease that may have altered patient management.

Identification of Distant Metastases

FDG-PET can be used in patients with recently diagnosed melanoma and those who have clinical, laboratory, or radiologic evidence of distant metastases, in patients with previously resected melanoma with findings suspicious for recurrent disease in the form of distant metastases, and, finally, in patients with previously treated distant metastases requiring restaging to plan future surgical or medical management.

Gritters et al.³⁶⁸ studied 12 patients with various stages of melanoma (thick primaries, palpable lymph nodes, or presumed metastases on CT), and they found intraabdominal visceral and lymph node metastases that were not seen on CT. Steinert et al.³⁶⁹ found a 92% sensitivity for FDG-PET in 33 patients with known metastatic melanoma or high-risk primaries (greater than 1.5 mm).

TABLE 33.16. Representative literature of FDG-PET findings in melanoma.

Author	Year	No. of patients	Sensitivity			Specificity			Accuracy		Remarks
			PET	CI	SNB	PET	CI	SNB	PET	CI

SNB, sentinel node biopsy.

Rinne et al.³⁷⁰ examined 48 patients with clinical or CT findings suggesting local or distant metastatic disease, and FDG-PET was found to be 92% sensitive, 95% specific, and 93% accurate, compared with 58%, 45%, and 56% for sensitivity, specificity, and accuracy, respectively, for CT.

Eigtved et al.³⁷¹ confirmed the superiority of FDG-PET in a study of 38 patients with either local recurrence, in-transit recurrence, regional lymph node metastases, or distant metastases, with sensitivity and specificity of 97% and 56%, respectively, compared with 62% and 22% for conventional imaging.

It is obvious now that PET is indeed superior for localization of distant metastases outside of the lungs and brain, independent of the particular stage of the high-risk patient. Swetter et al.,³⁷² in a study of 104 patients, reported a sensitivity and specificity for PET of 84% and 97% and for CT of 58% and 70%, respectively, for the detection of metastatic disease.

Gulec et al.³⁷³ studied 49 patients and found that FDG-PET identified more metastatic sites in 55% of the patients and changed the management in 49% of them. Dietlein et al.³⁷⁴ and Krug et al.³⁷⁵ reported that FDG-PET was inferior in the detection of pulmonary and liver metastases, but these studies suffered from various methodologic weaknesses. Distant metastases can be identified by FDG-PET either in patients with locoregional disease or in patients with known distant lesions, and these findings can change their clinical management.

Response to Therapy

The usefulness of FDG-PET in evaluating response to therapy was shown by Mercier et al.,³⁷⁶ who studied three patients who underwent a FDG-PET scan before and 1 month after treatment (isolated limb perfusion therapy with melphalan) and found a reduction in the number of lesions and diffuse radiotracer uptake, most likely because of posttreatment inflammation.

¹¹C-Methionine,³⁷⁹ ¹²⁵I-alpha-methyl-tyrosine (AMT), ¹⁸F-DOPA,³⁸⁰ ¹⁸F-FLT,³⁸¹ ¹¹C-N-methylspiperone,³⁸² and radio-labeled alpha-melanocyte-stimulating hormone³⁸³ are some of the new promising radiopharmaceuticals in the field of melanoma.

In conclusion, FDG-PET is the modality of choice for evaluating patients who fit in one of these four categories:

1. Individuals at high risk for distant metastases based on the extent of locoregional disease
2. Patients with findings that are suspicious for distant metastases
3. Individuals with known distant tumor deposits who still stand to benefit from customized therapies if new lesions are discovered or treated lesions regress
4. Patients at high risk for systemic relapse who are considering aggressive medical therapy

SECTION FIVE

Solid Tumors

Central Nervous System Tumors

Ravi D. Rao, Paul D. Brown, Caterina Giannini,
Cormac O. Maher, Fredric B. Meyer,
Evanthia Galanis, Brad J. Erickson,
and Jan C. Buckner

The term *primary central nervous system tumors* refers to a heterogeneous group of tumors characterized by their location in the central nervous system (CNS). These tumors exhibit a wide range of clinical behavior from extremely lethal (e.g., glioblastoma) to potentially curable (e.g., germ cell tumors and medulloblastomas). The occurrence of these tumors has devastating effects on patients, and their management can be a major challenge to physicians. By virtue of their location, brain tumors cause a disproportionate amount of disability and pose a threat to a patient's sense of self that is unparalleled by any other disease. The currently available therapies for most primary CNS tumors have limited activity with significant toxicity. Survivors of these tumors often have significant residual neurologic and cognitive deficits that limit their functioning for the rest of their lives.

Epidemiology

The incidence of primary CNS tumors is between 4 and 5 cases per 100,000 per year. They represent about 2% of all cancers, but account for a disproportionate amount of morbidity and mortality. They may occur in any age group from infancy to old age, with a slight male preponderance. Half of all CNS tumors are diffuse gliomas. CNS tumors are the third leading cause of cancer-related death in adolescents and adults between the ages of 15 and 34 years. The peak age of incidence is between 60 and 80 years. The incidence appears to be increasing among the elderly,¹ although this finding may be the result of increased availability of better imaging technology.

Etiology of Primary Central Nervous System Tumors

Most malignant CNS tumors arise as a consequence of acquired somatic mutations in genes that are responsible for control of cell growth and proliferation. Genetic predisposition to these tumors appears relatively uncommon. Gliomas

are more common in patients with type 1 neurofibromatosis, Turcot's syndrome, and Li-Fraumeni syndrome.

Although the etiology of most primary CNS tumors is unknown, a few environmental factors have been identified as being important in causation, such as ionizing radiation and human immunodeficiency virus (HIV) infection. Currently, the role of several other putative environmental links (e.g., artificial sweeteners and cell phones) in the causation of gliomas remains speculative.

Pathology of Primary Central Nervous System Tumors

The spectrum of primary CNS tumors includes a wide variety of neoplasms and includes tumors of primary neuroectodermal derivation and those derived from the supportive elements and brain coverings. Classic histopathologic techniques during the past century have resulted in the accumulation of a large amount of information regarding morphologic characteristics and patterns of growth of a variety of tumors, which have resulted in the present approach to CNS tumor classification and grading. During the past 15 years, advances in molecular genetics have led to the delineation of some of the molecular mechanisms underlying tumorigenesis and tumor progression. Although histopathologic diagnosis is (and will most likely remain for a long time) the gold standard in the approach to classification and grading of a large variety of CNS tumors, molecular genetics data are now being added as complementary data to tumor diagnosis.

Prognostic Factors and Markers

It has been long recognized that several patient-related factors (age, performance status, disease-related symptoms, and mental status), tumor variables (histologic tumor type and grade, contrast enhancement, size, location, and biologic markers of proliferation rate, apoptosis, and genetic abnormalities), and treatment variables (extent of surgical resection, radiation dose, and chemotherapy) influence outcomes.

Age has been most consistently shown to influence the survival in multiple studies. Another important factor appears to be the performance score (PS). In multiple clinical trial settings, a favorable PS has been shown to positively influence outcomes. In addition, normal versus abnormal mental status has been shown to be a significant prognostic. In nearly all models tested, baseline Mini-Mental Status Exam (MMSE) score correlated more strongly with both time to progression and survival than did the performance status, suggesting that mental status may be a more important determinant of clinical outcome than physical functioning in patients with high-grade glioma. Some symptoms, specifically seizures that have occurred for longer than 6 months, are associated with a favorable survival prognosis.^{2,3} Abnormalities in the epidermal growth factor receptor (EGFR), p53, and phosphatase and tensin analogue (PTEN, a tumor suppressor gene) have been long recognized as having a pathogenetic role in astrocytoma. The prognostic value of these markers is a subject of much ongoing research. In one study, EGFR amplification was found to be associated with a good prognosis in one subset of patients [those over age 60 with glioblastoma multiforme (GBM)]. Several of these markers are closely linked to several other clinical covariables, making analyses of benefits of individual effects difficult. Multiple reports have attested to the association between 1p and 19q deletions in oligodendrogliomas and responsiveness to chemotherapy and a better outcome. Analyses of these mutations are now being used to guide therapy.^{4,5} Evaluation of the relative expression levels of DNA and RNA of several tumor suppressor genes and oncogenes (by techniques such as gene expression analysis and comparative genomic hybridization) has identified the existence of subgroups of tumors with distinct clinical behaviors.^{6,7} Differences in patterns of gene expression can be found to occur between gliomas of different grades, as well as in other tumor types. More interestingly, these analyses can identify subtypes among tumors within a single diagnostic category that have different outcomes. Research is currently under way to develop prognostic models and markers that may be clinically useful.

Clinical Presentation of Central Nervous System Tumors

Patients with primary CNS tumors can present with a variety of neurologic symptoms and signs. The clinical symptomatology is variable and depends on a number of patient- and tumor-related factors, such as age, histology, location, rate of growth, and presence of cerebral edema (Figure 34.1). The spectrum of symptoms seen at presentation has changed considerably over the past few decades as advanced imaging techniques have become increasingly available.

The symptoms caused by CNS tumors are typically progressive, with evolution of newer symptoms over time. Headaches are the most common symptom of primary brain tumors in general and have been noted to occur in half of patients at presentation.⁸ Over the course of their illness, a majority of patients have headaches. The features of a headache thought to be “classic” for brain tumors (i.e., association with nausea and vomiting and being worse in the morning) occur only in one-fifth of patients.⁸ Most commonly, headaches have features associated with tension,

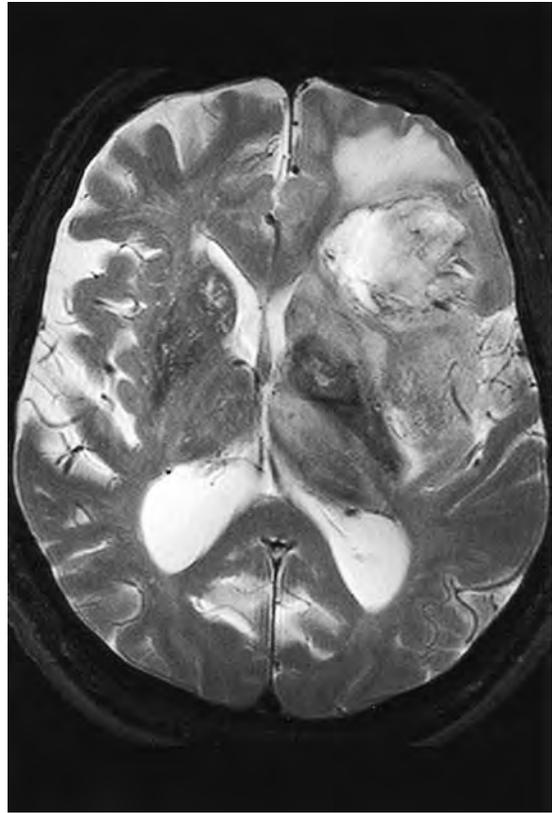

FIGURE 34.1. Head magnetic resonance imaging (MRI) demonstrates a grade 3 astrocytoma as it appears on T2-weighted images. Note the presence of a mass effect and edema in the frontal lobe.

migraine, or sinus headaches. Primary brain tumors are the most feared diagnosis in someone with a new seizure. The incidence of seizures as a presenting feature appears to depend upon the rate of growth of the tumor and the location. Mental status alterations ranging from subtle to severe deficits in cognition, personality, and perception commonly occur in patients with brain tumors. These symptoms may be present at diagnosis in 15% to 20% of patients. Patients may present with several focal neurologic signs such as cranial nerve deficits, hormonal deficiencies, visual field deficits, papilledema, weakness, aphasia, and alterations in sensation.

Therapy of these symptoms in patients with CNS tumors presents a challenge. Anticonvulsants can be used to treat those patients who develop seizures. There is no proven benefit to using prophylactic anticonvulsant medications in patients who have not yet had a seizure.⁹ Cerebral edema occurs commonly and is treated with steroids. Increases in intracranial pressure (ICP) necessitate additional measures such as fluid restriction, use of osmotic agents and diuretics, hyperventilation, elevation of the head of the bed, and placement of ventriculoperitoneal shunts.

Imaging in CNS Tumors

Patients suspected of having CNS tumors based on symptoms need imaging studies performed for diagnostic reasons. Over the past few decades, major advances in diagnostic imaging

technology have taken place. More importantly, this technology has become widely available. These imaging studies provide digital cross-sectional images of the brain and surrounding structures based on differences in physical properties between various structures. There are many similarities in the appearance of brain tumors (primary or secondary) on computed tomography (CT) and magnetic resonance imaging (MRI), but there are some unique features that can allow a specific tumor type to be suggested as the likely candidate.

Computerized Tomography

On nonenhanced CT, tumors may have intensity similar to or slightly lower than brain tissue. Some tumors (e.g., metastases and high-grade gliomas) may have gross hemorrhage, recognized as amorphous moderately hyperdense areas typically within tumors. The presence of a fluid–fluid level in a mass may be useful in differentiating benign hemorrhages from malignant. Calcification occurs in some tumors, and the pattern can be of diagnostic importance.

Magnetic Resonance Imaging

MRI has been a substantial advance over CT for intracranial tumors. MRI provides direct multiplanar acquisitions, which can be useful for differentiating some intra- and extraaxial masses. However, the biggest advantage is the many different tissue properties that MRI can identify. Early “sequences” (images are created by broadcasting sequences of radiofrequency pulses into the patients, and then “listening” to how the hydrogen protons of the patient react) could show the T_1 and T_2 relaxation properties (so-called T_1 - and T_2 -weighted images) and proton density. MRI imaging studies based on the flow of blood have also been developed. More recently, techniques for looking at non-water chemicals of the brain (spectroscopy), the diffusion of water (diffusion-weighted imaging, DWI), and perfusion imaging, as well as the ability to suppress the signal from specific classes of protons (e.g., fat suppression, magnetization transfer suppression, and bulk water suppression, known as fluid-attenuated inversion recovery or FLAIR) have been developed.

Contrast Enhancement

Both CT and MRI have intravenous agents that can demonstrate blood–brain barrier (BBB) breakdown, which is referred to as enhancement. Higher-grade tumors enhance whereas most lower-grade tumors do not. However, there are many notable exceptions to this generalization, including meningiomas, most metastases, and some low-grade gliomas such as pilocytic astrocytomas and gangliogliomas (GG). Generally, MRI has more sensitivity to contrast enhancement. When CT was the primary evaluation tool, so-called double-dose delayed scanning was performed to improve the detection of enhancement. Although sensitivity with MRI is usually adequate, the use of three times the standard dose (“triple dose”) has been shown to demonstrate enhancement when the standard dose does not.

T_1 -Weighted Imaging

T_1 -weighted images are bright in areas where the protons quickly realign with the main magnetic field after being “perturbed” by the radiofrequency (RF) pulses. Protons found in lipids have this property and are bright, whereas bulk water (similar to cerebrospinal fluid, CSF) does not and is dark. Gadolinium has paramagnetic properties and causes change in the property of water protons, making them realign faster and thus become bright. Hemorrhage, calcium, and protein breakdown products can have a variable appearance.

T_2 /Proton Density/Fluid-Attenuated Inversion Recovery

T_2 , proton density (PD), and FLAIR images have a similar appearance, except for the appearance of bulk water. Bulk water (e.g., CSF) is bright on T_2 , similar to white matter on PD, and dark on FLAIR. Abnormal tissue (tumor, edema, gliosis, and necrosis) is bright on all three sequences whereas normal brain is intermediate, with gray matter being brighter than white matter. Because tumor and edema are bright on these images, this presents a problem when trying to precisely demarcate tumor boundary.

Perfusion-Weighted Imaging

Perfusion-weighted imaging (PWI) uses the effect of flow on MRI signal to measure perfusion of tissue. The most common clinical tool for this uses a bolus injection of gadolinium, which produces a reduction in signal on T_2 -weighted images. Integrating the signal reduction over the course of the bolus produces an image that is proportional to the cerebral blood volume. Areas of treatment-related necrosis tend to have low blood volume; this may be helpful in differentiating recurrent tumor from necrosis.¹⁰

Magnetic Resonance Spectroscopy

Magnetic resonance spectroscopy (MRS) measures the concentration of chemicals other than water. Because water is about 10,000 times more concentrated than these chemicals, it requires long acquisition time and/or low resolution to obtain reasonable spectra. The most prevalent form of MRS is to select a single sample of tissue that typically measures about 2 cm³. The chemicals of greatest interest for brain tumors are choline, *N*-acetylaspartate (NAA), creatine, and lactate. Creatine is not a metabolite specific for brain tumors, but tends to be fairly constant in concentration in the brain, and because the other chemicals are typically not measured as absolute concentrations, they are expressed as ratios of the creatine concentration. NAA is a chemical that is quite specific for axons and is highest in areas of healthy brain. Any process that replaces or destroys axons reduces NAA levels. Choline is a marker of cell membranes. It is increased in areas of high membrane activity (such as tumors) and decreased in areas of necrosis or atrophy.^{11,12} Lactate is a marker of anaerobic metabolism; as such, it is not detectable in normal brain (Figure 34.2). It is often elevated in tumors, particularly the higher-grade tumors, and in necrotic tissue.

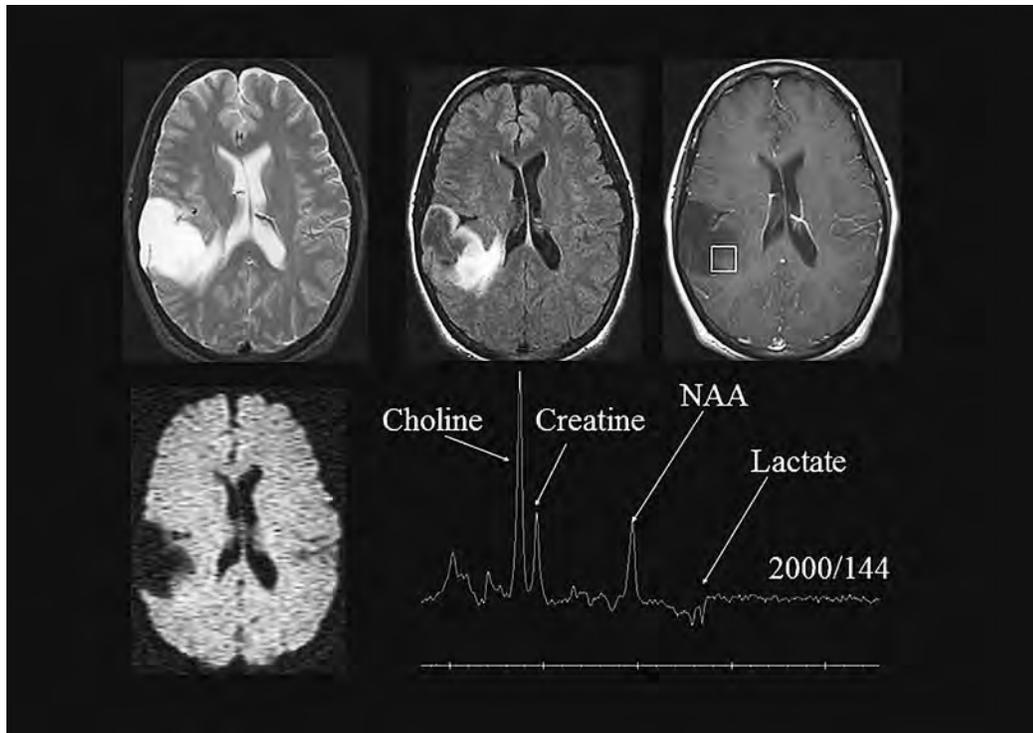

FIGURE 34.2. T2 and post-gadolinium (Gd) images in a patient with a grade 2 astrocytoma. The spectrum shown is obtained from the region shown on the post-gadolinium image. This particular spectrum was obtained with an echo time of 144 milliseconds (ms), which inverts the lactate peak, allowing one to be certain that lactate is present and is not hidden by other chemical species.

Special Considerations in Management of CNS Tumors

Thromboembolism

Patients with primary CNS tumors (especially gliomas) have an increased incidence of thromboembolic phenomena. Several hypotheses have been proposed to explain this predisposition, including elevated prothrombotic clotting factor levels, presence of a consumptive coagulopathy, and venous stasis due to paresis of extremities. The incidence of thrombotic phenomenon in patients undergoing therapy for high-grade gliomas is 20% to 30%.¹³ Risk factors for development of thrombotic events include increased age, previous history of thromboembolism, higher-grade tumors, hemiparesis, use of chemotherapy, prolonged neurosurgery, and AB blood group.¹⁴ The recommended therapy for diagnosed venous thromboembolic in these patients is similar to that in other situations.

Cognitive Deficiencies in Patients Treated for CNS Tumors

The deleterious effect of radiotherapy (RT) on the long-term cognitive performance of patients with CNS tumors is a major concern. As more effective treatments for intracranial lesions have become available and long-term survival has increased in some diseases, attention has been placed on identifying and quantifying the adverse effects of RT on cognition and neuropsychiatric functioning. Studies of neurocognitive function in patients treated for various intracranial tumors are confounded by differences in distribution of factors such as age at therapy, surgery, chemotherapy, tumor characteristics, tumor progression, concurrent medical illnesses, neurologic comorbidity, insensitivity of tools used (e.g., MMSE) and medications. In several disease states, the risks of neurocognitive

deficits caused by therapy are quite small and are greatly overshadowed by deficits caused by the tumor itself. There appears a clear relationship between age at therapy, dose of radiation, and the extent of the deficiency.¹⁵ The effect of radiation is of greatest concern in young patients (e.g., medulloblastomas)^{16,17} and in diseases in which therapy leads to long disease-free survival. These patients are in their most productive years, and cognitive deficits that occur have a larger impact on their capacity to function socially and to be gainfully employed. Several pharmacologic strategies are currently being studied to minimize neurocognitive dysfunction associated with therapy in patients with CNS tumors.¹⁸⁻²²

Retrospective studies of patients treated for low-grade glioma (LGG) with whole-brain radiotherapy (WBRT) have detected an increased incidence of neurocognitive difficulties when compared to controls (e.g., those treated with surgery or focal RT).²³ Patients treated with higher doses of WBRT have greater deficits than those receiving lower doses.²⁴ Patients with high-grade glioma (HGG) have also been found to have cognitive impairments after completion of therapy in retrospective studies.²⁵ However, in this particular group of patients, the dominant cause of neurocognitive deficits appears to be largely the effect of the tumor, and not that of therapy.^{26,27} Long-term neurotoxicity remains a major problem in patients treated for primary CNS lymphoma (PCNSL), especially in those older than 60 years.

Diffuse Gliomas

Gliomas include a variety of neuroectodermal tumors that show morphologic and immunohistochemical evidence of their glial lineage, primarily glial fibrillary acidic protein (GFAP) positivity. These tumors include astrocytomas, oligodendrogliomas, ependymomas, and tumors with mixed differ-

TABLE 34.1. World Health Organization (WHO) classification and grading of diffuse gliomas.

Tumor type	WHO grade
Infiltrating astrocytomas:	
Astrocytoma	II
Protoplasmic	
Fibrillary	
Gemistocytic	
Anaplastic astrocytoma (AA)	III
Glioblastoma multiforme (GBM)	IV
Giant cell astrocytoma	
Gliosarcoma	
Oligodendrogliomas:	
Oligodendroglioma	II
Anaplastic oligodendroglioma	III
Mixed oligoastrocytomas:	
Oligoastrocytoma	II
Anaplastic oligoastrocytoma	III

Pilocytic astrocytoma, pleomorphic xanthoastrocytoma, subependymal giant cell astrocytoma, and the rare desmoplastic infantile astrocytoma represent distinct clinicopathologic entities, distinct from diffuse astrocytomas and characterized by a relatively circumscribed pattern of growth and a favorable prognosis.

entiation, generally oligoastrocytomas (Table 34.1). A fundamental distinction among different glial tumors is based on their pattern of growth; they can be circumscribed and relatively demarcated from surrounding parenchyma, or diffuse and widely infiltrative of brain parenchyma. Ependymomas represent the best example among gliomas of tumors with a solid, noninfiltrative growth pattern. Infiltration is virtually

absent in intracranial ependymomas. Diffuse gliomas include diffuse astrocytomas, oligodendrogliomas, and mixed oligoastrocytomas. These tumors are characterized by their marked tendency to grow through preexisting gray and white matter, resulting in the formation of distinctive "secondary structures." These structures include perivascular aggregation, when neoplastic cells cluster around preexisting small vessels; perineuronal satellitosis, in which neoplastic cells grow into cortex surrounding the cell body of cortical neurons; and subpial aggregation, with neoplastic cells clustering in the molecular layer just below the pia. Common to diffuse gliomas is also the tendency to progress into higher grades of malignancy over time. These tumors are classified and graded in the most recent World Health Organization (WHO) classification as grade II to IV. Fundamental in distinguishing grade of malignancy of diffuse gliomas are histologic features such as presence of mitotic activity, endothelial vascular changes (endothelial proliferation), and necrosis with or without presence of pseudopalisading (Figure 34.3). These same morphologic features may be of no importance in different tumor types such as pilocytic astrocytoma, hence the absolute necessity of identifying tumor type *before* grading them.

High-Grade Diffuse Gliomas

High-grade diffuse glioma refers to a group of diffusely infiltrative tumors that are characterized by a somewhat variable but relatively poor prognosis; these include grade 3 and 4 astrocytomas [anaplastic astrocytoma (AA) and GBM],

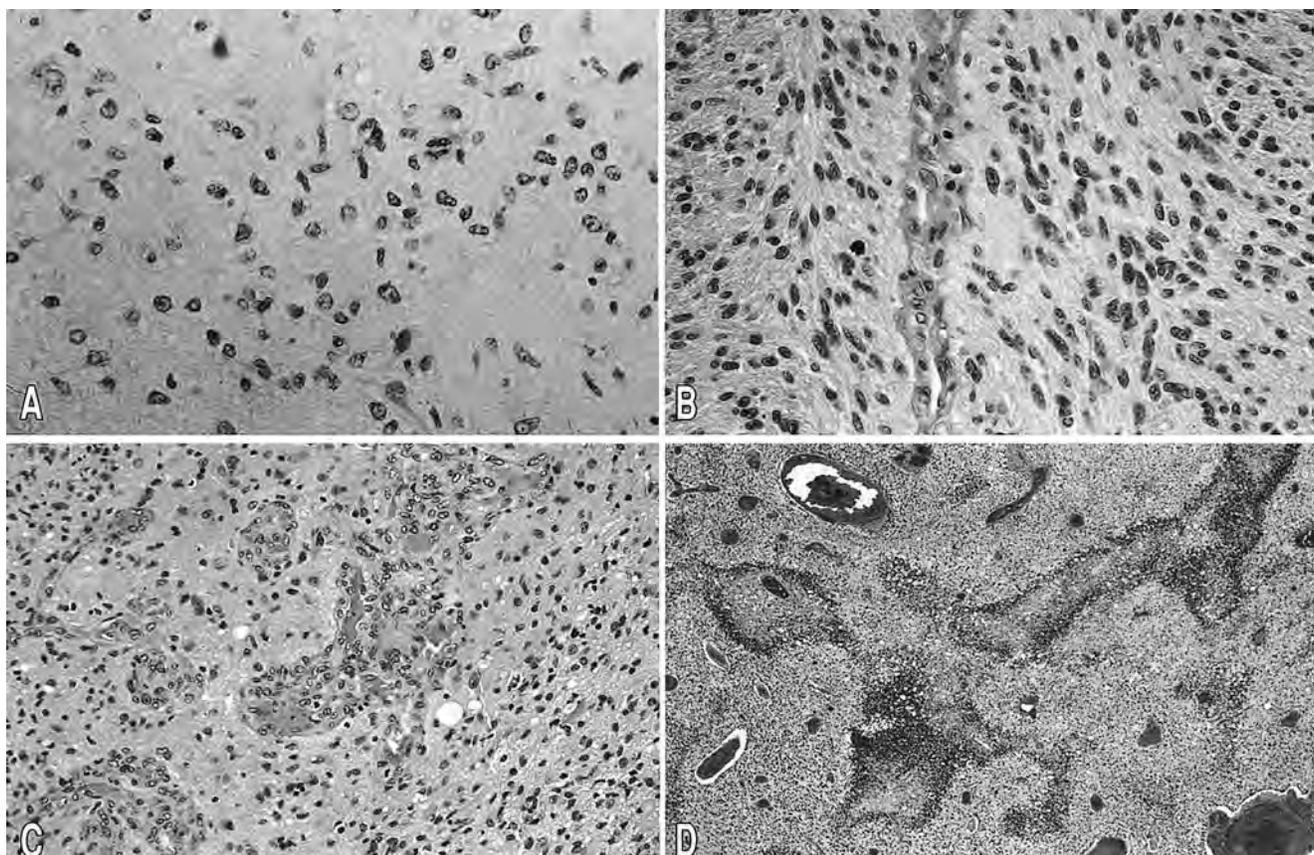

FIGURE 34.3. Morphologic features used in the diagnosis and grading of diffuse/infiltrating astrocytomas include atypia (A), mitotic activity (B), endothelial proliferation (C), and necrosis (D).

Necrosis may be serpiginous and occur in association with pseudopalisading of neoplastic cells (as shown in this picture), or it may involve large areas of tumor.

anaplastic oligodendroglioma, and anaplastic oligoastrocytoma mixed tumors. Because of the infiltrative nature of these tumors, surgical resection alone is insufficient to cure patients. These tumors are resistant to radiation and chemotherapy, and long-term survival is rare. Outcomes are poor, with median survivals of 1 to 2 years.

Surgery

Surgical resection of hemispheric gliomas is indicated when it may be performed without significant morbidity, when it will improve preoperative symptoms such as increased intracranial pressure and seizures, and when it might improve the long-term prognosis. The relative indications for resection of gliomas therefore vary according to tumor location, preoperative symptoms, and the specific histologic diagnosis. The role of surgical resection in improving prognosis is controversial.²⁸

Radiation

The role of RT in the treatment of newly diagnosed high-grade gliomas was firmly established by two prospective randomized trials conducted in the 1960s and 1970s. Brain Tumor Study Group (BTSG) 69-01 randomized high-grade glioma patients in the postoperative setting to supportive care or RT (60Gy WBRT).²⁹ Median survival was 14 weeks in the supportive care group and significantly improved to 35 weeks in the RT group. The significant survival benefit of postoperative RT has been confirmed in other studies and in a number of meta-analyses.³⁰ Unfortunately for the majority of high-grade glioma patients, the benefit from RT is only temporary, with eventual tumor recurrence, progression, and ultimately death. Therefore, a number of studies have prospectively tested multiple RT parameters (e.g., treatment volume, total dose, dose fractionation, dose escalation, special radiation procedures) to further improve the therapeutic ratio for these patients. Presently, complex radiation treatment plans (e.g., three-dimensional conformal RT) deliver high doses of radia-

tion to the tumor volume with margin (e.g., 2-cm margins) while significantly sparing surrounding normal structures from these high doses of radiation. This approach is supported by studies demonstrating that focal RT was not inferior to WBRT.^{31,32} This paradigm shift in treatment volumes has occurred in an effort to reduce acute and late toxicity and the recognition that the vast majority of tumor progressions recur locally. Other strategies that have been investigated include dose escalation, various fractionation schedules, and brachytherapy (Table 34.2). Various modifications that have been studied include hyperfractionation (delivery of multiple smaller-sized fractions at shorter intervals), accelerated fractionation (decreases the overall treatment time), brachytherapy, radiosurgery, and particle. Each of these strategies has some theoretical advantage beyond conventional radiation. Unfortunately, none of these techniques has resulted in an improvement in the therapeutic ratio compared to standard conventional focal RT. Elderly patients, especially those with a poor PS, constitute a subset that may derive benefit even with a shortened RT course, an important consideration for patients with a short survival. A number of prospective trials have shown equivalent results for elderly patients with shortened course of RT (e.g., 30Gy in 10 fractions) compared to a more protracted course of RT (e.g., 60Gy in 30 fractions).^{33,34}

In summary, postoperative RT to 55–60Gy in 1.8- to 2-Gy fractions results in a significant survival benefit, albeit temporarily, and is the standard of care. To date, radiation dose escalation has not shown to result in improved outcomes despite extensive study.

Chemotherapy

Chemotherapy has a limited role in the therapy of high-grade astrocytomas. One of the earliest trials to test the role of chemotherapy was a BTSG phase III four-arm randomized trial comparing best supportive care, BCNU (carmustine) alone, RT alone, and a combination of BCNU and RT. The median survival of the patients in the groups was as follows:

TABLE 34.2. A selected review of randomized radiotherapy (RT) studies in newly diagnosed high-grade gliomas.

TABLE 34.3. Important randomized clinical trials testing adjuvant chemotherapy in high-grade gliomas.

<i>Study</i>	<i>Concept/therapy tested</i>	<i>Conclusions</i>
BTSG trial 6901 ¹⁵¹	Compared best supportive care; BCNU alone; BCNU + RT and RT alone	All treatment groups had longer survival than the best supportive care group
BTSG trial 7201 ²⁹	Compared MeCCNU alone; radiotherapy; BCNU + RT and MeCCNU + RT	MeCCNU-alone arm did the worst; RT is an essential component of therapy
BTCG trial 7501 ¹⁵²	Compared combination of RT (60Gy) with one of four therapies: BCNU; high-dose steroids; procarbazine; or BCNU + high-dose steroids	High-dose steroids-only group had the worst outcome; no advantage to adding steroids to BCNU
BTCG trial 7702 ¹⁵³	Compared RT + BCNU; RT + streptozocin; hyperfractionated RT (twice daily) + BCNU; RT + misonidazole (radiation sensitizer) + BCNU	Outcomes similar in all arms; no advantage to using streptozocin, misonidazole, or hyperfractionation
BTCG trial 8001 ³¹	Compared use of BCNU alone with combinations of BCNU + procarbazine; BCNU + hydroxyurea; BCNU + procarbazine + epipodophyllotoxin	Combination chemotherapy did not improve survival
BTCG trial 8301 ¹²³	Compared IA to IV BCNU, in a four-arm trial that also tested benefit of adding 5-FU to regimens; all patients received RT	IA BCNU worsened survival in those with AA and was more toxic; 5-FU did not impact on outcomes
RTOG/ECOG trial 7401 ¹⁵⁴	Compared 60Gy RT alone; 60Gy RT followed by a 10-Gy boost; 60-Gy RT + BCNU and RT + methyl-CCNU + DTIC	No advantage to using multiagent therapy or RT boost
CNS Cancer Consortium ¹⁵⁵	Comparing BCNU with alternative chemotherapy agent diaziquone (AZQ); all patients received RT	No difference between the two arms
NCCTG ¹⁵⁶	Compared BCNU with an alternative nitrosourea PCNU; all received RT	PCNU more toxic and did not improve outcomes
ECOG/SWOG ¹⁵⁷	Pre-RT chemotherapy with three cycles of BCNU and cisplatin compared with RT + concurrent BCNU; GBM patients only	Pre-RT chemotherapy was significantly more toxic and did not improve outcomes

BCNU, carmustine; RT, radiation therapy; MeCCNU, semustine; IA, intraarterial; IV, intravenous; Gy, gray; 5-FU, 5-fluorouracil; PCNU, 1-(2-chloroethyl)-3-(2,6-dioxo-3-piperidyl-1-nitrosourea); GBM, glioblastoma multiforme; DTIC, dacarbazine; BTSG, Brain Tumor Study Group; BTCG, Brain Tumor Cooperative Group; RTOG, Radiation Therapy Oncology Group; ECOG, Eastern Cooperative Oncology Group; NCCTG, North Central Cancer Treatment Group; SWOG, South West Oncology Group.

best supportive care, 14 weeks; BCNU alone, 19 weeks; RT alone, 36 weeks; and combined therapy arm, 35 weeks. Although survival distribution curves were identical for the first 12 months from initiation of treatment, there was a higher survival rate at 18 months among the patients receiving the combination therapy, with 10% still alive at that time, as compared to only 4% of patients in the radiation-alone group.²⁹ Several other studies have been conducted to address the role of chemotherapy in high-grade gliomas, with most having failed to demonstrate an advantage of adding chemotherapy to radiation in the adjuvant setting (Table 34.3). To address this issue further, two meta-analyses have been performed. Fine et al. evaluated 16 randomized trials of patients with high-grade astrocytomas. The estimated increase in survival for patients treated with combination radiation and chemotherapy was 10.1% at 1 year and 8.6% at 2 years.³⁵ In another meta-analysis, the use of chemotherapy (all received a nitrosourea compound, alone or in combination) was associated with a 15% relative decrease in the risk of death; this translated into an absolute increase in 1-year survival of 6%.³⁶ The median survival was prolonged by 2 months with chemotherapy. One potential explanation for the negative results in several of the clinical trials may be that they were not adequately powered to detect the benefit of chemotherapy. More recently, Stupp et al. reported results of a randomized phase III trial of radiation alone (standard therapy arm) compared with the combination of temozolomide (75 mg/m²/day for 42 days) and concomitant radiation followed by six additional cycles of temozolomide (150–200 mg/m²/day × 5 days every 28 days). Temozolomide therapy resulted in an increase in the median survival by 3

months (from 12 to 15 months); the 2-year survival was 26% in the study arm, which was statistically superior to 8% in the control arm. Therapy with concomitant temozolomide and radiation appears to be well tolerated in this setting.³⁷ Consequently, it is appropriate to use either temozolomide or BCNU in addition to RT for patients with glioblastoma multiforme.

Several investigators have evaluated the potential benefits of using combinations of drugs over single-agent chemotherapy (usually BCNU). However, based on the data available currently, the benefit of using any combination regimen over single-agent therapy is questionable at this time.

Currently available data suggest that, similar to their low-grade counterparts, high-grade oligodendrogliomas (both pure and mixed) are relatively chemotherapy sensitive when compared to pure astrocytomas. The use of combination therapy with PCV (a combination of procarbazine (PCBZ), lomustine (CCNU) and vincristine) or single agent TMZ appears to lead to responses in large proportions of patients with progressive high-grade oligodendroglial tumors, though in some of the studies, confirmatory biopsies were not obtained at time of progression.^{4,38,39} Until recently, there has been a paucity of randomized trial data on which to base decisions. In June 2004, the first report of R9402 was released. Patients with anaplastic oligodendroglioma or oligoastrocytoma were randomized to immediate radiation therapy, or four cycles of PCV, followed by radiation. Although there was no difference in overall survival in the two groups, disease-free survival was prolonged in the group receiving chemotherapy. Regardless of treatment, patients with chromosome 1p and/or 19q deletion

had longer survival. These preliminary data suggest that adjuvant PCV may be appropriate for patients with anaplastic oligodendroglial-containing tumors.⁴⁰

Therapy for recurrent gliomas remains a challenge in spite of much research evaluating different agents, combinations, and strategies (including high-dose chemotherapy with stem cell rescue). Response rates are generally low (10% to 30%) and time to progression is short, varying from a few to several months.^{41,42} Given the minimal efficacy of standard treatments, investigational therapies are appropriate as initial treatment for these patients.

Chemotherapy Implants

An approach that has been tested in HGG with some evidence of benefit is the use of biodegradable BCNU-impregnated wafers (Gliadel). These wafers are composed of a complex of BCNU and a polymer. After implantation into a tumor cavity at the time of surgical resection, the complex degrades over a period of a few weeks, delivering high local concentrations of BCNU. Data from trials in both newly diagnosed and recurrent GBM patients demonstrated a small but significant benefit in both these groups.^{43,44}

Low-Grade Diffuse Glioma

Low-grade glioma (LGG) is a term applied to members of a group of tumors that have a more indolent clinical course than high-grade astrocytomas (Figure 34.4). The term LGG

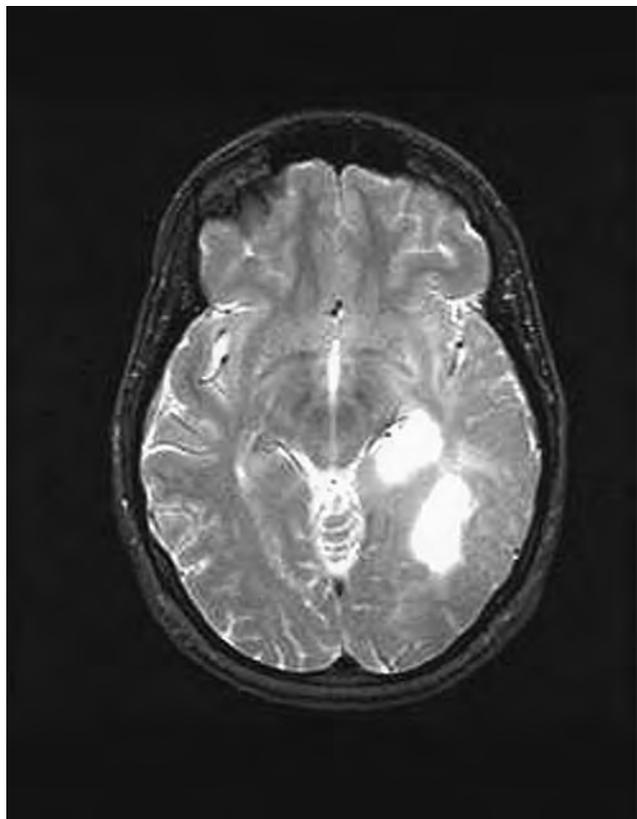

FIGURE 34.4. Brain MRI of patient with a low-grade oligoastrocytoma in the left temporoparietal region demonstrates area of enhanced T2 signal. This tumor had decreased T1 intensity and did not enhance with Gd contrast (not shown). This 31-year-old patient had stable disease for 2 years before requiring therapy for her tumor.

encompasses a number of disease entities that are predominantly characterized by their clinical behavior: slow growth and tendency for local recurrences. Patients with diffuse infiltrative LGGs have a median survival of around 5 to 10 years, depending upon histology.⁴⁵ These tumors occur in young adults (twenties and thirties) and typically present with seizures.⁴⁶ Favorable prognostic features include oligodendroglial histology, younger age at diagnosis, tumor size less than 5 cm, and, possibly, greater extent of tumor resection. Late recurrences are relatively common, and patients should be followed lifelong for recurrences. When these tumors do recur, they may recur either as low-grade or as higher-grade tumors. Management of these patients includes symptomatic therapy of symptoms (e.g., seizures). Therapy of the tumors includes a combination of surgery and radiation. Most of the data on which to base treatment decisions in LGGs are derived from retrospective studies; very few prospective randomized trials have been performed in patients with this disease.

Symptom Control

Deferring therapy until there is an unequivocal need for anti-tumor therapy appears to be a reasonable option in LGGs. Retrospective^{47,48} data suggest that patients who have radiologically suspected LGGs and are observed have outcomes similar to those who underwent immediate therapy. This strategy, which has the advantage of avoiding therapy-related toxicity, has been supported by the results of a recent randomized prospective study.⁴⁹

Surgery

Most patients with low-grade gliomas require at least a diagnostic brain biopsy. In some cases, more-extensive resections may be indicated. The surgical decision is guided by the location of the tumor, age and the functional status of the patient. Gliomas that extensively involve eloquent cortex or deep tracts or nuclei are usually not candidates for a large resection. Specialized surgical techniques with functional imaging and awake resections may allow for a greater amount of tumor resection. The therapeutic benefit of more-aggressive resection remains controversial.

Radiation Therapy

A prospective randomized trial has shown RT at diagnosis delays tumor recurrence in comparison to delayed radiation at the time of tumor progression.⁴⁹ However, in the absence of data demonstrating a survival benefit to this approach, it is acceptable to defer irradiation until there is evidence of symptomatic tumor growth. The rationale for delaying radiation is to reduce the risk of radiation-induced neurocognitive deficits. Two prospective randomized trials between intermediate- and high-dose RT have failed to demonstrate a benefit for the higher dose^{49,50} (Table 34.4). Typically, at the present time, doses between 45 and 54Gy delivered in 180- to 200-Gy fractions are considered acceptable.

Chemotherapy

The role of chemotherapy in the therapy of the majority of adult LGG remains under investigation. Interpretation of data

TABLE 34.4. Randomized radiotherapy trials for newly diagnosed low-grade gliomas.

Study	No. enrolled	Therapy	Five-year PFS (%)	Five-year OS (%)

		64.8 Gy	52	64
			NS	NS

PFS, progression-free survival; OS, overall survival; NS, not significant.

from retrospective studies on the use of chemotherapy is confounded somewhat by the fact that some of the series describe the use of chemotherapy at the time of recurrence and others at initial treatment. There are two situations in which chemotherapy has a role in the therapy of LGG: children and patients with oligodendroglial components.

Chemotherapy has a definite role in the therapy of children with LGG. A study testing a combination of carboplatin and vincristine in children with unresectable low-grade gliomas demonstrated prolonged periods of progression-free survival (68% at 3 years). The benefit was far greater in those younger than 5 years when compared to older patients.⁵¹ Similar encouraging results were seen in a study using single-agent carboplatin in children with optic pathway tumors.⁵² Other studies have confirmed the observation about chemotherapy responsiveness in children with LGG to some agents.^{53–55} Areas of ongoing investigation in children include benefits of multidrug therapy (as compared to single-agent therapy) and the role of adjuvant chemotherapy.

Oligodendroglial tumors are chemotherapy sensitive. Because high-grade oligodendroglial tumors were shown to respond to PCV,^{4,41} several investigators have evaluated the role of this regimen in LGG with oligodendroglial elements. The data from these reports are difficult to interpret, as the patient population tested is heterogeneous. A Phase II trial that evaluated this combination postoperatively (and before RT) found that a substantial minority of patients (up to half) attains objective responses with this regimen.⁵⁶ Other investigations into PCV use in oligodendroglial tumors have confirmed that there is a definite substantial objective response rate (~60%), with a median duration of response of approximately 1 to 1.5 years.^{57,58} However, PCV has a high rate of hematologic toxicity, which limits its use. More recent investigations have demonstrated that temozolomide (TMZ) may be an active agent in this disease as well.⁵⁹ A recent European Phase II trial demonstrated a 52% response rate with a median duration of response of 13 months.³⁸ Oligodendroglial tumors that progress after initial therapy with radiation or PCV seem to maintain responsiveness to other chemotherapeutic agents (e.g., TMZ).⁶⁰ The implications of a response to either of these regimens on overall neurologic status, long-term disease-free survival, or overall survival remain to be evaluated. Another area of interest in oligodendroglial tumors is the correlation between responses and genetic markers (1p and 19q deletions), which may allow for better patient selec-

tion.⁵⁶ Other approaches under investigation are the use of chemotherapy before radiation (in an effort to delay the use of radiation), based on data that suggest that this may be a viable strategy.⁶¹ The role of adjuvant chemotherapy for these patients is also under investigation. A Phase III trial of radiation alone compared with radiation followed by procarbazine, CCNU, and vincristine (PCV) has completed accrual (RTOG-9802), and outcome results are pending.

At present, the role of chemotherapy in the primary therapy of adult low-grade gliomas remains to be defined. There has been only one randomized study to evaluate the benefit of adding chemotherapy (CCNU) to RT (55 Gy) in the adjuvant setting; this study failed to show any improvements in the CCNU arm.⁶² A more-recent Phase II trial testing the use of TMZ in patients with progressive LGG demonstrated response rates of 73% in patients with astrocytomas, with most of these responses lasting more than a year.⁵⁹ Phase III trials to test the utility of TMZ are planned and will help clarify the role of this agent in LGGs.

Circumscribed Astrocytomas

Pilocytic Astrocytoma

Pilocytic astrocytoma (PA) is a distinct clinical entity that occurs generally in children and young adults, hence the old name of *juvenile pilocytic astrocytoma*. It represents the most common childhood glioma, with the cerebellar location being the most frequent. These tumors have a distinct radiologic appearance; they are well circumscribed, are frequently cystic, and enhance significantly with contrast administration (Figure 34.5). Histologically, PA is frequently a biphasic tumor with densely fibrillated areas rich in Rosenthal fibers and loosely arranged, often microcystic areas in which eosinophilic granular bodies can be found. Cellular pleomorphism and hyperchromasia can be marked. Therapy is mainly surgical, with excellent outcomes with a gross total resection (GTR).⁶³

Pleomorphic Xanthoastrocytoma

Pleomorphic xanthoastrocytoma (PXA) is a rare tumor representing less than 1% of all astrocytic tumors. Its most frequent location is the temporal lobe, where it occurs frequently as a cystic lesion with a mural nodule, superficially located and involving the leptomeninges. PXA is typically a tumor of children and young adults, who typically present with seizures. PXA frequently demonstrates immunohistochemical expression of neuronal markers; however, it is fundamentally a glial astrocytic tumor.⁶⁴ Morphologically, PXA is characterized by marked cellular pleomorphism with frequent presence of giant cells. Xanthic changes with cell vacuolation are frequent, but not invariable, as the name would appear to suggest. This tumor has a relatively favorable prognosis when compared to diffuse astrocytomas. Ability to achieve a GTR is the stronger predictor of disease-free and overall survival. Increased mitotic activity and presence of necrosis have been associated with frequency of recurrence and survival. In a small proportion of patients, PXAs progress to higher-grade tumors.⁶⁴ Factors that underlie such a transformation are unknown.

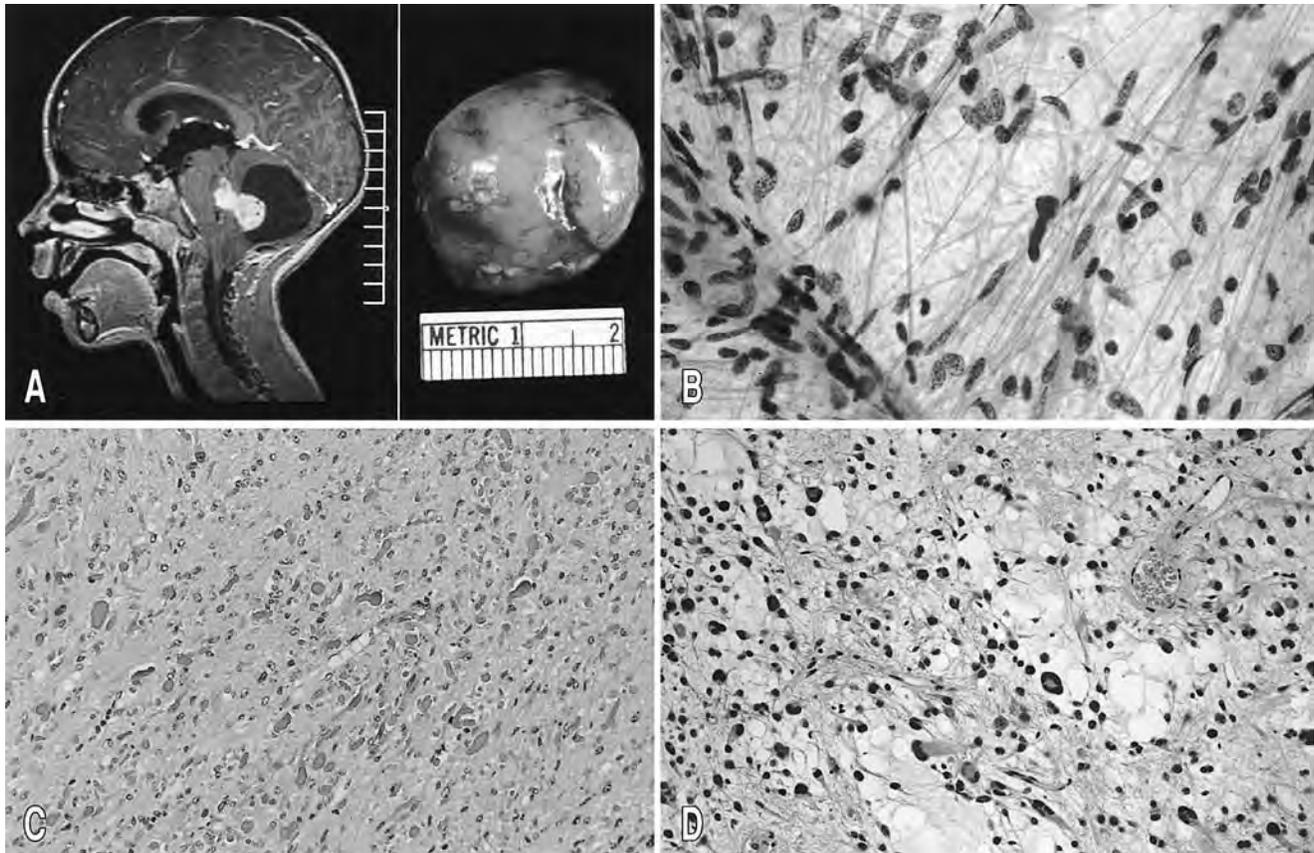

FIGURE 34.5. Typical example of pilocytic astrocytoma. The tumors typically occur in young adults. The most typical location is in the cerebellum, frequently in the midline. Pilocytic astrocytomas may often have a cystic component as demonstrated on the MRI (A). A strongly enhancing mural nodule is characteristic, which grossly appears as a well-demarcated, glistening hypervascular nodule. Mor-

phologically, the tumor is characteristically biphasic, with densely fibrillated areas rich in Rosenthal fibers (C) and loosely arranged microcystic areas with eosinophilic granular bodies (D). Characteristic long bipolar cells and Rosenthal fibers can often be recognized on smear preparations (B).

Meningioma

Meningiomas are tumors of the meninges that are believed to arise from the arachnoidal cap cells. According to the most recent WHO classification (2000), meningiomas are classified in three grades: grade I (classic), grade II (atypical), and grade III (anaplastic or malignant). Grade I meningiomas include a variety of characteristic histomorphologic patterns, but none of these has prognostic significance. Classic meningiomas, following GTR, have a very low frequency of recurrence. Grade II meningiomas (including two morphologic variants, clear cell and chordoid meningioma) are associated with a more-aggressive biologic behavior. Atypical meningiomas, despite GTR, tend to recur at increased frequency, up to 50% to 60% at 5 years. Atypical tumors are defined by the presence of an increased mitotic index (more than 4 mitoses/mm²) and/or at least three among the following criteria: presence of macronucleoli, pattern-less growth, small cell appearance, and necrosis. Grade III meningiomas are tumors with a very high mitotic index (more than 20 mitoses/10 high-power field, HPF) and/or have a frankly malignant appearance resembling carcinoma, melanoma, or sarcoma. Independent of their morphologic appearance, meningiomas may show invasion of the underlying brain parenchyma.

Although most (90%) meningiomas are slow-growing low-grade tumors, even low-grade tumors can be “biologically malignant” if their location makes treatment impossible. In

most cases, the diagnosis can be made using imaging studies such as CT and MRI (Figure 34.6). Most patients are completely asymptomatic and are diagnosed incidentally at autopsy. Asymptomatic meningiomas that are discovered incidentally can be observed,^{65,66} as the majority of them do not require therapy. Patients treated with GTR have longer disease-free survival.⁶⁷ Features that have been found to be associated with postoperative recurrences are: incomplete resections, age less than 40 years, male sex, and presence of anaplastic features. Several retrospective reviews have shown that external-beam and stereotactic radiation can reduce and delay recurrences in those with residual disease.^{68–70} Cytotoxic chemotherapy and biologic agents (e.g., hydroxyurea, interferon, and antiprogesterational agents) have not been shown to have any benefit.

Craniopharyngiomas

Craniopharyngiomas are midline tumors that typically arise in the sellar or suprasellar region from residual nests of epithelial cells from Rathke’s pouch. They occur most commonly in infants and children. They account for 5% to 10% of all pediatric primary intracranial malignancies and are the third most common intracranial tumors in children.

The symptoms and signs caused by craniopharyngiomas can be explained by the displacement of surrounding struc-

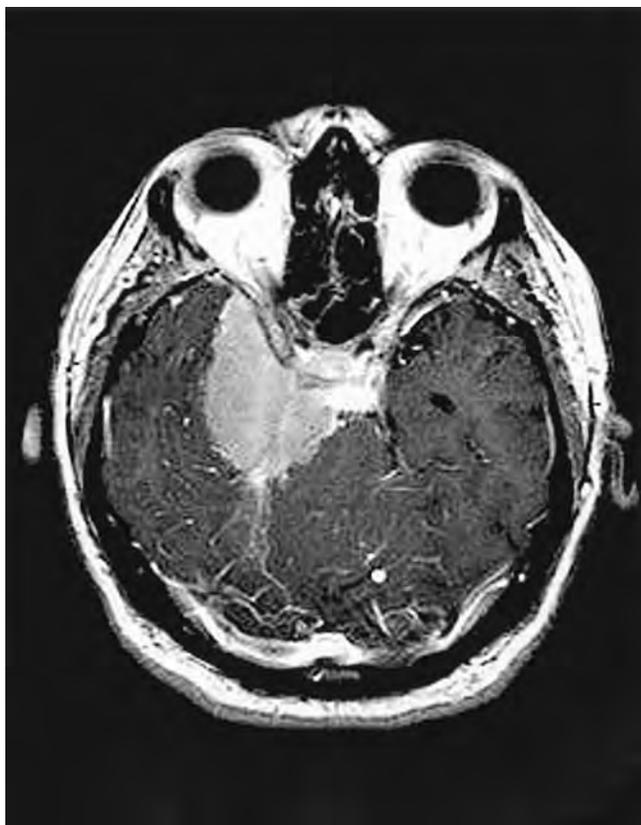

FIGURE 34.6. Post-Gd enhancing images from a head MRI study of a patient with a skull base meningioma. This homogeneously enhancing mass involved the right cavernous sinus, right suprasellar cistern, medial aspect of the right middle cranial fossa, right preponine cistern, right petrous ridge, and right tentorium. Therapy was necessitated by neurologic dysfunction caused by tumor-associated cerebral edema.

tures, primarily the pituitary gland and optic chiasm. In a majority of cases the diagnosis can be made by radiologic studies, such as, CT or MR scanning. The present of a calcified, cystic, suprasellar mass is diagnostic of craniopharyngioma (Figure 34.7). Poor prognostic factors include severe hydrocephalus, intraoperative adverse events, mucoid epithelial type,⁷¹ and young age (less than 5 years).

The optimal goal of treatment is to achieve a total resection,⁷² as recurrences are uncommon after complete resections. No adjuvant therapy is required if a complete resection is achieved.^{73,74} However if a complete resection is not technically feasible, or significant morbidity (e.g., visual loss) is expected with an aggressive resection, a more-limited debulking followed by RT is the preferred approach. Patients treated with postoperative RT after subtotal resections have local control rates comparable, or superior, to those achieved by GTR. Other supplemental and sometimes alternative treatment modalities are intracavitary irradiation (with ³²P), stereotactic radiosurgery, and intracystic chemotherapy (bleomycin).

Ependymoma

Ependymomas are uncommon intracranial tumors that arise from ependymal cells which line the ventricles in the brain and spinal cord. They occur primarily in children, with most

patients being less than 5 years of age at diagnosis. The symptoms at diagnosis correlate with the location of the tumor. As these tumors involve the central canal, and interrupt the normal flow of CSF, patients present with signs of raised ICP.⁷⁵ Surgical removal is the preferred initial treatment of choice for posterior fossa ependymomas in children. The extent of resection is a significant factor in prognosis; in several studies the presence of residual tumor was the most important factor that predicts for relapse.^{76,77} Although debulking may extend symptom-free survival, it is clear that only a GTR confers any chance for a cure.^{76,78} Therefore, aggressive surgical strategies are often justified for patients with this diagnosis. Factors that prevent the GTR of an ependymoma are adherence to the floor of the fourth ventricle, extension out of the foramina of Luschka, or invasion of the surrounding brain.⁷⁹⁻⁸¹ Some subsets of patients may do well without any additional therapy following surgery.^{82,83} On the other hand, radiation (greater than 50 Gy) is indicated for the therapy of patients with residual disease and for those with posterior fossa tumors. Routine prophylactic radiation to the entire craniospinal axis is not recommended, as this strategy does not improve outcomes^{84,85} and is toxic.

Chemotherapy agents such as carboplatin, vincristine, and ifosfamide appear to have some activity in children with ependymoma. A Pediatric Oncology Group (POG) trial in patients younger than 3 years demonstrated that prolonged chemotherapy (up to, but not beyond, 1 year) with delayed radiation was a viable option.

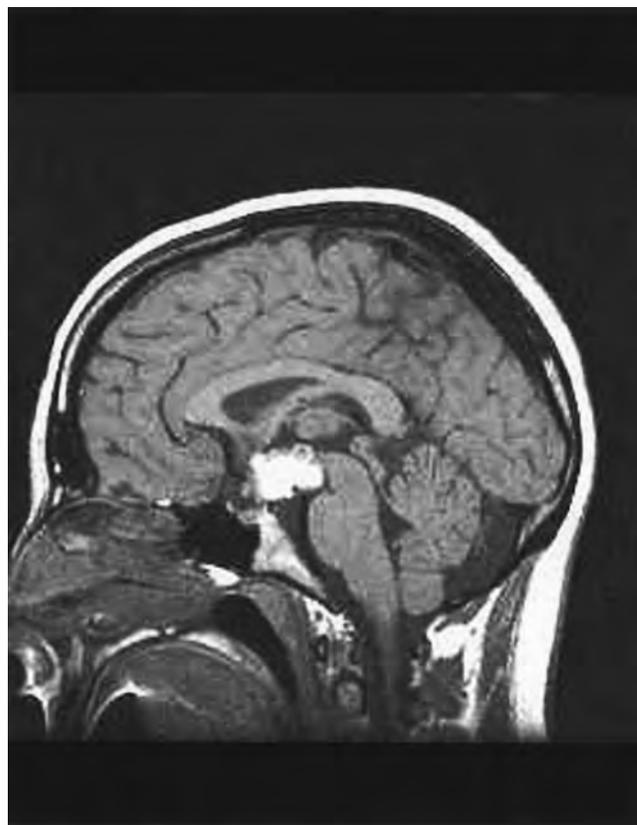

FIGURE 34.7. MRI of head and sella demonstrating a craniopharyngioma. The image demonstrates a large multilobulated mass in the suprasellar cistern. This 21-year-old patient had stable disease for many years before requiring surgery.

Primary Central Nervous System Germ Cell Tumors

Primary intracranial germ cell tumors (GCTs) occur in the brain, in the absence of any disease outside the CNS. These tumors occur predominantly in late childhood, with two-thirds occurring in the second decade of life, with a slight male predominance.

Histologically, GCTs are analogous to their extra-CNS counterparts.⁸⁶ Histology is the primary determinant of outcome, with patients with pure germinomas having higher rates of cure (5-year survival greater than 90%), whereas those with nongerminomatous components do much worse.^{82,86-88} These tumors occur predominantly in the midline, with the most favored location being the pineal gland (Figure 34.8). The symptoms depend upon location, with the most common presenting features being nausea, vomiting, pituitary hormonal deficiencies, hydrocephalus, and visual disturbances. Tumor markers [beta-human chorionic gonadotropin (beta-HCG), alpha fetoprotein (AFP), or lactic dehydrogenase (LDH)] can be elevated in the CSF and sometimes in the serum as well.⁸⁹ The presence of elevated tumor markers is sufficient to make the diagnosis in the presence of an appropriate radiologic image. Cytologic evaluation of the CSF for malignant cells is an essential part of the initial diagnostic workup.

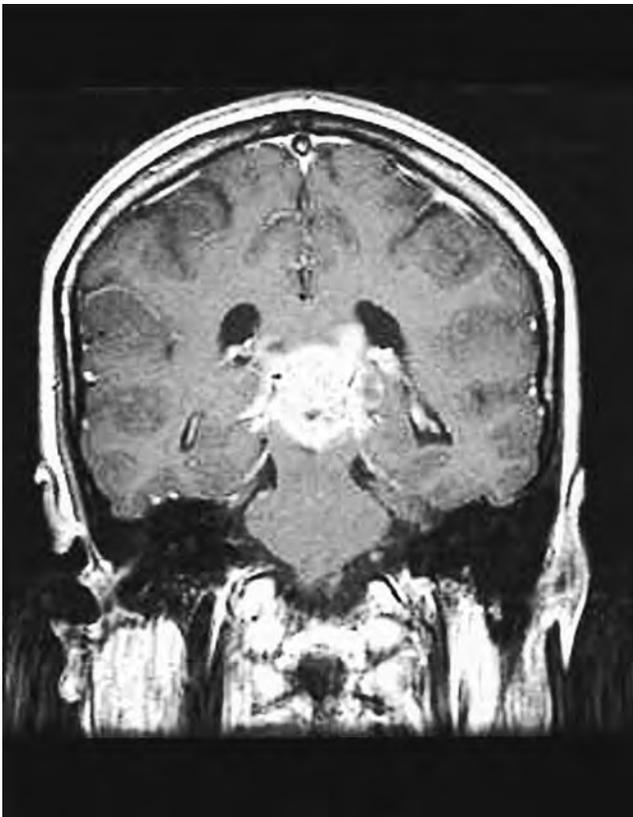

FIGURE 34.8. Brain MRI study demonstrating a sellar tumor. This 19-year-old man presented with hormonal imbalances and was found to have a germinoma on biopsy. MRI spine (not shown) demonstrated multiple meningeal metastases. He was cured with multimodality therapy.

The marked efficacy of RT and chemotherapy (with active agents such as cisplatin, etoposide, bleomycin, and ifosfamide) has led to the development of multimodality therapy for these patients. Patients with negative serum and CSF markers require an open exploration of the mass. If the intraoperative biopsy is consistent with the diagnosis of germinoma, it is not necessary or indicated to remove the tumor. Patients with germinoma achieve excellent results achieved with RT alone, which can achieve high cure rates (greater than 90%). Because of concerns about long-term toxicity of RT, attempts are under way to reduce the toxicity by reducing the radiation dose and fields^{88,90-92} and by using neoadjuvant chemotherapy followed by lower radiation doses.⁹³ Patients with evidence of disseminated germinoma are treated with craniospinal radiation. The standard approach in nongerminomas that cannot be completely resected is to administer chemotherapy and to perform a “second-look” surgery for persistent masses. Residual masses may consist of benign elements (e.g., mature teratoma) that have not responded to therapy. Trials using chemotherapy as the sole adjuvant therapy in GCTs have demonstrated impressive (greater than 75%) response rates to chemotherapy. However, because most of these patients relapse, this approach is clearly inadequate.

Medulloblastoma

Medulloblastoma is the most common among the embryonal tumors (a group that includes supratentorial PNET, ependymoblastoma, and medulloepithelioma). They account for 20% to 25% of all childhood tumors. The peak incidence is between 5 and 9 years, with a second peak in the late teens. This tumor is rare beyond 40 years of age. Medulloblastomas occur predominantly in the midline (cerebellar vermis).⁹⁴ Under the WHO classification, medulloblastomas are listed as grade IV tumors. Histologically a classic variant of medulloblastoma is described; in addition, there are other well-defined morphologic variants that have prognostic significance, including desmoplastic medulloblastoma, medulloblastoma with extensive nodularity, and large cell medulloblastoma.

Patients with medulloblastomas typically present because of symptoms and signs of raised intracranial pressure. Imaging studies demonstrate midline tumors in the cerebellum that are typically contrast enhancing. The enhancement can often be heterogeneous, with cysts, hemorrhage, or necrosis (Figure 34.9).⁹⁵ Appropriate staging at diagnosis includes imaging of the entire neuraxis and CSF sampling. The best identified prognostic features have been taken into account in the Chang staging system.⁹⁶ Outcomes of patients with medulloblastomas have improved dramatically in the past few decades.

An attempt at surgical removal of a medulloblastoma is almost always indicated as the initial therapy; the extent of surgical resection has prognostic significance.⁹⁷⁻¹⁰¹ Medulloblastoma is a radioresponsive disease with a propensity for dissemination throughout the CSF. Hence, craniospinal axis radiation is a requirement for all patients. Attempts at developing regimes that exclude radiation have been unsuccessful, with the majority of patients failing in the CNS.^{102,103} Craniospinal radiation remains one of the most technically complex treatments in radiation oncology in spite of

improved technology. Using reduced radiation doses in conjunction with chemotherapy appears to be a more-promising strategy.¹⁰⁴ The results of these studies are of great importance for the pediatric population, yet they have little bearing on the treatment of adults with medulloblastoma because the concerns for late toxicity are not as great. Therefore, even with the addition of chemotherapy to the treatment regimen of adults with medulloblastoma, the craniospinal dose is not typically lowered.

Prospective randomized trials in children have demonstrated that delaying RT (until after chemotherapy) is detrimental.^{105,106} Because the majority of failures occur locally after chemotherapy and craniospinal radiation followed by posterior fossa boost, there is growing interest in boosting only the tumor bed and not the entire posterior fossa.¹⁰⁷

Medulloblastomas are chemotherapy-sensitive tumors, with the most active regimens containing CCNU (lomustine), vincristine, cyclophosphamide, etoposide, and cisplatin. Subsequent studies revealed that although adjuvant chemotherapy (with CCNU and vincristine) did not benefit patients with medulloblastomas as a group, patients with high-risk features (i.e., young age, presence of residual disease, brainstem involvement, and T3–T4 disease) had a survival advantage.^{99,108} As noted previously, the use of chemotherapy

may allow for reductions to be made in the dose of RT.¹⁰⁴ One recently reported randomized trial testing chemotherapy in the adjuvant setting found a benefit in event-free survival even in average-risk patients; at the same time, overall survival was not any different between the groups.¹⁰⁹ The use of preradiation chemotherapy has some theoretical advantages and led to a high proportion of responses. However, as noted earlier, this strategy leads to delays in institution of RT, which can be detrimental.¹⁰⁶ One other indication to use chemotherapy may be in the setting of an autologous stem cell transplant and as a strategy to avoid radiation in some young children, with some success.^{110–112}

Outcomes are very poor for patients with recurrent medulloblastoma, with very few long-term survivors. High-dose chemotherapy with stem cell rescue (i.e., autologous stem cell transplant) is currently under investigation for therapy of relapsed disease.¹¹³

Primary Central Nervous System Lymphoma

Primary CNS lymphoma (PCNSL) is a relatively rare disorder whose incidence has been increasing. Most patients are between 40 and 70 years, with the median age at diagnosis being 60 years. These tumors remain localized to the CNS and only rarely metastasize to the outside. Epstein–Barr virus (EBV) is associated with PCNSL, especially in immunosuppressed patients. The increased incidence during the past few decades seems to be independent of HIV disease.¹¹⁴

PCNSL can present in almost any location in the CNS, including the meninges, vitreous, and the spinal cord. These tumors appear as hyperintense lesions on T₂-weighted MRI images that enhance with contrast (Figure 34.10). Edema is usually minimal, and hemorrhage, necrosis, calcification, and cysts are unusual. Resolution with the use of steroids suggests (but does not confirm) the diagnosis of PCNSL. A biopsy is required to confirm the diagnosis and to differentiate PCNSL from metastatic lesions and rule out other etiologies (e.g., infections in HIV-infected patients).

Untreated patients with PCNSL have a median survival of 1.5 months. Therapy with steroids and radiation improves the quality of life and prolongs survival of these patients. The response rate to radiation therapy alone is greater than 90%.¹¹⁵ However, prognosis is extremely poor, with 1-, 2-, and 5-year survival rates being 48%, 28%, and less than 5%, respectively. Almost all patients have relapses and eventually die of the disease. The use of combination chemotherapy regimens leads to high response rates, with small improvements in survival. However, the benefits seemed to be limited to those younger than 60 years. In older patients, the toxicity is significant, with a very high risk of dementia (greater than 80%).^{116,117} Currently the most effective regimens are those that incorporate high-dose systemic methotrexate (MTX) as initial therapy.¹¹⁸ Response rates noted have ranged from 80% to 90%,^{119,120} the median survival of patients has been between 32 and 54 months, and the 5-year survival has been in the range of 30% to 40%.^{121,122} Radiation may be used as salvage therapy in those with relapses.

FIGURE 34.9. MRI of head of a patient with cerebellar medulloblastoma demonstrates a large mass lesion with indistinct borders. This lesion had a low T₁ signal and a high T₂ signal with hazy Gd enhancement. Note areas of necrosis, hemorrhage, and effacement of the fourth ventricle. At the time of this study, the patient had cerebellar tonsillar herniation. This patient was successfully treated with multimodality therapy.

FIGURE 34.10. Fluid-attenuated inversion-recovery (FLAIR) image from a head MRI image of a patient with primary central nervous system (CNS) lymphoma. Note areas of hyperintense signal in the pons, adjacent to the cerebellum. This patient responded to initial therapy (with high-dose methotrexate) and recurred, but was successfully salvaged by therapy with high-dose therapy and autologous stem cell rescue. He subsequently relapsed in the vitreous humor bilaterally.

Novel Therapeutic Approaches

To improve outcomes in patients with high-grade astrocytomas, various novel therapies and drug delivery methods for conventional therapies have been employed. Some of these are discussed here.

Intraarterial Chemotherapy

The use of intraarterial (IA) chemotherapy (into the carotid artery) was first investigated in the 1980s and found to be feasible, albeit with a certain degree of neurotoxicity (ocular pain, visual impairment, and leukoencephalopathy). A Phase III randomized trial in patients with high-grade gliomas comparing intraarterial and intravenous BCNU¹²³ demonstrated significant toxicity (ipsilateral visual loss in 15%) and *decreased* survival in the patients with AA. A similar high rate of toxicity was seen with the use of IA cisplatin.^{124–126} This approach to therapy of CNS tumors using currently available chemotherapeutic agents is not justified in view of the excessive neurotoxicity noted in these studies.

Blood–Brain Barrier Disruption

The value of blood–brain barrier (BBB) disruption by osmotic agents (e.g., mannitol) with chemotherapy to in-

crease drug delivery to gliomas remains under investigation. In one such study, patients with GBM were treated with IA mannitol and combination chemotherapy (a regimen of MTX, cyclophosphamide, and PCBZ). Significant neurotoxicity was noted, with 3 (of 38) patients experiencing stroke-like events during therapy,¹²⁷ although survival seemed to be better than historic controls.

Studies using positron emission tomography (PET) scanning have demonstrated that although IA administration of mannitol can increase the permeability of the BBB in the tumor, the increase is even greater (and lasts longer than) in the normal brain.¹²⁸ Thus, although BBB disruption can enhance drug delivery to the tumor, this is accompanied by an even greater increase in the drug delivered into the normal brain. These factors may explain the high rate of toxic events. Based on the toxicity data, and the lack of confirmatory clinical evidence that BBB modification in conjunction with chemotherapy improves the outcome of patients with glioma, this approach should be considered investigational at this time.

Immune Therapies for CNS Tumors

The role of immunologic therapies in CNS tumors is currently experimental. It is now recognized that GBMs are immunogenic and have several tumor-specific antigens [such as interleukin 13 receptor- α -2 chain, PHD finger protein 3, and glioma-expressed antigen 2 (GLEA2)], which can be exploited for therapeutic purposes. Several immune-based therapies are currently being investigated, including tumor vaccines, conjugated antibody therapies, adoptive immunotherapy, and intracavitary cytokine plus antigen therapy.

Ongoing areas of research include attempts at identifying tumor-specific antigens, mechanisms of immune tolerance, and appropriate methods to deliver immune effector cells or antibodies to the tumor. A few early clinical trials have been reported and have demonstrated the feasibility and safety of these approaches.^{129–134}

Convection-Enhanced Delivery of Agents to Brain Tumors

Convection-enhanced delivery (CED) is a method of delivering therapeutic agents to the tumor cavity directly using implantable catheters. Catheters are left in the tumor cavity at the time of surgery, and therapeutic agents are perfused into the tumor cavity through the catheter under pressure using pumps. This technique has the advantage of completely bypassing the BBB, achieving high volumes of distribution, and achieving local concentrations of the agent that would be impossible to achieve by any other method of delivery. Various kinds of therapeutic agents are currently being tested for their safety and utility when administered in this manner; these include traditional chemotherapeutic agents, antibodies, fusion products of toxins with antibodies, viral vectors carrying genes, and labeled cytokines.¹³⁵

Gene Therapy

Gliomas are ideal targets for gene transfer approaches because of their limited ability to metastasize and have been among the earliest tumor types to be included in clinical gene trans-

fer trials. The gene most extensively used in gene therapy of gliomas is the herpes simplex virus thymidine kinase (HSV-tk), a gene that does not normally exist in mammalian cells. Transferring HSV-tk gene into tumor cells renders them able to phosphorylate ganciclovir into an active form that is lethal to tumor cells. Several retroviral and adenoviral vectors have been studied as vehicles for transferring the HSV-tk gene in gliomas.^{136,137} A multicenter Phase III trial testing the delivery of this gene, in conjunction with RT, did not demonstrate any survival advantage to this therapy over RT alone.¹³⁸ A different gene transfer approach under investigation consists of tumor suppressor gene (p53) reconstitution. Early clinical studies of Adp53 a non-replicating adenoviral vector encoding the p53 gene administration in patients with recurrent glioma have been conducted and have demonstrated excellent tolerance.¹³⁹ Major limitations to the further development of this strategy include lack of adequate dissemination of the virus, low expression of viral receptors on tumor cells, lack of animal models that adequately replicate the behavior of human tumors, and inability to adequately monitor the effects of therapy.¹⁴⁰

Signal Transduction Inhibitors

During the past few years, research into the biology of CNS tumors has led the identification of several aberrant signaling pathways that appear to be important in the causation of, and in the maintenance of, the malignant phenotype. Several new agents have been developed designed to target key members of these pathways. Examples of agents that may potentially be used in CNS tumor (mainly glioma) patients are EGFR inhibitors such as ZD1839 (gefitinib, Iressa), OSI-774 (erlotinib, Tarceva), CI-1033 and EKB-569, mTOR inhibitors (such as rapamycin, RAD-001, and CCI-779), and inhibitors of platelet-derived growth factor (PDGF) such as imatinib mesylate (STI-571, Gleevec). Recent released results of clinical trials using CCI-779,¹⁴¹ OSI-774,^{142,143} and imatinib¹⁴⁴ have demonstrated a small but definite degree of anticancer activity in high-grade gliomas. Ongoing trials with these agents will demonstrate if these signal transduction inhibitors have enough activity to make an impact on the overall outcome of these patients. However, based on currently available data, it appears unlikely that signal transduction inhibitors would have enough anticancer activity on their own to impact the natural history of these tumors. Combinations of these agents with other therapies (such as cytotoxic agents or radiation) need to be investigated.

Primary Ocular Tumors: Melanoma

Two distinct populations of pigmented cells can be found in the eye. The pigmented epithelial cells of the iris, ciliary body, and retina are derived from the neural tube. These cells undergo reactive hyperplasia in response to a variety of stimuli, but they only rarely undergo malignant transformation. The other population consists of the stromal melanocytes, which can be found in the skin, conjunctiva, and uveal tract. These are neural crest in origin and do not undergo reactive hyperplasia, but they are the source of the most common primary intraocular tumor: uveal melanoma. The uveal melanocytes are considered the counterpart of dermal melanocytes, the source of cutaneous melanoma. (Dermal melanoma is discussed elsewhere in this text. This chapter focuses on eye-related melanomas.)

DIFFERENCE FROM SKIN MELANOMA

Melanoma of the eye differs from melanoma of the skin in several respects. (1) It is much less common, occurring with an incidence that is approximately one-eighth that of skin melanoma.¹ (2) As a result of the ocular anatomy, the clinical appearance of uveal melanoma is different from that of skin melanoma. (3) The genetics, histology, and growth pattern of the two tumors are different as well.

Uveal melanoma is the most common primary intraocular malignancy in Caucasians, accounting for nearly 70% of all primary intraocular tumors.² Melanomas may occur in the conjunctiva as well, but these make up only 2% of ocular melanomas.

The uvea is defined as the vascular layer of the globe and includes the iris, ciliary body, and choroid. The uveal melanocytes are distributed within the stroma of this layer. Pigmented tumors of the iris are usually slow growing and metastasize infrequently. Melanomas of the ciliary and choroid are more common, more aggressive, and of greater concern to the clinician.

Much of the information in this chapter is derived from the recent Collaborative Ocular Melanoma Study (COMS) sponsored by the National Eye Institute and National Cancer Institute. This investigation was a very large study involving approximately 9,000 patients with choroidal melanomas.³ In

addition to gaining insight into the natural history and identifying prognostic factors, the COMS evaluated treatment modalities, its primary focus.

EPIDEMIOLOGY

The Third National Cancer Survey found that melanoma accounted for 70%, or most, of all primary ocular malignancies, followed by the childhood tumor retinoblastoma.² The incidence of ocular melanoma has been reported to be between 5 and 7.3 cases per 1,000,000 persons.^{2,4-7} In several of these studies, the precise site of origin was not identified; however, melanoma arising from the posterior uveal tract accounted for the majority.

The incidence of ocular melanoma increases with age and peaks in the seventh decade; however, the median age at diagnosis is 56 years.^{1,4} Melanoma, in rare instances, does occur in young persons. In an analysis of the cases seen at the Armed Forces Institute of Pathology and Wills Eye Hospital, between 1.08% and 1.59% of uveal melanoma cases were in patients younger than 20 years old.¹

There appears to be no gender predilection,⁸ however, there is a large discrepancy among races. In the 3,586 patients encountered at Wills Eye Hospital, only 0.39% were African-American.¹ In addition, among Caucasians, uveal melanoma is more prevalent in lightly pigmented individuals with lightly pigmented irides.⁹ Other populations in which there is a greater prevalence include patients with dysplastic nevus syndrome, melanosis oculi, and oculodermal melanocytosis.¹⁰⁻¹²

PRESENTING SYMPTOMS

Many uveal melanomas are asymptomatic and are found on screening examinations, but some patients present with decreased vision, positive visual phenomena such as flashing lights, or a red eye with prominent sentinel vessels. Occasionally melanoma presents as a mass visible on the sclera or in the pupil (Figure 35.1). The latter is much more likely if the tumor is located anteriorly or reaches a large size. The mechanisms producing decreased visual acuity or a visual field defect include localized lens cataract or subluxation from an anterior ciliary body tumor. Choroidal tumors produce retinal detachment, bleeding into the vitreous, and

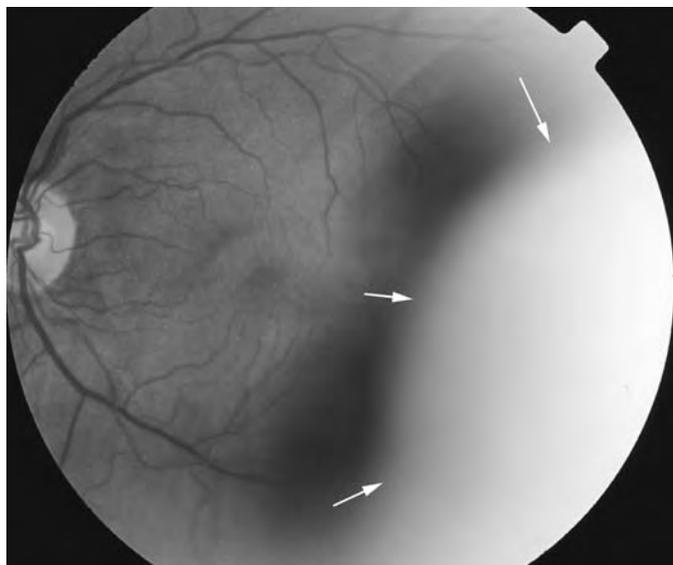

FIGURE 35.1. Choroidal mass representing choroidal melanoma as seen on indirect ophthalmoscopy. Edge is marked with arrows.

direct obscuration due to the mass (Figure 35.2). Large tumors can also present with glaucoma caused by anatomic crowding of the anterior chamber angle or neovascularization secondary to ischemia or inflammation induced by the tumor. There may or may not be associated pain.

ETIOLOGY

The genetic basis for uveal melanoma is unknown. The etiology of melanoma, however, involves both genetic predisposition (described previously) and predisposing environmental stimuli. Cigarette smoking¹³ and ultraviolet radiation (UV)¹⁴ appear to increase the risk.

PATHOLOGY

From the pathologic characteristics of melanoma, including location, structure, size, and cellular phenotype, much can be inferred about the prognosis in each case.

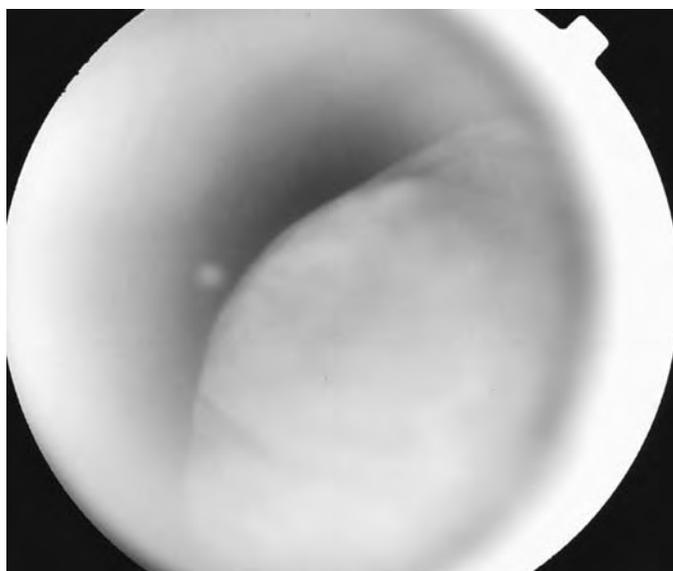

FIGURE 35.2. Higher-magnification view of choroidal melanoma.

METASTASIS

About 2.5% of patients with choroidal and ciliary body melanomas have metastases at the time of diagnosis.¹⁵ Obviously, if a secondary tumor is found at a distant location, the patient will have a greatly worsened prognosis. Metastases result from hematogenous dissemination, and the liver is the most frequent site of spread. In the large choroidal melanomas study, the COMS data showed that in tumor-related death, liver metastases were extremely common (93%); these were followed in frequency by lung metastases (24%) and bone metastases (16%).¹⁶

EXTRASCLERAL EXTENSION

Extension of the tumor through the outer layer of the eye is termed extrascleral extension (Figure 35.3). Large extrascleral extensions (greater than 4mm) drastically worsen the prognosis.³ The overall incidence is 13% in patients with uveal melanoma.¹⁷ It is generally detected anteriorly at the limbus or posteriorly adjacent to or within the optic nerve. The tumor spreads typically along the vortex veins and ciliary vessels or nerves, and extensions occur more frequently in larger tumors.¹⁷ The COMS showed that 55.7% of enucleated eyes had scleral invasion on histologic examination and 8.2% had extrascleral extension.¹⁸

LOCATION

The location of the tumor within the globe is an important factor with regard to time of diagnosis. Ciliary body tumors are often obscured from direct visualization by the irides and often are not detected until they are quite large. Ciliary body melanomas occasionally grow in a ringlike fashion to encompass the entire 360° of the ciliary body, making tumor resection impossible. For posterior choroidal tumors, those adjacent to the optic nerve have a worse prognosis, and there is a suspicion that proximity to the foveal avascular zone also worsens prognosis.³

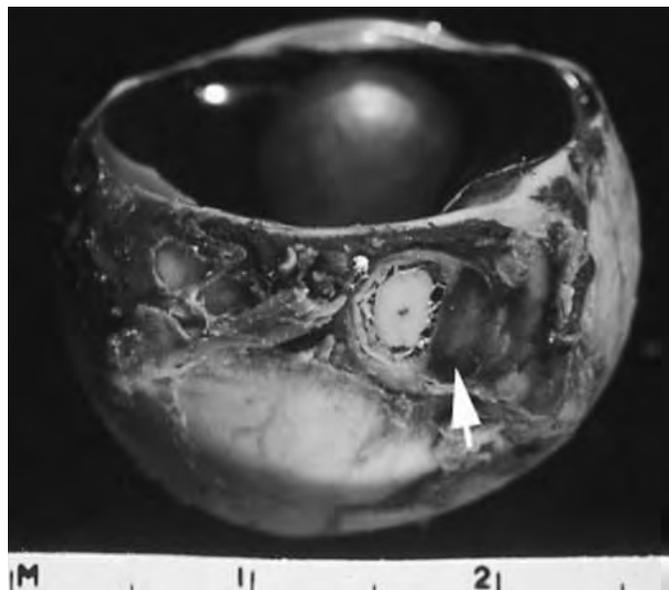

FIGURE 35.3. Extrascleral extension of choroidal melanoma evident as pigmented mass (arrow) adjacent to the optic nerve.

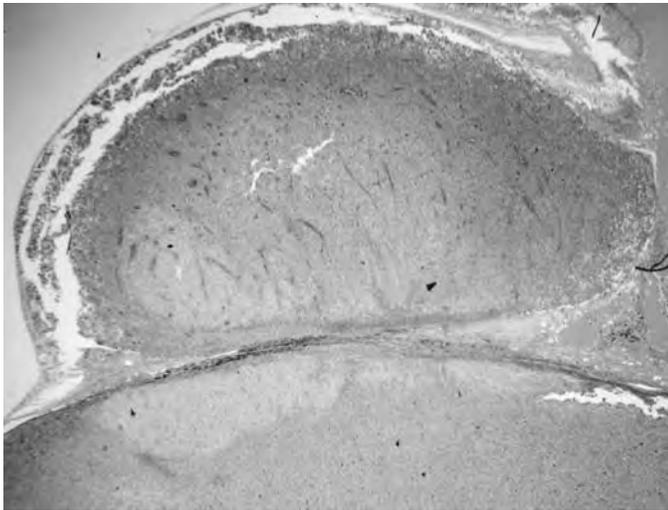

FIGURE 35.4. Dilated blood vessels seen in a choroidal melanoma internal to Bruch's membrane, secondary to the bottleneck effect of Bruch's membrane. 4 \times .

INTRAOCULAR INVOLVEMENT

Evidence of intraocular spread also worsens the prognosis. Small melanomas generally begin as discoid lesions and grow thicker to assume an almond-like shape while progressively displacing Bruch's membrane and the retina inward. When Bruch's membrane is disrupted, the tumor begins to grow in the subretinal space and assumes more of a mushroom configuration. The portion of the tumor internal to Bruch's membrane can be seen to have dilated blood vessels as it is squeezed by the collar of Bruch's membrane, limiting outflow (Figure 35.4). Some tumors extend through the retina and seed the vitreous. Conversely, other tumors do not follow this pattern of forming a bulky, clinically obvious mass, but rather spread within the plane of the uvea diffusely, thickening this coat and making detection more difficult.

TUMOR SIZE

Size of tumor as it affects prognosis has been studied extensively; tumor size served as the basis for the classification of patients in the COMS. The dimensions of these categories, along with the 5-year melanoma-associated mortality rate, are given in Table 35.1.

TABLE 35.1. Classification of tumor size according to boundary lines.

Type	Apical height	Basal diameter	Five-year mortality
Small	1–3 mm	More than 5 mm	1%
Medium	3.1–8 mm	Less than 16 mm	10%
Large	More than 8 mm	More than 16 mm	30%–35%

Am J Ophthalmol 1998;125:779–796.

TUMOR CELL TYPE

In 1931, Callender recognized certain distinguishing cellular characteristics of melanomas and found that they correlated with prognosis after enucleation. These characteristics were subsequently modified slightly by the Armed Forces Institute of Pathology (AFIP), but they are still routinely evaluated and are described in Table 35.2.

Tumors were characterized as spindle cell (A, B, or a combination); mixed (when less than one-half of the tumor is composed of epithelioid cells); or epithelioid (when greater than one-half of the tumor is composed of these cells). Spindle cell tumors carry the best prognosis and epithelioid the worst. Large tumors and more anterior tumors tend to be of the epithelioid type more commonly than do smaller tumors.

OTHER CLASSIFICATION METHODS

Folberg and coworkers have extensively studied the vascular pattern in melanoma. They hypothesized that the blood vessels within the melanoma may be tumor derived. They demonstrated that certain vascular patterns have a strong correlation with the presence of metastatic disease.^{18,19} Sorenson et al. and Gamel et al. attempted to objectify the histopathologic nuclear characteristics by basing a measurement on the 10 largest nucleoli identified in the tumor.^{20,21} This, in conjunction with largest tumor diameter, is among the best objective cytologic measures of a tumor's malignant poten-

TABLE 35.2. Armed Forces Institute of Pathology (AFIP) modification of the Callender classification.

Cell type	Size/shape	Cytoplasm	Nucleus	Nucleolus	Other
Spindle A	Elongated and small with indistinct cell membrane	Sparse	Elongated, but plumper than nevus cells, fine chromatin pattern, \pm line in chromatin	Not present or indistinct	Cohesive, mitoses rare
Spindle B	Plumper spindle with indistinct cell membrane	Relatively sparse	Larger and plumper than spindle A, more coarse and clumped chromatin	Sharper definition, small, round, deeply stained, eccentric	Less cohesive, \pm fascicular arrangement, occasional mitosis
Epithelioid	Larger, polygonal, pleomorphic, distinct cell border	Abundant, eosinophilic	Largest, round, \pm multiple, pleomorphic, chromatin margination	Largest, multiple, eosinophilic, central, distinct	Loss of cohesiveness, more mitoses

tial.²¹ Marcus et al. counted nucleolar organizing regions and achieved similar results.²² According to Whelchel et al., the presence of tumor-infiltrating lymphocytes is associated with death from metastasis.²³ On the molecular level, researchers have shown that metastases are more likely to occur from growing tumors,^{24,25} so cell-cycle studies are being performed²⁶ and markers of cell division are being tested. DNA ploidy analysis is another important way to gather information relevant to prognosis.²⁶⁻²⁸

DIAGNOSIS AND WORKUP

DIFFERENTIAL DIAGNOSIS

Misdiagnoses of melanoma are uncommon in recent years and are generally less than 2% at most clinical centers in the United States. The diagnostic accuracy of the COMS study was 99.7%.²⁹ Nevertheless, the differential diagnosis of uveal neoplasms must be considered when evaluating a patient with suspected melanoma.

The differential diagnosis includes retinal detachment, choroidal detachment, metastatic tumor to the choroid, exudative age-related macular degeneration, ectopic disciform degeneration, localized choroidal hemangioma, large choroidal nevus, and congenital hypertrophy of the retinal pigment epithelium (CHRPE). The principal distinguishing features of melanoma are described next.

CLINICAL EVALUATION AND IMAGING

More than 90% of the time melanoma can be diagnosed by clinical evaluation and imaging. Indirect ophthalmoscopy is the most important and widely used diagnostic technique, allowing a wide field of view and good stereopsis. Oftentimes, skilled observers can make accurate estimates of the tumor size and height by visualization; however, the most reliable measurements are obtained by ultrasound imaging. Examination of the uninvolved eye may reveal lesions there as well. Such findings make the likelihood of a primary choroidal melanoma less likely.

A transilluminatron can be a useful adjunct to indirect ophthalmoscopy. Solid lesions such as melanoma and organized hemorrhage do not transilluminate light, whereas lesions associated with relatively clear fluid such as retinal detachment and choroidal effusion do.

Lenses with mirrors, or gonioscopes, are particularly helpful in determining the anterior borders of tumors in the posterior choroid and in visualizing the far periphery of the retina, the ciliary body, and the anterior chamber angle. Melanoma appears on ophthalmoscopy or gonioscopy most often as a fairly well circumscribed, brownish-gray, elevated subretinal mass. It is important to remember, however, that approximately 25% of melanomas are relatively amelanotic. Oftentimes there is associated pathology of the overlying retina, such as a detachment or a retinopathy producing orange lipofuscin exudates.

Choroidal nevi, in contrast to most melanomas, are flat, being rarely greater than 3mm in height and infrequently greater than 10mm in basal diameter. The overlying subretinal fluid, orange pigment, and clinical symptoms associated with melanomas are not normally present with nevi. Metastases to the choroid differ from melanomas in that there are often multiple foci metastases and they tend to be flat with indistinct margins. CHRPE is generally not difficult to dis-

tinguish from melanoma because it is flat and darker black in color. The borders of CHRPE are distinct, and nonpigmented spots or lacunae are often seen centrally. Advanced age-related macular degeneration (ARMD) can produce lesions with characteristics similar to melanoma. These lesions tend to be symmetric and occur in the known setting of ARMD. Also, there is a much greater tendency to have associated subretinal hemorrhage with ARMD.

ULTRASOUND IMAGING

Different types of tissue have characteristic reflectivities on ultrasound. The A mode is used to distinguish melanoma from other tumors that can be very similar in ophthalmoscope appearance, such as choroidal hemangioma. The A mode can also be used to measure tumor height. The B mode generates an image of the globe and is therefore helpful in measuring the greatest basal diameter as well as tumor height (Figure 35.5). It can also be used to look for an underlying tumor in the setting of a retinal detachment or cloudy media. Finally, B mode ultrasonography is used to look for evidence of extrascleral extension.

FLUORESCEIN ANGIOGRAPHY

Fundus fluorescein angiography has limited usefulness in the diagnosis of uveal melanomas because there is no diagnostic staining pattern for these tumors. Typically there is mottled hyperfluorescence with "hot spots" and a double circulation. A clinical situation in which angiography may be helpful is when attempting to differentiate a choroidal melanoma, which will show mottled fluorescence with late staining, from exudative ARMD with hemorrhage, which would block fluorescence.

PHOTOGRAPHY

Serial clinical photographs are a standard method for following the growth of a melanoma and are useful for distinguishing it from other suspicious lesions. The photographs allow for observation of the lesion over time and for documenting growth. Fundus photography is also useful for monitoring the tumor during and after therapeutic intervention.

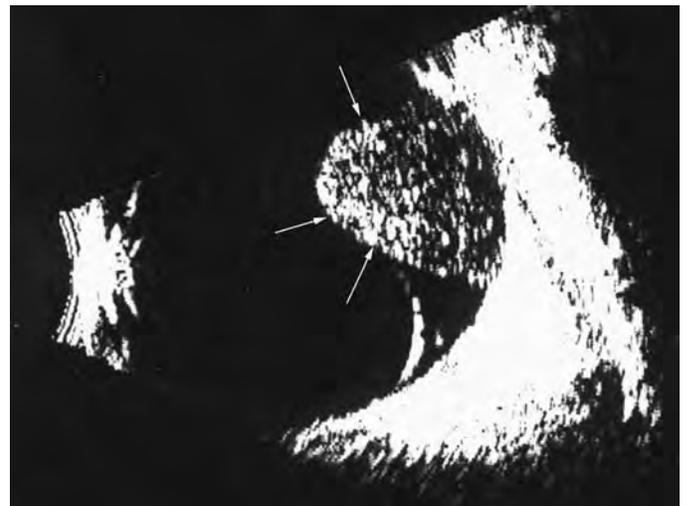

FIGURE 35.5. B-scan ultrasound of a choroidal melanoma (arrows).

*CHEST RADIOGRAPHY/COMPUTED TOMOGRAPHY
(CT)/MAGNETIC RESONANCE IMAGING (MRI)*

These modalities are used to rule out potential primary tumors such as carcinomas of the lung and breast if a secondary eye metastasis is a concern. Imaging studies, particularly of the liver, help to determine whether distant metastases are present in a patient with known uveal melanoma. When there is clinical suspicion of extrascleral extension, MRI imaging of the orbits may also be of benefit; this is particularly true as current imaging sequences allow a detailed view of anatomy.

BLOOD TESTING

Liver enzymes are monitored to help detect hepatic metastases. Immunologic testing is not yet reliable. Folberg showed that 78% of patients with melanoma tested positive for tumor-associated antibodies (TAA), but 24% of controls tested positive as well.

TREATMENT AND PROGNOSIS

The management of uveal melanoma has long been the subject of considerable controversy, and enucleation of any tumor was the accepted therapy in all cases for many years. This choice was the result of two factors: (1) the data regarding the natural history of these tumors were (and remain) limited; and (2) there was a lack of an organized, reliable clinical trial. The aforementioned COMS trial is the largest of its type and has set the treatment standards of today.

There are certain variables a clinician must consider before generating a treatment protocol: these are (1) size, location, and extent of tumor; (2) visual status of the affected and fellow eye; and (3) age and general health of the patient. The ultimate goal should be to destroy or inactivate the neoplasm, to maintain useful vision in the involved eye, to employ a treatment with as few side effects as possible, and, most importantly, to provide the patient with the best prognosis and quality of life. The different modalities are discussed in the following section with the general indications for each.

OBSERVATION

Serial observation is acceptable if the tumor is small and dormant, if the patient is seriously ill or elderly, or if the tumor is in the patient's only useful eye and is growing slowly. Appropriate observations consist of ophthalmoscopic examination with ultrasound measurements with or without photographic documentation every 3 months.

The COMS study found growth in 21% of small tumors at 3 years and 31% at 5 years. Because of the positive correlation between tumor size and occurrence of metastases, the risk factors for growth were identified by several different researchers, and these were formalized into an algorithm by Shields and colleagues. The five risk factors predictive of growth are tumors with thicknesses greater than 2 mm, posterior tumor margin touching the optic disc, visual symptoms, orange pigment, and subretinal fluid. Shields and colleagues, in the same paper, suggest "timely treatment" of some small melanomas that show substantial risk of growth.³⁰

PHOTOCOAGULATION

Photocoagulation has been employed in the treatment of small melanomas. Its effectiveness has been debated. It uses

laser energy to destroy the lesion. The criteria for selecting patients with melanoma for photocoagulation were suggested by Meyer-Schwickerath and Vogel^{31,32} and were adapted by Shields:³³

1. The diagnosis of melanoma and evidence of growth should be documented thoroughly.
2. The tumor should not be greater than 5 diopters in elevation and 6 disc diameters in greatest diameter.
3. It must be possible to completely surround the tumor without damage to the fovea or optic disc.
4. There must be sufficient mydriasis and clear ocular media for the procedure.
5. The tumor surface should not have large retinal vessels.

In a 54-patient series by Vogel at 20 years, 63% of patients treated with photocoagulation were alive, although not all these patients were considered cured by photocoagulation.^{32,33}

Transpupillary thermotherapy (TTT) is a related technique and consists of delivering heat to the tumor via infrared light; this is intended to induce necrosis of the tumor tissues. Shields et al. had a 14-month follow-up of 100 patients, and in 94% there was local tumor control. There was, however, worsening of visual acuity in 42%.³⁴ A longer follow-up is necessary to properly assess this modality.

EPISCLERAL RADIOACTIVE PLAQUE

This highly specialized multidisciplinary approach is much more widely available than charged-particle therapy (discussed later). Based on preoperative tumor measurements, tumor shape, and tumor location, a concave plaque housing several small radioactive beads is fashioned to fit over the tumor while avoiding treatment of uninvolved areas. Although iodine-125 is the most commonly used isotope, ruthenium-106 is used frequently in Europe, and other isotopes such as palladium-103 are being tried.^{35,36}

Under general or retrobulbar anesthesia, this plaque is sutured onto the sclera overlying the tumor. The tumor location and plaque placement are confirmed by transillumination, ophthalmoscopic observation, and intraoperative ultrasonography. This plaque remains in place 2 to 5 days and is then removed.

The COMS study specifically evaluated iodine-125 plaque therapy versus enucleation for 1,317 medium-sized melanomas. The outcome was no difference between the two modalities in survival at 5 and 12 years.³⁷ Of the patients who received plaque therapy, 50% lost substantial vision in 3 years.

CHARGED-PARTICLE BEAM THERAPY

Cyclotrons and synchrotrons produce hydrogen or helium ion beams that have been successfully used to treat ocular melanomas. Only a handful of centers have these capabilities, and this is a comparatively costly form of treatment.³⁸ Wilson and Hungerford found no better local tumor control with proton beam as compared to iodine-125 brachytherapy. Tumor recurrences at 5 years were 5% and 4%, respectively.³⁹ In addition, although the procedure involves sophisticated planning techniques and precise tumor mapping, damage to the adjacent retina and optic nerve are still problematic. Finger et al. reported that 32% of patients maintained visual acuity better than 20/100.³⁶

ENUCLEATION

Enucleation or resection of the globe and proximal optic nerve continues to be recommended in selected cases. Current indications include large ciliary body or choroidal melanomas, melanoma associated with significant visual loss or secondary glaucoma, and any melanoma invading the optic nerve.⁴⁰

In the COMS medium-size tumor trial,³⁷ patients with medium-size tumors were given the option of enucleation. It was found in 1,317 patients randomized to enucleation or iodine-125 brachytherapy that neither mortality rates at 12 years nor quality of life differed between the two groups.^{41,42}

For the 1,003 large-melanoma patients enrolled in the COMS, there was another query, whether preenucleation radiation of 2,000 cGy was associated with a more favorable outcome. It was determined that such treatment neither favorably nor unfavorably influenced outcomes in terms of 5-year survival or local orbital complications. Thus, enucleation should not normally be preceded by radiation.^{43,44}

LOCAL SURGICAL EXCISION

Sclerouvectomy, developed by Peyman et al.,⁴⁵ is a surgical excision of the melanoma in which the tumor is approached from the scleral surface. Normally this surgery follows multiple sessions of photocoagulation therapy. This treatment has limited usefulness due to the concern of incomplete resection. Damato and Foulds⁴⁶ found that residual tumor was seen in a significant number of cases. This rate appears to be reduced by the use of adjunctive brachytherapy.

Still in an experimental stage is a procedure called transvitreal endoresection. In this technique, the tumor is approached from the retina. Obviously, this technique carries risk of tumor dissemination and incomplete resection.³

Primary Ocular Tumors: Retinoblastoma

EPIDEMIOLOGY

Retinoblastoma is the most common primary malignant intraocular tumor of infancy and early childhood. It is the third most common intraocular malignancy, second to choroidal melanoma and metastases. Retinoblastoma has an incidence of from 1 in 14,000 to 1 in 20,000 live births, therefore affecting approximately 350 children each year in the United States. It is responsible for approximately 1% of all cancer deaths under the age of 15.^{47,48} Its distribution is worldwide; however, there is a higher incidence in Haiti, Jamaica, Nigeria, South Africa, Africa, Asia, and parts of Latin America.⁴⁹ There is no gender predilection. Retinoblastoma is one of the most common congenital tumors, and approximately 90% present before age 3. Retinoblastoma affects each eye equally. Sixty percent to 70% of cases are unilateral, with mean age at diagnosis being 24 months. Thirty percent to 40% are bilateral, with mean age at diagnosis of 14 months. For small tumors, there are some potentially vision-sparing treatments, including radiation therapy, photocoagulation, and cryotherapy. With larger tumors, treatment includes chemoreduction and/or enucleation. It was formerly considered fatal when it spread beyond the eye and optic nerve. However, with recent advances in combined chemotherapy, there are reports of cure even with distant spread.⁵⁰

PRESENTING SYMPTOMS

Presenting signs include leukocoria (56.2%); strabismus (23.6%); poor vision (7.7%); and family history of retinoblastoma (6.8%). Leukocoria has been found to correlate to advanced disease, and strabismus is associated with macular disease⁵¹ (Figure 35.6). Less frequently, children may have a wide variety of presentations: pain, hypopyon, hyphema, heterochromia, spontaneous globe perforation, proptosis, cataract, glaucoma, nystagmus, tearing, or anisocoria.

BASIC SCIENCE: GENETICS

Retinoblastoma arises from defects in the retinoblastoma gene at the Rb 1 locus located at the q14 band of chromosome 13.⁵² The gene is large, containing 180kb DNA. The initial mutation of the gene inactivates one copy of the gene. This initial mutation can be of any size, even as small as a point mutation. It should be noted that all retinoblastoma tumors have other mutational events, and additional unknown stochastic events may be required for full malignant transformation. Both hereditary and sporadic forms of retinoblastoma arise as a consequence of mutations in both alleles at the Rb1 locus. In other words, to give rise to retinoblastoma, a second mutation is required in the second, homologous copy of the Rb gene so that no functional gene product is produced.^{53,54} The loss of the second copy of the gene is always somatic. There is a high rate of spontaneous mutation at this locus, and 94% of all cases are considered sporadic. Only 6% have a positive family history, but 30% to 40% of cases are hereditary. The differences between hereditary and nonhereditary retinoblastoma are of great importance for prognosis and genetic counseling for family members because there is an increased risk of second malignancies with the hereditary form.

FIGURE 35.6. Leukocoria in the right eye of patient with retinoblastoma.

If the initial mutation occurs in a germ-line cell, the patient has *hereditary retinoblastoma*. Each tumor arises from a distinct retinal cell that independently loses the second copy of the retinoblastoma gene through a deletion or mutation. In this instance, the mutation is transmitted as a dominant trait with virtually complete penetrance; carriers are at high risk (greater than 90%) of developing retinoblastoma in childhood and other primary cancers such as osteosarcoma later in life.^{55,56} The cumulative risk of developing a second primary malignancy is 1% per year; this risk is increased in patients treated with radiation.⁵⁵ In addition, other family members may be at high risk. Forty percent of retinoblastoma cases are hereditary; the majority of patients with hereditary retinoblastoma have bilateral disease.⁵⁶ Almost every case with multifocal disease is hereditary, and approximately 10% to 20% of unilateral cases are hereditary. Most patients have a new germ-line mutation and therefore have no previous family history of retinoblastoma. These patients may also have multifocal, unilateral, or unifocal retinoblastoma associated with additional independently arising tumors, *trilateral retinoblastoma*, in the central nervous system (pineal gland or in the suprasellar/parasellar region). There are still a small number of carriers that remain unaffected. Carriers may be unaffected for a variety of reasons, including incomplete penetrance, balanced carriers, and 13q14 trisomics.

If the mutation occurs in a somatic cell, the patient has *nonhereditary retinoblastoma*, and relatives are not at an increased risk for developing retinoblastoma. Sixty percent of retinoblastoma cases are nonhereditary. Almost all cases of nonhereditary retinoblastoma have a single primary tumor in only one eye. These patients are not at increased risk of developing other cancers later in life.

PATHOLOGY

LOCATION AND GROWTH PATTERN

The origin of retinoblastoma has been widely debated. The most widely accepted view is that retinoblastoma arises from a multipotential precursor cell that may develop into nearly any type of inner or outer retinal cell.⁴⁷ As a result, there is heterogeneity of the histopathologic, ultrastructural, and immunohistochemical features.

Spread of the tumor into the vitreous (vitreous "seeds") can give rise to viable tumor implants throughout the eye. Tumor cells may disseminate through the choroidal vasculature, spread extraocularly through the substance of the optic nerve, and grow into the orbit in advanced cases. The tumor may also extend into the subarachnoid space and gain access to the cerebrospinal fluid. Following overt extraocular extension, there are frequently palpable preauricular and cervical lymph nodes. In advanced cases, there may be distant metastatic spread to the central nervous system, skull and distal bones, and lymph nodes.⁴⁸

There are two main patterns of growth of retinoblastoma tumors: endophytic and exophytic. Endophytic retinoblastomas tend to originate on the inner surface of the retina (and accordingly can be viewed directly with ophthalmoscopy) and grow toward the vitreous (Figure 35.7). Exophytic retinoblastomas originate from the outer retinal surface and grow toward the choroid, producing elevation of the retina and possibly retinal detachment (Figure 35.8). Most commonly,

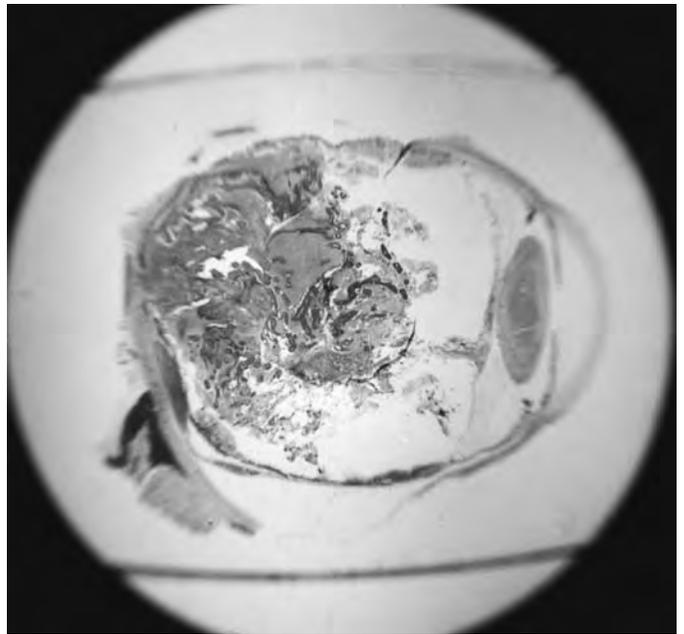

FIGURE 35.7. Endophytic retinoblastoma replacing retina with invasion of vitreous. 1 \times .

the two types of growth patterns coexist in the same eye. Characteristically, retinoblastoma outgrows its blood supply, leading to ischemic coagulative necrosis and marked apoptosis.

HISTOLOGIC FEATURES

Retinoblastomas are typically nodular masses with frequent satellite seedings. On macroscopic view, smaller tumors appear as translucent, gray to white intraretinal tumors that are fed and drained by dilated tortuous retinal vessels. More advanced tumors appear chalky white and can fill a large portion of the eye (Figure 35.9). On light microscopic examination, there may be areas of undifferentiated tumor together with tumor containing differentiated structures. Undifferentiated areas are composed of cells resembling embryonic retinoblasts, small round cells with large hyperchromatic

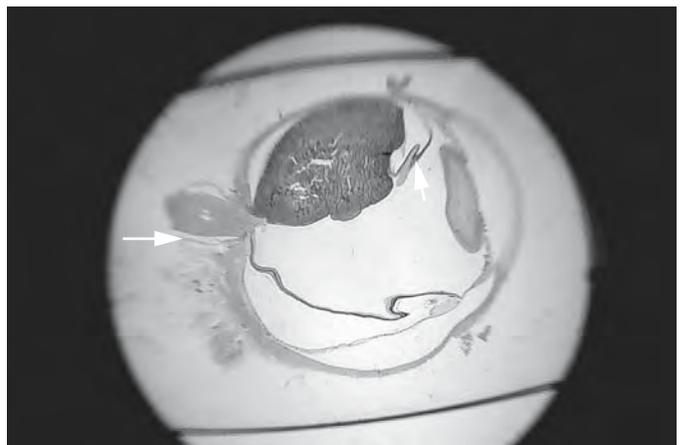

FIGURE 35.8. Exophytic retinoblastoma limited to the subretinal space. Retina marked with *arrow*. 1 \times .

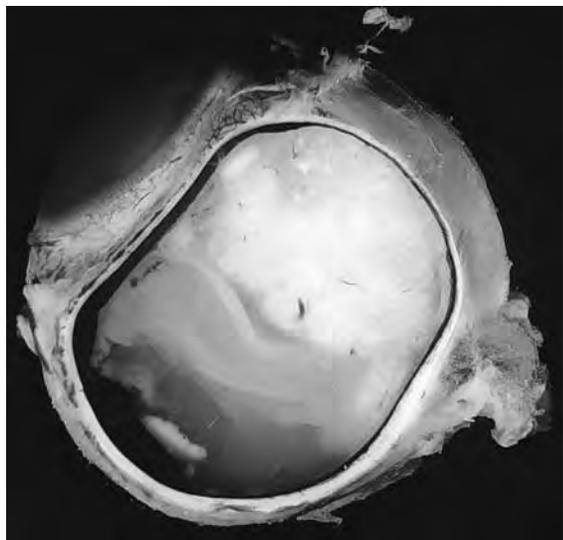

FIGURE 35.9. Retinoblastoma filling almost the entire vitreous cavity. Extensive calcification contributes to the chalky-white appearance.

nuclei and scant cytoplasm. Differentiated structures include Flexner–Wintersteiner rosettes, Homer–Wright rosettes, and fleurettes (Figure 35.10).

Flexner–Wintersteiner rosettes are the most common distinguishing feature and are specific for retinoblastoma. They consist of clusters of cuboidal or short columnar cells with peripherally displaced nuclei surrounding a central lumen. The lumen has a limiting membrane, resembling the external limiting membrane of the retina, through which photoreceptor-like elements protrude; some photoreceptor elements taper into fine filaments.

Less common are Homer–Wright rosettes, which have radially arranged cells around the central tangle of fibrils. These are also seen in neuroblastoma and medulloblastoma. The fleurette is present in a small percentage of tumors. It represents the tumor cells' attempt at photoreceptor differentiation.

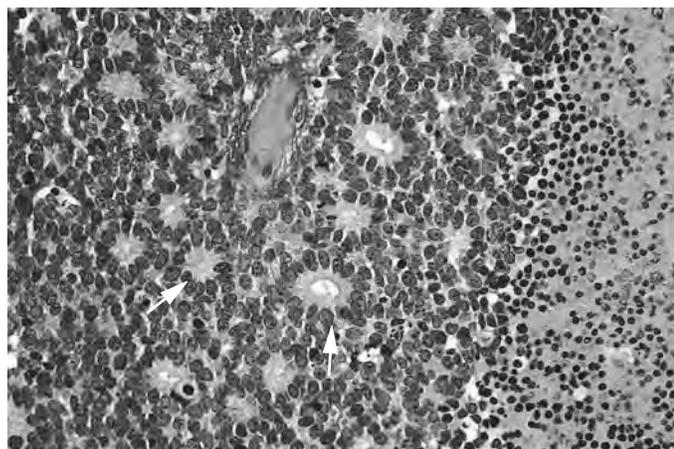

FIGURE 35.10. Retinoblastoma histology with Flexner–Wintersteiner rosettes (arrows). 20 \times .

REGRESSION

Retinoblastoma is unusual in that it may undergo spontaneous necrosis or regression; this has been estimated to occur in about 1 of 100 tumors. The mechanism is unknown. Eyes with tumors that undergo spontaneous necrosis may develop phthisis marked by calcification and severe inflammation. Histologically, the eyes are filled with islands of calcified cells embedded in a mass of fibroconnective tissue. There also may be proliferation of retinal pigment epithelium.

STAGING AND PROGNOSTIC INDICATORS

The Reese–Ellsworth classification system⁴⁷ (Table 35.3) is the most frequently employed method of staging retinoblastoma. It classifies the tumors into five groups based on tumor size and location and predicts the likelihood of local tumor control and preservation of vision. In general, group I is considered very favorable whereas group V is considered very unfavorable. There are new international classification criteria for intraocular retinoblastoma (Table 35.4).

The more numerous and highly differentiated the rosettes, the better the prognosis. Smaller tumors have a better prognosis, and they are more likely to have a greater concentration of well-formed rosettes than are larger, more-advanced tumors. Larger tumors, especially those with extraocular extension, tend to have smaller, less-differentiated rosettes. The most important prognostic indicator is optic nerve invasion.^{47,49}

RELATION TO RETINOCYTOMA

Retinocytoma, also called retinoma, is clinically indistinguishable from retinoblastoma; however, retinoblastoma is histologically malignant whereas retinocytoma is histologically benign. Retinoblastoma cells are histologically different from retinocytoma cells. They are larger, with scanty cytoplasm and more hyperchromatic nuclei with frequent mitotic figures and necrosis with calcification. Retinocytoma cells, in contrast, are smaller, with abundant cytoplasm and intercellular matrix and more evenly displaced nuclear chromatin with no evidence of mitotic figures, and although there may be some calcification, there is no necrosis in retinoma. Retinocytomas have numerous fleurettes admixed with individual cells that demonstrate varying degrees of photoreceptor differentiation. Histologically, the fleurette is composed

of cells with prominent eosinophilic cellular processes that are filled with mitochondria.

Clinical characteristics of retinocytomas include a functional eye with clear media and no evidence of retinal detachment. There is proliferation and migration of retinal pigment epithelial cells. Retinocytomas have a cottage-cheese appearance: opaque with white calcified flecks. They are also comparatively small, homogeneous, translucent, gray, slightly elevated placoid masses that have functional retinal blood vessels looping into the mass. Although histologically benign, retinocytomas can be locally invasive. Typically, retinocytomas are found admixed with retinoblastomas, although there may be cases of pure retinocytoma. In contrast to retinoblastomas, retinocytomas are radioresistant.

DIAGNOSTIC WORKUP

The differential diagnosis of retinoblastoma is essentially the differential diagnosis of leukocoria and includes persistent hyperplastic primary vitreous, cataract, retinopathy or prematurity, toxocariasis, colobomas of choroid and disc, uveitis, Coats' disease, vitreous hemorrhage, retinal dysplasia, retinal detachment, Norrie's disease, and other tumors.⁵⁹

A patient who has any of the aforementioned presenting signs needs prompt workup for possible retinoblastoma. It is extremely important for any child with strabismus to have a dilated fundoscopic examination. It is important to get a careful family history, specifically asking about family history of retinoblastoma, eye tumors, childhood cancer, or history of enucleations. Further workup entails documenting the existence of retinoblastoma and determining if there is any evidence of metastasis. A complete eye examination, including dilated fundus examination bilaterally, is performed. Frequently an examination under anesthesia needs to

be performed if the child is over 2 months of age. Fundus photographs and detailed retinal drawings should be made to help follow the effects of treatment. Ultrasonography may help distinguish retinoblastomas from other noncancerous tumors.^{58,59} Orbital CT and ultrasound may reveal characteristic calcific densities within the tumor (Figure 35.11).

Several methods are employed to determine if metastases are present. Computed tomography (CT) and magnetic resonance imaging (MRI) are used to evaluate orbital and central nervous systems (CNS) anatomy for extraocular disease. Head CT may reveal an early pinealoblastoma,⁶⁰ and this may help to provide more treatment options. CT generally does not reveal optic nerve spread because this is usually infiltrative and does not enlarge the nerve. Consultation with a pediatric

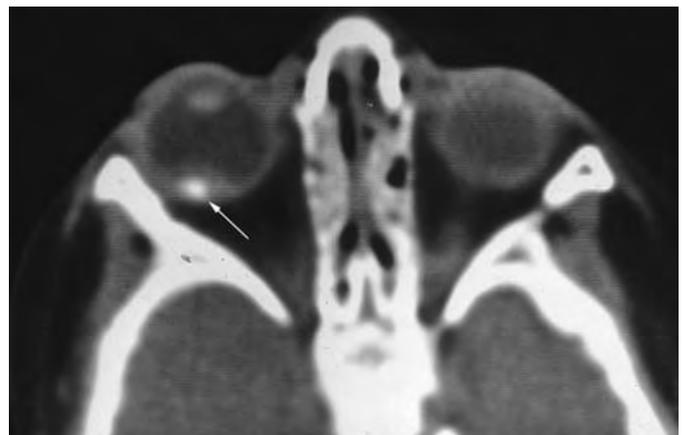

FIGURE 35.11. Calcification in retinoblastoma (arrow) seen on computerized tomography scan.

oncologist affords bone marrow aspiration and biopsy along with lumbar puncture for the evaluation of tumor cells. With smaller tumors, the need for the routine use of these methods has been questioned.⁶¹ Bone marrow biopsy and lumbar puncture are often reserved for patients with neurologic abnormalities or evidence of extraocular extension. Given the possible hereditary component, parents and siblings should obtain DNA analysis to assist in genetic counseling. It is recommended that children at risk for familial hereditary retinoblastoma be screened until age 4 years to detect early disease.⁶²

THERAPY, PROGNOSIS, AND COMPLICATIONS

The goal of treatment is complete control of the tumor while preserving useful vision. Although enucleation was at one time extensively employed, recent advances in other treatment options yielding globe salvage rates of 66% to 78% have been reported.⁶³⁻⁶⁵ Currently, the mainstays of treatment are enucleation, laser therapy, cryogenics, radiation therapy, and chemotherapy. The visual prognosis is excellent in most cases. A study by Abramson and associates in children with bilateral retinoblastoma revealed visual acuity of 20/20 to 20/40 in 58%, visual acuity of 20/50 to 20/400 in 31%, and visual acuity worse than 20/400 in only 9%.⁶⁶ Five-year survival is greater than 90% after successful treatment of ocular disease when there is no evidence of metastasis.⁶⁷ If there is metastatic disease, the prognosis is quite poor.⁶⁸

ENUCLEATION

Enucleation is the treatment of choice only when the eye cannot be salvaged by other means of treatment. It is considered appropriate in eyes with large tumors (involving more than 50% of the globe); where there is no expectation for useful vision; and where long-standing retinal detachment, neovascular glaucoma, pars plana tumor seeding, anterior chamber or choroidal involvement, and optic nerve or orbital tumor extension exist.^{69,70} Care must be taken during the procedure to avoid penetrating the globe and to resect the greatest amount of optic nerve possible (usually more than 10 mm).

CHEMOREDUCTION WITH LOCAL TUMOR ABLATION

Local/systemic chemotherapy is used to reduce tumor volume to allow for more focused (and less-damaging) consolidative ablative therapies such as laser, cryotherapy, or radiotherapy in an effort to avoid enucleation and external-beam radiation therapy (EBRT). The appropriate regimen is debated; however, the current standard includes carboplatin, either etoposide or teniposide, and vincristine with or without cyclosporine. Chemoreduction has improved the ocular salvage rate. At 5-year follow-up, the globe salvage rate is 85% for Reese-Ellsworth groups I through IV and 47% for group V.⁷¹ More recent studies prove chemoreduction to be successful in treatment and avoidance of enucleation or EBRT without significant systemic toxicity in Reese-Ellsworth eye groups I, II, and III.⁷² More-effective methods of treatment are required for groups IV and V. Chemotherapy produces a mean decrease in tumor base by 35% and a nearly 50% decrease in thickness.⁷³ Although chemotherapy is effective at reducing tumor volume, it is not curative. Focal therapy is necessary for complete eradication.⁷⁰ It is extremely important to note

that all these chemicals are mutagenic and may contribute to the development of second tumors in patients with hereditary retinoblastoma.

LASER PHOTOCOAGULATIVE ABLATION

Laser therapy is used for small, posteriorly located tumors that are less than 4.5 mm in basal diameter and less than 2.5 mm in thickness. The current method employs direct confluent treatment with argon or xenon lasers over the entire tumor to coagulate the entire blood supply. There is a 70% tumor control rate and a 30% recurrence rate.⁶⁹ Complications include retinal vascular occlusions, retinal traction, retinal hole formation, and preretinal fibrosis.

CRYOTHERAPY

Similar to laser therapy, cryotherapy is used to treat small tumors that are less than 3.5 mm in basal diameter and less than 2.0 mm in thickness.⁶⁹ It uses a triple freeze-thaw technique under direct visualization. Most commonly, it is administered before chemotherapy to enhance the likelihood of cure. This procedure may be associated with rhegmatogenous retinal detachment.⁷⁰

THERMOTHERAPY AND CHEMOTHERMOTHERAPY

The use of heat alone for treatment of retinoblastoma is controversial. Heat has been found to have a synergistic effect with chemotherapy and radiation therapy.⁶⁹ It is useful for tumors in the posterior pole, within 6 mm of the fovea or optic disc, that are 6 mm or less in basal diameter and 3 mm or less in thickness.⁶⁹ Complete tumor regression is found in 86%; predictors of local tumor recurrence were male sex and previous use of chemoreduction (and therefore larger tumor).⁷⁴ Complications include focal iris atrophy, peripheral focal lens opacity, retinal traction, retinal vascular occlusion, and transient localized serous retinal detachment.⁷⁴

BRACHYTHERAPY (PLAQUE RADIOTHERAPY)

Brachytherapy is typically used for small-to-medium-sized tumors (less than 16 mm basal diameter and less than 8 mm in thickness) and also as a salvage therapy when the other globe-conserving strategies have failed. The use of intraoperative ultrasound can enhance local tumor control. Brachytherapy involves the placement of a radioactive implant over the base of the tumor to irradiate transclerally. The average length of treatment is 2 to 4 days. Overall, there is approximately 90% tumor control.⁷⁵ Given that the plaque therapy limits the radiation dose to periocular structures, the incidence of secondary radiation-induced malignancies may be lower than with EBRT. However, there is a higher incidence of radiation optic neuropathy and retinopathy. Visual outcome varies with tumor size and location, but it is considered good in 62% (visual acuity of 20/20 to 20/30 in more than half of the cases).⁷⁶

EXTERNAL-BEAM RADIATION THERAPY

Retinoblastoma tumors are responsive to radiation. The current standard of treatment for groups I, II, and III is chemotherapy plus local therapy as described previously. Groups IV and V require EBRT or enucleation. Current techniques involve megavoltage radiation treatments, often lens sparing, with 4,000 to 4,500 cGy over 4 to 6 weeks. The ocular salvage rate depends on the stage of the disease. The

Reese–Ellsworth criteria are employed to help determine the success of therapy based on the stage of the tumor (see Table 35.3). Group I has a very favorable prognosis of eye preservation when treated with external beam radiation, whereas group V has a very unfavorable prognosis. Nearly all children in groups I through IV will be cured of retinoblastoma using this technique; in group V, the cure rate is 85% to 90%.⁷⁷ Recurrence continues to be problematic; retinoblastoma typically recurs within the first 1 to 2 years after treatment. The potential side effects of radiation that limit its use are increased risk of secondary or independent primary malignancies in a population with germ-line alterations of a tumor suppressor gene in addition to radiation-induced cataracts, optic neuropathy, and vasculopathy or hypoplasia of bone and soft tissues. Overall, 58% of patients with hereditary disease receiving EBRT developed second malignancies compared to only 27% in the group not treated with radiation.⁵⁵ There is controversy over the role of prophylactic radiation in children with heritable retinoblastoma.⁶⁹

CHEMOTHERAPY

The role of systemic chemotherapy as monotherapy is controversial. Although systemic chemotherapy has not been successful in treating intraocular retinoblastoma, there has been some success in treating metastatic disease.^{78–80} Systemic chemotherapy may be considered when there is metastatic disease or extension into the optic nerve, choroid, or orbit. Concern exists over the leukemogenic and mutagenic effects of chemotherapy.

Metastatic Tumors of the Eye

Metastatic cancers of the eye and adnexa are now being recognized with much greater frequency as a result of earlier detection of malignancies and increasing patient survival. In fact, metastatic tumors are the most common malignancies to involve the eye and orbit.^{81–84}

It is therefore imperative that oncologists keep this diagnosis in mind when considering eye symptoms that may be experienced by their patients. Metastatic hematopoietic tumors that also commonly affect the eye are discussed in a subsequent chapter.

Epidemiology

In patients with known malignancy, 4.7% to 12% have been shown at autopsy to have involvement of the eye or orbit.^{83,85} Shields et al., in a study of 520 eyes, found that there is a gender difference in the incidence of ocular metastases. Women are affected two times as often as men.⁸⁶ After the identification of a metastatic tumor in the uvea or orbit, the prognosis for survival is uniformly bad, and few patients survive more than 1 year.⁸¹

Location

The most frequent site of metastases in the eye, orbit, and adnexa is the uveal tract, specifically the choroid, with the orbit being the second most frequent site. In children this is reversed, with the orbit the most common site. Freedman and Folk⁸⁷ reviewed 112 patients presenting with ocular and

orbital metastases who were evaluated clinically with modern methods and found that 56 had choroidal involvement, 49 had orbital involvement, and 5 had involvement of both sites. The remaining 2 patients had lesions involving the optic nerve and retina.

Tumor Type

In a large study performed by the Shields and their associates, the site or origin of globe metastases was evaluated. Breast (47%) and lung (21%) represented more than two-thirds of the primary tumor sites. There was a gender difference in tumor type. The three most common primary tumors in women were breast (68%), lung (12%), and gastrointestinal tract (2%). In men, 40% of primary sites were lung, followed by (and to a much lesser extent) gastrointestinal tract and kidney. In breast carcinoma metastases to the eye, 90% of the patients had a known history of breast cancer.⁸⁶ The figure was less than this for lung and renal tumors.

Presenting Symptoms

CHOROIDAL METASTASIS

According to Stephens and Shields, choroidal metastases most often present with blurry vision (80%); pain (14%); photopsias or flashes of light (13%); red eye (6%); floaters (6%); and visual field defects (3%).⁸⁴ Most often the tumors are flat, creamy, yellow choroidal lesions with overlying retinal pigment epithelial changes, specifically with breast metastases having a peau d'orange pattern of pigmentary changes.^{86,88,89} Oftentimes a small lesion can be associated with a relatively large serous retinal detachment. Multiple foci in one eye occur in approximately 20% of patients, and 20% to 40% of cases are bilateral.⁹⁰ Metastatic carcinomas grow rapidly and spread quickly. Often tumors develop in the second eye within 1 month after the diagnosis of a clinically unilateral tumor.⁹¹

ORBITAL METASTASIS

Orbital metastases may present with unilateral or bilateral symptoms of pain, periocular redness, double vision, or eyelid malposition. In addition, the patient or the patient's family might note a progressive bulging or sinking in of the eye. Examination of patients with orbital metastases may reveal periorbital inflammation, restricted extraocular movements, ptosis, lid retraction, exophthalmos, or enophthalmos.

Diagnosis and Workup

Workup of patients with suspected ocular or orbital metastases includes a detailed clinical history, review of systems, and physical examination. In addition, to further support the diagnosis of ocular metastases, fluorescein angiography can be employed. The typical staining pattern for choroidal metastases includes early hypofluorescence, followed by mottled fluorescence with pinpoint foci, and increasing hyperfluorescence late in the study.⁸⁸ Other useful imaging methods are ultrasonography (A scan and B scan) and MRI to look for transscleral extension or optic nerve involvement. Transocular fine-needle aspiration and wedge biopsy may be performed when noninvasive methods have failed to establish the diagnosis.

In a patient with suspected orbital metastasis, imaging studies and history alone can sometimes establish the diagnosis. For example, it may be unnecessary to perform a biopsy in a patient with known metastatic breast cancer who develops enophthalmos and has findings consistent with metastatic orbital carcinoma on MRI. In many situations, however, an orbitotomy with biopsy may be necessary to determine the site of the primary or determine the presence or absence of receptor sites or other features pertinent to decisions regarding therapy.

Pathology

The pathologic descriptions of primary tumors are provided elsewhere in this text. In general, metastatic lesions usually appear more anaplastic than the primary tumor. Oftentimes the tumor is so anaplastic that special immunohistochemical staining and/or electron microscopy is required to reach a diagnosis when the primary is undetected.

Treatment

A multidisciplinary team approach is required in the treatment of metastases to the eye. The ophthalmologist or oculoplastic surgeon is involved in identifying the tumor by examination or biopsy, defining the extent of the tumor, and monitoring its activity. In addition, the ophthalmologist can monitor changes in visual acuity, visual field, or orbital symptoms. Observation is acceptable for small, peripheral ocular lesions or lesions in terminally ill patients.⁸⁸ External-beam radiation is the most common method of treating uveal and orbital metastases.^{92,93} Many times this is combined with systemic chemotherapy, although both can be used alone as well. Other modes of treatment for choroidal metastases are brachytherapy, laser photocoagulation, local excision, and enucleation.

Visual acuity may remain quite good. Even in cases of vision loss, most patients show complete (26% to 50%) or partial (33% to 67%) return of their visual signs and symptoms.⁹⁴ Unfortunately, the prognosis for survival is very poor. The mean survival period is approximately 8 months.^{84,87,90-92} This period is increasing for breast cancer and now is reported to be 31 months.⁹⁰

The Phakomatoses

The term *phakomatosis* was originally described by Brouwer in 1917 and van der Hoeve in 1923 to classify hereditary diseases with tumorous growths arising in disparate organ systems, some of which have the potential for malignant transformation. The tumorous growths are classified as *hamartomas*, an abnormal proliferation of tissue normally present in the involved site, and *choristomas*, an abnormal proliferation of tissue not normally present at the involved site. The original three disorders characterized as phakomatoses include von Recklinghausen's neurofibromatosis; tuberous sclerosis (Bourneville's syndrome); and von Hippel-Lindau disease (cerebellar-retinal angiomas). All the original phakomatoses are inherited in an autosomal dominant fashion and have been linked to mutations in recessive tumor suppressor genes. Brouwer and Van der Hoeve

added a fourth disorder, Sturge-Weber syndrome, to the phakomatoses in 1937. Sturge-Weber syndrome, unlike the primary phakomatoses, has no established pattern of inheritance and can occur sporadically. There are several other disorders that have occasionally been included in the classification of phakomatoses: Wyburn-Mason syndrome; ataxia telangiectasia (Louis-Bar syndrome); linear nevus sebaceous syndrome; Klippel-Trenaunay-Weber syndrome; and encephalooculoangiomas.⁹⁵

Neurofibromatosis 1

Neurofibromatosis type 1 (NF-1), also known as von Recklinghausen disease or peripheral neurofibromatosis, is an inherited disorder of the neuroectoderm resulting in hamartomas of the skin, eyes, central nervous system, and viscera. These hamartomas increase in both size and number throughout life. Inheritance is autosomal dominant, with nearly 100% penetrance, with highly variable expressivity even among affected siblings.^{96,97} NF-1 occurs in approximately 1 in 3,000 to 5,000 of the population with no predilection for race or sex. The NF-1 gene has been mapped to the long arm of chromosome 17 (17q11.2).⁹⁸ The gene is large (more than 300 kilobases, kb) and therefore has a high rate of mutation, approximately 1 in 10,000 live births.^{96,97} Approximately 30% to 50% of cases arise from new mutations, typically paternal in origin.⁹⁹

The diagnosis of NF-1 is made when two or more of the following seven criteria established by the NIH are met:¹⁰⁰

1. Six or more café-au-lait spots greater than 5 mm in diameter in prepubescents or greater than 15 mm in diameter in postpubescents
2. Two or more neurofibromas of any type or one plexiform neurofibroma
3. Freckling of axillary, inguinal, or other intertriginous areas
4. Optic nerve glioma
5. Two or more Lisch nodules of the iris
6. A distinctive osseous lesion, such as sphenoid bone dysplasia or thinning of the long-bone cortex, with or without pseudarthrosis
7. A first-degree relative with NF-1 according to the preceding criteria

There are many abnormalities associated with NF-1: café-au-lait spots; axillary/inguinal freckling; pigmented iris nodules (Lisch nodules) (Figure 35.12); fibroma molluscum (nodular cutaneous/subcutaneous neurofibromas); plexiform neurofibromas of eyelid and orbit resulting in a characteristic S-shaped lid fissure; retinal and optic nerve gliomas; congenital glaucoma; and dysplasia of orbital bones resulting in pulsating exophthalmos. Mild mental retardation is present in approximately 45%.¹⁰¹ Café-au-lait spots, axillary freckling, and Lisch nodules are all melanocytic in origin, whereas neurofibromas are derived from Schwann cells.⁹⁷ There are also many hamartomas present in the central and peripheral nervous system and the gastrointestinal (GI) tract.¹⁰¹ It is important to note that malignant transformation is possible. There is a 3% to 15% lifetime risk of malignancy; these are most commonly neurofibrosarcoma and optic nerve gliomas.^{102,103}

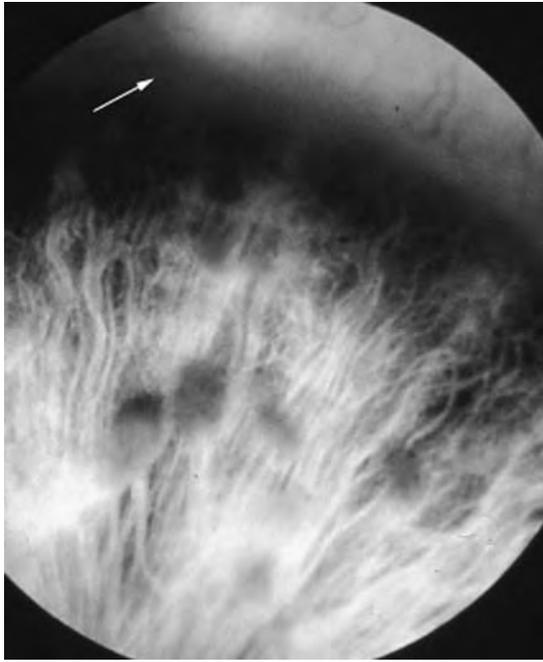

FIGURE 35.12. Lisch nodules on iris of patient with neurofibromatosis type 1. Limbus indicated by the arrow.

The most common presenting sign is the café-au-lait spot, a flat, hyperpigmented macule, which is present in 94% to 100% of affected adults.¹⁰⁴ Typically, a few lesions are present at birth, and they increase in size and number during the first decade of life. Histologically, there is hyperpigmentation of the basal cell layer secondary to a nonspecific increase in the number of dopa-positive melanocytes.^{105,106} On electron microscopy, giant pigment granules in the melanocytes known as macromelanosomes are found; this finding, however, is not specific for NF-1.¹⁰⁷ Axillary/intertriginous freckling is frequently seen and is relatively unique to NF-1. Although freckling is common in the general population, in contrast to NF-1, it does not occur in areas of skin apposition. The freckles seen in NF-1 generally appear in late childhood and are approximately 1 to 3 mm in diameter. The freckles are histologically similar to café-au-lait spots. Neither freckles nor café-au-lait spots have malignant potential.¹⁰⁵ Neurofibromas, in contrast, do have malignant potential.

There are three types of neurofibromas in NF-1: dermal neurofibromas (fibroma molluscum); nodular neurofibromas; and plexiform neurofibromas. Dermal neurofibromas can be widely distributed throughout the body and appear as pedunculated pigmented nodules. Histologically, they are composed of enlarged cutaneous nerves surrounded by a proliferation of Schwann cells and connective tissue¹⁰¹ (Figure 35.13). Appearing in late childhood and increasing in number throughout adulthood, they are present in nearly all patients with NF-1 and can cause severe disfigurement.⁹⁷ Nodular neurofibromas are similar to dermal neurofibromas, but they are only present in approximately 5% of patients with NF-1 and can occur in patients without the disease. They are firmer lesions with better defined margins located along deeper peripheral nerves. Plexiform neurofibromas occur in approximately 10% of patients and are pathognomonic for NF-1. They are extensive subcutaneous swellings of prominently enlarged nerves in

deeper nerve trunks. Plexiform neurofibromas are diffuse masses with indistinct borders that have extensive interdigitations and occasionally feel like a “bag of worms.” They are associated with surrounding hyperpigmentation and hypertrophy of underlying soft tissues and bone, leading to regional gigantism.⁹⁷ Gross pathology reveals a myxoid gelatinous appearance. Histologically, there is a thickened perineural sheath surrounding each enlarged nerve. Plexiform neurofibromas are often present at birth. They may develop in infancy or early childhood and may enlarge significantly over time, causing severe disfigurement. The upper eyelid exhibits a characteristic S shape when affected by a plexiform neurofibroma, and 25% of eyelid plexiform neurofibromas extend to involve the orbit.⁹⁷ When there is a neurofibroma of the upper lid in association with ipsilateral hemifacial hypertrophy, there may also be obstruction of the channels for aqueous outflow; approximately 50% of patients with plexiform neurofibromas develop glaucoma in the ipsilateral eye.^{97,101,108} Other mechanisms of congenital glaucoma in patients with neurofibromatosis include infiltration of the angle by a neurofibroma; closure of the angle secondary to neurofibromas thickening the ciliary body and choroid; and secondary fibrovascularization and synechial closure of the angle.¹⁰⁸ Nodular and plexiform neurofibromas in 1% to 4% of patients may undergo malignant degeneration with development of a neurofibrosarcoma.¹⁰⁹ This transformation is frequently accompanied by rapid tumor growth and pain.¹⁰³

Optic nerve gliomas are low-grade pilocytic astrocytomas typically presenting in the first decade of life. They occur in approximately 15% of NF-1 patients but are only symptomatic in 1% to 5%.^{97,110} Although usually considered to be benign tumors, optic nerve gliomas can behave as low-grade malignancies (Figure 35.14). If the glioma involves the optic chiasm, mortality is at least 50%. On CT or MRI imaging,

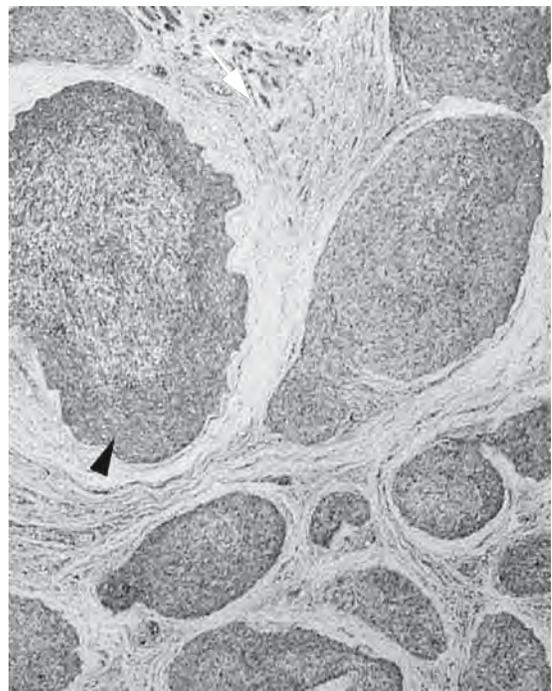

FIGURE 35.13. Enlarged cutaneous nerves (arrowhead) in a fibrous matrix (arrow) of a neurofibroma. 20 \times .

FIGURE 35.14. Proptosis and conjunctival chemosis secondary to optic nerve glioma.

optic nerve gliomas appear as cylindrical or fusiform enlargements of the optic nerve⁹⁷ (Figure 35.15). In general, because the great majority of optic nerve gliomas are self-limited with slow growth, the recommendation is for observation. If there is evidence of rapid progression, various treatment methods may be used, including surgical excision, radiotherapy, or chemotherapy.

Lisch nodules are the most common ocular finding (see Figure 35.12). Rarely present earlier than the age of 3 years, Lisch nodules occur in nearly 100% of affected adults. The number of nodules per iris increases with age.⁹⁶ The presence of Lisch nodules in a patient with café-au-lait spots confirms the presence of NF-1. Lisch nodules are melanocytic hamartomas of the iris pigment epithelium presenting as sharply demarcated, elevated, dome-shaped lesions with a gelatinous

FIGURE 35.15. Computerized tomography scan of optic nerve glioma (arrow) in patient in Figure 35.14.

appearance.⁹⁷ They typically arise from the anterior border of the iris and protrude into the anterior chamber, but they may also be located deep in the stroma.¹⁰¹ Histologically, they consist of uniform, spindle-shaped melanin-containing cells within the anterior layers of iris stroma and are similar to iris nevi.^{97,111}

Choroidal lesions are present in 30% to 50% of adults.^{112,113} These are flat, hyperpigmented, avascular proliferations with indistinct borders and are located in the posterior pole.⁹⁷ There may be single or multiple lesions. Histologically, these are composed of melanocytic and neuronal elements. A characteristic finding is layers of proliferated Schwann cell processes arranged in contact with axons (the ovoid body).^{114,115} The various ocular lesions of NF-1 typically do not produce symptoms or affect vision.

Less-common manifestations of NF-1 include enlarged corneal nerves (6%–22%),^{112,113} seizure disorder (3%–13%),^{97,116} scoliosis (10%); pseudoarthroses; and mild intellectual impairment. Of great concern is the association of NF-1 with certain malignant tumors: neurofibrosarcoma, optic pathway gliomas, Wilms' tumor, rhabdomyosarcoma, pheochromocytoma (5%),¹⁰¹ astrocytomas, and several types of leukemia.⁹⁷ There is also an association with juvenile xanthogranuloma and capillary hemangiomas. Patients with NF-1 have been stated to have an increased risk of uveal melanoma.¹¹⁷

Treatment of lid and orbital neurofibromas is surgical excision because the tumors are radioresistant. Surgical treatment improves cosmesis, but the lesions tend to recur.⁸⁹ Life expectancy is substantially reduced in patients with NF-1 secondary to systemic hypertension, expansive growth of intracranial neoplasms and associated cancers, sarcomas, leukemias, and lymphomas.¹¹¹

Neurofibromatosis 2

Neurofibromatosis type 2 (NF-2), or central neurofibromatosis, is an inherited disorder clinically distinct from NF-1, characterized by bilateral schwannomas of the eighth cranial nerve (frequently termed acoustic neuromas). The mode of inheritance is autosomal dominant with high penetrance, although it can occur sporadically.^{101,118} NF-2 is much less common than NF-1, occurring in approximately 1 in 50,000 live births.¹¹⁹ The gene has been mapped to an area near the center of the long arm of chromosome 22 and encodes for a cytoskeletal protein and a tumor suppressor gene.¹²⁰ Patients with NF-2 typically present in their teens to early adulthood with decreased hearing or tinnitus secondary to acoustic neuromas.

The characteristic acoustic neuromas become symptomatic with tinnitus, hearing loss, and balance problems around the second or third decade of life. There is a high rate of CNS spinal cord gliomas (67.4%); meningiomas (49.2%); and neurofibromas of the vestibular (98.4%) or optic nerve roots (4.8%).¹¹⁸ The gliomas are typically low-grade astrocytomas with little malignant potential, but they can result in disabling pain and neurologic deficits. The relentless progression of these gliomas can lead to loss of vision, paresis, and even death secondary to brainstem compression.¹¹⁹ Presenile cataracts are present in 67% to 85%; the majority are posterior subcapsular cataracts or cortical cataracts occurring before age 30.^{118,121} Other findings in NF-2 are optic nerve

meningioma (4.8%);^{118,119} epiretinal membranes;¹²² and retinal hamartomas (9%–21%)¹¹⁸ in the form of combined hamartomas of retinal pigment epithelium and retina¹²³ or bilateral retinal hamartomas.¹²⁴

Treatment options for vestibular schwannomas include surgical excision (total or subtotal), irradiation, and observation. Surgical excision is the preferred treatment, but it may be associated with perioperative complications, including loss of hearing in the operated ear, air embolism, intracranial hemorrhage, and stroke. Radiotherapy is reserved for patients unable or unwilling to undergo surgical excision.¹²⁵ As with NF-1, patients with NF-2 also have substantially reduced life expectancy secondary to growth of the CNS neoplasms.¹¹¹

Tuberous Sclerosis

Tuberous sclerosis (TS) is also an autosomal dominant disorder. It has been mapped to chromosome 9q34 and 16p13.3. Inheritance is autosomal dominant, with high penetrance but variable expressivity. However, at least two-thirds of cases occur as a result of new mutations.¹²⁶ Prevalence estimates range from 1 in 6,000 to 1 in 100,000. There is no racial or sex predilection. TS is characterized by benign tumor growth in multiple organ systems, specifically skin, brain, eye, heart, and kidney.

Gomez established criteria for the diagnosis of TS in 1979. This scheme included primary and secondary criteria. Diagnosis was made on the presence of one primary criterion or two secondary criteria. The primary criteria included facial angiofibromas, unguis fibromas, cortical “tubers,” subependymal hamartomas, and multiple retinal hamartomas. The secondary criteria included infantile spasms, hypopigmented macules, shagreen patches, single retinal hamartoma, bilateral renal angiomyolipomas or cysts, cardiac rhabdomyoma, or a first-degree relative with a primary diagnosis of TS.¹²⁷ The criteria for diagnosis of TS were updated in 1998. Currently, diagnosis of TS requires the presence of two major criteria or one major criterion along with two minor criteria. The major diagnostic criteria for TS include facial angiofibroma, nontraumatic unguis fibromas, three or more hypomelanotic macules, shagreen patch, multiple retinal nodular hamartomas, cortical tubers, subependymal nodules, cardiac rhabdomyoma, lymphangiomyomatosis, and renal angiomyolipomas. Minor criteria include multiple dental pits, hamartomatous rectal polyps, bone cysts, cerebral white matter radial migration lines, gingival fibromas, nonrenal hamartomas, retinal achromic patch, “confetti” skin lesions, and multiple renal cysts.^{128,129} The classic triad of TS (the *Vogt triad*) consists of epilepsy, mental retardation, and adenoma sebaceum (angiofibromas of the face). However, the *Vogt triad* is only present in about 30% of cases.¹³⁰

The most common neurologic symptom of TS is seizures, which are present in approximately 85% of patients. The seizures of patients with TS are usually infantile spasms or partial seizures with rapid secondary generalization. Mental retardation and autism are also common, affecting 50% to 60% of TS patients. Seizures and mental retardation are associated with benign periventricular brain tumors, astrocytic hamartomas, and “tuber”-like areas of sclerosis in the brain.¹²⁸

Adenoma sebaceum is one of the hallmarks of TS. Present in approximately 50% to 80% of cases, this is a reddish-brown

papular rash on the malar region of the face and on the chin.^{127,128} Frequently mistaken for acne, these lesions are actually angiofibromas that first appear in childhood and increase in number with age.¹³¹ The earliest skin finding is an “ash leaf” spot, a hypopigmented macule present in at least 90% of TS patients at birth or in early infancy.¹²⁷ This lesion is sharply demarcated in the shape of an ash leaf. Histologically, the spots have normal numbers of melanosomes, but they are smaller with decreased melanin. UV light may help to visualize the spots in lightly pigmented individuals. Another classic lesion is a shagreen patch, or collagenoma. Shagreen patches occur in about 20% to 35% of cases.¹²⁷ They are thickened, yellowish plaques of skin that typically appear in the lumbosacral area. Less common are café-au-lait spots, nevi, and fibromas.

Retinal phakomas are present in 50% of cases.¹³² These lesions are bilateral in 30% to 50%. Arising from the innermost layer of the retina, they are composed of nerve fibers and undifferentiated cells that appear glial in origin and are frequently referred to as astrocytic hamartomas. Phakomas rarely affect vision significantly. There are three distinct forms of retinal phakomas. One type occurs in young children and is translucent, gray-white in color, with a flat, smooth surface with indistinct margins in the nerve fiber layer. It is not calcified. The more common retinal hamartoma is calcified, giving the lesion a yellow-white, glistening appearance (Figure 35.16). The lesion is elevated, with sharply demarcated borders and an irregular surface, giving rise to the classic *mulberry* appearance. This type of lesion is occasionally referred to as giant drusen because it is located on or near the optic disc. A third type is intermediate between the first two, with a plaque-like appearance. Histologically, the retinal phakomas consist of elongated, fibrous astrocytes with small oval nuclei and long processes forming a meshwork and containing relatively large blood vessels.⁹⁵ The giant drusen may

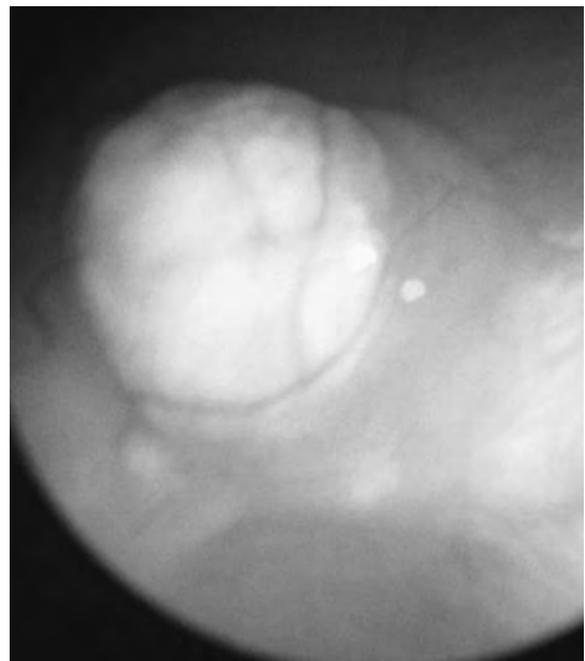

FIGURE 35.16. Retinal hamartoma as seen on indirect ophthalmoscopy.

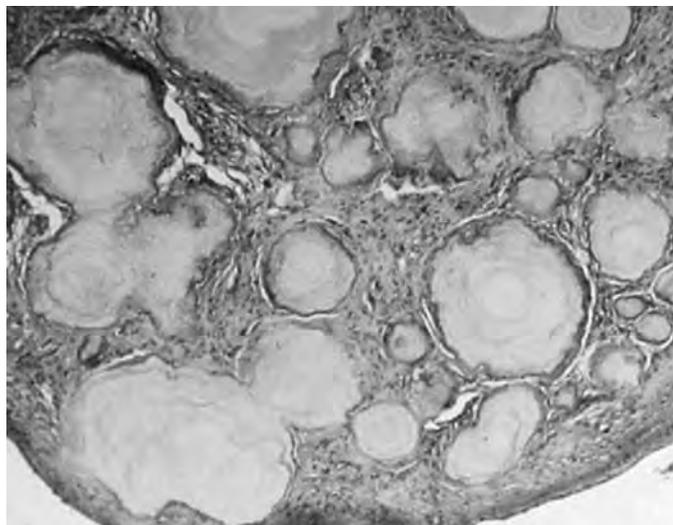

FIGURE 35.17. Giant drusen adjacent to optic nerve seen in retinal phakomas. 20 \times .

contain hyaline and calcium deposits (Figure 35.17). The retinal phakomatoses can be confused with retinoblastoma or a retinal detachment.

Currently, treatment is merely symptomatic. Patients undergo periodic physical examinations along with imaging modalities to identify potentially treatable conditions such as cardiac rhabdomyosarcomas, enlarging astrocytomas, or renal tumors. Life expectancy is substantially reduced in patients with TS, most commonly secondary to renal failure or problems from enlarging CNS tumors such as obstructive hydrocephalus.¹¹¹ Approximately 2% of patients with TS develop renal cell carcinoma.¹⁰⁹ Less-common causes of mortality include cardiac conduction defects, heart failure from cardiac rhabdomyoma, or pulmonary insufficiency from lymphangiomyomatosis of the lung.¹¹¹

von Hippel–Lindau Disease

von Hippel–Lindau (VHL) disease, also known as retinal angiomas, is an autosomal dominant disorder with irregular penetrance caused by germ-line mutations in the von Hippel–Lindau tumor suppressor gene, located on chromosome 3p25; 20% to 25% are familial cases. Incidence is approximately 1 in 36,000. There is no sex or racial predilection.¹¹¹ VHL disease is associated with multiple benign and malignant tumors of many organ systems: the central nervous system, eyes, kidneys (renal cell carcinoma), pancreas, liver, epididymis, and adrenal glands (pheochromocytoma). The origin of the lesions is primarily from the mesoderm, unlike TS and NF, which arise from the ectoderm.

The diagnosis of VHL was originally made only in individuals with both retinal and cerebellar hemangioblastomas, or with either entity alone if the patient had a positive family history. Melmon and Rosen expanded the diagnostic criteria in 1964 to include patients with any single manifestation of the syndrome complex, provided that a CNS hemangioblastoma had been proved in the family.¹³³

VHL is characterized by hemangioblastomas of the central nervous system, cerebellum, and retina. Hemangioblastomas are tumors composed of capillaries and lipidized stromal

cells. The most common abnormality is the Lindau tumor, a cerebellar hemangioblastoma. It is present in approximately 60% of cases; the majority are cystic, and 20% are solid.¹³⁴ Patients typically develop symptoms, typically headache or signs of cerebellar dysfunction, in their mid-thirties. The tumors are typically located in the lateral and posterior cerebellum and are clearly demarcated from surrounding normal tissue, making complete surgical removal possible. Twenty-five percent of patients develop renal cell carcinoma, and 75% of cases are bilateral: 5% by age 30, and more than 40% by age 60.^{134–136} The diagnosis of renal cell carcinoma associated with VHL occurs in the fifth decade of life, earlier than the sporadic form, which is diagnosed typically in the sixth decade of life. Three percent to 10% of patients develop pheochromocytomas, which are often bilateral. However, it appears pheochromocytomas are present only within certain families because these cases are typically clustered within few family groups. On electron microscopy, pheochromocytomas have predominantly norepinephrine granules with characteristic eccentrically located electron-dense cores. This histology differs from pheochromocytomas present in patients with multiple endocrine neoplasia 2 (MEN-2) syndrome, which have both epinephrine and norepinephrine secretory granules.¹³⁷ There are many other visceral disease manifestations: renal cysts or adenomas, pancreatic cysts, epididymal adenomas or cysts, hepatic cysts, or cystic lesions of the lung, adrenals, bone, omentum, and mesocolon.^{134,138} Unlike the other phakomatoses, VHL rarely has cutaneous manifestations, although café-au-lait spots, melanocytic nevi, and port-wine stains (nevus flammeus) can occur.

Ocular involvement occurs in nearly all cases of VHL. Ocular lesions are typically among the first VHL lesions to be diagnosed, occurring about 10 years before the cerebellar disease. Fifty percent to 60% develop retinal capillary hemangiomas.¹³³ These retinal angiomas are typically located in the peripheral fundus; they may be present at birth but are often not detected until the second or third decade of life. Thirty percent of cases have multiple tumors in one eye and 50% have lesions bilaterally.¹³⁹ Initially, the retinal lesions are focal collections of capillaries that appear clinically as small, reddish nodules that are flat or slightly elevated and associated with normal-sized vessels. They enlarge to form mature pink globular masses that are each characteristically supplied by a single, markedly dilated and tortuous artery and a similar-appearing venule running between the lesion and the optic disc. Histologically, retinal angiomas consist of relatively well-formed, thin-walled capillaries forming an anastomosing pattern that are separated by large nodules of plump vacuolated cells which contain birefringent material.¹⁰¹ Although these capillaries histologically appear well formed, they are leaky and lead to lipid accumulation in the subretinal space and retinal detachments. As a result, vision may be lost, and there may be secondary degenerative changes, including glaucoma or cataracts.

Early diagnosis and treatment are crucial for the preservation of vision, although there have been occasional reports of spontaneous regression of tumors that were left untreated. The typical course of untreated tumors is continued exudation beneath the retina, which leads to extensive retinal detachment along with neovascularization of the retina and iris, peripheral anterior synechiae, intractable secondary glaucoma, and phthisis.¹⁰¹

Treatment includes surrounding the angiomas with photocoagulation or cryotherapy.¹⁰¹ It is extremely important to examine all family members. The median age of death is 45 to 50 years of age secondary to associated renal and intracranial tumors.¹⁴⁰

Sturge–Weber Syndrome

Sturge–Weber syndrome (SWS), also known as encephalofacial or encephalotrigeminal angiomatosis, involves lesions of the eye, skin, and brain that are always present at birth.¹¹¹ Unlike the primary phakomatoses, SWS occurs sporadically. How often the entire triad of symptoms involving the skin, brain, and eye occurs in more than one family member is still unknown.¹⁰¹ SWS is apparently not familial and does not follow a clear pattern of genetic inheritance. In the few familial clusters described, patients do not have clear-cut autosomal inheritance as is seen in NF, TS, and VHL. The lesions of SWS result from an abnormality of the primordial vascular system during early embryogenesis, likely at 4 to 8 weeks, involving the development of the cephalic neuroectoderm, a neural crest derivative.¹⁴¹ The prevalence is unknown, and there is no racial or sex predilection.

The diagnosis of SWS established by Reese involves at least two of the following: facial hemangioma (port-wine stain) with ipsilateral intracranial hemangioma, ipsilateral choroidal hemangioma, or congenital glaucoma. The ipsilateral leptomeningeal vascular malformations result in multiple abnormalities: cerebral calcification, seizures, hemianopia, hemiparesis, or mental retardation.¹⁴²

The port-wine stain of SWS can be very disfiguring. It is well demarcated and consists of an abnormally large number of dilated, well-formed capillaries in the dermis. The lesion is deep purple in color and partially blanches with pressure. It typically follows the distribution of the first and second divisions of the trigeminal nerve and is located in the forehead and upper eyelid; it may also involve the lower eyelid and maxillary/mandibular regions¹⁴³ (Figure 35.18). If the lesion does not extend to the supraorbital portion of the face, there is no associated epilepsy or intracranial calcification.¹¹⁵ There may be hypertrophy of the underlying soft tissues and bone along with thickening of the affected skin. Histologically, the dermal angioma is composed of a flat to moderately thick zone of dilated, telangiectatic, cutaneous capillaries lined by a single layer of endothelial cells.¹⁴³

Leptomeningeal hemangiomas occur ipsilateral to the facial angiomas in the parieto-occipital region. They consist of a cluster of small, uniform-caliber venules. There is progressive calcification of cerebral blood vessels and cortical gyri. The characteristic calcium deposits in the brain parenchyma form after birth and are evident by skull radiographs at age 1, and also by CT scan, by the “railroad-track sign,” a curvilinear, double-contoured density that parallels cerebral convolutions that are most prominent in the occipital and temporal lobes. Mental retardation occurs in 50% of SWS patients with leptomeningeal hemangiomas and is secondary to maldevelopment and/or brain atrophy. Leptomeningeal angiomas are also associated with seizure disorders in approximately 83% percent of SWS patients.¹⁴⁴ The seizures are typically Jacksonian type on the side contralateral to the angiomas, and they frequently begin in infancy.¹⁴⁵ The seizures typically generalize with age, and

FIGURE 35.18. Port wine stain representing cavernous hemangioma involving the lower lid of a patient with Sturge–Weber syndrome.

patients may develop transient or permanent hemianopia or hemiparesis.¹⁴⁶

Choroidal hemangiomas located ipsilaterally to the facial angioma are present in 40% to 50% of SWS patients. They consist of increased numbers of well-formed choroidal vessels yielding a deep red coloration to the retina, called a “tomato catsup” fundus.¹⁴⁷ Histologically, choroidal hemangiomas consist of numerous large, thin-walled vascular channels that are lined by a flat layer of endothelial cells and divided by thin intervascular septa (Figure 35.19). This choroidal angiomatosis is typically asymptomatic in childhood. However, the choroid can become quite thick as the lesion enlarges, producing visual symptoms in adulthood. There is frequently progressive hyperopia as the lesion enlarges. Long-standing lesions cause destruction of the overlying choriocapillaris, degeneration of the retinal pigment epithelium with loss of photoreceptors, and cystoid degeneration of the outer surface of the retina with gliosis. A serous retinal

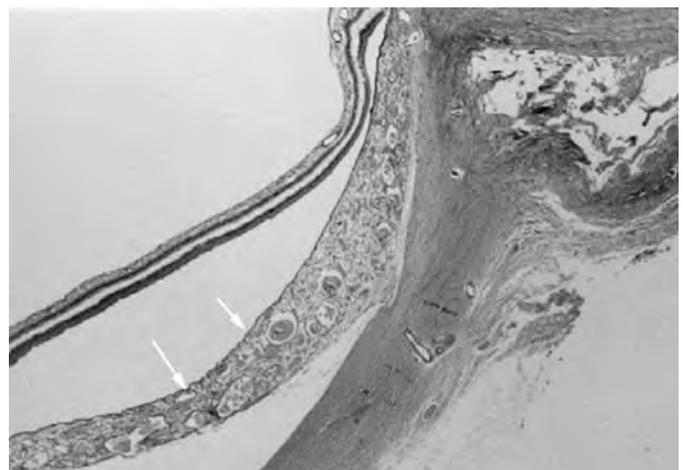

FIGURE 35.19. Choroidal hemangioma causing thickening of choroid (arrows) in a patient with Sturge–Weber syndrome. 10 \times .

detachment may occur and progress to total exudative retinal detachment, which can lead to severe secondary glaucoma.

Glaucoma occurs frequently, in 30% to 70% of cases, and is usually congenital, unilateral, and ipsilateral to facial angioma.^{143,148} Patients whose hemangiomas affect the upper eyelid are particularly susceptible to the development of glaucoma.¹⁴⁹ Of the patients with glaucoma, 60% develop buphthalmos (ocular enlargement) as a result of increased intraocular pressure. Forty percent of patients do not develop glaucoma until later in childhood and therefore do not exhibit buphthalmos. The typical mechanisms for glaucoma development are (1) occlusion of the anterior chamber angle by peripheral anterior synechiae (PAS), which frequently develops secondary to iris neovascularization in patients with retinal detachment, or (2) malformation of the anterior chamber angle, which leads to obstruction of aqueous humor outflow.¹⁰¹ Of note, some patients who develop glaucoma do not have either PAS or a malformed anterior chamber angle. Other ocular findings include a pinkish discoloration of the conjunctiva secondary to increased conjunctival vascularity, heterochromia iridis with the darker iris ipsilateral to facial angioma, and arteriovenous communications within the retina.

Treatment is generally symptomatic. Facial nevus flammeus may be treated with laser therapy to improve cosmesis. Occasionally, intractable seizures are treated surgically with subtotal hemispherectomy.¹⁵⁰ Life expectancy is reduced in patients with SWS. Most early deaths occur in patients with severe forms of the disease, including profound mental retardation and intractable seizures.

Ataxia-Telangiectasia and Wyburn-Mason Syndrome

Ataxia-telangiectasia and Wyburn-Mason syndrome are frequently considered among the phakomatoses, although they do not fit the original description. Ataxia-telangiectasia (AT) is characterized by cerebellar ataxia, telangiectasias, immune deficiency, and propensity to develop neoplasms. Its inheritance is autosomal recessive. Homozygous patients present in early childhood with symptoms of cerebellar ataxia that are progressive.¹⁴⁹ Neoplasms associated with AT include lymphocytic leukemia,¹⁵¹ medulloblastomas, and gliomas.¹⁵² Of note, patients who are heterozygous for AT also have an increased risk of cancer.¹⁵³

Wyburn-Mason syndrome (WMS) is characterized by arteriovenous malformations that are not distinct tumors, and the condition is therefore not a true phakomatosis. The retinal and ipsilateral CNS arteriovenous malformations (AVM) of WMS are congenital and progress with age.¹⁵⁴ There is no established hereditary pattern and no sex or racial predilection. No effective treatment is currently available for retinal AVMs. CNS AVMs can be managed with surgery or radiation.⁹⁵ Life expectancy is reduced secondary to intracranial bleeds from the AVMs and strokes related to their treatment.¹¹¹

Systemic Malignancies

It is important for the oncologist to be familiar with potential ocular complications associated with systemic malignancies. Patients may be referred from the ophthalmologist

for a systemic workup, or they may present to their oncologist with ocular symptoms that warrant a referral to an ophthalmologist. This section reviews the common and distinct ocular signs and symptoms associated with systemic malignancy.

There are two main mechanisms by which systemic malignancy can have ocular manifestations. (1) Certain genetic syndromes, such as Wilms' tumor, are associated with neoplasia and have eye findings. (2) Remote malignancies can produce paraneoplastic effects in the eye.

Aniridia

Although the term implies an absence of iris tissue, affected patients most commonly have some iris tissue. The amount of iris varies widely from minimal tissue present to minor defects in an otherwise normal iris. Aniridia is associated with Wilms' tumor in the "WAGR syndrome." Genitourinary abnormalities and mental retardation are the other components in the pneumonic WAGR. The syndrome is caused by an autosomal dominant mutation on chromosome 11p13,¹⁵⁵ the proximity of the WT-1 gene and the AN2 gene being responsible for the constellation of findings.¹⁵⁶ The AN2 gene is also responsible for other elements of ocular histogenesis, which explains the higher incidence of additional ocular findings such as peripheral corneal pannus, cataract, lens dislocation, foveal dysplasia, and optic nerve hypoplasia.^{157,158} Photophobia and nystagmus can also occur in Wilms' tumor patients.^{159,160} Glaucoma is present in 50% to 75% of patients with the autosomal dominant WAGR syndrome, but it does not normally appear until late childhood.¹⁶¹ In patients with sporadic aniridia, 25% to 33% develop Wilms' tumor.¹⁶²⁻¹⁶⁴

Atypical Congenital Hypertrophy of the Retinal Pigment Epithelium (RPE)

Inclusion of the term *atypical* is used to distinguish this entity from the more common congenital hypertrophy of the retinal pigment epithelium (CHRPE). In contrast to the latter, atypical congenital hypertrophy is typically bilateral. Multiple lesions are present, with larger lesions in the periphery and smaller lesions near the posterior pole of the eye. These areas of hypertrophy are typically black, but they can be non-pigmented and their shape can be round, oval, kidney shaped, or pisciform. From 1 to 30 lesions are seen per fundus quadrant.^{165,166} The areas of RPE hypertrophy are usually present at birth and are often the first manifestation of patients with the autosomal dominant syndromes familial adenomatous polyposis (FAP) and Gardner's syndrome.¹⁶⁷ These are syndromes in which thousands of precancerous colonic polyps develop at a young age. Please see elsewhere in this text for more details regarding these entities. There is a high concordance between the presence of these lesions and the development of Gardner's syndrome. Traboulsi and associates found atypical RPE hypertrophy in 90.2% of patients with Gardner's syndrome.¹⁶⁸ Further strengthening this connection is a study by Olea et al., which found that 100% of patients with a family history of FAP and five or more bilateral retinal lesions developed adenomatous polyposis.¹⁶⁹ For more information on FAP/Gardner's syndrome, please see the discussions elsewhere in this text.

Hyperplastic Corneal Nerves

Hyperplastic corneal nerves are observed with the biomicroscope as long, thin, linear opacities, running in various directions through the corneal stroma. They are a consistent finding in multiple endocrine neoplasias (MEN) type 2B;¹⁷⁰ however, they have also been described in 57% of patients with MEN type 2A.¹⁷¹ MEN syndromes develop as the result of a mutation of the RET gene on chromosome 10.¹⁷² The other ocular findings in MEN 2B include thickening and eversion of the upper eyelid margin and visible tarsal plates, large and prominent eyebrows, and neuromas of the eyelids and the conjunctiva.¹⁷⁰ MEN syndromes are discussed in detail elsewhere in this text.

Bilateral Diffuse Uveal Melanocytic Proliferation

Bilateral diffuse uveal melanocytic proliferation (BDUMP) is a rare paraneoplastic syndrome consisting of two striking findings in the eye: (1) multiple red patches in the posterior fundus that exhibit striking areas of hyperfluorescence on fluorescein angiography, and (2) multiple, slightly elevated uveal melanocytic tumors associated with diffuse thickening of the uveal tract.¹⁷³ These changes can produce vision loss, but when associated with retinal detachment or rapid cataract progression they produce a more swift and profound visual decline.

Machemer in 1966 reported the first case of a patient with bilateral uveal melanoma and pancreatic carcinoma.¹⁷⁴ The syndrome may occur slightly more frequently in females. Systemic tumors commonly associated with BDUMP are most commonly ovarian cancer in women and lung cancer in men. Multiple other malignancies, however, have also been associated with BDUMP, such as cancers of the colon, pancreas, gallbladder, breast, and esophagus.¹⁷⁵⁻¹⁸² No treatment has succeeded in arresting the visual field loss associated with BDUMP. Aggressive treatment of the underlying systemic malignancy offers the best hope for the patient's survival but may not prevent further visual loss.

Cancer-Associated Retinopathy

Cancer-associated retinopathy (CAR) is a retinal degeneration experienced by patients with systemic carcinomas. The visual decline can progress to complete blindness and may be rapid or prolonged over several years. Frequently, the visual symptoms of blurred vision, visual field defects, and impaired color vision are manifest before any cancer is diagnosed.

This syndrome has been most frequently recognized in association with small cell lung carcinoma, but it has also been observed with other types of cancer, including uterine cervical cancer, non-small cell carcinoma of the lung, infiltrating ductal adenocarcinoma of the breast, and undifferentiated endometrial carcinoma.^{183,184}

Funduscopy examination typically reveals narrowing of the arterioles, changes in the retinal pigment epithelium, and inflammatory cells in the vitreous. The electroretinogram is markedly diminished in all cases.^{183,184} Autoantibodies against recoverin, a 23-kDa calcium-binding protein expressed in rod and cone photoreceptors, are responsible for the changes seen in CAR. The gene for recoverin is located in close proximity to p53, and some tumors with elevated p53 expression might aberrantly express recoverin and induce the production of

antirecoverin antibodies as well as the activation of antirecoverin-specific T cells.¹⁸⁵⁻¹⁸⁷

Melanoma-Associated Retinopathy

Melanoma-associated retinopathy (MAR) has been seen in 17 patients with cutaneous melanomas.¹⁸⁸⁻¹⁹⁸ MAR is a retinal degenerative paraneoplastic syndrome that affects the bipolar cells of the retina, thus reducing the B wave on electroretinography.¹⁹⁹⁻²⁰³ The symptoms are normally less severe than those of CAR and include mild visual loss, night blindness, and shimmering or flickering light sensations.¹⁸⁸ Only one patient developed severe visual loss.¹⁸⁸ The B-wave reduction in the electroretinogram of MAR patients is most compatible with disorders in the neuronal transmission pathways beyond photoreceptor cells.

Ocular Flutter

Ocular flutter consists of episodic horizontal rapid eye movements without evidence of a slow phase. Each burst lasts only slightly longer than 1 second. It can coexist with saccadic dysmetria (inaccurate saccades) and opsoclonus (described in the next section). This eye movement abnormality, in the absence of known toxic-metabolic encephalopathy or encephalitis, should warrant workup, including cerebrospinal fluid analysis, MRI, and comprehensive search for occult malignancy.

Opsoclonus

Opsoclonus is defined as involuntary, arrhythmic, chaotic, irregular eye movements that are predominantly horizontal but can have vertical or oblique components. In children, opsoclonus can be related to neuroblastoma. In adults most commonly, opsoclonus is simply the sequela of a viral infection, but it has also been observed as part of a neoplastic process. Fourteen cases of adult opsoclonus associated with systemic carcinoma have been reported.²⁰⁴

Various types of cancer have been associated with opsoclonus, including undifferentiated lung carcinoma, oat cell carcinoma of the lung, uterine cancer, adenocarcinoma of the breast, and infiltrating ductal breast carcinoma.²⁰⁴ There is no sex predilection, and generally there is no prodromal illness. Removal or treatment of the primary tumor has resulted in improvement.²⁰⁵

Histopathologic analysis of some cases at autopsy has demonstrated a loss of cerebellar Purkinje's cells, and blood samples from patients with this syndrome have contained anti-Purkinje cell antibodies. Although opsoclonus can be associated with a variety of disease processes, it can herald the onset of an occult malignant tumor, and an extensive evaluation (including anti-Ri and ANNA-2 antibodies) must be made when it is observed in an older individual.

Eyelid Malignancies and Other Malignancies

Basal Cell Carcinoma

Basal cell carcinomas (BCCs) are tumors derived from a pluripotent stem cell within the basal epithelium that rests on the basement membrane separating the epidermis from

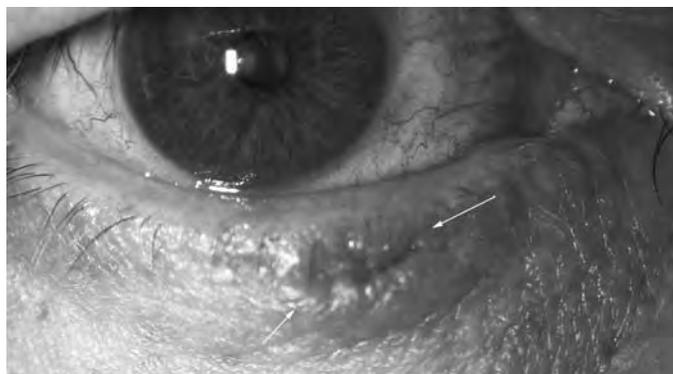

FIGURE 35.20. Basal cell carcinoma with typical pearly edges and excavated center occurring on lower lid.

the dermis. This type of tumor is also discussed in the chapter on skin disease. BCCs are the most common eyelid malignancy, accounting for 85% to 90% of malignant eyelid tumors.²⁰⁶ These most often occur in fair-skinned individuals; more than 99% of those affected are Caucasian.²⁰⁷ BCCs typically occur in older adults around the age of 60 but can occur in younger individuals as well. They have a predilection for males (2:1). BCCs arise in areas of sun-exposed skin, and the proposed etiology is actinic damage from ultraviolet light. In the area around the eye, they most commonly occur on the lower lid (50%–60%) followed by the medial canthus (25%–30%), upper lid (15%), and lateral canthus (5%).²⁰⁸

Their clinical appearance is that of a firm, raised, pink-pearly papule with a rolled translucent pearly border as the lesion increases in size. There are associated telangiectatic vessels, loss of lashes, and chronic conjunctivitis.

There are two major types of basal cell carcinomas: undifferentiated and differentiated. The subtypes of undifferentiated BCC include noduloulcerative, pigmented, morpheaform or fibrosing, superficial, and fibroepithelioma. The differentiated type of BCC includes adenoid (adenocystic) and basosquamous (metatypical). The most common form of BCC is the nodular type, accounting for 75% of all tumors. This

type is the classic pink-pearly papule that has overlying telangiectasia and develops a translucent rolled border as it increases in size (Figure 35.20). The pigmented form is similar to the nodular form, but the pigment results in a bluish, black, or brown discoloration. The pigmented BCC may be confused clinically with malignant melanoma. The morpheaform or sclerosing type, accounting for 15% of all BCCs, is aggressive and can invade deep into the dermis, paranasal sinuses, and orbit. Clinically, it is a poorly defined, pale, yellowish-pink, flat plaque with induration. The superficial and fibroepithelioma forms arise more frequently on the trunk than on the eyelids. The superficial form has an erythematous, scaly patch with raised pearly borders. Fibroepithelioma BCC is a smooth, pink nodule that is pedunculated or sessile.

The basic pathology of undifferentiated BCC includes nests, lobules, and cords with peripheral palisading and stromal retraction (Figure 35.21). The tumor cells have small, hypochromatic cells of uniform size with scanty cytoplasm yielding a characteristically high nuclear-to-cytoplasm ratio. Unlike the other undifferentiated forms, the morpheaform BCC does not typically have peripheral palisading. This type is characterized by intense stromal fibrous proliferation with tumor cells in narrow cords that are only one to two cell layers thick (see Figure 35.21). The differentiated types have a glandular structure with mucinous stroma and a histopathologic appearance somewhere between basal cell carcinoma and squamous cell carcinoma.

Diagnosis is made based on the clinical appearance and is confirmed by histopathologic examination of a biopsy. The differential diagnosis includes malignant melanoma, sebaceous cell carcinoma, squamous cell carcinoma, squamous cell carcinoma in situ, actinic keratosis, keratoacanthoma, seborrheic keratosis, papillomatous lesions, and blepharitis.²⁰⁹

The most effective method of treatment is Mohs' micrographic surgery. With this method, the lesion is excised in layers and mapped three-dimensionally.²¹⁰ The margins are carefully examined for residual tumor using frozen sections.

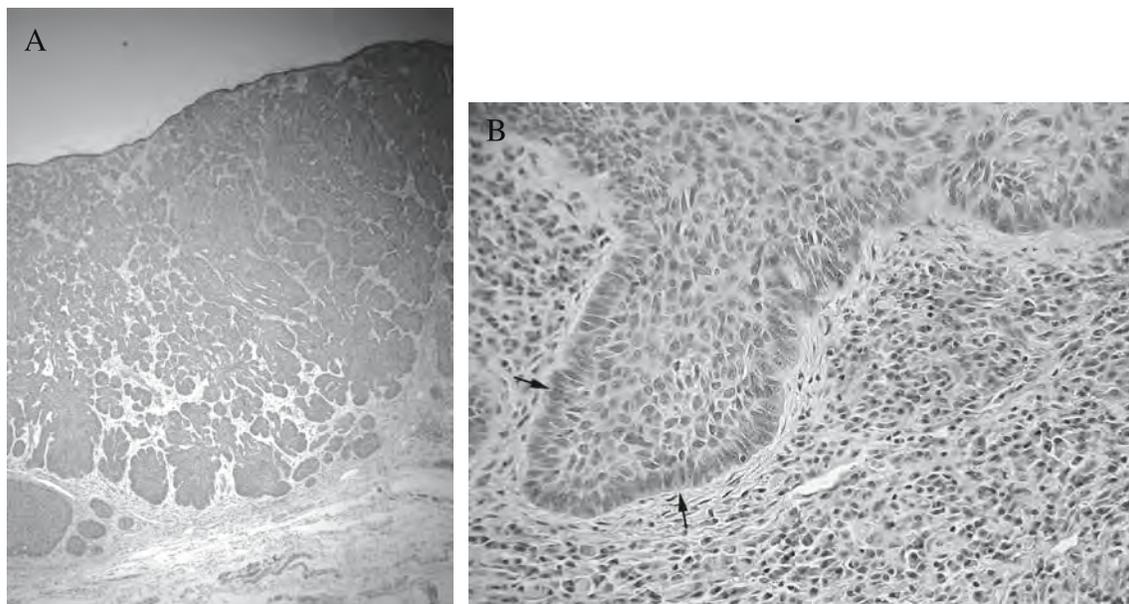

FIGURE 35.21. (A) Nodular basal cell carcinoma with characteristic dermal invasion. 2 \times . (B) Peripheral palisading of nuclei (arrows). 20 \times .

FIGURE 35.22. Hyperkeratotic plaque of squamous cell carcinoma involving the medial canthus. Note the erythema and irregular margins of the lesion.

Areas of residual tumor are identified, and the map is used to locate the areas for further excision until all the margins are free of tumor. One may also use a non-Mohs' technique of excision, also employing frozen section examination of margins to ensure that the tumor is completely excised. There are several other methods of treatment available, but they are generally not recommended for the periorbital region; these include radiation therapy, cryotherapy, chemotherapy, and photodynamic therapy.

Complete surgical excision of basal cell carcinoma is thought to be curative because the lesions rarely metastasize. Rates of metastasis vary from 0.028% to 0.55%,²¹¹ and, in fact, many pathologists believe that if metastases occur, then the primary tumor was not basal cell. Death secondary to basal cell carcinoma is very rare, but it can occur with direct orbital and intracranial extension.

There are a few associated systemic syndromes. The most common syndrome, occurring in less than 1% of individuals with BCC, is basal cell nevus syndrome, also known as Gorlin–Goltz syndrome. This syndrome is characterized by multiple BCCs, jaw cysts, plantar/palmar pits, skeletal abnormalities, neurologic abnormalities, and endocrine disorders. Other rare syndromes include albinism and xeroderma pigmentosa, which are inherited autosomal recessive disorders, along with nevus sebaceous, Bazex's syndrome, linear unilateral basal cell nevus, and Rombo syndrome.²⁰⁹

Squamous Cell Carcinoma

Squamous cell carcinoma (SCC) is another malignant tumor that commonly affects the eyelids. Although SCC is approx-

imately 40 times less common than BCC, it is more common on the upper eyelid and lateral canthus than basal cell carcinoma.²¹¹ Unlike BCC, SCC has a greater potential for metastatic spread. SCCs typically arise from actinic damage, but they can arise *de novo*. Risk factors for developing SCC include ultraviolet light, ionizing radiation, human papillomavirus, and arsenic ingestion. Systemic conditions with a propensity to develop SCC include xeroderma pigmentosa and oculocutaneous albinism, both inherited autosomal recessive disorders.

Clinical presentation reveals an erythematous, indurated, hyperkeratotic plaque or nodule that has irregular margins (Figure 35.22). The lesions typically ulcerate. As noted, SCC commonly affects the upper and lower eyelid margins as well as the medial and lateral canthi.

Histopathologic examination of SCC reveals polygonal cells with abundant eosinophilic cytoplasm and hyperchromatic nuclei with mitotic figures (Figure 35.23A). There may also be evidence of dyskeratosis (Figure 35.23B), keratin pearls, and intercellular bridges.²¹²

Diagnosis is made based on clinical appearance and confirmed by histopathologic examination of a biopsy. Differential diagnosis includes basal cell carcinoma, sebaceous cell carcinoma, squamous cell carcinoma in situ, actinic keratosis, keratoacanthoma, inverted follicular keratosis, seborrheic keratosis, verruca vulgaris, and papillomatous lesions.²⁰⁹

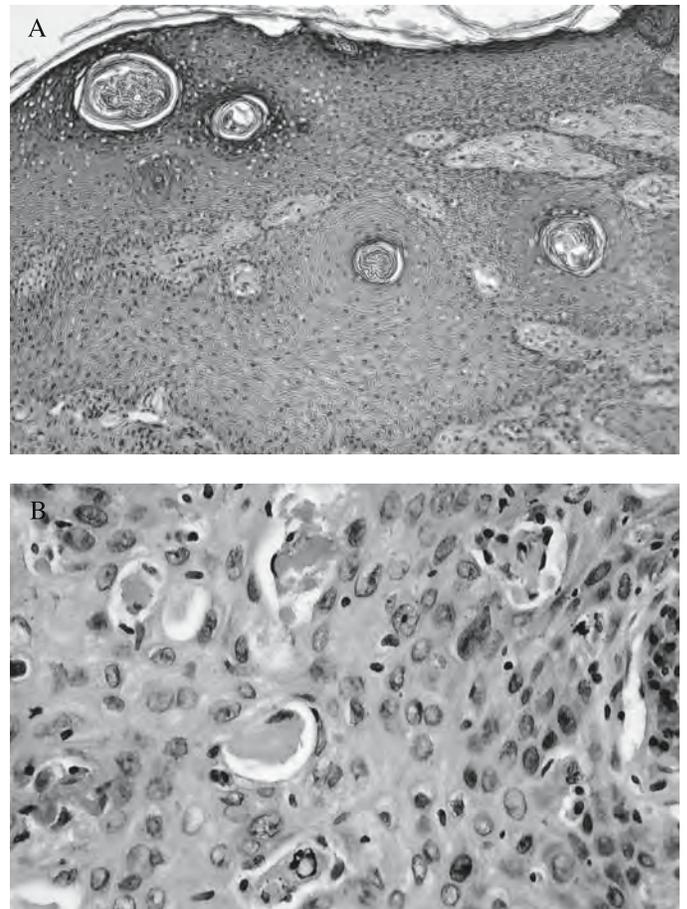

FIGURE 35.23. (A) Dermal invasion by squamous cell carcinoma. 4 \times . (B) Dyskeratosis in squamous cell carcinoma. 40 \times .

Treatment for SCC is similar to treatment for BCC. SCC is more aggressive and invasive, but SCC lesions of the eyelid rarely metastasize. Methods of treatment include Mohs' micrographic surgery, irradiation, and cryotherapy. More-extensive surgery may be needed for local control, such as orbital exenteration, if the tumor is deeply invasive.

As with BCC of the eyelid, SCC of the eyelid treated with wide local surgical excision is considered curative; however, metastasis can occur to the preauricular or submandibular lymph nodes, which would yield a guarded prognosis. For further discussion of SCC, including Broder's grading scale, see Chapter 60.

Sebaceous Gland Carcinoma

Sebaceous gland carcinoma (SGC) arises most commonly from the meibomian glands and less frequently from the glands of Zeis and the sebaceous glands of the caruncle and eyebrow. This is a highly malignant, aggressive tumor that has a high rate of metastasis, a high recurrence rate, and a relatively high mortality rate. It is the third most common eyelid malignancy after BCC and SCC but accounts for only 1% to 5.5% of all eyelid malignancies.²¹³⁻²¹⁵ It occurs more frequently in women. Typically presenting in the sixth to seventh decade of life, it can also occur in younger individuals. The etiology is currently unknown. SGC most frequently affects the upper eyelid, with this being the site in approximately two-thirds of all cases. Nonetheless, it can occur in any periocular site. SGC invades overlying epithelium. In about 50% of cases, it may display pagetoid spread, forming nests of cancer cells. It may behave as an intraepithelial carcinoma with diffuse spreading and replacement of the conjunctiva.²⁰⁹ The primary lesion may spread to other periocular structures, including the conjunctiva, cornea, lacrimal system, or nasal cavity.

The clinical appearance is often that of a firm, yellow nodule similar to a chalazion with possible thickening of the tarsal plate, destruction of meibomian gland orifices, and loss of eyelashes. It is considered to be one of the "masquerade syndromes" because it may mimic chalazion, meibomianitis, or chronic blepharconjunctivitis, which are refractory to usual therapy.

Because it is uncommon and mimics many other conditions, SGC may be difficult to diagnose. A high index of suspicion is required when lesions do not respond to standard therapies. Diagnosis is confirmed by full-thickness wedge biopsy of the eyelid. Evaluation of the extent of spread may require a sampling of other local structures, given the propensity of this cancer for multicentric spread. Fresh tissue should be submitted for special lipid staining.²¹¹

Histologically, SGC has highly pleomorphic cells in irregular lobules or nests with hyperchromatic nuclei and a characteristic vacuolated (frothy) cytoplasm secondary to the high lipid content within the cell (Figure 35.24). There are four histologic variants: lobular, comedocarcinoma, papillary, and mixed. On staining for lipids, the cells are found to have fine lipid globules.²⁰⁹ Given that SGC may exhibit pagetoid spread of malignant cells, the histologic differential diagnosis includes clear cell carcinoma, squamous cell carcinoma, malignant melanoma, and extramammary Paget's disease.²¹⁶

Diagnosis is made on the basis of clinical suspicion confirmed by histopathologic examination of a biopsy. Differen-

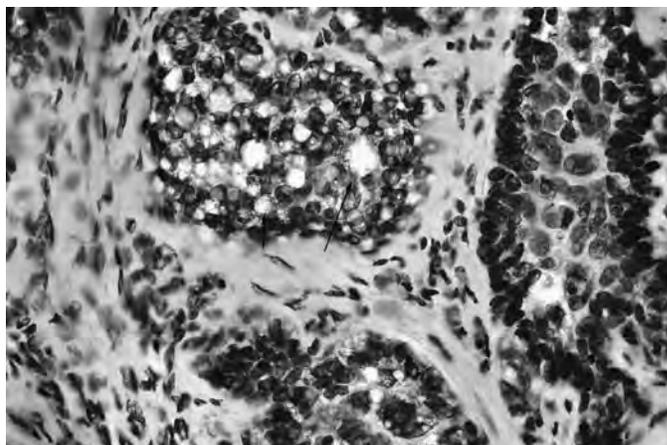

FIGURE 35.24. Sebaceous cell carcinoma with frothy cytoplasm (arrows) of tumor cells. 40 \times .

tial diagnosis includes basal cell carcinoma, squamous cell carcinoma, papillomatous lesions, blepharitis, conjunctivitis, and superior limbic keratoconjunctivitis.²⁰⁹

Treatment for SGC is similar to treatment for BCC and SCC with Mohs' micrographic surgery; this consists of wide excision with microscopic monitoring of the margins. However, given the likelihood of multicentric spread, this treatment is not always successful. If the tumor is large or involves deep orbital tissues, or if there is evidence of metastasis, a more-complex treatment plan is needed with possible orbital exenteration and radiation. The rate of mortality is 0% to 15% with no evidence of metastasis; with distant metastasis, the mortality rate rises to 50% to 67% at 5 years.¹³² Although traditionally considered to be radioresistant with radiation reserved only for palliation, there has been some recent success reported with radiation therapy of greater than 55 Gy.^{216,217}

Melanoma and Other Eyelid Malignancies

Briefly, malignant melanoma is more common in fair-skinned individuals. The major risk factor for developing malignant melanoma is a history of severe sunburns. Other risk factors include family history, Caucasian race, age over 20 years, congenital/dysplastic nevi, changing moles, or excessive sun exposure/sun sensitivity.²¹⁸ It causes only 1% of eyelid malignancies; however, it is responsible for two-thirds of all tumor-related deaths from skin cancers.²⁰⁹ Pathology reveals diffuse hyperplasia of atypical melanocytes throughout the basal cell layer; there may be a mixture of epithelioid, spindle, and nevus-like cells. Treatment involves wide surgical excision leaving a 1-cm tumor-free margin. Metastatic evaluation should be performed if the tumor is greater than 1.5 mm in depth or shows evidence of lymphatic/vascular spread. For a more complete discussion, including staging, course, and outcome, see Chapter 59.

Other eyelid malignancies, which are quite uncommon, include Kaposi's sarcoma, Merkel cell tumor, mucinous sweat gland adenocarcinoma, adenocarcinoma of the gland of Moll, and metastasis.

Head and Neck Cancer

Ezra E.W. Cohen, Kerstin M. Stenson,
Michael Milano, and Everett E. Vokes

Cancers of the head and neck include a variety of tumors of different histology and behavior. The different subtypes represented by these tumors include squamous cell cancers, paranasal sinus cancers, nasopharyngeal carcinomas, salivary gland cancers, thyroid gland malignancies, melanomas, sarcomas, small cell neuroendocrine carcinoma, and lymphomas. By far the most commonly encountered cancers in this group, accounting for more than 90% of tumors, are the squamous cell carcinomas of the oral cavity, oropharynx, hypopharynx, larynx, and paranasal sinuses. This chapter concentrates on squamous cell carcinoma of the head and neck (SCCHN), nasopharyngeal carcinoma (NPC), and cancers of the salivary glands.

The annual worldwide incidence of head and neck cancer is approximately 500,000, whereas, in the United States, approximately 40,000 new cases are diagnosed annually.^{1,2} Cancer of the head and neck accounts for 3% of all cancers in incidence in the United States and is the eighth most prevalent and deadly malignancy worldwide.^{1,3} SCCHN is more common in individuals over the age of 60, in males, and in lower socioeconomic groups. These differences likely parallel the most common environmental risk factors (see following). Despite progress in diagnosis, staging, and therapy of these cancers over the past several decades, the 5-year overall survival rate remains essentially unchanged at 50%. These mortality rates are influenced by competing causes such as cardiac and respiratory disease and second primary tumors to which these individuals can be susceptible.^{4,5} Nevertheless, significant developments have occurred on many fronts in the management of head and neck cancer, driven by evidence from laboratory-based and clinical research.

Squamous Cell Carcinoma

Etiology and Epidemiology

ENVIRONMENTAL RISK FACTORS

There are well-recognized risk factors for SCCHN (Table 36.1), with tobacco and alcohol being the two most significant. In fact the use of these agents parallels endemic areas of SCCHN incidence such as France, Southeast Asia, and the Indian subcontinent.⁶ The form of tobacco use varies with culture, but all have been associated with a higher risk of developing SCCHN. The relative risk does increase with the quantity and time of tobacco exposure, with rough estimates

of 10 to 20 times greater relative risk.⁷⁻⁹ In addition, although SCCHN is associated with heavy alcohol consumption without concurrent tobacco use (approximately 5 times greater risk), the dual exposure seems to increase risk synergistically up to 100 times compared with nonexposed individuals.¹⁰ It is unclear whether second-hand smoke increases risk, although some studies have reported a 2- to 3-fold increased risk.¹¹

Betel quid or areca nut chewing is practiced in many parts of Asia, although the habit is becoming less common. There are several variations of the habit depending on region, but overall, it does appear to increase risk of SCCHN, especially of the oral cavity, although odds ratios vary widely with the population studied.¹² The combination of tobacco smoking, alcohol, and betel quid chewing is especially dangerous and can increase risk of oral cancer significantly.¹²

FIELD CANCERIZATION

The concept of field cancerization is an important one in SCCHN as the foremost risk factor for the disease, tobacco, results in exposure of the entire upper aerodigestive tract. The hypothesis, first described in 1953,¹³ contends that environmentally related malignancies develop in a tissue that is exposed to the implicating carcinogen. Because the entire tissue is exposed, metachronous or simultaneous cancers can develop in different parts of the tissue. The upper aerodigestive tract serves as a model for this hypothesis, as evidenced by molecular derangements found in normal-appearing mucosa of SCCHN patients, the high incidence of second SCCHN primary tumors, and the high incidence of lung and upper esophageal malignancies in these patients. In fact, investigators have been able to establish clonality between second lung or esophageal tumors and the original SCCHN.^{14,15} The occurrence of second cancers in this patient population accounts for a significant cause of mortality, with annual incidence rates of approximately 5%.

VIRAL AGENTS

Despite the strong association of tobacco and alcohol consumption with SCCHN, approximately 25% of patients have had no significant exposure to these carcinogens. The human papillomavirus (HPV) has been implicated in cancer of other sites including the uterine cervix, and in the early 1980s pathologists began noting morphologic changes in SCCHN that were reminiscent of HPV exposure.¹⁶ Thus, it was hypothesized that HPV may play an etiologic role in a subset

TABLE 36.1. Risk factors for squamous cell carcinoma of the head and neck (SCCHN).

Environmental	Tobacco (smoking, chewing) Alcohol Betel quid chewing
Infectious	Human papilloma virus (oropharynx) Epstein-Barr virus (nasopharynx) <i>Candida albicans</i>
Genetic (e.g., Fanconi anemia, Li-Fraumeni syndrome)	
Ultraviolet or ionizing radiation	
Poor oral health	

of SCCHN patients. Several reports have now confirmed the presence of HPV DNA in SCCHN tissue samples,¹⁷ and a recent meta-analysis examining 94 studies including 4,680 specimens revealed that, compared to normal oral mucosa, HPV was 2 to 3 times more likely to be detected in precancerous mucosa and 4.7 times more likely to be detected in oral carcinoma.¹⁸ Although there are more than 100 known types of the virus, HPV 16 has been most consistently linked with SCCHN.¹⁹

Studies have begun to define a subset of SCCHN patients in whom HPV may be the etiologic agent.^{17,20} This subset is composed of oropharyngeal cancers, specifically palatine and lingual tonsil and base of tongue, younger patients, non-smokers, and nondrinkers. The molecular biology of these cancers appears also to be different in that they are less likely to contain inactivating mutations of p53^{17,20,21}; this may be due to the ability of the HPV E6 gene to inactivate p53, a necessary step during infection and propagation of the virus. In addition, several reports have also suggested that HPV-positive tumors tend to have a better prognosis compared to their non-HPV-containing counterparts.¹⁷ To date there are few data supporting an etiologic role of other viruses in SCCHN, with the exception of Epstein-Barr virus (EBV) and NPC (see following).

Molecular Biology

Studies have shown that SCCHN harbors common molecular derangements including chromosomal, epigenetic, and specific protein alterations. Deletion of specific chromosome arms is often found including loss of 3p, 5q, 8p, 9p, 17p, 18q, and 21q.^{22,23} Chromosomal deletions that appear to be particularly common, especially in precancerous lesions, are 9p21, 3p21, and 17p13. Genes of interest in these areas include p16 (9p21), FHIT and RASSF1A (3p21), and p53 (17p13).²⁴⁻³⁰ Meanwhile, by using comparative genomic hybridization investigators have commonly observed amplification of 3q, 5p, 11q13, and 19q.³¹⁻³³ Of these, 11q13 contains a number of oncogenes including cyclin D1, which has been shown to be overexpressed in 40% to 60% of SCCHN.^{34,35}

High expression levels of the epidermal growth factor receptor (EGFR) and its primary ligand, transforming growth factor- α (TGF- α), have also been observed in SCCHN and form an autocrine loop spurring tumor growth and survival.^{36,37} Expression of EGFR has been linked with poorer survival in patients undergoing surgery or radiation.^{36,38} There is also evidence that the EGFR pathway contributes to angiogenesis and metastasis of SCCHN tumors.^{39,40} Other oncogenes that have been linked with worse outcome in SCCHN

include the eukaryotic initiation factor 4E (eIF4E),⁴¹ cyclooxygenase 2,⁴² and p63.⁴³ Hypermethylation, the addition of methyl groups to CpG islands in the promoter region of a gene, is commonly observed in the context of specific genes in SCCHN,⁴⁴ including p16,^{29,45,46} E-cadherin,⁴⁷ O-6-methylguanine-DNA-methyltransferase (MGMT),^{45,47} and death-associated protein (DAP) kinase,^{45,47} resulting in their silencing.

By comparing the pattern of gene expression in normal, precancerous, and cancerous tissue, investigators have created an hypothetical model of SCCHN tumorigenesis.⁴⁸ It appears that deletion of 3p and 9p are relatively early events, followed by deletion of 17p, inactivation of p16, and overexpression of cyclin D1. Mutation of p53, deletion of 10q, 13q, and 18q, and other aberrations occur later in the progression model. It is important to note that the exact sequence of events is not universal or necessary and that any lesion causing genetic instability is more likely to progress to the malignant state.

Recent evidence highlights the significance of genetic instability in SCCHN development. DNA aneuploidy, even more than grade of dysplasia, appears to be a reliable predictor of subsequent development of carcinomas in lesions of the oral cavity including leukoplakias and erythroplakias.⁴⁹⁻⁵¹ In fact, lesions with aneuploid DNA predicted a higher recurrence rate and mortality rate from SCCHN.

Although not associated with a single molecular event, angiogenesis is implicated in the development of every solid tumor and SCCHN is not excepted. Several proangiogenic factors including interleukin 8,⁵² basic fibroblast growth factor,⁵³ platelet-derived growth factor,⁵⁴ and vascular endothelial growth factor (VEGF)^{55,56} are secreted in SCCHN. Angiogenesis has been shown to be essential to development of early lesions and is often associated with a higher recurrence rates, distant failure, and poor survival.

Diagnosis

The great majority of SCCHN patients are diagnosed with locoregional disease, whereas only 10% of patients present with metastatic disease, usually to the lungs or bone.⁵⁷ The initial spread of SCCHN is to regional lymph nodes and is usually predictable based on anatomic drainage patterns (Figure 36.1). Patients often present with local symptoms including pain, dysphagia, and odynophagia. Specific symptoms depend on the location of the primary tumor and lymph node metastases and can include otalgia, loose teeth, poor tongue mobility, speech impairment, and hoarseness. Cranial nerve deficits are uncommon in locoregionally advanced SCCHN, with the exception of NPC and salivary gland tumors.

Clinical suspicion is confirmed by pathologic examination, which includes grading of the tumor as well-, moderately, or poorly differentiated carcinoma. Although this descriptive system is applied to almost all cases of SCCHN, tumor grade has little influence on prognosis and management.

The diagnostic evaluation also includes radiologic imaging of the head and neck, usually by computed tomography (CT) scanning. Additional studies can include panoramic radiographs if mandibular invasion is suspected and magnetic resonance imaging if CT scanning is inadequate, although these studies are often complementary. A

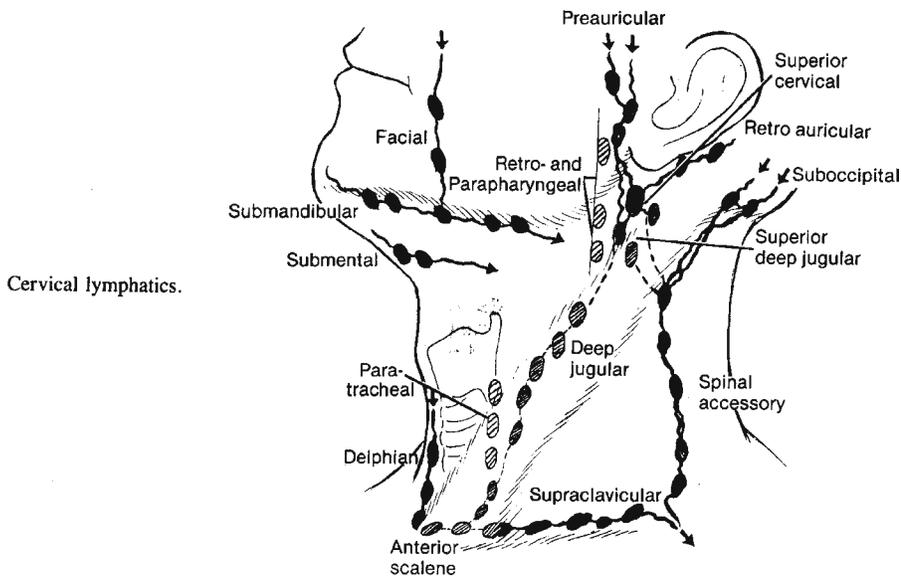

FIGURE 36.1. Cervical lymph node drainage of the head and neck. (Adapted from Cummings et al.,¹⁷² by permission of *Otolaryngology—Head & Neck Surgery*.)

determination of baseline swallowing function is usually performed by videofluoroscopy.⁵⁸ CT scanning of the chest is often also performed, especially if advanced neck nodal spread is encountered. This practice, however, has not been tested in clinical trials, although it appears prudent to exclude metastatic disease in stage III, IVa, and IVb patients.

A subset of patients, approximately 2% to 9% of SCCHN cases, present with an expanding cervical lymph node metastasis without an obvious primary tumor.⁵⁹ When a primary site is found it is often of the oropharynx, especially the tonsil and base of tongue, likely secondary to the extensive lymphatic supply to this region, allowing early nodal spread. Often a careful clinical examination followed by radiographic tests reveals the location of the primary tumor. Occasionally patients require random biopsies of the base of tongue, pyriform sinus, and nasopharynx, or bilateral tonsillectomy depending on the location of cervical nodes. The availability of fluorodeoxyglucose positron emission tomography (FDG-PET) scanning does not appear to aid significantly in the diagnostic evaluation, allowing detection of the primary tumor in a small minority of cases.⁶⁰ For patients in whom the primary tumor is never found, the approach to treatment in these instances varies and randomized trials are lacking.⁶¹ Neck dissection followed by extensive radiation including bilateral neck and mucosa appears to reduce local recurrence and improve survival, especially in advanced nodal disease (N2 or higher).⁶¹

Staging

Staging of SCCHN is based on the tumor-node-metastasis (TNM) system, which forms the single most important determinant of therapy and prognosis, making accuracy paramount. Specific staging varies with location of the primary tumor; however, some generalizations can be made across disease sites with NPC being the notable exception (see following). T4 implies that the primary tumor has invaded adjacent soft tissue or bony structures. Nodal staging is classified by the size and of involved lymph nodes, and N2 stage is further divided into N2a (one lymph node between 3 and

6 cm in diameter), N2b (two or more ipsilateral lymph nodes less than 6 cm in diameter), and N2c (contralateral lymph nodes less than 6 cm in diameter). Of note in the staging system is that stage IV does not necessarily imply distant disease. In fact, stages IVa and IVb are still confined to locoregional involvement and only stage IVc indicates metastatic disease. Across tumor sites, T4 tumors tend to have higher local failure rates whereas N2 and N3 tumors are prone to distant failure.

Therapy

MODALITIES

SURGERY

The Role of Endoscopy Patients with head and neck cancer are more likely to develop second primary cancers than any other group of patients with malignancies. In addition, the development of second primary tumors is the most common cause of posttreatment failure after 3 years, with an annual rate of development of 2.7% to 4% per year.⁵ Panendoscopy (laryngoscopy, esophagoscopy, bronchoscopy) is typically completed during primary site tumor staging and has been appraised by many surgeons in terms of its ability to detect second primaries. The overall second primary incidence ranges from 13.5% to 16.2% (2.6%–6.4% synchronous and 8%–9.8% metachronous).^{62,63} Lung and head and neck were the most common sites of second primary tumor, followed by esophageal primary. The role of prospective panendoscopy, as a means to detect second primaries at an earlier stage, has also been studied.⁶⁴ A 2.5-fold-improved yield of metachronous tumors was seen for patients undergoing prospective panendoscopy. Routine panendoscopy remains controversial in terms of cost-effectiveness. Nonetheless, many head and neck surgeons view panendoscopy as a low-risk procedure that may greatly influence treatment decisions.

Control of Primary Site Control of the primary tumor site, regardless of modality or stage, is paramount. Local

primary site failure is highly correlated with ultimate treatment failure and decreased survival. Complete wide surgical resection with adequate margins is critical when surgery is employed as primary therapy. Resected tumors with margins less than 5 mm are as likely to locally recur as a frankly positive margin.⁶³ Intraoperative methods to assess margin status have received attention recently. Portugal et al. prospectively studied 50 consecutive patients undergoing surgical resection of various head and neck primaries.⁶⁵ The authors applied toluidine blue, a dye that binds to nuclear material of early malignant lesions, to the remaining in situ mucosa. The toluidine blue identified a positive margin in 3 cases, which was confirmed by frozen and permanent pathologic analysis. In addition, three cases of second primary tumors were identified with this staining technique.

Postoperative techniques of assessing surgical margins have focused on application of immunostaining to paraffin-embedded mucosal margins. Ball et al. immunostained surgical margins from 24 patients with oral cavity/oropharyngeal carcinomas for abnormal p53 (tumor suppressor gene) protein.⁶⁶ There was a 5.33-fold-higher chance of local recurrence with at least one surgical margin p53 positive by sample odds ratio test. Nathan et al. evaluated the histologically free tumor margins of 52 tumor specimens for presence or absence of eIF4E, p53, and MMP-9.⁶⁷ The authors found that overexpression of eIF4E occurred in 98% of tumors and that eIF4E was a significant predictor of recurrence and disease-free interval.

The head and neck surgeon may find that the measured in situ margin differs from that reported by histopathologic measurement. Johnson et al. quantified the change in muscle and mucosal margins after resection, fixation, and slide preparation of simulated mucosal tumors in 10 mongrel dogs.⁶⁵ They found that mucosal and muscle margins shrunk significantly, 30% to 47%. The greatest proportion of shrinkage occurred immediately after resection. To obtain a 5-mm margin, the surgeon must have an in situ margin of at least 8 to 10 mm.

THE CLINICALLY NEGATIVE NECK

The hallmark of advanced (stage III or IV) head and neck cancer when associated with a small (T1 or T2) primary is the presence of a metastatic cervical node. Although there are several radiographic methods of detecting carcinoma in a cervical node, none can currently identify microscopic or occult nodal disease. The negative impact of nodal status on survival is well known and introduces the controversies surrounding the treatment of the N0 neck. The possibility of carcinoma in the cervical lymphatics, the uncertainty over who will develop clinical disease if left untreated, and the choice of modality to most effectively detect, prevent, and treat occult nodal disease are areas of fervent debate. Complete discussion of these issues extends beyond the scope of this section. However, several recent studies could help clarify the ongoing uncertainties.

Treatment recommendations for the N0 neck can be analyzed on a site-by-site basis.⁶⁸ There is a significant incidence of occult nodal disease in all but the earliest and most superficial carcinomas of the oral cavity, oropharynx, larynx, and hypopharynx. Expectant management of the neck is not recommended given the observation that neck failures after observation tend to be high stage and portend a

poor prognosis.⁶⁸ Therefore, most surgeons support the following management philosophy: if the risk of occult metastatic disease exceeds 15%, the neck should be electively treated. If surgery is chosen for the primary tumor, elective selective neck dissection is advised. Alternatively, if the primary tumor is to be irradiated, the neck should be electively irradiated.

Functional neck surgery represents a shift in the surgical management of occult cervical metastatic disease. By saving important anatomic structures that were routinely sacrificed in the classic radical neck dissection, the selective neck dissection produces less functional morbidity and aesthetic defects than the radical neck dissection.

Several authors have studied the utility of selective neck dissection in patients with a clinically and radiographically N0 neck.⁶⁹ Selective neck dissection was found to be as effective as a comprehensive neck dissection, and recurrences outside the dissected levels in the selective neck dissection group were not significant. The authors strongly advocate elective neck dissection in patients with N0 disease, as this is the most accurate method available to diagnose occult metastatic disease. The prognostic information obtained from the pathologic specimen is invaluable in terms of staging accuracy and in identifying high-risk patients who would benefit from postoperative therapy.

SENTINEL LYMPH NODE BIOPSY

Sentinel lymph node mapping was originally developed as a means to stage the first-echelon lymphatics of cutaneous melanoma. Recent literature has supported its application in mucosal head and neck squamous cell carcinoma.⁷⁰ Researchers have found that the technique is minimally invasive, technically feasible, and predictive of cervical metastatic disease. This method is currently under investigation at several institutions and promises to further refine the assessment of occult regional metastases.

RADIOTHERAPY

For early-stage cancer, surgery or radiotherapy alone is effective. Radiotherapy can be delivered via external beam and/or interstitial brachytherapy (where radioactive sources are inserted into needles that are placed into the tumor). For intermediate- and advanced-stage cancer, surgery and radiation or definitive radiation alone is effective. Unresectable cancers, particularly most early-stage nasopharyngeal cancers, can be cured by radiation alone.

Radiation Therapy Techniques Radiation is delivered to the primary site, including involved lymph nodes, as well as lymph nodes at risk for occult, microscopic disease. Hence, radiation planning requires a thorough understanding of the risk of clinical lymph node involvement, the risk of pathologic, occult lymph node involvement, and the patterns of nodal failure; these vary by the site of the primary and stage of disease.^{71,72} Knowledge of subclinical spread at the primary site is also important.

Traditionally radiation has been delivered to the primary site and upper cervical lymph nodes with opposed lateral (OL) fields, with the dose prescribed to midplane. A supraclavicular is delivered with an anteroposterior (AP) field, matched to the opposed lateral field. A block on either the OL or AP field protects the spinal cord at the match line, although it is

important that this block not traverse through gross tumor. Periodic field shifts at the match line (termed feathering) allow for any radiation hot spots to be better distributed. After spinal cord tolerance has been reached (~45 Gy), the opposed lateral fields are modified such that an anterior opposed lateral field is matched to a posterior electron field; because electrons are less penetrating, the spinal cord does not receive any further dose.

Three-dimensional (3-D) planning necessitates a CT scan during planning and provides detailed dose-volume information on the target as well as normal structures. Modification of the fields with either multiple segmented fields or variable weighting of fields can improve the homogeneity of the dose distribution. Intensity-modulated radiation therapy (IMRT) is a form of 3-D planning that allows more conformal radiation delivery by varying the radiation beams spatially and/or temporally.⁷²⁻⁷⁴ Hence, IMRT allows for greater sparing of normal structures such as salivary glands, esophagus, optic nerves, brainstem, and spinal cord.^{75,76} IMRT avoids the limitations of tumor boost doses, eliminates the need for posterior neck electron therapy, and enables simultaneous boosting, a technique that allows for higher doses to be delivered to regions at higher risk for failure (such as gross disease), with lower doses prescribed to areas of microscopic disease.⁷⁷

IMRT is readily applied to head and neck cancer as the region is readily immobilized and gross disease will often be adjacent to critical normal tissue. Patients who are most likely to benefit, therefore, are those in whom the tumor volume may be compromised to spare normal tissue or where standard radiotherapy fields would encompass the salivary glands. Thus far randomized trials comparing IMRT with standard radiotherapy have not been completed. However, failures that have been observed on Phase I and II IMRT trials have been noted within high-dose regions, suggesting inherent tumor resistance rather than underdosing of subclinical disease.^{78,79}

Postoperative Radiation Therapy Radiation is delivered post-operatively (PORT) to patients with locoregionally advanced disease. M.D. Anderson Cancer Center (MDACC) conducted a randomized trial comparing 57.6 Gy versus 63 Gy PORT in low-risk patients and 63.0 versus 68.4 Gy in high-risk patients, with patients stratified by stage, margin status, perineural invasion, extracapsular extension (ECE), number of lymph nodes, and size of lymph nodes.⁸⁰ The higher-dose arms did not afford any benefit in outcome. Performance status and radiation delay resulted in a worse prognosis. Adverse tumor-related factors included ECE and/or two or more of oral cavity primary site, positive margins, perineural invasion, more than two lymph nodes, and lymph nodes greater than 3 cm. In a follow-up study by MDACC, patients were stratified by risk factors.⁸¹ Low-risk patients had no adverse tumor-related factors and therefore received no PORT. Intermediate-risk patients had one adverse risk factor, except ECE; these patients received 57.6 Gy PORT. High-risk patients were defined as having ECE and/or two or more other adverse risk factors. Five-year locoregional control in these groups was 90%, 94%, and 68%, respectively; 5-year overall survival was 83%, 66%, and 42%, respectively. The MDACC experience provides a guide to which patients may benefit from PORT and the doses to administer.

The Role of Edoscopy Conventional radiation fractionation (CF) implies daily radiation delivered 5 days a week. Altered fractionation is a variation of this. Important tempo-

ral variables include the repair of sublethal damage, reassortment of cells within the cell cycle, repopulation, and reoxygenation. Ideally, radiation is delivered in such a manner to maximize damage to cancerous cells while minimizing normal tissue damage. Altered fractionation schemes should be delivered such that they provide a biologically equivalent (or greater) dose than conventional fractionation. Hyperfractionation (HF) entails an increased number of fractions, with a decreased fraction dose, but unchanged overall treatment time. Accelerated fractionation (AF) implies the same number of fractions, same total dose, but delivered over shorter time duration.

Several randomized trials comparing CF to AF have shown no survival or tumor control benefit, and worse toxicity with AF.⁸²⁻⁸⁴ The CHART trial compared 66 Gy in 2-Gy fractions to continuous delivery of 54 Gy in 1.5, three-times-daily fractions. Severe mucositis was worse in the CHART arm. Two randomized trials have shown improved outcomes with HF regimens delivering radiation in six or seven daily treatments per week.^{85,86} Skladowski et al. showed improved overall survival and locoregional control with a 7-day-per-week versus a 5-day-per-week radiation regimen.⁸⁶ A Norwegian trial has shown improved locoregional control and disease-free survival with a 6-day-per-week versus 5-day-per-week radiation regimen, although overall survival was not significantly impacted.⁸⁵

The RTOG conducted a randomized trial with four arms: (1) CF 70 Gy in 2-Gy daily fractions; (2) HF 81.6 Gy in 1.2-Gy twice-daily fractions; (3) AF split (2-week break) 67.2 Gy in 1.6-Gy twice-daily fractions; and (4) 32.4 Gy in 1.8-Gy daily fractions followed by twice-daily radiation, with 1.8 Gy to delivered to a large field and 1.5 Gy to the boost field (63 Gy total). The HF arm and simultaneous boost arm yielded the best locoregional control and disease-free survival, whereas overall survival was similar in all arms.

CHEMOTHERAPY

Traditionally, chemotherapy had been reserved for patients with incurable SCCHN, usually as a palliative measure. Several randomized trials have now clearly demonstrated that chemotherapy as part of a multimodality approach that includes surgery and radiotherapy does improve survival and allow for organ preservation in almost every setting (see following).⁸⁷ There are a number of chemotherapy agents that are active in SCCHN (Table 36.2), with platinum compounds being the mainstay of most chemotherapeutic regimens.⁸⁸ Cisplatin appears to be superior to carboplatin, as demonstrated by at least two randomized trials.^{89,90} Antimetabolites are also active in SCCHN, with 5-fluorouracil commonly used in

TABLE 36.2. Active agents in SCCHN.

Agent	Relative risk (RR)	Reference
Methotrexate	6%–10% ^a	90, 187
5-Fluorouracil	13% ^a	188
Cisplatin	14%–17% ^a	187–189
Paclitaxel	40%	190
Docetaxel	20%–42%	191–193
Ifosfamide	4%–42%	194–197
Vinorelbine	8%–14%	198, 199
Gemcitabine	0%–13%	200, 201

^aThese response rates are based on Phase III randomized trials.

combination with cisplatin, and capecitabine more recently introduced. In addition, taxanes (paclitaxel and docetaxel), vinorelbine, gemcitabine, bleomycin, and mitomycin C also have single-agent activity in this disease.⁸⁸

STAGE-SPECIFIC THERAPY

EARLY STAGE

In general, patients with early-stage carcinomas of the upper aerodigestive tract enjoy an overall good prognosis when treated with a single curative-intent modality. Radiotherapeutic or surgical approaches are chosen based on anatomic location, surgical access, functional outcome, and long-term consequences of radiation. The following discussion focuses on operative management of early-stage head and neck cancer and highlights issues surrounding the choice of radiation versus surgery.

Oral Cavity The oral cavity includes the lip, anterior tongue, floor of mouth, hard palate, alveolar ridge, retromolar trigone, and buccal mucosa. Because of the permanent dry mouth that invariably develops from radiation to these areas, wide local excision is the preferred management of these early-stage patients. The resections are by nature both organ- and function preserving. Achieving negative margins is critical.^{91,92} The lymphatics in the oral cavity are rich and often bilateral. In addition, occult cervical metastatic disease is highly correlated with tumor thickness.⁹³ Hence, the surgeon strongly considers selective neck dissection(s) for all but the most superficial carcinomas, as curative salvage neck surgery is associated with poor outcomes.⁹⁴ Rim mandibulectomy is performed for those tumors adjacent to or inseparable from the mandible, ascertaining that at least 10 mm of inferior rim remains to prevent fracture.⁹⁵ Early-stage hard palate malignancies are resected en masse with palatal bone, preserving the underlying nasal mucosa if possible, or reconstruction with local flaps.⁹⁶

There are many options for reconstruction of the surgical defect. Tongue, floor of mouth, and buccal defects can be left to granulate or grafted with split-thickness skin. The buccal myomucosal flap has been a very reliable and technically easy method to reconstruct a myriad of other oral cavity defects in many surgeons' hands.⁹⁷

Oropharynx Carcinomas of the tongue base, soft palate, and tonsil areas have been historically and preferentially treated with radiotherapy because of difficult surgical access and reported poor functional outcomes with resection.⁹⁸ Currently, there are numerous acceptable treatments for carcinomas of the oropharynx, reflecting advances in imaging and operative and cytoreductive techniques.⁹⁹⁻¹⁰¹ Recent analyses of tongue base treatments have found that similar dysfunctions of the tongue remain after either surgical or nonoperative therapy.¹⁰² More surgeons are performing a transhyoid pharyngotomy as a means for surgical access to the oropharynx.^{100,103} This approach provides wide exposure and avoids the potential morbidity of lateral or paramedian mandibular osteotomy. Steiner et al. have popularized transoral laser microsurgery, which represents a recent innovation in the treatment of tongue base cancers.¹⁰⁴ This organ-preserving resection has exceptional functional and oncologic results for early-stage tongue base cancers. In addition, most surgeons would perform staging-selective neck dissection(s) for these lesions.

Hypopharynx Early-stage cancers of the piriform sinus, posterior pharyngeal wall, and postcricoid areas are fairly rare. Even small lesions often present with cervical and/or distant metastatic disease.¹⁰⁵ Although radiation offers similar survival rates for T1-T2 lesions, proponents of surgical therapy believe that salvage surgery for radiation failures yields dismal results. In addition, surgeons found that patients who underwent larger resections (laryngectomy or pharyngolaryngectomy) had significantly better survival than those who underwent partial pharyngectomy.¹⁰⁶ Fortunately, surgeons have pioneered resection and reconstructive techniques that permit organ and function preservation.

Lesions of the posterior pharyngeal wall can be accessed via a transhyoid pharyngotomy, resected with laryngeal preservation, and functionally reconstructed with free tissue transfer.¹⁰⁷ A technique called supracricoid hemilaryngopharyngectomy has gained recognition as a means to perform oncologically sound resection and tracheotomy decannulation while preserving phonation and swallowing.¹⁰⁸ Moreover, endoscopic laser microsurgery for piriform sinus carcinomas has resulted in preservation of function and high recurrence-free survival.¹⁰⁹ These state-of-art methods challenge the historical dogma of laryngopharyngectomy and may progress the standard of care for early-stage hypopharyngeal carcinoma.

Larynx Both radiation and surgery offer high survival rates for patients with early glottic and supraglottic carcinoma. Treatment recommendations are based upon careful radiologic and clinical staging, appropriate patient selection, methods available to the radiation oncologist, and expertise of the surgeon.

Glottis Endoscopic laser microresection has emerged as an oncologically sound, cost-effective, and voice-preserving modality for many patients with T1-T2 carcinoma of the vocal cords, including the anterior commissure.¹¹⁰⁻¹¹⁴ The use of the operating microscope enhances the surgeon's detection of dysplastic versus normal wound architecture and ultimately enables simultaneous staging and definitive treatment in one setting. The neck is typically observed in early glottic cancers, due to the sparse lymphatics draining this region. Vertical hemilaryngectomy remains a viable option for selected patients, but unlike laser resection, requires laryngeal framework disassembly and reconstruction. More surgeons are reserving hemilaryngectomy for local radiation failures.

Supraglottis Supraglottic laryngectomy is the time-honored method for controlling early cancers of the supraglottic structures.^{115,116} Temporary pulmonary aspiration frequently results from this voice-sparing surgery. Therefore, patients must preoperatively demonstrate adequate pulmonary reserve. Transoral laser resection limits much of the morbidity of open/transcervical surgery and is evolving into an important technique that provides oncologic, functional, and cost-effective results.¹¹⁷ Unlike the glottic larynx, the supraglottic structures have rich, bilateral lymphatic drainage, which dictates bilateral selective neck dissections.

INTERMEDIATE STAGE

Intermediate-stage tumors usually consist of stage III tumors and selected stage II malignancies, such as those arising from

the base of the tongue or pyriform sinus. The term characterizes malignancies that are too advanced to be readily curable by a single-modality therapy such as surgery or radiation therapy yet carry a more-favorable prognosis than stage IV (M0) cancers, with cure rates ranging from 40% to 60%. Historically, treatment for this group of patients has consisted of surgery with postoperative radiation therapy.

The use of postoperative concurrent chemoradiotherapy has been of more interest. Initial pilot studies combining surgery with postoperative radiation and simultaneous cisplatin chemotherapy were promising. Recently, two large randomized trials investigating postoperative concurrent chemoradiotherapy have been reported. First was a trial conducted by the EORTC that compared postoperative radiation therapy with postoperative radiation (66 Gy) given with concurrent cisplatin administered 100 mg/m² on days 1, 22, and 43.¹¹⁸ Eligible patients included "high-risk" resected patients defined by pathologic criteria such as positive surgical margins, involvement of two or more cervical lymph nodes, or extracapsular spread. The results of this trial were favorable and supported the administration of concomitant chemoradiotherapy. Progression-free survival (47% versus 36%; $P = 0.04$) and overall survival (53% versus 40%; $P = 0.02$) at 5 years were significantly in favor of the chemoradiotherapy arm. This result was attributed to the effect of combined treatment on locoregional control with 5-year locoregional relapse rates of 31% for radiotherapy and 18% for chemoradiotherapy ($P = 0.007$). A similar trial was conducted by the RTOG, comparing postoperative radiotherapy to 60 Gy with or without three doses of cisplatin on days 21, 42, and 63.¹¹⁹ Again, locoregional control was improved with combination therapy (82% versus 72% at 2 years; $P = 0.01$). In addition, disease-free survival (hazard ratio, 0.78; $P = 0.04$), but not overall survival (hazard ratio, 0.84; $P = 0.19$), was also improved. With two positive trials showing similar findings, it can be argued that the combined evidence of these studies supports the administration of concomitant chemoradiotherapy in the postoperative setting.

Another recent randomized study with a focus on intermediate-state disease was the Larynx Intergroup Trial.¹²⁰ This trial followed up on the previous observations in the Veterans Administration laryngeal preservation trial that had compared surgery and postoperative radiotherapy with three cycles of induction chemotherapy followed by radiotherapy and surgical salvage.¹²¹ That trial showed no difference in survival in patients treated on either arm of the study but confirmed a larynx preservation rate of 64% in patients receiving chemotherapy. Subsequently, the Intergroup conducted a three-arm trial comparing the induction chemotherapy arm as defined by the VA Larynx Trial with either radiation alone or radiotherapy with concomitant cisplatin.¹²⁰ Eligible patients included those with stage III and IV laryngeal cancer. However, patients with advanced T4 lesions characterized by invasion of the thyroid cartilage were excluded. Thus, this trial can be considered as applying to intermediate-stage patients. There was no difference in survival between the three arms. However, the larynx preservation rate was highest (85%) in patients receiving concurrent chemoradiotherapy. Similarly the proportion of patients alive with a functioning larynx was highest on the concurrent chemoradiotherapy arm (45% at 5 years versus 41% for patients treated with induction chemotherapy and 37% for the radio-

therapy-alone group). Thus, concomitant chemoradiotherapy (with surgical salvage for patients with residual disease following completion of therapy or with later local recurrence) is the current standard therapy for patients with intermediate-stage larynx cancer.

Finally, pilot trials investigating concomitant chemoradiotherapy with surgical salvage for a broad group of patients with stages II and III head and neck cancer have been conducted. Haraf et al. from the University of Chicago reported on a Phase II trial in which patients received concurrent chemoradiotherapy utilizing fluorouracil (5-FU) and hydroxyurea administered with concurrent hyperfractionated radiation therapy every other week.¹²² In this phase II trial, the 5-year disease-specific survival was 82%, with 86% of patients achieving long-term locoregional control, whereas the overall 3- and 5-year survival rates were 74% and 65%, respectively. These data suggested that concurrent chemoradiotherapy is a highly efficacious approach for intermediate-stage head and neck cancer and, similar to the aforementioned larynx Intergroup trial, suggest that most patients do not need to be exposed to a surgical approach as a first treatment option.

LOCALLY ADVANCED HEAD AND NECK CANCER

Patients with locoregionally advanced head and neck cancer have traditionally been treated with surgery and PORT or radiotherapy alone for patients with unresectable disease. As overall survival rates following this approach were low and significant functional and psychologic sequelae frequent, combined modality therapies have been investigated. Initially, strategies focused on the use of induction chemotherapy. Although regimens such as the combination of cisplatin and 5-FU were shown to be active, resulting in overall response rates exceeding 80% and complete response rates of approximately 50%,^{121,123} most subsequent randomized trials demonstrated no significant effect on survival.⁸⁷ Meta-analyses evaluating the impact of chemotherapy on survival rates of advanced head and neck cancer also suggested no benefit from the use of induction chemotherapy.¹²⁴ Only an analysis of those trials specifically utilizing the combination of cisplatin and 5-FU suggested a small impact of approximately 5% on 5-year survival rates. However, despite the positive impact of induction therapy on distant failure, at this time there is no convincing evidence justifying the use of induction chemotherapy outside of a well-designed clinical trial in patients with SCCHN.

At the same time, several trials were initiated investigating the concurrent administration of chemotherapy and radiation. Because many patients with head and neck cancer fail locoregionally, the radiosensitizing effects of chemotherapy appear of particular importance. Early trials utilized single agents such as methotrexate,¹²⁵ bleomycin,¹²⁶ mitomycin-C,¹²⁷ or cisplatin¹²⁸ and were usually conducted in patients with unresectable disease. Many of these trials were in themselves inconclusive. However, a meta-analysis confirmed an 8% increase in absolute 5-year overall survival rate favoring concurrent chemoradiotherapy compared with radiotherapy alone.¹²⁴ This finding suggested that, for unresectable disease at least, concurrent chemoradiotherapy might be a more successful approach.

In recent years, several larger randomized trials comparing multiagent concurrent chemoradiotherapy (such as cis-

platin and 5-FU) with radiation therapy alone have confirmed this prior observation.⁸⁷ Studies conducted both in the United States and Europe have demonstrated an increase of up to 20% in 3-year absolute survival rates for patients treated on the concurrent chemoradiotherapy arm.

Additional trials have utilized concurrent chemoradiotherapy as a definitive treatment strategy hoping for organ preservation in addition to increasing survival rates. Pilot trials conducted by the RTOG,¹²⁹ investigators at the University of Chicago,^{130,131} and the Cleveland Clinic¹³² have all suggested that high survival rates exceeding 50% can be achieved for patients with locoregionally advanced disease even when omitting surgery. For example, a study at the University of Chicago treating patients with a combination of paclitaxel, 5-fluorouracil, hydroxyurea, and twice-daily radiation therapy administered every other week, to a total radiation dose of 75 Gy, demonstrated a 3-year survival rate of 60% in patients with stage IV regionally advanced disease.¹³¹

Of note, when evaluating the pattern of failure in patients with regionally advanced disease treated with concurrent chemoradiotherapy alone, it became clear that a higher proportion of patients were failing distantly than were failing locally. This finding represents a reversal of the failure pattern observed in patients treated with surgery and/or radiotherapy and has led to recent interest in studies combining both induction chemotherapy (for better distant disease control) and concurrent chemoradiotherapy (for improved locoregional control). Pilot trials from the University of Chicago^{133,134} as well as the University of Pennsylvania¹³⁵ have indicated that this approach is feasible and highly active. Randomized evaluation of the use of induction chemotherapy with concurrent chemoradiotherapy is planned for the near future.

SURGERY AND RECONSTRUCTION IN THE PATIENT WHO HAS UNDERGONE MULTIMODALITY THERAPY

The goals of multimodality strategies for patients with advanced head and neck cancer encompass organ preservation through less-radical surgery and improved survival. As multimodality organ preservation strategies are becoming more successful, the role of surgery is being redefined. Individualized treatment, with attention to important perioperative factors and utilization of vascularized tissue, is critical. These treatment approaches may help prevent surgical complications as well as help resolve the complications of multimodality therapy for these challenging patients. It is a general dogma held by most surgeons that performing surgery upon a patient who has previously undergone radiation or chemoradiation (CRT) is a challenging task. The surgery may not only be technically difficult but may be associated with a higher incidence of complications such as wound healing problems and infection.

Type of Neck Dissection The patient should undergo biopsy of the primary tumor site with frozen-section pathologic analysis. If the biopsy is negative for carcinoma, a selective neck dissection is completed at the same sitting as the biopsy. If the biopsy is indeterminate or positive, neck dissection is deferred until permanent pathology is available. In this manner, the primary tumor site and the neck may be operated at the same time if there is viable cancer at the primary site. The patient is consented to reflect these scenarios.

The selective type of dissection preserves the sternocleidomastoid muscle (SCM), internal jugular vein, and accessory nerve.¹³⁶ A supraomohyoid (levels 1–3) or lateral (levels 2–4) neck dissection is most often performed. If the SCM must be sacrificed (e.g., for gross tumor in SCM in salvage neck dissection), one should strongly consider placement of a pectoralis myofascial flap (PMMF) for vessel coverage and to provide the patient with a more aesthetic neck contour.¹³⁷ These flaps are straightforward, efficient to elevate, and can prevent the potentially catastrophic complication of carotid exposure and rupture.

Primary Site Recurrence In general, resection of primary site recurrences transgress the pharyngeal barrier and are prone to fistula and wound breakdown. Use of vascularized tissue and prolonged use of large suction drains has improved our wound management strategies.¹³⁸

Larynx It is imperative that a patient requiring laryngectomy be evaluated by the Speech and Swallowing Pathologist before surgery. Patients who require laryngectomies for recurrence also undergo bilateral selective neck dissections if feasible and undergo G-tube placement before or at the same sitting as the laryngectomy. A Provox or other tracheoesophageal prosthesis is placed.¹³⁹ A “prophylactic” PMMF is placed over the suture line to prevent fistula and/or to hasten healing if a fistula should form. For laryngectomy defects that require resection of a large portion of pharynx (leaving 2 cm or less of pharyngeal wall), one should also consider use of free radial forearm. Large-bore drains are placed and remain for 10 days to 3 weeks to manage potential fistulas.

Tongue Hemitongue defects can be managed with radial forearm flap reconstruction.¹⁴⁰ The more-radical total glossectomy defects are better managed with the more bulky rectus free flap.¹⁴¹ One should strongly consider laryngeal preservation in the young motivated patient with adequate pulmonary reserve. The bulk of the rectus flap allows control of oral secretions as well as understandable speech.

Composite Defects Patients who are edentulous and who have low-volume posterolateral jaw defects without significant soft tissue loss may heal and function well with PMMF. The bulk of the PMMF will prevent significant “drift” of this nonreconstructed edentulous mandible. Mandible–floor of mouth–tongue defects in the chemoradiated patient are best managed with vascularized bone flaps such as the fibula free flap with or without a radial forearm free flap. Often, external as well as internal coverage is provided with the fibula flap alone. A portion of the skin paddle is deepithelialized so that vascularized skin bridges both intraoral and skin defects.

RECURRENT OR METASTATIC DISEASE

Patients who fail therapy or present with metastatic disease are usually treated with palliative intent to preserve comfort and quality of life. Notwithstanding, there are occasional patients with only local recurrence who can be offered surgical salvage (see foregoing discussion). Reports of case series have suggested 15% long-term survival in these selected patients. Nevertheless, for the majority of patients with recurrent disease or for those with metastatic foci, the mainstay of treatment is systemic chemotherapy. These patients

have expected median survivals of 6 to 8 months and 1-year survival rates of 20% to 30%.⁸⁷

Randomized clinical trials would suggest that combination chemotherapy with two agents, compared with single agents, yields superior response rates in the range of 30% to 40% (Table 36.3). However, combination chemotherapy has not proven superior with respect to overall survival compared to single agents and has never been tested against best supportive care. Despite this, it is common practice to treat patients in this setting with combination chemotherapy, usually consisting of cisplatin with 5-FU or a taxane. In the only randomized trials comparing cisplatin with carboplatin, the agents were combined with 5-FU, revealing an improved response rate in the cisplatin-treated patients.^{89,90} The possible superiority of cisplatin, however, must be tempered by its toxicity, and carboplatin continues to be commonly administered, especially with a taxane.

The lack of a demonstrated survival advantage to cytotoxic chemotherapy and the poor survival of these patients have opened the door to testing targeted agents in this disease. The first class of agents to undergo testing in this setting is the EGFR inhibitors. The agents in clinical use include two small molecule inhibitors, gefitinib and erlotinib, and a monoclonal antibody, cetuximab. Both gefitinib and erlotinib have been tested in the Phase II setting, demonstrating 11%¹⁴² and 4%¹⁴³ response rates, respectively. Cetuximab has undergone testing in a Phase III trial in combination with cisplatin compared to placebo.¹⁴⁴ This trial, enrolling 123 patients, revealed an improved response rate in the cisplatin/cetuximab arm, but no differences were observed in progression-free survival, the primary endpoint, or overall survival.

CHEMOPREVENTION

The concept of chemoprevention asserts that medical therapy has the ability to interrupt or delay the progression of premalignant lesions. The rationale behind chemoprevention strategies applied in SCCHN is based on knowledge of fundamental molecular derangements in its carcinogenesis (see foregoing), the ability to identify a group of patients at relatively high risk of developing cancer, and lesions that are clinically apparent (oral leukoplakia or erythroplakia). Although it is clear that the majority of leukoplakic and erythroplakic lesions do not progress to malignancy and that histology is a poor predictor of outcome,¹⁴⁵ this model has been the most commonly employed in early pilot trials. Recent work suggests that molecular markers such as aneuploidy are much better prognostic markers.⁴⁹⁻⁵¹

The retinoic acid receptor (RAR) has been a subject of intensive research in chemoprevention as stimulation of the receptor is an integral part of mucosal differentiation and influences expression of several other key genes. Furthermore, RAR- β expression is reduced in premalignant lesions and can be restored by retinoic acid (RA) therapy (isotretinoin).¹⁴⁶ Early randomized trials employing high-dose 13-*cis* RA demonstrated efficacy in reversing premalignant lesions or fewer second malignancies^{147,148}; however, this therapy was associated with unacceptable mucocutaneous toxicity and relapses once therapy was discontinued. Thus far, low-dose RA therapy, although tolerable, has not been efficacious.^{149,150} A strategy of combination "bioadjuvant" therapy combining interferon- α , α -tocopherol, and 13-*cis* RA has shown promising results^{151,152} and is currently being evaluated in a Phase III trial versus observation alone in stage III or IV patients with previously treated SCCHN.

More-recent chemopreventative approaches have employed virally delivered gene therapy,¹⁵³ cyclooxygenase 2 COX-2 inhibition,¹⁵⁴ and Bowan-Birk inhibitor concentrate.¹⁵⁵ Clearly, future success in this area will hinge on improved definition of high-risk molecular markers and an understanding of the molecular mechanism of action of any therapy. In addition, it will be necessary for any agent to either possess the ability to eliminate the genetically altered clones or be administered for prolonged periods of time to otherwise healthy individuals.

Nasopharyngeal Carcinoma

Nasopharyngeal carcinoma (NPC) is a well-defined subset of head and neck cancer that requires separate discussion with respect to its pathology, epidemiology, and treatment options. Etiologically, nasopharyngeal cancer is linked to Epstein-Barr virus (EBV) exposure. Evidence of persistent EBV latency in nasopharyngeal cancer cells is present in the majority of cases.¹⁵⁶ Patients with nasopharyngeal cancer are also known to have high EBV antibody titers, which appear to correlate with tumor burden.¹⁵⁷ Measurement of serum EBV DNA has been used to predict clinical treatment outcome.¹⁵⁸ Additional factors contributing to carcinogenesis in the nasopharynx have been implied, such as high-temperature indoor cooking, consumption of salted preserved fish,¹⁵⁹ or, in the United States and Western Europe, more traditional risk factors including smoking and alcohol exposure.

The epidemiology of NPC is highly distinct from that of other head and neck cancers. The disease occurs in

TABLE 36.4. Definition of nasopharyngeal cancer (NPC) TNM.

<i>Tumor</i>	
T1	Tumor confined to the nasopharynx
T2	Tumor extends to soft tissues
T2a	Tumor extends to the oropharynx and/or nasal cavity without parapharyngeal extension ^a
T2b	Any tumor with parapharyngeal extension ^a
T3	Tumor involves bony structures and/or paranasal sinuses
T4	Tumor with intracranial extension and/or involvement of cranial nerves, infratemporal fossa, hypopharynx, orbit, or masticator space
<i>Regional lymph nodes</i>	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Unilateral metastasis in lymph node(s), 6 cm or less in greatest dimension, above the supraclavicular fossa ^b
N2	Bilateral metastasis in lymph node(s), 6 cm or less in greatest dimension, above the supraclavicular fossa ^b
N3	Metastasis in a lymph node(s) ^b more than 6 cm and/or to supraclavicular fossa
N3a	Greater than 6 cm in dimension
N3b	Extension to the supraclavicular fossa ^c

^aParapharyngeal extension denotes posterolateral infiltration of tumor beyond the pharyngobasilar fascia.

^bMidline nodes are considered ipsilateral nodes.

^cSupraclavicular zone or fossa is relevant to the staging of nasopharyngeal carcinoma and is the triangular region originally described by Ho. It is defined by three points: (1) the superior margin of the sternal end of the clavicle, (2) the superior margin of the lateral end of the clavicle, and (3) the point where the neck meets the shoulder. Note that this would include caudal portions of levels IV and V. All cases with lymph nodes (whole or part) in the fossa are considered N3b.

an endemic form in the Far East and the Mediterranean countries.¹⁶⁰ In addition, clustering in families has been observed.^{161,162} These observations suggest the presence of genetic susceptibility as a cofactor with latent EBV infection as well as additional aforementioned factors.

The pathology of NPC has been defined by the World Health Organization.¹⁶³ Generally, three types of malignancy are identified; these include the most frequent undifferentiated form of NPC (type III) frequently also referred to as lymphoepithelioma. This is the form associated with the endemicity. Types I and II represent less-common forms of keratinizing (type I) and nonkeratinizing (type II) squamous cell cancers. Lymphomas and plasmacytomas are also observed.

Clinical Presentation

The clinical presentation of NPC can be quite succinct. Patients can present with epistaxis, stuffy nose, uni- or bilateral otitis media caused by blockage of the eustachian tube, or headaches and visual problems related to skull base invasion or cranial nerve involvement. Because of the rich perfusion of the nasopharynx by lymphatic and blood vessels, early spread to lymph nodes is frequently seen. As a consequence, patients can present with massive bilateral lymphadenopathy including lymph nodes in the posterior cervical chains.¹⁶⁴ Similarly, systemic dissemination to lungs, bones, and liver

occurs more frequently and earlier than seen in other malignancies arising from head and neck mucosal tissues.¹⁶⁴

The staging of NPC also differs from that of the other head and neck malignancies. Criteria for T stage are displayed in Tables 36.4 and 36.5. Similarly, the staging of lymph node involvement is different from that of other head and neck malignancies. In particular, the specific location of involved lymph nodes in the neck area plays a more important part. Involvement of low cervical or supraclavicular lymph nodes has clearly been identified as negative prognostic factors. The definition of lymph node staging and TNM classification for overall stage classification are shown in Table 36.5.

Therapy

The therapy of nasopharyngeal cancer has largely been defined by randomized trials conducted exclusively in patients with this disease. Many of these originate in Europe and the Far East, consistent with the higher incidence in those regions. As a rule, NPC is considered unresectable, and as a consequence the primary treatment modality has been radiotherapy. Single-modality radiotherapy can be curative, particularly when administered in high doses. Combined modality therapies have been evaluated.^{165,166} In the United States, a randomized trial investigated the use of concomitant cisplatin followed by two cycles of adjuvant cisplatin and 5-FU.¹⁶⁵ It demonstrated a clear superiority in survival when compared with radiation therapy alone (3-year survival, 47% versus 78%; $P = 0.005$). This trial, Intergroup 0099, included a histologic mix of World Health Organization (WHO) types I, II, and III patients. In addition, the control arm of patients treated with radiotherapy alone did quite poorly. It has therefore been questioned whether these results could be applied to NPC in endemic areas. However, because NPC is rare in this country and the combined modality arm resulted in a significant survival advantage, it has been considered to provide sufficient evidence to adopt concurrent chemoradiotherapy as

TABLE 36.5. Stage grouping of NPC.

<i>Stage</i>	<i>T</i>	<i>N</i>	<i>M</i>
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage IIA	T2a	N0	M0
Stage IIB	T1	N1	M0

a current standard. Concomitant chemoradiotherapy has also been shown to be of benefit in meta-analyses.¹⁶⁷

Studies conducted in the Far East have been less conclusive. However, at least one study from Taiwan demonstrated an advantage for the concurrent administration of chemoradiotherapy with respect to progression-free and overall survival.¹⁶⁶ Another study, by Chan et al., showed a trend favoring concurrent chemoradiotherapy for progression-free survival that was statistically significant in patients with T3 and T4 disease.¹⁶⁸

Investigations of sequential combined modality therapy (induction or adjuvant chemotherapy) have not succeeded at increasing survival rates in randomized settings,^{169,170} although decreased systemic and local failure rates have been demonstrated.¹⁷¹ It has been argued that induction chemotherapy can reasonably be offered to patients with very bulky primary tumors extending into the brain or in close proximity to the optic chiasm and/or brainstem. Given the sensitivity of these structures to high-dose radiation, such tumors would not be readily amenable to curative intent radiotherapy. Initial tumor shrinkage with chemotherapy thus might benefit overall treatment outcomes in these cases.

Parotid Malignancies

The majority of parotid neoplasms are benign, have a predictable clinical course, and are treated successfully with superficial or partial parotidectomy. Parotid malignancies, on the other hand, are variable in clinical behavior. Accurate pathologic diagnosis has critical implications for appropriate surgical and postoperative therapy.

Pathology

Pathologists have classified salivary gland malignancies into two groups, based on the historical correlation of histopathology with biologic/clinical behavior.¹⁷² Low-grade malignancies include low-grade mucoepidermoid carcinoma and acinic cell carcinoma. High-grade malignancies consist of high-grade mucoepidermoid carcinoma, adenoid cystic carcinoma, adenocarcinoma, squamous cell carcinoma, carcinoma ex-pleomorphic adenoma, and the rare malignant mixed tumor. Mucoepidermoid carcinomas are the most common parotid gland malignancies.

Occult cervical nodal disease is frequently seen in high-grade malignancies. Other predictors of nodal involvement are facial nerve involvement, extraglandular tumor extension, T stage, and severe desmoplasia.¹⁷³⁻¹⁷⁵ In fact, the absence of histopathologic adenopathy has been found to be the major predictor of disease-free survival.¹⁷⁴

Diagnosis

Patients commonly present with an asymptomatic mass in the preauricular or mandibular angle regions. Rapid growth in a long-standing parotid mass is a classic sign of carcinoma ex-pleomorphic adenoma. Pain has been considered by some to be more frequently associated with malignancy.¹⁷² Paresis or paralysis of facial nerve branches or palpable lymphadenopathy represent indisputable signs of malignancy. The clinician should perform a careful head and neck history and

TABLE 36.6. Staging of parotid gland.

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor 2 cm or less in greatest dimension without extraparenchymal extension
T2	Tumor more than 2 cm but not more than 4 cm without extraparenchymal extension
T3	Tumor more than 4 cm and/or having extraparenchymal extension
T4a	Tumor invades skin, mandible, ear canal, and/or facial nerve
T4b	Tumor invades skull base, pterygoid plates, or encases carotid artery

Source: Used with the permission of the American Joint Committee on Cancer (AJCC), Chicago, Illinois. The original source for this material is the *AJCC Cancer Staging Manual*, sixth edition (2002), published by Springer-Verlag New York, www.springer-ny.com.

examination for these and other symptoms and signs. The parotid gland holds the first-echelon nodes for the surrounding scalp and auricular carcinomas. Therefore, a history of skin malignancy in the periparotid region dictates a thorough examination for detection of metastatic disease to the parotid gland.

Testing and Staging

Although not uniformly utilized, many surgeons have found that fine-needle aspiration of the parotid mass is a very useful diagnostic adjunct.¹⁷⁶ Preoperative recognition of malignancy facilitates therapeutic planning and helps prepare both the surgeon and patient for the planned procedures. CT scans are also useful in determining subclinical or metastatic disease.¹⁷⁷ Primary parotid malignancies are staged as shown in Table 36.6.¹⁷⁸

Treatment

Low-grade T1–T2 malignancies (acinic cell and low-grade mucoepidermoid carcinoma) are sufficiently treated by performing nerve-sparing parotidectomy with clear margins. No adjuvant therapy is indicated because of the indolent biologic and clinical behavior of these neoplasms. All high-grade and larger low-grade malignancies are treated with total parotidectomy and dissection of node-positive necks. Surgeons should strongly consider performing selective posterior-lateral (levels II–V) neck dissection for high-grade tumors because of the high incidence of occult metastatic disease. Postoperative radiation and/or chemotherapy may improve survival.¹⁷⁴

Electromyogram (EMG)-based continuous intraoperative facial nerve monitoring is utilized by many surgeons but is not considered the standard of care. Temporary nerve weakness was found to be decreased in monitored cases versus unmonitored parotid surgeries. However, the incidence of permanent paralysis (4% or less) is similar.^{179,180} The facial nerve is preserved unless directly involved with tumor. Intentional or inadvertent transection of nerve branches dictates immediate intraoperative neurolysis. There are numerous cervical sensory nerves that can be harvested individually or as a plexus. Composite facial nerve trunk grafting of cervical plexus to individual distal branches will provide tone and even voluntary facial movement over 12 to 18 months.¹⁸¹

Frey's syndrome (gustatory sweating) can be prevented by placing acellular dermis between the parotid duct and the external skin.¹⁸² In addition, symptomatic postoperative Frey's syndrome is treated successfully with botulinum toxin.¹⁸³⁻¹⁸⁶ Many patients with parotid malignancy receive postoperative radiotherapy, virtually eliminating the chance of gustatory sweating. If patients are expected to endure long-term paralysis, strong consideration should be given to surgical rehabilitation. Gold weight implantation, lower lid shortening, temporalis muscle transfer (to oral commissure), and lip-switch operations all provide cosmetic facial symmetry.

Lung Cancer

Hak Choy, Harvey I. Pass, Rafael Rosell,
and Anne Traynor

Etiology

Lung cancer is the leading cause of cancer death in the United States and throughout the world.¹ In the United States, the manufactured cigarette emerged as the tobacco product of choice shortly after the turn of the 20th century. Lung cancer surfaced after years of inhalation of cigarette smoke, first among men and then among women. From 1995 to 1999, cigarette smoking and exposure to environmental tobacco smoke (ETS) accounted for approximately 160,000 annual deaths in the United States. Each year, 127,813 Americans die from smoking-attributable lung cancer deaths.

Smoking

ACTIVE CIGARETTE SMOKING

Worldwide, approximately 4 million people die annually of tobacco-attributable diseases; the number of tobacco-attributable deaths is projected to rise to 8.4 million by 2020. China, with 20% of the world's population, smokes 30% of the world's cigarettes. Men smoke more than women, and the proportion of male deaths at ages 35 to 69 years attributable to tobacco has been predicted to rise over the next few decades from 13% (in 1988) to about 33%.² In Hong Kong, cigarette consumption reached its peak 20 years earlier than in mainland China. In the general population of Hong Kong, in 1988, tobacco caused about 33% of all male deaths at ages 35 to 69, plus 5% of all female deaths, and hence 25% of all deaths at these ages.²

A highly significant trend of increasing lung cancer mortality has been observed with increasing cigarette consumption. Smoking was considered causally related to cancers of the trachea, lung and bronchus, larynx, and lip by the first Surgeon General's Report in 1964.³ In studies conducted through the 1960s, cigarette smoking was strongly associated with squamous and small cell cancers of the lung, but less so with adenocarcinoma. However, during the past two decades, there has been a noticeable shift in lung cancer histology patterns. The relative frequency of squamous cell carcinoma has decreased, whereas that of adenocarcinomas, often of peripheral origin, is clearly increasing. This shift has been attributed to changing cigarette design, in which filters removed much of the tar from inhaled tobacco smoke. The tar fraction contains most of the polycyclic aromatic hydrocarbons (PAH), including numerous carcinogens known to produce squamous cell lung cancer in animals. However, filters also retain

some nicotine. As the use of filtered cigarettes has become predominant, smokers have inhaled more deeply and have retained smoke longer in the deep lung to satisfy nicotine craving.⁴

The mainstream smoke emerging from the mouthpiece of a cigarette is an aerosol containing about 1,010 particles/mL and 4,800 compounds. Experimentally, vapor-phase components of the smoke can be separated from the particulate phase by a glass fiber filter. The vapor-phase comprises more than 90% of the mainstream smoke weight. Potentially carcinogenic vapor-phase compounds include nitrogen oxides, isoprene, butadiene (BD), benzene, styrene, formaldehyde, acetaldehyde, acrolein, and furan. The particulate phase contains at least 3,500 compounds and many carcinogens including PAH, N-nitrosamines, aromatic amines, and metals.^{5,6} A key aspect of the link between cigarette smoke and lung cancer is the chronic exposure of DNA to multiple metabolically activated carcinogens, leading to multiple DNA adducts and mutations (Figure 37.1).

PAH and other aromatics are also found in ambient and indoor air and in the diet. PAH, a major class of carcinogens present in ETS, leads to the formation of DNA adducts, which cause mutagenic events involving chromosomal aberrations, DNA strand breaks, oncogene activation, and tumor suppressor gene inactivation. Several epidemiologic and experimental studies have shown a good correlation between PAH and aromatic DNA adducts in blood and lung tissue from the same subjects. Genetic susceptibility plays an important role in the risk of developing lung cancer, and at present there are multiple biomarker assays to predict exposure risk⁷ (Table 37.1).

PASSIVE SMOKING/ENVIRONMENTAL TOBACCO SMOKE

Active cigarette smoking, passive smoking, various occupational exposures, and carcinogens in heavily polluted air are causally related to lung cancer. Environmental tobacco smoke (ETS) is a form of indoor air pollution resulting from the mixture of sidestream smoke, emitted from the smoldering of the distal part of the cigarette in between puff drawing, and the portion of mainstream smoke that is released into ambient air by actively smoking individuals. Most epidemiologic studies support the view that exposure to ETS involves a carcinogenic risk to humans. In rats treated with very high doses of a mixture of sidestream smoke and mainstream smoke, mimicking exposure to ETS, the formation of DNA adducts was observed in different organs and tissues.⁸ The poor persistence of smoke-related adducts in the lung sug-

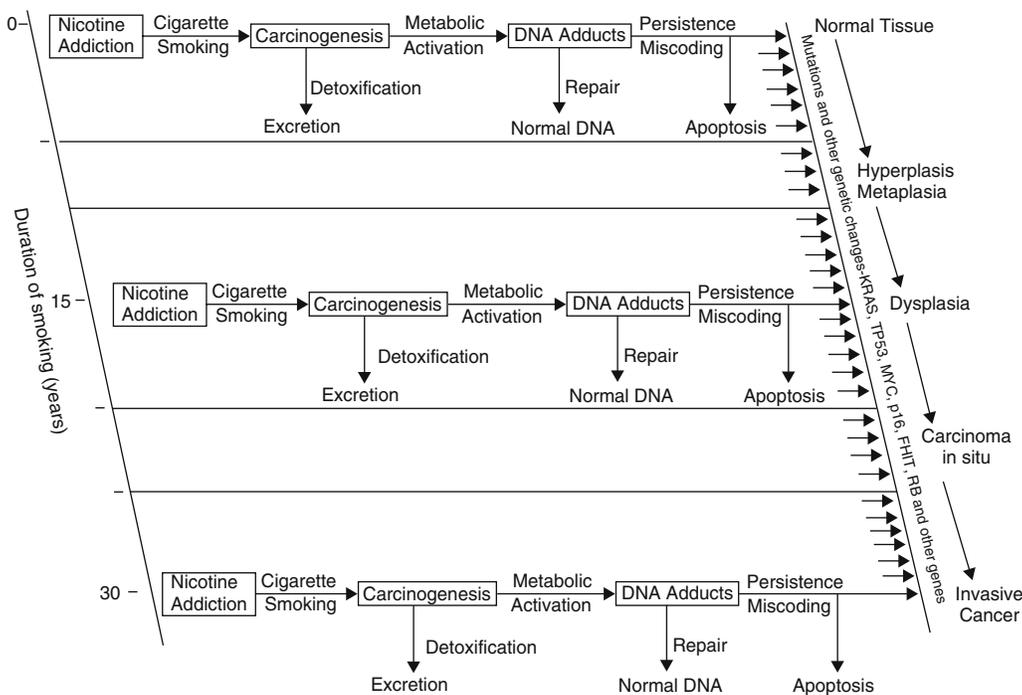

FIGURE 37.1. Genotoxicity of tobacco smoke.

gests that a continuative exposure is needed for fixation of DNA damage. It has been demonstrated that spending an average period of 3 hours in a smoky pub results in a considerably high exposure to carcinogenic ETS.

In one study, the mean ambient air concentration of benzo[a]pyrene, a widely known representative of carcinogenic PAH, was 6.3 ng/m³. The mean concentrations of this compound in smoking and nonsmoking homes were 1.0 and 0.4 ng/m³, respectively. The values in commercial buildings were 1.07 ng/m³ for smoking zones and 0.39 ng/m³ for nonsmoking zones. In the ambient air of Silesia, Poland, a highly polluted industrial city, the mean concentrations of benzo[a]pyrene were 60 to 90 ng/m³ in winter and 5 to 20 ng/m³ in summer.⁹

Significantly, formation of DNA adducts was observed in the induced sputum of 3 of 15 healthy nonsmokers consequent to ETS exposure, establishing a plausible link between ETS and lung cancer.⁹ The hypothesis that ETS is more potent

than mainstream tobacco smoke as a lung carcinogen is supported by observations that cigarette sidestream smoke condensate is more carcinogenic in skin painting studies than full-smoke condensate. ETS-induced lung tumor risk in A/J mice occurs by a predominantly genotoxic mechanism of action, which may be suppressed partially by sustained high-level ETS exposure.

TRENDS IN LUNG CANCER RISK AFTER SMOKING CESSATION

In both men and women, the age-related increase in lung cancer risk is lowest in people who have never smoked, intermediate in those who have quit at various ages, and highest in those who continue smoking. Among former smokers, the age-related increase is smaller the earlier the age of quitting.³ Widespread cessation of smoking in the United Kingdom has

TABLE 37.1. Classification and examples of biomarkers for lung cancer.

Category	Examples
External exposure	Questionnaire data, Federal Trade Commission (FTC) yield
Biomarker of exposure	Polycyclic aromatic hydrocarbon in lung tissue Urinary measurement of tobacco constituent or metabolite, exhaled CO; carboxyhemoglobin, urinary mutagenicity
Biologically effective dose	Carcinogen-DNA adducts in human lung tissue Carcinogen-DNA hemoglobin adducts, chromosomal aberrations in cultured lymphocytes, lipid peroxidation
Biomarker of harm	Changes in RNA or protein expression, somatic mutations and LOH in normally or abnormally appearing tissue; change in methylation or gene control; mitochondrial mutations, mRNA expression arrays or proteomics Osteoporosis, hypertension, hyperplasia, dysplasia, lipids, blood coagulant pathways, mRNA expression arrays or proteomics Leukocytosis, hprt mutations, mRNA or protein expression via microarrays in cultured blood cells
Effect modifiers	Genetic polymorphisms for genes involved in disease pathways Enzyme induction of metabolizing enzymes

LOH, loss of heterozygosity.

approximately halved the lung cancer mortality that would have been expected if former smokers had continued to smoke.¹⁰ However, for some individuals, such as those of advanced age and heavy smoking exposure, the risk of lung cancer may exceed 10% within 10 years even if they stop smoking.¹¹ The risk for lung cancer is increased for both current and former female smokers compared with female nonsmokers and declines for former smokers with increasing duration of abstinence.¹²

Occupational Exposure and Polluted Air

Workers in graphite-electrode manufacturing, as well as in coke-oven plants, are exposed to PAH by inhalation of volatile PAH and PAH bound to respiratory particulate matter. Mean 8-oxo-7,8-dihydro-2'-deoxyguanosine in white blood cells of exposed workers was between 1.38 and 2.15 times higher than levels found in control samples. An alkaline single-cell gel electrophoresis (Comet assay) was used to study DNA strand breaks that were found in exposed workers. These biomarkers may be appropriate for surveillance of workers exposed to PAH¹³ (see Table 37.1).

Vehicles powered by diesel engines are a major source of suspended particulate matter, which is a suspected cause of lung cancer and allergic respiratory disease, including bronchial asthma. Diesel exhaust contains potent carcinogens and mutagens, such as PAH and nitrated PAH. PAH released from diesel exhaust particulates also generate DNA adducts that cause mutations in oncogenes and tumor suppressor genes and act as initiators of carcinogenesis. DNA adducts were identified in rats after both short-term (12 weeks) and long-term (30 months) exposure to diesel exhaust, and the level of DNA adducts was shown to be higher in lung tumor tissues than in normal tissues after chronic exposure.¹⁴ Formation of DNA adducts is catalyzed by CYP1A1 and CYP1A2, which are inducible by PAH. CYPs oxidize PAH to reactive electrophilic metabolites, which bind to DNA bases to form DNA adducts. The level of cytochrome P-450 1A1 mRNA was shown by Northern blot analysis to be significantly increased in the lungs of rats exposed to 6 mg/m³ of diesel exhaust.¹⁴

1,3-BD is a major commodity chemical used in the manufacture of synthetic rubber and various plastics.¹⁵ Global consumption of BD was 6.1 million metric tons in 1995, with consumption expected to rise to more than 7.5 million metric tons in the year 2000. BD is also a common air contaminant found in auto emissions and cigarette smoke. It is a component of automotive exhaust and of the vapor phase of environmental smoke (~400 mg/cigarette). BD is carcinogenic in rodent bioassays, and exposure of mice to BD at 20 parts per million for 4 days induced mutations in spleen lymphocytes at the hypoxanthine-guanine phosphoribosyl transferase (HPRT) locus.

Coexposure to cadmium, cobalt, lead, and other heavy metals occurs in many occupational settings, such as pigment and batteries production, galvanization, and recycling of electric tools.¹⁶ The lifetime excess lung cancer risk for cadmium fumes of 100 mg/m³ was estimated to be approximately 50 to 111 lung cancer deaths per 1,000 workers exposed to cadmium for 45 years. The principal mechanisms of cadmium genotoxicity, mutagenicity, and carcinogenicity are generation of reactive oxygen species, inhibition of DNA repair,

depletion of glutathione, and possibly also suppression of apoptosis.

Diet and Lung Cancer Risk

Numerous epidemiologic studies have demonstrated a protective effect of vegetable or fruit consumption on cancer risk.¹⁷⁻²² Statistically significant inverse associations were found with total vegetables and most vegetable groups in a Netherlands study.¹⁷ The strongest effect was found for vegetables from the *Brassica* group (Brussels sprouts, cauliflower, cabbage, kale). Based on the results, it was calculated that a male current smoker who smoked 25 cigarettes per day for 40 years has a risk of lung cancer that is 18 times higher than that of a never-smoker. By eating 286 g vegetables per day, instead of 103 grams, he may reduce his risk by 29%.¹⁷ The mechanisms underlying a cancer protection by fruit and vegetables are still uncertain. The possible protective compounds in vegetables and fruits include a wide variety of phytochemicals. Among them are the carotenoids, colorful compounds that are abundant as pigments in plants. The main carotenoids are α -carotene, β -carotene, lutein, zeaxanthin, β -cryptoxanthin, and lycopene. They are potent quenchers of free radicals, which are by-products of metabolic processes originating from environmental pollutants such as cigarette smoke.²³

Blood levels of micronutrients and vitamins including beta-carotene have been inversely correlated with lung cancer risk.²⁴ However, large intervention studies with β -carotene supplementation found no clear protection against cancer or cardiovascular disease, and two studies were terminated because mortality or lung cancer incidence increased in the supplemented group.²⁵⁻²⁷ Subsequent analyses suggested that the deleterious effect might occur primarily among heavy current smokers and/or alcohol drinkers and asbestos-exposed subjects.²⁸ It has been speculated that this represents a pro-oxidant interaction effect of β -carotene with such exposures or that it could be related to a high supplementation dose and unnaturally high serum levels.

Lung Cancer Susceptibility

GENDER

It has been stated that females are more susceptible than males to tobacco carcinogenesis. Activation of gastrin-releasing peptide receptor (GRPR) in airways has been related to a proliferative response of bronchial cells to gastrin-releasing peptide and to long-term tobacco exposure. The GRPR gene is located on the X chromosome and escapes X-chromosome inactivation, which occurs in females. GRPR mRNA expression was detected in airway cells and tissues of more female than male nonsmokers and short-term smokers. Female smokers showed expression of GRPR mRNA at a lower mean pack-year (number of packs of cigarettes smoked per day multiplied by number of years of smoking) exposure than male smokers. These findings indicate that women may have a higher risk of developing lung cancer than men.²⁹ However, in a different study, the risk of lung cancer was comparable in women and men.³⁰

Estrogen and progesterone receptors have been found to be present in resected lung cancers, regardless of the sex of

the patient, although a female patient with squamous cell carcinoma showed an estrogen receptor level of 301 fmol/mg.³¹ Catechol estrogens may act as carcinogens either by forming DNA adducts or by acting as oxidative intermediates. The CYP1B1*3 polymorphism, which can cause enhanced conversion of estradiol to 4-hydroxy-estrogen and its catechol estrogen metabolite, was found frequently among 203 lung cancer cases in comparison with 205 controls (odds ratio, 2.6). Gene-gene interactive associations were observed among females, but not among males, with the CYP1B1*3 allele, including increased adjusted odds ratios for coinheritance of at least one copy of the CYP1B1*3 allele and the DNA repair enzyme XPD exon 23 (Gln) allele (odds ratio, 5.7), or for coinheritance of CYP1B1*3 and the high or intermediate activity alleles of epoxide hydrolase (odds ratio, 9.1). The microsomal epoxide hydrolase enzyme could activate catechol estrogens to reactive intermediate.³²

Lung cancer is the leading cause of cancer death in Taiwanese women, although less than 10% of female lung cancer patients are smokers. Half of the 141 lung tumors in these patients had human papillomavirus 16/18, compared with 26% of 60 noncancer control subjects. It is thought that the human papillomavirus infection is related to lung cancer development in nonsmoking females.³³

An aggregation of lung cancer was seen in first-degree relatives of more than 800 lung cancer probands, and a significantly lower intake of dietary folate, critical for maintaining DNA integrity and synthesis, was observed in lung cancer cases compared with controls.³⁴

GENETIC

ALTERATIONS IN MINISATELLITES AND VARIABLE NUMBER OF TANDEM REPEATS

Microsatellite instability, defined as changes in the number of short tandem DNA repeats in microsatellites, mainly associated with CA dinucleotides, has been reported in non-small cell lung cancer (NSCLC).³⁵ Genetic susceptibility to lung cancer is multifactorial, including alterations in minisatellites and variable number of tandem repeats (VNTR). The HRAS1 VNTR region, which maps 1 kb downstream from the canonical polyadenylation signal of the human proto-oncogene *H-ras-1*, consists of four common progenitor alleles, in addition to several rare variants that are thought to derive from germ-line mutations of the nearest common alleles. A higher percentage of rare HRAS1 VNTR alleles was found in lung cancer patients than in controls,³⁶ and a meta-analysis³⁷ showed suggestive but not statistically significant association for these alleles with lung cancer. Minisatellite alterations may cause dysregulation of gene expression. HRAS1 VNTR binds at members of the NF- κ B family of transcriptional regulatory factors, and some HRAS1 VNTR alleles show a tendency to bind more avidly to transcriptional regulatory factors. Frequent allele loss for the marker HRAS on chromosome 11p (deleted region designated LOH11B) has been associated with cigarette consumption and gender. None of the nonsmokers had allele loss, as compared with 28% of the patients with low and 43% of those with high cigarette consumption. Allele loss was also more frequent in men (43%) than in women (11%). Median survival was lower for patients with allele loss.³⁸

ADDUCTS

DNA adducts are markers not only of exposure but also of risk for cancer development. Healthy current smokers who had elevated levels of DNA adducts in leukocytes were approximately three times more likely to be diagnosed with lung cancer 1 to 13 years later than current smokers with lower adduct concentrations.³⁹ A recent meta-analysis found an overall 83% excess of adducts in cases compared to controls in current smokers.⁴⁰

DNA adducts have been found to be higher in women than in men with the same level of smoking.

S-TRANSFERASE

Glutathione *S*-transferase (GST) M1 is deleted in about half of Caucasians, and a GSTP1 polymorphism at codon 105 (Ile to Val) has been identified. The combined GSTM1 null/GSTP1 Val genotypes were associated with lung cancer before and after adjusting for adducts.⁴¹ In addition, a meta-analysis of 43 published case-control studies including more than 18,000 subjects found a slight excess risk for lung cancer in individuals with the GSTM1 null genotype.⁴²

INSULIN-LIKE GROWTH FACTOR

A case-control analysis of plasma insulin-like growth factor (IGF) levels from lung cancer patients revealed that elevated plasma IGF-I was associated with an increased risk of lung cancer. An increased risk of lung cancer was also associated with reduced levels of IGF-binding protein (IGFBP)-3, which moderates the effect of IGF-I but also inhibits all growth and induces apoptosis.⁴³ Elevated levels of IGF-II are associated with a poor prognosis in human lung adenocarcinoma. Transgenic overexpression of IGF-II in lung epithelium induces lung tumors in mice. These tumors display morphologic characteristics of human pulmonary adenocarcinomas, such as expression of prosurfactant protein C, surfactant protein B, and thyroid transcription factor 1. Moreover, IGF-II induced proliferation and CREB phosphorylation in human lung cancer cell lines.⁴⁴

POLYMORPHISMS IN DNA REPAIR CAPACITY (DRC) GENES

Host-specific factors modulate susceptibility to tobacco carcinogenesis, including variations in DNA repair, which may influence the rate of removal of DNA damage and of fixation of mutations. In a seminal study, DRC was measured in peripheral blood lymphocytes by means of the host-cell reactivation assay, which measured cellular reactivation of a reporter gene damaged by exposure to 75 mM benzo[*a*]pyrene diol epoxide. The mean level of DRC in lung cancer cases (3.3%) was significantly lower than in controls (5.1%). Younger cases (less than 65 years) and smokers were more likely than controls to have reduced DRC.⁴⁵ This finding was confirmed in a case-control study of 316 newly diagnosed lung cancer patients and 316 cancer-free controls. Case patients who were younger at diagnosis, female, or lighter smokers, or who reported a family history of cancer, exhibited the lowest DRC, suggesting that these subgroups may be especially susceptible to lung cancer.⁴⁶ Reduced DRC and increased DNA adduct levels are associated with increased risk of lung cancer.

Nucleotide excision repair (NER) is one of the principal pathways for repair of DNA adducts induced by smoking-related carcinogens. NER is also the main mechanism for

removing cisplatin adducts.⁴⁷ The NER molecular machinery includes proteins that are mutated in xeroderma pigmentosum (XP) and Cockayne syndrome (CS) patients. In the global genome repair pathway, the protein complex XPC-HHR23B, which appears to be essential for the recruitment of all subsequent NER factors in the preincision complex, binds to damaged DNA. Then, the multicomponent transcription factor TFIIH, which is responsible for unwinding the damaged region of the DNA, is recruited. Next, XPG nuclease cleaves the DNA on the 3'-end. Following cleavage on the DNA, XPA/RPA proteins join the complex and recruit the ERCC1-XPF complex, which cleaves the 5'-end.^{47,48}

Polymorphisms of a number of DNA repair genes involved in the NER pathway have the potential to affect protein function and subsequently DRC. In lung cancer patients, reduced expression levels of XPG and CSB have been observed in peripheral lymphocytes.⁴⁹ Moreover, ERCC1 and XPD mRNA levels in lymphocytes have been shown to correlate with DRC and could thus be useful surrogates of DRC.⁵⁰ A reduction in DRC was more significant in lung cancer patients who were homozygous for two XPD (also known as ERCC2) polymorphisms (Asp312Asn at exon 10 and Lys751Gln at exon 23) (-12.3% and -18.3%, respectively) than in controls (-3.3% and -5.4%, respectively). Lung cancer patients who were homozygous for XPD Asn312Asn or Gln751Gln had an increased risk of suboptimal DRC (odds ratios, 1.57 and 3.50, respectively), compared to those who were wild-type homozygous.⁵¹ The intron 9 polymorphism of XPC [an 83-bp poly(AT) insertion] has also been correlated with DRC. XPC PAT+/+ homozygous subjects exhibited lower DRC than those with other XPC PAT genotypes, suggesting that XPC PAT+/+ is an adverse genotype.⁵² A common single-nucleotide polymorphism (A to G) in the 5'-noncoding region of the XPA gene has been related to lung cancer. The presence of one or two copies of the G allele was associated with a reduced lung cancer risk. Control subjects with one or two copies of the G allele demonstrated more efficient DRC than those homozygous for the A allele.⁴⁸

Polymorphisms in other pathways have been identified also. The XRCC3 (belonging to the homologous recombination repair pathway) Thr241Met at exon 7 and the XRCC1 (belonging to the base excision repair pathway) Arg399Gln at exon 10 have been related to lung cancer. The XRCC3 241Met allele was associated with higher DNA adduct levels, while

the XRCC1 399Gln allele was associated with higher DNA adduct levels only in nonsmokers.⁵³ Gene-smoking interaction associations have been found for the XPD Asp312Asn and Lys751Gln and for the XRCC1 Arg399Gln polymorphisms. The odds ratios decreased as pack-years increased. For nonsmokers, the adjusted odds ratio was 2.4, whereas for heavy smokers (more than 55 pack-years), the odds ratio decreased to 0.5. When the three polymorphisms were evaluated together, the adjusted odds ratios for individuals with five or six variant alleles versus individuals with no variant alleles were 5.2 for nonsmokers and 0.3 for heavy smokers.⁵⁴

Basic Science

Lung cancers are believed to arise after a series of progressive pathologic changes (preneoplastic lesions). Many of these preneoplastic changes are frequently detected in the respiratory mucosa of smokers. The molecular abnormalities involved in the multistep pathogenesis of lung carcinomas have been examined in lung cancer cell lines, microdissected primary lung tumors, respiratory epithelium from patients with lung cancer, and respiratory epithelium from nonsmokers⁵⁵ (Figure 37.2). Historically, the carcinogenesis sequence for squamous cell carcinomas shows that invasive lung cancer develops through a series of stages from mild, moderate, and severe atypia, carcinoma in situ, and then invasive cancer. The genetic changes of preneoplastic lesions can be analyzed in cytologic specimens, including sputum samples, bronchial brushes and bronchoalveolar lavage fluids (BAL) from smokers.

Atypical adenomatous hyperplasia (AAH) is considered to be the preinvasive lesion of adenocarcinoma. AAH is valued as a good target for delineating the timing and sequence of genetic alterations in the development of lung adenocarcinomas. Activation of the *K-ras* oncogene seems to be an early event involved in the initiation of AAH. Progression of AAH through increasing degrees of morphologic dysplasia requires the silencing of key tumor suppressor genes, such as p16. Ultimately, activation of telomerase and inactivation of the p53 tumor suppressor gene appear to be important in triggering invasive tumor growth.

Importantly, as discussed later, alterations of LKB1 function may represent one of the critical steps in the transition

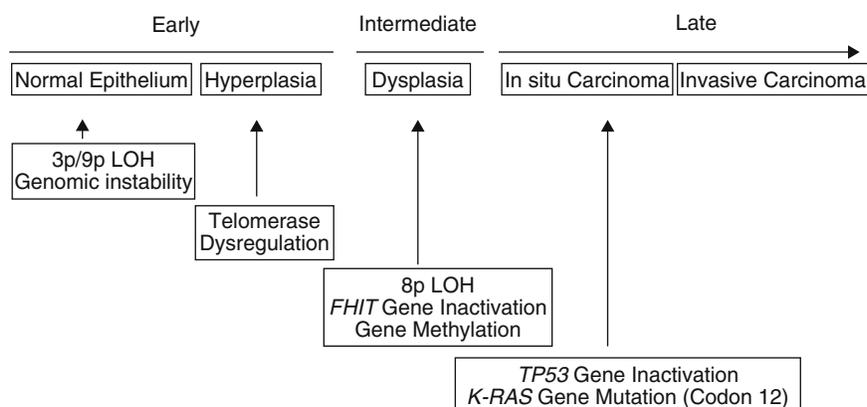

FIGURE 37.2. Sequential molecular changes during the multistage pathogenesis of squamous cell lung carcinoma.

from a benign to a potentially malignant proliferation of pneumocytes. Loss of LKB1 expression was more frequent (21%) in the high-grade AAH lesions (severe atypia) than in low-grade lesions (5%). Therefore, loss of LKB1 expression is associated with severe dysplasia.⁵⁶

Genetic

ONCOGENES AND TUMOR SUPPRESSOR GENES

In general, mutations follow a sequence. Allelic losses at chromosomes 3p, 9p, and 8p occur relatively early. Losses and inactivation of the retinoblastoma and p53 genes are intermediate, and losses at 5q are late events.⁵⁵ The losses at 3p are progressive, and advanced lesions and tumors have often lost most of the arm or the entire arm, whereas early lesions have more focal lesions.⁵⁷ In contrast, loss of heterozygosity (LOH) at 5q21 (APC-MMC region) and *K-ras* mutations are detected at the carcinoma in situ stage.⁵⁵ Some of the genetic changes involved in the pathogenesis of lung cancer are depicted in Table 37.2.

Mutations of the *K-ras* proto-oncogene are found in about 20% of the tumors with a mutation hot spot at codon 12. However, the mutation frequencies are significantly different among histologic subtypes of lung cancer. Most *K-ras* mutations are detected in lung adenocarcinoma.^{58,59} *ras* mutations are not observed in small cell lung cancer (SCLC).⁶⁰ *K-ras* mutations are not correlated with sex of the patient, tumor extent, or prior therapy status.⁶⁰

The p53 tumor suppressor gene is inactivated by mutations in more than 50% of NSCLC patients and in 90% of SCLC patients. p53 gene mutations in NSCLC cell lines with *ras* mutations tended to cluster at exon 8.⁶¹

EPIDERMAL GROWTH FACTOR PATHWAY

Overexpression and/or hyperactivity of the epidermal growth factor receptor (EGFR) has been shown to play a causal role in the progression of lung tumors. EGFR is activated by the binding of ligands to its extracellular domain, which leads to receptor homodimerization or heterodimerization with any of the other three members of this family of transmembrane tyrosine kinases: HER2 (erbB2), HER3, and HER4. This results in the binding of adenosine triphosphate (ATP) to the

receptor's catalytic site, activation of the receptor's tyrosine kinase, and autophosphorylation of C-terminal tyrosine residues, which in turn recruit several cytoplasmic signal transducers. These effector molecules include Ras-MEK-MAPK, phosphatidylinositol-3 kinase (PI3K) and its target Akt, p70S6 kinase, Src, and STATs, among others. Active Akt phosphorylates a number of substrates involved in apoptosis, cell-cycle regulation, protein synthesis, and glycogen metabolism, which include the Bcl-2 family member Bad, forkhead transcription factors, caspase 9, IKB kinase, p21, p27, mTOR, and nitric oxide synthase. Akt activity has been shown to be upregulated by loss of function of the phosphatase and tensin homologue (PTEN) phosphatase.⁶² In addition, the activation of receptor tyrosine kinases and Src also leads to activation of the signal transducers and activators of the transcription (STAT) pathway.

Tyrosine kinase growth factor receptors are overexpressed in a large number of human lung cancers, with NSCLCs demonstrating overexpression of EGFR and its ligands EGF, amphiregulin, and tumor necrosis factor- α (TGF- α), whereas some SCLCs demonstrate c-Kit overexpression. STAT activation leads to increased transcription of cyclin, D1, and Myc. In NSCLC cells, Stat3 DNA-binding capacity is upregulated by EGF, interleukin 6 (IL-6), and the hepatocyte growth factor (HGF).⁶³ A model proposed in NSCLC is that either EGF, IL-6, or the HGF-Src-Stat3 signaling cascade may protect lung cancer cells from death signals through the upregulation of Stat3 activity. Interestingly, no constitutive Stat3 activity was found in a human lung carcinoma cell line that had constitutive Akt activity. Therefore, Stat3 signaling may be dispensable for tumors that have upregulated other survival signals such as Akt.⁶³ An increased understanding of molecular biology is necessary to piece together all the critical factors in lung cancer cell growth.

ANGIOGENESIS

Angiogenesis is essential for tumor growth in vivo. Cytokines and growth factors, such as TGF- β , TGF- α , platelet-derived growth factor, basic fibroblast growth factor, and vascular endothelial growth factor (VEGF), are known to promote angiogenesis. VEGF expression is induced in cancer cells as a result of hypoxia and multiple genetic alterations, including p53 and PTEN loss-of-function, RAS and SRC gain-of-

TABLE 37.2. Summary of the histopathologic and molecular abnormalities of the major types of lung cancer.

<i>Abnormality histopathology</i>	<i>Small cell lung cancer (SCLC)</i>	<i>Squamous cell carcinoma</i>	<i>Adenocarcinoma</i>
Precursor	Unknown	Known	Probable
Lesion	Normal epithelium and hyperplasia	Squamous dysplasia and CIS	Adenomatous atypical hyperplasia (AAH)
Theory of development	Parallel	Sequential	Probably sequential
Molecular			
Gene abnormalities	<i>myc</i> overexpression TP53 LOH and mutation	TP53 LOH and mutation	<i>K-ras</i> mutation
LOH	High	Intermediate	Low
Frequency	90%	54%	10%
Chromosomal regions	5q21, 8p21-23, 9p21, 17p/TP53	8p21-23, 9p21, 17p/TP53	9p21, 17p/TP53
Genetic instability	High	Intermediate	Low
Frequency	68%	10%	13%

function and autocrine tyrosine kinase signaling pathways involving EGFR, HER-2/neu, and insulin growth factor 1 receptor (IGF-1R). In each case, VEGF expression is activated by hypoxia inducible factor 1 (HIF-1).⁶⁴ Cyclooxygenase (COX)-2, a catalyst in prostaglandin synthesis from arachidonic acid, also increases VEGF expression. Another angiogenesis modulator, nitric oxide synthase (NOS-2), stimulates VEGF as well. Immunohistochemical protein expression levels of COX-2, NOS-2, and VEGF correlated with microvessel density at the tumor-stromal interphase. NOS-2 and COX-2 levels correlated positively with VEGF status.⁶⁵

GENE AND PROTEIN EXPRESSION PATTERNS

Comprehensive analysis of gene expression patterns could provide detailed molecular portraits including differences in gene expression profiles among lung adenocarcinomas. Thyroid transcription factor 1, as well as several surfactant-related genes, was identified as one of the genes whose expression is primarily restricted to lung adenocarcinomas.⁶⁶⁻⁶⁹

High-resolution two-dimensional polyacrylamide gel electrophoresis (2-D PAGE) analysis allows the simultaneous assessment of hundreds of known and unknown polypeptides. Protein expression profiles (proteomic analysis) of lung adenocarcinomas identified triosephosphate isomerase, a key component of the glycolytic pathway that converts dihydroxyacetone phosphate to glyceraldehyde 3-phosphate, to be significantly elevated in more advanced lung adenocarcinomas.⁷⁰ A glucose-regulated (GRP58) protein that was increased in tumors with *K-ras* mutations was also elevated.^{70,71} Proteomic profiling of tumor tissue has the potential to uncover aberrantly expressed proteins resulting, in part, from numerous posttranslational modifications that may be altered in lung cancer.

ABERRANT METHYLATION

To determine the extent of RASSF1A promoter methylation, sputum samples from lung cancer patients and from current and former smokers were examined using the common procedure of methylation-specific PCR. Fifty percent of SCLC and 21% of NSCLC patients had RASSF1A methylation, whereas 1 of 2 former smokers and 4 of 13 current smokers showed RASSF1A methylation in sputum. Furthermore, 2 of the 4 current smokers and 1 former smoker showing RASSF1A methylation in their sputum developed lung cancer within 12 to 14 months of bronchoscopy.⁷²

Methylation status of p16, DAPK, and GSTP1 has been studied in bronchial brush samples from former smokers.⁷³ A total of 32% of the samples had methylation in at least one of the three genes tested.⁷³ Interestingly, in a study where DNA was isolated from sputum, bilateral BAL, and brushing taken at bronchoscopy, p16 promoter methylation and p53 mutations were observed in chronic smokers before any clinical evidence of neoplasia. However, *K-ras* mutations were exclusively seen in lung cancer patients.⁷⁴

Genetic Alterations in Serum/Plasma

Elevated levels of free DNA in the serum of lung cancer patients were reported more than 25 years ago.⁷⁵ The cancer fingerprint in the form of microsatellite alterations in plasma DNA was found in 50% of SCLC patients. A microsatellite

alteration was present in 76% of SCLC tumors and in 71% of plasma samples.⁷⁶ Microsatellite alterations, either as a shift (changes in the size of the microsatellite sequence), LOH, or both, have been found in tumor and serum/plasma DNA paired samples in NSCLC, using microsatellite markers at chromosome 3p.^{77,78}

Intriguingly, plasma DNA abnormalities were found in 45% of tumors up to 2 cm in maximum diameter.⁷⁸ Similarly, findings indicate that quantification and molecular characterization of plasma DNA in lung cancer patients are valuable noninvasive tools for discriminating patients from unaffected individuals and for detecting early recurrence during follow-up.⁷⁹ LOH in plasma samples also predated a diagnosis of lung cancer by several months.⁸⁰ Other studies have reported p53 and *K-ras* mutations in serum DNA. Aberrant methylation of at least one of p16, DAPK, GSTP1, or MGMT was noted in 15 of 22 (68%) NSCLC tumors but not in any paired normal lung tissue. In these primary tumors with methylation, 11 of 15 (73%) samples also had abnormal methylated DNA in the matched serum samples.⁸¹ Other genes are also methylated in primary tumors and paired preoperative serum samples from lung cancer patients.

Genetic and Molecular Alterations in Sputum

Sputum is the most commonly utilized biologic material to detect lung cancer cells in a noninvasive manner. Cancer cells harboring point mutations of oncogenes such as *K-ras*⁸² and p53 might be detected in sputum of patients with early-stage lung cancer. Bronchoalveolar lavage has also been used as biologic material for the detection of lung cancer.⁸³ Microsatellite alterations might be detectable in cytologically negative sputum from patients with lung cancer.⁸² In lung cancer, aberrant promoter methylation is frequently found in tumor suppressor genes.^{84,85} Aberrant methylation of the p16 and/or O-6-methyl-guanine-DNA methyltransferase (MGMT) promoter can be found in 100% of patients with squamous cell lung carcinoma up to 3 years before clinical diagnosis.⁸⁶ Aberrant promoter methylation of p16 has also been seen in normal bronchial epithelium.⁸⁷

Pathology

Premalignant Lesions

Bronchial preneoplastic lesions may be divided into three broad categories: reactive changes (histologically normal epithelium, hyperplasia, and metaplasia) having no increased risk other than smoke exposure; intermediate changes (mild and moderate dysplasia) having moderately increased risk; and high-risk lesions (severe dysplasia and carcinoma in situ) having considerably increased risk. The proportion of individuals with mild, moderate, or severe sputum cell atypia who will develop invasive lung cancer within 10 years was found to be 4%, 10%, and 40%, respectively.⁸⁸

In a study of high-risk subjects enrolled because of a cigarette-smoking history of at least 30 pack-years, an airflow obstruction, and either an abnormal sputum cytology or a previous or suspected lung cancer, laser-induced fluorescence endoscopy (LIFE) was more sensitive than white-light bronchoscopy (WLB) in detecting preneoplastic bronchial

changes.⁸⁹ LIFE was also better at identifying angiogenic squamous dysplasia (ASD) lesions than WLB. ASD is a unique lesion consisting of capillary blood vessels closely juxtaposed to and projecting into metaplastic or dysplastic squamous bronchial epithelium. ASD represents a qualitatively distinct form of angiogenesis in which there is architectural rearrangement of the capillary microvasculature. LOH at chromosome 3p was observed in 53% of ASD lesions. ASD was described in 34% of high-risk smokers without carcinoma and in 6 of 10 patients with squamous cell carcinoma who underwent LIFE.⁹⁰

Atypical adenomatous hyperplasia (AAH) is considered to be the preinvasive lesion of adenocarcinoma. These lesions are usually less than 7 mm in diameter and are detected on computed tomography (CT) scan as small, ground-glass densities. In resected lungs, the incidence of AAH was estimated to be 9% to 21% in patients with primary lung cancer and 4% to 10% in patients without lung cancer.⁸⁸ The mere presence of AAH does not necessarily indicate sure and unremitting progression to adenocarcinoma.

Lung cancer is classified into two major clinicopathologic groups: small cell lung carcinoma (SCLC) and non-small cell lung carcinoma (NSCLC). Squamous cell carcinoma (SCC), adenocarcinoma, and large cell carcinoma are the major histologic types of NSCLC.

Non-Small Cell Lung Cancer (NSCLC)

SQUAMOUS CELL CARCINOMA (SCC)

SCC (epidermoid carcinoma) of the lung is a malignant epithelial tumor with the differentiating features of squamous epithelium: keratinization, intercellular bridges, or both. SCC varies from small endobronchial obstructive tumors to large cavitated masses that can replace an entire lung. The masses are gray-white or yellowish, often with a dry flaky appearance that reflects the keratinization. Necrosis and hemorrhage are common; cavitation is seen in one-third of cases. Secondary infections may occur in cavitated masses. SCC of the lung may be divided into well-differentiated, moderately differentiated, and poorly differentiated subtypes depending on the degree of squamous differentiation present. Intercellular bridges and keratinization are most marked in well-differentiated tumors. SCCs tend to grow as nests of cells with surrounding stroma that may be desmoplastic and infiltrated by acute or chronic inflammatory cells. The nuclei are hyperchromatic, sometimes with prominent nucleoli and thick chromatin condensation along the nuclear membrane. SCC typically stains for both high and low molecular weight keratins. Other intermediate filaments may also be present, including vimentin and synaptophysin. SCC may also stain positively for epithelial membrane antigen (EMA), human milk fat globule (HMFG-2), S-100 protein, Leu-M1, and carcinoembryonic antigen (CEA).⁹¹

ADENOCARCINOMA

Adenocarcinoma of the lung is a glandular epithelial malignancy manifesting tubular, papillary, or acinar growth patterns or a solid growth pattern with mucin production. Unusual patterns include signet-ring adenocarcinoma, spindle cell adenocarcinoma, and adenocarcinoma showing

hepatoid differentiation. Adenocarcinomas are generally peripheral, well-circumscribed masses often associated with overlying pleural fibrosis or puckering. On cut section, they are gray-white, sometimes lobulated, and often have central scarring that may contain anthracotic pigment. The cells comprising adenocarcinoma are large, cuboidal, columnar, or polygonal with large vesicular nuclei and prominent nucleoli. Solid adenocarcinomas may be virtually indistinguishable from large cell carcinomas except for the mucin production. Mucin stains (mucicarmine, periodic acid-Schiff diastase, Alcian blue) are required for diagnosis. Mucin production varies from occasional positive cells to large pools containing nests of tumor cells. Some pleomorphic adenocarcinomas have foci of spindle cells. Pulmonary adenocarcinomas may be positive for a number of neuroendocrine markers.⁹¹

BRONCHOALVEOLAR CARCINOMA

Bronchoalveolar carcinoma (BAC), also called alveolar cell carcinoma or bronchoalveolar tumor, is a subset of pulmonary adenocarcinoma in which cylindrical tumor cells grow upon the walls of preexisting alveoli. The key feature is the preservation of the underlying architecture of the lung. BACs are separated into two major subtypes: nonmucinous, comprising two-thirds of cases, and mucinous, comprising most of the remainder. Nonmucinous BACs are composed of cells with Clara cell or type 2 cell differentiation or both. Mucinous BACs are composed of goblet or mucin-producing cells and are usually very well differentiated.⁹¹

LARGE CELL CARCINOMA

Large cell carcinoma, also called large cell anaplastic carcinoma and large cell undifferentiated carcinoma, is defined as a malignant epithelial tumor with large nuclei, prominent nucleoli, and usually well-defined cell borders without the characteristic features of SCC, small cell, or adenocarcinoma. This definition is one of exclusion and is dependent on extensive sampling of a given tumor.⁹¹

Small Cell Lung Cancer

The International Association for the Study of Lung Cancer (IASLC) proposed that small cell carcinoma be divided into three categories: small cell carcinoma; mixed small cell/large cell carcinoma; and combined small cell carcinoma, which also has components of squamous cell and/or adenocarcinoma.⁹² Small cell carcinoma is composed of small tumor cells with a round to fusiform shape, scant cytoplasm, finely granular nuclear chromatin, and absent or inconspicuous nucleoli. The tumor has a very hyperchromatic appearance because the cells have little cytoplasm and are situated very close to each other. Nuclear molding may be conspicuous but is more difficult to visualize in histologic sections than in cytologic preparations. Mitotic rates are characteristically high, sometimes exceeding 10 per single high-power field.⁹¹

NEUROENDOCRINE TUMORS

SCLC and large cell neuroendocrine (NE) carcinomas are high-grade NE tumors, whereas typical carcinoid and atypical carcinoid are low and intermediate grade, respectively. Large cell NE carcinoma is defined as a tumor with NE mor-

phology, including organoid nesting, palisading, trabecular pattern, and rosette-like structures. A mitotic count of 11 or more mitoses per 2mm² is the main criterion for separating large cell NE carcinoma and SCLC from atypical carcinoid. Large cell NE carcinoma and SCLC usually have very high mitotic rates, with an average of 70 to 80 per 2mm². Large cell NE carcinoma and SCLC also generally have more extensive necrosis than atypical carcinoid. Large cell NE carcinoma is separated from SCLC using a constellation of criteria, which include larger cell size, abundant cytoplasm, prominent nucleoli, vesicular or coarse chromatin, polygonal rather than fusiform shape, less-prominent nuclear molding, and less-conspicuous DNA encrustation of blood vessel walls.⁹³

Clinically, approximately 20% to 40% of patients with both typical and atypical carcinoids are nonsmokers, whereas virtually all patients with SCLC and large cell NE carcinoma are cigarette smokers. In contrast to SCLC and large cell NE carcinoma, both typical and atypical carcinoids can occur in patients with multiple endocrine neoplasia (MEN) type I. Histology heterogeneity with other major histologic types of lung carcinoma (squamous cell carcinoma, adenocarcinoma) occurs with both SCLC and large cell NE carcinoma but not with typical or atypical carcinoids. Furthermore, large cell NE carcinomas and SCLC have a high frequency of retinoblastoma direct inactivation related to retinoblastoma loss of protein expression. However, the typical carcinoids remain the only tumor type in the spectrum of neuroendocrine tumors that retain an intact retinoblastoma pathway. Moreover, p53 mutations leading to immunohistochemical aberrant overexpression of p53 protein are observed in 60% of large cell NE carcinomas and SCLC, in 20% of atypical carcinoids, and in no typical carcinoids. E2F1 regulated by p53-retinoblastoma pathways is overexpressed, as well as all its transcriptional target genes, in the majority of SCLC and large cell NE carcinomas, but not in carcinoids.⁹⁴

Biologic Differences Between Histologic Subtypes

EGFR expression varies according to histologic subtypes. Squamous cell carcinoma expressed EGFR in 84% of tumors, adenocarcinoma in 65%, large cell carcinoma in 68%, and SCLC in 0%. Interestingly, a study of a small number of patients with bronchioloalveolar carcinoma (BAC) found that the large majority had either intermediate or high expression of EGFR by immunostaining. There was also a significant correlation between nonmucinous BAC and EGFR expression, while mucinous BAC histology was more frequently related to HER2 overexpression.⁹⁵

In addition to differences in *K-ras* and p53 mutation frequencies between SCLC and NSCLC, there are other significant genetic distinctions. RASSF1A is inactivated by promoter methylation in more than 90% of SCLCs and in 40% of NSCLCs. Retinoblastoma is inactivated in more than 90% of SCLCs but only 15% of NSCLCs. p16 is almost never abnormal in SCLCs but is inactivated in more than 50% of NSCLCs. A study of hypermethylation in lung cancer for eight genes (p16, APC, CDH13, GSTP1, MGMT, RARb, CDH1, RASSF1A) revealed that the profile of methylated genes in SCLC was different from that of NSCLC.⁸⁴ Further details on methylation, including FHIT and DAPK, have been reviewed elsewhere.⁸⁵

Prognostic Factors

Clinical

In a retrospective analysis of 2,531 NSCLC patients treated in the Southwest Oncology Group (SWOG) with extensive disease defined either as distant metastases or locoregional recurrence after definitive radiotherapy, a Cox modeling and recursive partitioning and amalgamation (RPA) was performed to determine independent predictive factors of outcome.⁹⁶ Patients were treated between 1974 and 1988. Performance status (PS) was defined as good (SWOG 0–1, no symptoms or with symptoms but fully ambulatory) or poor (SWOG 2–4, nonambulatory). Good performance status (PS), female sex, and age greater than 70 years were significant independent predictors. In a second Cox model for patients with good PS, hemoglobin levels above 11 g/dL, normal calcium, and a single metastatic site were significant favorable factors. The use of cisplatin was an additional independent predictor of improved outcome. An RPA performed in 904 patients from more-recent SWOG trials, almost all of whom were treated with cisplatin, revealed three distinct subsets based on PS, age, hemoglobin, and lactate dehydrogenase (LDH); 1-year survivals were 27%, 16%, and 6%, respectively. Until 1980, additional variables, such as weight loss (less than 10 or more than 10 pounds), were not included. In the multivariate survival analyses by prognostic variables and therapy discriminants, significant favorable SWOG factors were PS 0 to 1, female sex, age greater than 70 years, and then greater than 45 years in females, single metastatic lesion, less than 10 pounds of weight loss, normal LDH, normal alkaline phosphatase, and hemoglobin above 11 g/dL. Median survival was 1 to 3 months better for the good PS, female, single-lesion, and cisplatin-based therapy categories.⁹⁶ Intriguingly, LDH was important in the poor PS subset; patients with a normal LDH level and poor PS had a survival outcome similar to other subsets with a good PS.⁹⁶

In the analysis of 1,052 patients included in clinical trials conducted by the European Lung Cancer Working Party (ELCWP), a Cox regression model found the following variables: Karnofsky PS (greater than 80 = SWOG 0–1; less than 70 = SWOG 2–4), neutrophil counts, metastatic involvement of skin, serum calcium level, age, and gender, as well as disease extent, because patients with stages I to III were included in the analysis. According to an RPA model, the best subgroup of patients was defined as female with limited disease and Karnofsky PS above 80.⁹⁷ In a third, smaller analysis including a homogenous group of stage III unresectable or inoperable patients receiving cisplatin 120mg/m² plus vinca alkaloid combination chemotherapy, a multivariate analysis disclosed the following parameters associated with outcome: initial PS, with patients having a good PS displaying an increased objective response and survival; bone metastases, which were adversely predictive of response rate and survival; elevated LDH and male sex, both of which were associated with shortened survival; and the presence of two or more extrathoracic metastatic organ sites, which was associated with shortened survival.⁹⁸ When objective response with chemotherapy was included in the analysis, it was also strongly associated with longer survival.⁹⁸

In a prospective Spanish Lung Cancer Group (SLCG) study⁹⁹ including 557 cisplatin combination-treated NSCLC

patients, PS, gender, and weight loss were significant prognostic factors. Second, weight loss in lung cancer patients is associated with both impaired therapy outcome and reduced survival.⁹⁷

In studies of multimodality treatment in stage IIIA (N2) and IIIB NSCLC, the SWOG study of concurrent cisplatin plus etoposide and chest radiotherapy followed by surgery observed that the strongest predictor of long-term survival after thoracotomy was absence of tumor in the mediastinal lymph nodes at surgery (median survivals, 30 versus 10 months and 3-year survival rates, 44% versus 18%).¹⁰⁰

Some of these predictive markers of survival, such as PS, hemoglobin level, and bone, liver, or skin metastases, are understandable; however, why gender, LDH, or weight loss influence survival remains unclear. New pieces of information should shed light on these prognostic factors. First, there are interindividual differences in DRC that are accentuated according to age and gender, with females having a reduced DRC.⁴⁶ Based on this difference in DRC, females would have greater chemosensitivity than males. In vitro intrinsic cisplatin resistance was associated with elevated DRC in NSCLC cells.¹⁰¹ DRC is a surrogate of the NER pathway, which eliminates cisplatin adducts,^{47,50} and it has been demonstrated that NSCLC patients with effective systemic (host) DRC have poorer survival than patients with suboptimal DRC.¹⁰² Patients who were in the top DRC quartile of the group (DRC greater than 9.2%) had a risk of death more than two times that of patients in the bottom quartile (DRC less than 5.8%). Median survival was 8.9 months for patients in the top DRC quartile, compared with 15.8 months for those in the bottom quartile ($P = 0.04$).¹⁰²

Earlier findings suggest that the formation and persistence of cisplatin or carboplatin adducts in buccal cells or in leukocytes predict better response.^{103,104} Cisplatin DNA adducts in nuclei of buccal cells were studied in a small group of patients who received radical radiotherapy and daily administration of low-dose cisplatin for inoperable NSCLC.¹⁰⁵ Nuclear staining was performed in buccal cells collected 1 hour after cisplatin on the fifth treatment day (after five daily doses of cisplatin 6 mg/m²). Cisplatin DNA adduct staining remained a significant independent predictor of survival. Patients with low levels of induced DNA adducts in buccal cells showed a meager median survival of 5 months, in contrast with 30 months for patients with elevated DNA adduct levels.¹⁰⁶ Beyond the stratification for gender in future clinical trials, measuring DRC by functional assays or surrogates such as ERCC1 or XPD mRNA in peripheral lymphocytes⁵⁰ could help to predict responders.⁹⁸

Metabolism

In contrast to normal mammalian cells, which use oxygen to generate energy, cancer cells rely on glycolysis for energy. Lung cancer patients with weight loss have elevated 3-phosphoglycerate and phosphoenolpyruvate, components of the glycolysis pathway¹⁰⁷ (Figure 37.3). Furthermore, c-Myc and HIF-1 overexpression deregulate glycolysis through the activation of the glucose metabolic pathway, which regulates lactate dehydrogenase and induces lactate overproduction¹⁰⁸ (Figure 37.3). Elevated serum LDH was associated with shortened survival and remission duration.⁹⁸ Elevated mRNA levels of phosphofructokinase, glyceraldehyde-3-phosphate

dehydrogenase, phosphoglycerate kinase, and enolase were also reported.¹⁰⁸ Systematic identification of lung adenocarcinoma proteins using 2-D PAGE and mass spectrometry found that at least four proteins (phosphoglycerate kinase 1, phosphoglycerate mutase, alpha enolase, and pyruvate kinase M1), all of which are components of the glycolysis pathway (see Figure 37.3), were increased in expression and associated with poor survival in resected lung adenocarcinoma.¹⁰⁹ Expression of phosphoglycerate kinase 1, the sixth enzyme of the glycolytic pathway (Figure 37.3), reflects increased glycolysis in the tumor cells and is related to the induction of a multidrug resistant phenotype distinct from MDR1. The hypoxic nature of solid tumor triggers VEGF expression, which stimulates angiogenesis and glycolytic enzymes, including phosphoglycerate kinase, which facilitates anaerobic production of ATP.¹¹⁰

A surrogate of the cancer glycolytic pathway could be positron emission tomography (PET) reflecting the biochemical and physiologic processes occurring in the tissues being imaged. The most frequently used positron-emitting radiopharmaceutical is 18-fluor, labeled 2-deoxy-d-glucose (¹⁸F-FDG), a radioactively labeled glucose analogue. The clinical use of ¹⁸F-FDG-PET is based on the premise that cancer cells exhibit a higher glycolytic rate than do nonneoplastic cells. It is reasonable to speculate that a higher tumor uptake of the radiolabeled glucose analogue could be a surrogate of the glycolytic pathway. PET imaging has been used to assess changes in tumor glucose use during chemotherapy. In NSCLC, median time to progression and overall survival were significantly longer for ¹⁸FDG-6-PET metabolic responders in the interval before and after the first chemotherapy cycle.¹¹¹

Overexpression of ERCC1 mRNA and Other NER Genes

Moving toward a new prognostic classification, overexpression of ERCC1 mRNA and other NER genes has been associated with repair of cisplatin-induced DNA damage and clinical resistance to cisplatin. In a small study of cisplatin/gemcitabine-treated metastatic NSCLC patients, performance status, weight loss and low ERCC1 mRNA expression were independent prognostic factors. ERCC1 mRNA levels were even more significant than that of performance status.¹¹² Median survival for patients with low ERCC1 expression was 15 months in contrast to only 5 months for those harboring high expression.

M2 Subunit of Ribonucleotide Reductase

Also to be considered as a potential new predictive and prognostic marker is the ribonucleotide reductase activity, which is increased in cancer cells. The subunit M2 (or RRM2) is directly involved in a number of signaling pathways.¹¹³ Among other drugs, gemcitabine decreases ribonucleotide reductase activity. In a retrospective analysis, better time to progression and survival were observed in gemcitabine/cisplatin-treated metastatic NSCLC patients who had low ribonucleotide reductase subunit M1 (or RRM1) mRNA expression.¹¹⁴ Interestingly, retinoblastoma is sequentially phosphorylated by cyclin D-CDK4/6 and cyclin E/CDK2 during G₁/S cell-cycle transition. This modification leads to the dissociation of retinoblastoma from E2F/DP heterodimers, leaving them in a transcriptionally active state

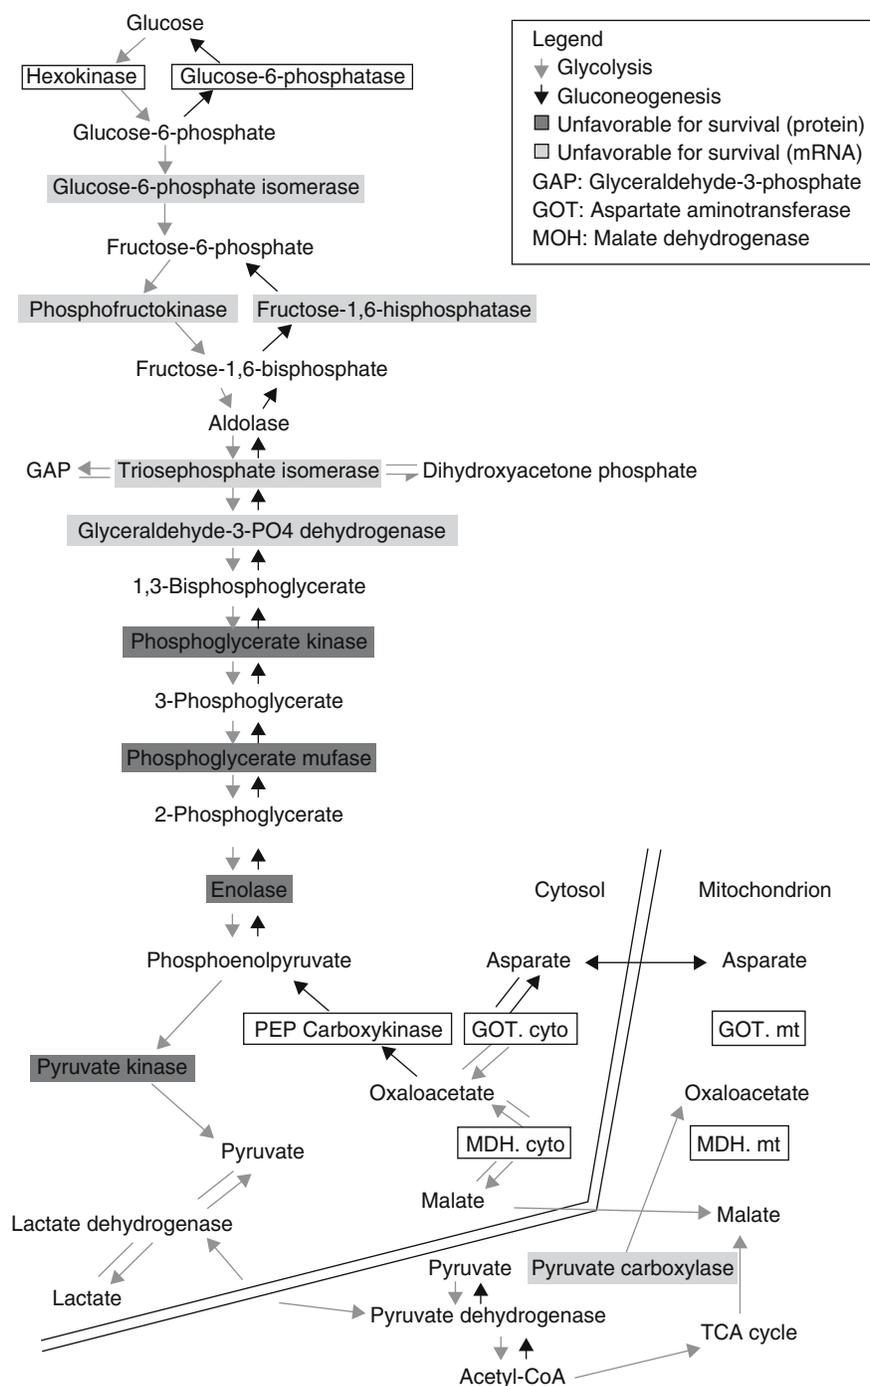

FIGURE 37.3. Glycolysis and gluconeogenesis pathway.

that regulates several DNA synthesis enzymes also involved in chemotherapy response, such as dihydrofolate reductase (DHFR), thymidylate synthase (TS), and ribonucleotide reductase.¹¹⁵ In SCLC and NSCLC, p16/INK4A and retinoblastoma are reciprocally inactivated, resulting in the inactivation of the same p16/INK4A/RB pathway.¹¹⁶ Therefore, in prospective studies the predictive and/or prognostic value of certain transcripts should be kept in mind. For example, in ribonucleotide-dependent chemotherapy combinations, the role of RRM1 and TS mRNA levels could influence response and survival, as proposed in the model in Figure 37.4.

Genetic

Since the first article describing *K-ras* mutations in lung adenocarcinomas,⁵¹ a continual list of new genetic markers has been described, predicting disease-free survival and overall survival, mainly in surgically resected stage I NSCLC (Table 37.3). Tumors with *K-ras* mutations tend to be smaller and less differentiated than those without. The normal DNA sequence GGT at codon 12 is commonly switched to TGT.⁵² *K-ras* mutations in NSCLC cell lines were related to poor survival in stage IIIB-IV.¹¹⁷ Numerous reports have pointed out

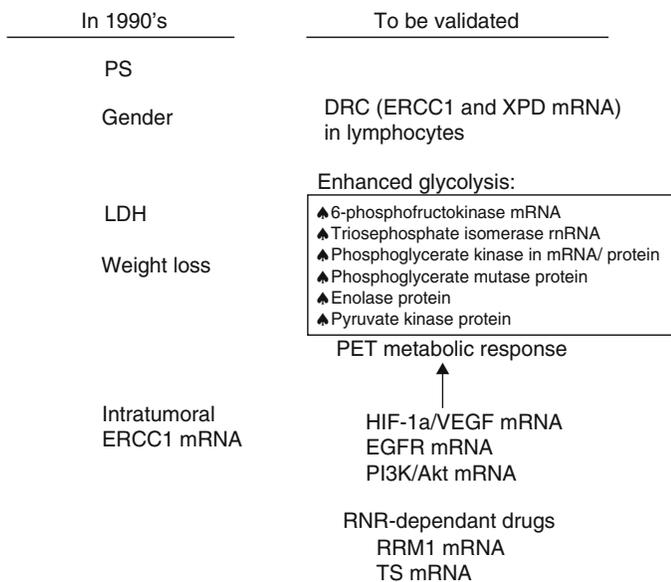

FIGURE 37.4. Factors associated with impaired therapy outcome and reduced survival.

the prognostic value of *K-ras* codon 12 mutations in stage I NSCLC.^{52,118–120} However, in a recent report, neither *K-ras* nor p53 mutations influenced survival in all patients, although in patients receiving adjuvant chemotherapy, those without *K-*

ras mutations had a median survival of almost 42 months, whereas for those with mutations, median survival bottomed out at nearly 25 months ($P = 0.09$; risk ratio = 0.59).¹²¹ Such differences were not seen in patients who did not receive adjuvant chemotherapy. In a randomized neoadjuvant trial, *K-ras* mutations were more often found in the surgery-alone arm than in the neoadjuvant arm.¹²² In a small neoadjuvant chemotherapy study of stage III NSCLC, the presence of *K-ras* mutations in the surgical specimens was a significant predictor of poor disease-free survival.¹²³

Retinoic Acid Receptor and COX-2

In several retrospectively analyzed surgical series, high retinoic acid receptor- β mRNA levels by in situ hybridization correlated with poor survival in stage I NSCLC.¹²⁴ A significant relationship between elevated expression of cyclooxygenase 2 (COX-2) and worse survival has also been observed in stage I disease.^{125,126}

Aberrant Methylation

Hypermethylation of death-associated protein kinase (DAPK) was found in 44% of tumors and linked to significantly poorer survival.¹²⁷ Similarly, hypermethylation of RASSF1A was linked to worse survival.¹²⁸ However, in a recent study, neither DAPK nor RASSF1A methylation in tumor or

^b Another study found no survival differences according to methylation patterns.

serum influenced survival in surgically resected NSCLC patients.¹²⁹

Real-time (RT)-PCR of lung cancer specimens showed that reduced expression of collapsin response mediator protein 1 was statistically significantly associated with advanced disease, lymph node metastases, early postoperative relapse, and shorter survival.¹³⁰ Interleukin (IL)-8 mRNA overexpression was also associated with advanced disease, lymph node metastases, early relapse, and shorter survival.¹³¹ Intriguingly, immunohistochemical analysis showed that patients whose tumors lacked IL-10 had worse survival than those whose tumors retained IL-10 expression.¹³² Along the same lines, using RT-PCR, overexpression of macrophage migration inhibitory factor was associated with poor survival.¹³³ Regulated upon activation, normal T-cell-expressed and -secreted (RANTES) overexpression was a predictor of significantly better survival in stage I lung adenocarcinoma.¹³⁴ Also in stage I disease, patients with hypermethylated insulin-like growth factor-binding protein 3 (IGFBP-3) had a significantly lower disease-free and overall survival than those without IGFBP-3 methylation.¹³⁵ LOH on chromosome segment 11p15.5, which includes the gene for ribonucleotide reductase, confers poor survival in patients with stage I NSCLC.¹³⁶ Stage I patients with high ERCC1 mRNA expression also had significantly better survival than those with low ERCC1 expression, who could potentially benefit from adjuvant chemotherapy.¹³⁷ However, patients with efficient DNA repair mechanisms (high ERCC1 expression or without LOH on 11p15.5) could be chemoresistant and may not require adjuvant chemotherapy.

Proteomic and Gene Expression Signatures

Using microarray platforms, metastases-associated gene-expression signature has been identified. There were no survival differences in lung adenocarcinoma according to 9,248 highly varying genes; however, survival differences surfaced when using 128 metastases-associated genes.¹³⁸ Interestingly, these differences were also evident with the use of only 17 genes (8 upregulated and 9 downregulated genes). This signature, taken as a whole, seems to contain predictive information. Intriguingly, the gene-expression signature associated with metastases arises from both malignant and stromal elements in primary tumors, indicating that the large stromal component of the signature would have been missed had only malignant epithelial cells been isolated by laser capture microdissection.¹³⁸ Moreover, the use of mRNA-based gene expression profiles predicted survival in surgically resected NSCLC.^{68,139} Interestingly, increased phosphoglycerate kinase 1 mRNA was significantly associated with poor survival in lung adenocarcinoma and mRNA levels correlated with the expression of the phosphoglycerate kinase 1 protein isoform.^{109,139} Upregulation of genes in the pathway involving glycolysis and the Krebs cycle has been demonstrated in mesotheliomas with significant increases of glyceraldehyde-3-phosphate dehydrogenase, LDH, and phosphoglycerate kinase 1¹⁴⁰ (see Figure 37.3). Proteomic patterns could be used to accurately classify surgically resected NSCLC and identify individual protein isoforms that become tumor markers.¹⁴¹ This knowledge opens the doors to the assessment of HIF-1 levels as a putative prognostic marker, because the upregulation of each HIF-1 in cancer functions as a key transcrip-

tion factor that potentially regulates 9 of the 11 glycolytic enzymes (see Figure 37.3). Table 37.3 summarizes some genetic markers that have been identified as prognostic and predictive markers in stage I NSCLC.

Microvessel Density

A meta-analysis of more than 4,400 surgically resected NSCLC patients analyzed the microvessel count assessed on surgical samples by immunohistochemistry using factor VIII, CD34, and CD31. A high microvessel count in the primary lung tumor was a statistically significant poor prognostic factor for survival, regardless of the marker used.¹⁴² A strong correlation between IL-8 mRNA expression and microvessel counts or macrophage counts has also been observed.¹⁴³ Higher IL-8 mRNA levels and higher macrophage counts were associated with lower survival. In addition, VEGF expression was positively related to microvessel density and negatively related to the degree of dendritic cell infiltration.¹⁴⁴ A multivariate analysis showed VEGF expression, microvessel density, and dendritic cell infiltration to be independent prognostic factors. The patient group with both high VEGF expression and low dendritic cell infiltration showed a worse prognosis. Angiopoietin 2 expression was significantly correlated with higher CD105-stained microvessel density in NSCLC.¹⁴⁵ CD105 is a proliferation-related endothelial antigen that is more selective than CD34, which is a pan-endothelial antigen reacting not only with newly forming vessels but also with stable vessels just trapped in tumors. Five-year survival for resected NSCLC patients was 71% when VEGF was low and angiopoietin was negative and 41% when angiopoietin was positive and VEGF was high.

Screening of Lung Cancer

Lung cancer screening is controversial. A number of studies have been performed using all three methods for the evaluation of screening tests, including randomized trials of screening, population-based studies of screening, and observation studies of screening in select cohorts. For lung cancer screening to be accepted as beneficial, it must unequivocally prolong life expectancy by detecting the disease at a time when its course will be altered with the institution of therapy. Moreover, the screening test should be specific enough not to create an inordinate number of false-positive exams that could do psychologic or physical harm to the participants through anxiety or through the advocacy of potentially harmful tests. Finally, the use of a screening test must be cost-effective and conform to an accepted standard for cost/lives saved.

To validate the utility of lung cancer screening, choices must be made that focus these efforts to enrich for those at highest risk. These choices include proper target (i.e., high-risk population), the choice of central or peripheral screening, the appropriate algorithm for patient follow-up once an abnormality has been detected, and the timing and magnitude of the intervention to prove that the detected abnormality is a life-threatening abnormality. Once confirmed as a life-threatening lung cancer, the management of the disease must conform to present standards of care until well-conducted

studies prove that these treatment standards are excessive for these newly detected abnormalities.

Randomized Trials of Lung Cancer Screening

The earliest randomized trial for lung cancer screening started in 1960 with a randomization of 55,034 London men to either chest X-ray every 6 months for 3 years or to chest X-ray at the beginning and the end of the 3-year period. The detection rate and the number of respectable cancers was higher in the screened group, but there was no difference in lung cancer mortality.^{146,147} In the 1970s and 1980s, the National Cancer Institute sponsored a study of 10,000 high-risk volunteers at Sloan Kettering,¹⁴⁸ Johns Hopkins,¹⁴⁹ and another 10,000 high-risk volunteers at the Mayo Clinic.¹⁵⁰⁻¹⁵² These trials, whose participants were all male smokers over 45 years of age who had a smoking history of at least 1 pack per day, were designed to investigate the efficacy of lung cancer screening using a combination of chest X-ray and conventional sputum cytology. A fourth study similar to the Mayo Clinic study was performed in Czechoslovakia.¹⁵³⁻¹⁵⁵ In the Johns Hopkins and Memorial Sloan-Kettering trials, both experimental and control participants had annual screening chest radiography, and the experimental arm had sputum cytology every 4 months to address the incremental benefit of sputum cytology analysis rather than chest radiographs per se. Although they found that sputum analysis did not favorably influence outcome, these studies achieved survival rates among all groups three times higher than predicted by epidemiologic data.

A prevalence screening with chest X-ray and sputum cytology was performed in all individuals in the Mayo Lung Trial followed by randomization to radiographs and sputum cytology every 4 months or the recommendation to have these annually. The Czechoslovakian study, a 3-year study with 3-year follow-up, also began with a prevalence screen, then randomization to a screened or control group, and the control group was told not to get either radiograph or cytology during the 3-year study period. In both the Mayo and Czech studies, more lung cancers were found in the screened group, and there was a tendency toward earlier stage at diagnosis, resectability, and survival for the screened group. Five-year survival for the control group in the Mayo Study was 15% compared to 33% in the screened group.¹⁵¹ Both studies demonstrated increases in cumulative lung cancer incidence in the experimental group above that of control groups, demonstrating significant improvements for the experimental groups in case fatality (number of cancer deaths/number of individuals with cancer) but not in significant reductions in lung cancer mortality (number of cancer deaths/number of individuals screened).

Lead-time bias, length bias, and overdiagnosis have been used to potentially explain the differences between lung cancer mortality and earlier stage at diagnosis, improved resectability, and survival of the screened.¹⁵⁶⁻¹⁵⁹ Lead-time bias operates when the timing of diagnosis between screening and nonscreening cases is not adjusted; that is, earlier detection may result in longer survival from the time of diagnosis even if death is not delayed. Length bias occurs when conditions are not adjusted for the rate of cancer progression and the screening examination purportedly detects slow-growing cancers. In other words, the slower the growth of the

neoplasm, the longer it is present without symptoms, and the greater the likelihood of detection. Overdiagnosis bias refers to the phenomenon of detecting a lung cancer that would otherwise have remained subclinical before death from other causes.

Supporters of the concept of lung cancer screening have argued that these original trials were flawed.¹⁶⁰ Arguments include the observations that (1) they did not include a "no-screening" study arm and thus no determination of true efficacy could be made; and (2) the sample size of these studies was inadequate, because both the Mayo Lung Project and the Czechoslovakian studies were powered to detect a 50% reduction in lung cancer mortality in the screened group compared with the control group, and the power to detect a smaller 10% reduction in mortality, which is still clinically significant, was much lower (only 0.21 and 0.16, respectively).^{161,162}

High-Risk Populations: Smokers and Nonsmokers

The risk of lung cancer is influenced by duration of smoking, the number of cigarettes smoked per day, and the age at which a smoker stopped smoking; that is, the longer one lives after cessation of smoking, the greater the risk for developing lung cancer. The greater the consumption of tobacco as measured by pack-years, the greater the risk that one will develop lung cancer. Lung cancer prevalence is also influenced by the presence of airway obstruction. For individuals smoking 30 to 40 pack-years or more with airflow obstruction, defined by FEV₁/FVC less than 70% and an FEV₁ less than 70% predicted, the risk of lung cancer is three to four times higher than those individuals with normal airflow.¹⁶³ Individuals with previously surgically treated stage 1 NSCLC or head and neck primary neoplasms are also at increased risk for the development of a new lung primary cancer for up to 20 years, at an approximate rate of 1% to 2% per patient per year.¹⁶⁴ Occult lung cancers detected by sputum cytology also have an especially high rate of metachronous tumors, approaching 11% at 5 years with an incidence per patient-year of surveillance of 2.2%.¹⁶⁵ The incidence of a second primary tumor in patients treated for squamous cell carcinoma of the aerodigestive tract can be as high as 16.2%, with 6.4% being synchronous and 9.8% being metachronous.¹⁶⁶ Metachronous tumors are most likely in the lung (57%), placing these patients in one of the highest risk categories for the development of lung cancer.

Present Screening Efforts

There has been a realization by the medical community that the efficacy of lung cancer screening should now be investigated in a research setting using newer computed tomographic techniques. Moreover, individual centers as well as lung specialized program of research excellence (SPORES) have enrolled patients on either radiographic, sputum-based, or combination programs for lung cancer screening to develop potential molecular markers. All lung cancer screening programs are based on the premise that high-risk populations must be chosen to have any hope of cost-effectiveness, and, in addition to the technologic evolution alluded to above, there has been a greater refining of the demographics of the

individual at high risk for lung cancer who may be a candidate for enrolling in lung cancer screening programs.

CHEST X-RAY

The National Cancer Institute initiated a large randomized controlled screening trial using chest radiographs for lung cancer screening as part of the Prostate-Lung-Colorectal-Ovarian (PLCO) trial. One of the objectives of the trial, which is ongoing, was to determine whether screening reduces lung cancer-specific mortality by at least 10% relative to unscreened groups.¹⁶⁷ This trial remains under analysis at this writing.

LOW-DOSE HELICAL CT SCANNING OF THE CHEST

NONRANDOMIZED APPROACHES

The Japanese Anti-Lung Cancer Association screened approximately 26,000 male smokers over 50 years of age from 1975 to 1993 with chest radiography and sputum cytology, and added spiral CT scanning to the regimen in 1993.¹⁶⁸ Significantly more cancers were detected in the CT era (36 over 5 years) compared to the pre-CT era (43 over 18 years), and 81% of the CT screened lung cancers were stage IA compared to 42% in the pre-CT era. There was a striking increase in the 5-year survival, from 48% to 82%. Single-spiral CT prevalence scanning was performed by another Japanese group in 3,967 of 5,483 persons aged 40 to 74 years, individuals who had previously been screened with yearly chest X-rays and sputum cytologic screening. Of the 223 individuals with abnormal findings, 19 cancers were detected, and 84% of these were found to be stage I;^{169,170} the addition of CT scanning increased the rate of lung cancer diagnosis by approximately 12 fold.

The Early Lung Cancer Action Project (ELCAP) was initiated in the United States in 1993 to define the frequency with which malignancy was found in screen-detected nodules and the frequency with which malignant nodules were curable. A cohort of 1,000 high-risk persons was experimentally screened using a noncomparative design in which a single cohort was recruited for baseline and annual repeat CT screening.^{170,171} The medically fit volunteers were aged 60 years or older, with at least 10 pack-years of cigarette smoking and no previous cancer.

Chest radiographs and low-dose CT were done for each participant, with the diagnostic/interventional investigation of screen-detected noncalcified pulmonary nodules by short-term high-resolution CT follow-up dictated primarily by size of the nodule. Noncalcified nodules were detected in 233 [23%; 95% confidence interval (CI), 21–26] participants by low-dose CT at baseline, compared with 68 (7%; 95% CI, 5–9) by chest radiography. Malignant disease was detected in 27 (2.7%; 95% CI, 1.8–3.8) by CT and 7 (0.7%; 95% CI, 0.3–1.3) by chest radiography, and stage I malignant disease in 23 (2.3%; 95% CI, 1.5–3.3) and 4 (0.4%; 95% CI, 0.1–0.9), respectively. Of the 27 CT-detected cancers, 26 were respectable. Biopsies were done on 28 of the 233 participants with noncalcified nodules; 27 had malignant noncalcified nodules and 1 had a benign nodule. Another 3 individuals underwent biopsy against the ELCAP recommendations; all had benign noncalcified nodules. No participant had thoracotomy for a benign nodule.¹⁷¹

A follow-up report concentrating on 1,184 annual repeat screenings defined a positive result from the screening test as a newly detected nodule or one to six noncalcified pulmonary nodules with interim growth. Of the 1,184 repeat CT screenings, the test result was positive in 30 (2.5%). In 2 of these 30 cases, the individual died (of an unrelated cause) before diagnostic workup, and the nodule(s) resolved in another 12 individuals. In the remaining 16 individuals, the absence of further growth was documented by repeat CT in 8 individuals and further growth was documented in the remaining 8 individuals. All 8 individuals with further nodular growth underwent biopsy, and malignancy was diagnosed in 7. Six of these 7 malignancies were non-small cell carcinomas (5 of which were stage IA and 1 of which was stage IIIA), and the 1 small cell carcinoma was found to be of limited stage. The median size dimension of these malignancies was 8 mm. In another 2 subjects, symptoms prompted the interim diagnosis of lung carcinoma. Neither of these malignancies was nodule associated but rather was endobronchial; 1 was a stage IIB non-small cell carcinoma and the other was a small cell carcinoma of limited stage. The data from the ELCAP experience will be pooled with that of two initiatives, which are outgrowths of the original ELCAP, the New York ELCAP (NY-ELCAP) and the International Early Lung Cancer Action Program (I-ELCAP). These efforts share the same set of principles and protocol as well as the ELCAP web-based management and data-recording system and its associated teaching files.¹⁷²

The Mayo Clinic also evaluated CT-based lung screening in a prospective cohort study of 1,520 individuals aged 50 years or older who had smoked 20 pack-years or more.¹⁷³ Participants underwent three annual low-dose CT examinations of the chest and upper abdomen. Two years after baseline CT scanning, 2,832 uncalcified pulmonary nodules were identified in 1,049 participants (69%). Forty cases of lung cancer were diagnosed: 26 at baseline (prevalence) CT examinations and 10 at subsequent annual (incidence) CT examinations. CT alone depicted 36 cases, and sputum cytologic examination alone, 2. There were 2 interval cancers. The mean size of the non-small cell cancers detected at CT was 15.0 mm. The stages were as follows: IA, 22; IB, 3; IIA, 4; IIB, 1; IIIA, 5; IV, 1; limited small cell tumor, 4. Twenty-one (60%) of the 35 non-small cell cancers detected at CT were stage IA at diagnosis.

PRESENT RANDOMIZED STUDIES

The National Cancer Institute and the American College of Radiology Intervention Network is sponsoring a multicenter, randomized controlled trial of 88,000 individuals at high risk of developing lung cancer to see whether screening with low-dose helical CT can reduce lung cancer-specific mortality relative to chest radiographs. High risk is defined by age 55 to 74 years with a current or previous heavy smoking history equaling at least 30 pack-years; former smokers must have quit within the preceding 15 years. The experimental group will undergo screening with low-dose helical CT, and the control group will undergo screening with chest radiographs. Both groups will be screened annually for at least two incidence screens, and both groups will complete quality of life questionnaires. The primary endpoint of the trial is lung cancer-specific mortality. Intermediate endpoints include all-cause mortality; surgical stage at diagnosis; medical resource

utilization; the impact of screening on quality of life and psychological effects; and the economic consequences of helical CT screening.

SPUTUM CYTOLOGY SCREENING

Sputum cytology studies for lung cancer screening require huge numbers of subjects and are less attractive because of the low sensitivity (65%) of sputum analysis, as well as the inability to detect peripheral cancers with the same sensitivity as central tumors.¹⁷⁴ To be successful as a population-screening tool, sputum cytology sensitivity must be improved using such approaches as (1) immunostaining of abnormal epithelial cells, (2) computer-assisted image analysis of exfoliated sputum cells, (3) PCR-based assays to detect changes in dominant and recessive oncogenes, and (4) genetic epidemiology markers to more precisely define at-risk populations of current and former smokers.¹⁷⁵ Tockman has reported that an antibody to heterogeneous nuclear ribonucleoprotein (hnRNP) may improve the accuracy of preclinical lung cancer detection. HnRNP is overexpressed in exfoliated airway cells as a prelude to the development of lung cancer.^{163,176,177} In a background of normal-appearing airway cells, abnormal staining for hnRNP with the antibody can be performed by quantitative densitometry of immunostained slides. In separate, ongoing prospective studies, sputum has been collected annually from stage I resected non-small cell lung cancer patients at high risk of developing a second primary lung cancer and Yunnan tin miners at high risk of primary lung cancer. These two prospective studies accurately predicted that 67% and 69% of those with hnRNP upregulation in their sputum would develop lung cancer in the first year of follow-up. Other investigators are quantitating malignancy-associated changes by computer-assisted image analysis to report nuclear distribution of DNA in histologically normal cells adjacent to preinvasive or invasive cancers. In a retrospective analysis, malignancy-associated changes in sputum cytology were able to correctly identify 74% of subjects who later developed lung cancer.¹⁷⁸ Other molecular markers that are being examined in sputum include microsatellite alterations,¹⁷⁹ methylation changes,¹⁸⁰ and point mutations in p53 and *ras* genes.^{181–183}

The detection of sputum atypia and subsequent identification of the source of cells demands improvements in endoscopic visualization. Only 30% to 40% of carcinoma in situ are visible to an experienced endoscopist on conventional bronchoscopy. Autofluorescence bronchoscopy is now being used with greater frequency as a complementary technology to sputum screening to provide targeted biopsies of dysplastic lesions.¹⁸⁴ The technique is based on the observation that when the bronchial surface is illuminated by a blue light (405–442 nm), such as light from a helium-cadmium laser, there is a progressive reduction in the fluorescence intensity as the tissue becomes more abnormal, especially in the green wavelength band of the autofluorescence spectrum. The marked reduction in fluorescence intensity (up to 10-fold decrease in the green and about 5-fold in the red) in precancerous and cancerous tissue is thought to be caused by the combination of an increase in the thickness of the bronchial epithelium, a very slight increase in blood content in the area of the submucosa of the lesion, and a loss of fluorophore concentration or fluorescence quantum yield.¹⁸⁵ A multicenter clinical trial in 173 subjects with known or suspected lung

cancer was performed in which conventional bronchoscopy was followed by fluorescence examination. The relative sensitivity of both examinations versus conventional bronchoscopy alone was 6.3 for intraepithelial neoplastic lesions and 2.71 when invasive carcinomas were also included.¹⁸⁶

Staging

TNM Staging Classification

Staging of lung cancer (Table 37.4) uses the TNM staging system and was most recently revised in 1997.¹⁸⁷

Mediastinal Staging

Staging of the mediastinum by either invasive or noninvasive techniques should efficiently and accurately determine whether patients are candidates for a potentially curative surgical resection, or for protocols involving multimodality approaches before or instead of attempted surgical resection. The most confounding aspect of the surgical staging of lung cancer involves accurate assessment of the mediastinum, which ideally should define (1) mediastinal lymph node status and (2) mediastinal invasion.

MEDIASTINAL INVOLVEMENT: LYMPH NODES

Approximately 26% to 44% of patients with newly diagnosed lung cancer have mediastinal lymph node involvement. Adverse prognostic factors associated with positive mediastinal nodes include extracapsular spread of tumor, multiple levels of involved lymph nodes, bulky enlarged nodes, and the size of the primary tumor.^{188–191} Multiple studies have found that metastatic disease to the subcarinal lymph nodes adversely affected prognosis compared to other lymph nodes.^{192–198} It is generally believed that multistation nodal disease has a somewhat worse prognosis than single-station disease, but the location of metastatic disease to a single nodal station probably has no significant effect.

The poor survival rates with surgery alone in N2 disease, without significant survival benefit for adjuvant postoperative radiotherapy,^{199–201} has led to designing protocols that use nonsurgical (radiotherapy and/or chemotherapy) therapy first, often to convert the “unresectable” tumor to resectable, to improve long-term survival.²⁰² In general, patients with lymph nodes greater than 2 cm in short-axis diameter measured by CT, who have extranodal involvement, and multistation disease along with groups of multiple involved smaller lymph nodes, are considered to have bulky, unresectable disease. These patients are referred for protocols involving chemoradiation if they are functionally fit to tolerate the therapy. The heterogeneity of N2 prognostic categories can certainly confound ongoing prospective trials attempting to define good-risk candidates for multimodality therapy. The heterogeneity phenomenon of mediastinal lymph node involvement has been reviewed by Andre et al. in 702 consecutive patients having surgical resection of N2 non-small cell lung cancer.²⁰³ A multivariable analysis using Cox regression identified four negative prognostic factors: clinically apparent N2 disease; the involvement of multiple lymph node stations; either pathologic stage T3 or T4 status; or no preoperative chemotherapy. For patients having primary

TABLE 37.4. Stage Grouping: TNM subsets.

Stage	TNM subset	TNM descriptors	
0	Carcinoma in situ		
IA	T1N0M0	T1	Tumor 3 cm or less in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus* (i.e., not in the main bronchus)
IB	T2N0M0	T2	Tumor with any of the following features of size or extent: More than 3 cm in greatest dimension; involves main bronchus, 2 cm or more distal to the carina; invades the visceral pleura; associated with atelectasis or obstructive pneumonia that extends to the hilar region but does not involve the entire lung.
IIA	T1N1M0	T3	Tumor of any size that directly invades any of the following: chest wall (including superior sulcus tumors), diaphragm, mediastinal pleura, parietal pericardium; or tumor in the main bronchus less than 2 cm distal to the carina, but without involvement of the carina; or associated atelectasis or obstructive pneumonia of the entire lung.
IIB	T2N1M0 T3N0M0	T4	Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, esophagus, vertebral body, carina; or separate tumor nodules in the same lobe; or tumor with malignant pleural effusion.**
IIIA	T3N1M0 T1N2M0 T2N2M0 T3N2M0	N0 N1	No nodal involvement involving ipsilateral hilar or bronchial nodes
IIIB	T4 any N, M0 Any T, N3, M0	N2 N3	involving ipsilateral mediastinal nodes involving contralateral nodes or <i>scalene nodes</i>
IV	Any T, Any N M1	M0 M1	no distant metastases distant metastases present

*Note: The uncommon superficial tumor of any size with its invasive component limited to the bronchial wall, which may extend proximal to the main bronchus, is also classified T1.

**Note: Most pleural effusions associated with lung cancer are caused by tumor. However, there are a few patients in whom multiple cytopathologic examinations of pleural fluid are negative for tumor. In these cases, fluid is nonbloody and is not an exudate. Such patients may be further evaluated by video thoracoscopy and direct pleural biopsies. When these elements and clinical judgment dictate that the effusion is not related to the tumor, the effusion should be excluded as a staging element and the patient should be staged T1, T2, or T3.

surgery, the 5-year survivals varied according to N2 characteristics: one-level involvement with microscopic disease (34%); multiple level lymph nodes with microscopic disease (11%); single-level clinically apparent disease (8%); and multilevel clinically apparent disease (3%). For patients with single-level microscopic disease, there was no difference in survival between different lymph node stations.

It is just as important to determine whether the extent of mediastinal involvement is T3 (nontransmural involvement of the pericardium, involvement of the phrenic nerve focally, or extrapericardial involvement of the pulmonary artery or veins) or T4 (involvement of the superior vena cava, aorta, main pulmonary artery, esophagus).²⁰⁴ Extension of tumor into these structures radically alters the T status of the tumor and influences surgical decision making toward primary resection or protocol-directed induction therapy with later surgical consideration. The limited studies that deal with T3 involvement of the mediastinum report a 5-year survival approaching 25% if the mediastinal lymph nodes are not involved.²⁰⁵ However, with T4 involvement of the superior vena cava, main pulmonary artery, or aorta, the 5-year survival rate in very limited series is approximately 15%, with the best survivals (30%) reported in patients with localized superior vena caval involvement.²⁰⁵

NONINVASIVE STAGING MODALITIES

COMPUTED TOMOGRAPHY

A recent review of 20 studies published since 1993 with a cohort of 3,438 patients evaluated the accuracy of CT scan-

ning for the mediastinal staging of lung cancer.^{204,206} There was marked heterogeneity for the sensitivity (pooled value = 0.57) and specificity (pooled value = 0.82), with positive predictive value of 0.56 and negative predictive value of 0.83. These data reinforce that findings on a CT scan cannot be used solely to determine mediastinal lymph node status and reveal that the accuracy of CT scanning of the mediastinum has not changed despite improvements in technology. Obstructive pneumonia with resulting enlarged lymph nodes can account for the fact that 40% of lymph nodes thought, on CT scan, to be malignant were actually benign, and microscopic involvement of lymph nodes is encountered in up to 15% of patients having a complete mediastinal lymph node dissection for presumed stage I disease. The obvious conclusion for the standard of care in 2004 is that CT scanning findings of the mediastinum, when using the 1-cm cutoff limit, must be supplemented by other noninvasive and invasive techniques to have a higher confidence that abnormally enlarged lymph nodes truly represent IIIA or IIIB disease.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) currently has a limited role in the noninvasive staging of bronchogenic carcinoma but may be used to evaluate for vascular or vertebral body invasion with suspected T4 tumors or to assess the integrity of the brachial plexus in patients with a Pancoast tumor.²⁰⁷ Due to poorer spatial resolution and motion artifact, it is less sensitive in evaluation of the pulmonary parenchyma.

*NONINVASIVE STAGING BEYOND CT: POSITRON
EMISSION TOMOGRAPHY*

Positron emission tomography (PET) scanning has become an ideal supplement to CT scanning because of its higher sensitivity and specificity for the evaluation of mediastinal lymph nodes. Toloza et al.²⁰⁶ evaluated PET scanning for mediastinal staging in 1,111 patients from 29 reports in the literature, finding a pooled sensitivity of 0.85 and a pooled specificity of 0.88. The overall positive predictive value and negative predictive value were superior to CT scanning (0.78 and 0.93, respectively). Other reports have noted that the use of PET scanning can change decision strategies for patients in 10% to 20% of instances.²⁰⁸ PET scanning, however, is limited in its anatomic interpretation and sensitivity when analyzing lesions less than 1.2 cm. Lymph node stations can be accurately identified when PET images and CT images are fused or interpreted simultaneously, but the volume or number of involved lymph nodes cannot be determined with present PET technology. The size limitations for sensitivity may not only have to do with spatial resolution software but with the type of lesion that is being visualized, as the PET intensity is known to be lower in bronchoalveolar lung cancer compared to other histologies.²⁰⁹

SURGICAL STAGING

MINIMALLY INVASIVE TECHNIQUES FOR MEDIASTINAL STAGING

Bronchoscopic Techniques Including Transbronchial Needle Aspiration Biopsy Bronchoscopy can play a key role in the staging of lung cancer. Carinal biopsy alone in the presence of an endobronchial tumor can have a yield as high as 5%,²¹⁰ and bronchoscopy may also detect other lesions unsuspected in the airway. Fluorescence bronchoscopy is being evaluated not only for finding occult lesions but also to define margins of resection of the bronchus that could influence stage, that is, proximity to the carina.²¹¹ The yield for transbronchial needle aspiration (TBNA) varies widely in the literature (20% to 89%) and seems to be related to the size and location of the lesion as well as operator experience.²⁰⁴ In a recent review regarding the accuracy of TBNA of the mediastinum in patients with lung cancer, the sensitivity was determined to be 76% with a specificity of 96%.²⁰⁴ The problem with TBNA is that the false-negative rate can be as high as 30%, and the yield is reported to improve with at least seven passes with the TBNA needle.

Endobronchial Ultrasound Biopsy (EBUS) Endobronchial ultrasound allows visualization of the tracheobronchial and peribronchial lesions, mediastinal lymph nodes, and adjacent vascular structures as well as peripheral pulmonary tumors, but studies of its efficacy are limited because of its limited use by specialty centers. In 207 of 242 patients investigated using EBUS, the lymph nodes were successfully sampled (86%), and a diagnosis or cancer stage could be obtained in 172 patients (72%).²¹²

Endoesophageal Ultrasound Fine-Needle Aspiration (EUS-FNA) Because the esophagus lies posteriorly and to the left of the trachea and is in proximity to the lymph nodes between these two structures, lymph node levels 5, 7, 8, and possibly 9 are accessible by endoesophageal ultrasound fine needle. Right-sided levels 2, 4, and the pretracheal space are not accessible with EUS-FNA. EUS-FNA is usually performed

in the outpatient setting with conscious sedation. Wiersema et al.²¹³ reported that EUS-FNA was superior to TBNA in the diagnosis of mediastinal metastases in NSCLC. When performed in patients with enlarged lymph nodes, EUS-FNA has a high sensitivity and specificity (0.88 and 0.91, respectively), with an overall positive predictive value of 98% and negative predictive value of 77%.²¹⁴ EUS-FNA can also detect malignancy in normal-sized lymph nodes, and when successful has altered the staging of patients with normal-size lymph nodes from 18% to 42%. The sensitivity and specificity are low, however, with normal-sized lymph nodes due to the necessity to perform many aspirations of different sites to increase the yield.²¹⁴

Transbronchial and Transesophageal Needle Biopsy: Recommendations These techniques are most useful for patients who have documented enlarged, nondiscrete lymph nodes with extensive mediastinal infiltration (clinical/radiographic evidence of N2/N3 disease). In this situation TBNA and EUS-NA provide the best chance for obtaining a diagnosis with the least morbidity. Multiple aspirates should be performed to avoid sampling error.

INVASIVE SURGICAL STAGING OF THE MEDIASTINUM

Based on the relationship between prognosis and the level of lymph node involvement, Naruke and colleagues developed a thoracic lymph node map that illustrates the location of various lymph nodes.²¹⁵ This map has been most recently revised in 1997 by Mountain and Dresler.²¹⁶ Each lymph node is assigned to a specific nodal station (N0, N1, N2, or N3) representing a prognostic subgroup or stage. In 1986 and subsequently in 1997, Mountain introduced and modified a new international staging system in which the extent of nodal spread serves as the principal prognostic determinant,^{187,217} and multiple reports have validated the prognostic value of this staging system.

The method by which the mediastinum is explored depends on the site of the lesion. Cervical mediastinoscopy involves an initial digital exploration palpating suspicious nodes followed by placement of the scope to visualize and biopsy the appropriate lymph nodes. The N2 (levels 4, 7) and N3 nodal stations (2, scalenus/supraclavicular) with the exception of the aortic nodes (levels 5 and 6), the inferior pulmonary ligament nodes (level 9), and the paraesophageal nodes (level 8), are accessible for biopsy using this technique. Ginsberg has emphasized the importance of combining standard cervical mediastinoscopy with exploration of the scalenus fat pad²¹⁸ in patients with central nonsquamous tumors. Extended cervical mediastinoscopy is a technique that combines cervical mediastinoscopy with mediastinoscopic evaluation of the subaortic space as a single procedure.²¹⁹ More commonly, the subaortic space is approached using the Chamberlain procedure, which permits the surgeon to directly palpate the subaortic extrapleural space and biopsy the lymph nodes in this region.²²⁰ Some surgeons prefer to use a mediastinoscope through a small anterior incision in the left chest and not remove the costal cartilage to perform a Chamberlain procedure.

Video-assisted thoracoscopic surgery (VATS), a minimally invasive surgical technique, is an alternative method to assess levels 5 and 6 as well as the paraesophageal (level 8) and pulmonary ligament (level 9) nodes.²²¹ Whether a surgeon surgically stages the ipsilateral and the contralateral mediastinal

nodes in a lung cancer patient is being increasingly dictated by the use of PET scanning, although there are recommendations in the absence of PET scan findings (see following). In the absence of PET scanning availability, staging of the contralateral side usually is defined by nodal size on computerized tomography.

Mediastinoscopy or Mediastinotomy Mediastinal nodal enlargement by CT is an absolute indication for mediastinoscopy. For patients with mediastinal nodes of any size, the documentation of metabolic activity within single nodes or in multiple nodal basins in an individual with suspected lung cancer is also an indication for surgical staging of the suspicious mediastinum. For patients whose eligibility criteria require documentation of mediastinal disease, as in randomized or nonrandomized trials of induction therapy for locoregional lung cancer, mediastinal biopsy is mandated. A large mass or a lesion of any size located within the inner one-third of the lung field, especially if it is an adenocarcinoma or large cell carcinoma, correlates with an increased incidence of N2 nodal spread despite the finding of a normal mediastinum on CT scan.²²² Left-sided lung cancers also merit mediastinoscopy at certain centers. Because of the tendency for left lower lobe lesions to spread contralaterally, some centers recommend biopsy of bilateral mediastinal nodes, using mediastinoscopy to sample anterior 7, 2R, 4R, 2L, and 4L, and extended mediastinoscopy, mediastinotomy, or EUSNA to sample 5L and 6L. Mediastinoscopy evaluation is also warranted for left upper lobe lesions to sample the level 4L nodes.²²³

In a review of more than 5,687 patients undergoing mediastinoscopy between 1983 and 1999, the overall sensitivity of standard cervical mediastinoscopy was 81%, with a negative predictive value of 91%.²⁰⁴ Extended cervical mediastinoscopy used in combination with standard cervical mediastinoscopy will increase the overall sensitivity by 17% to 44% and improve negative predictive value by 10% to 20% when compared directly to standard mediastinoscopy.²¹⁹ The Chamberlain procedure or anterior mediastinotomy has a sensitivity of 63% to 86%, and its negative predictive value remains high whether it is performed alone (89% to 100%) or in combination with standard cervical mediastinoscopy (89% to 92%).²⁰⁴

Video-Assisted Thoracic Surgery and Mediastinal Staging Thoracoscopy has been used to not only assess left-sided lymph node stations not accessible by standard mediastinoscopy and for the inferior pulmonary ligament and paraesophageal lymph nodes, but also in very limited series to assess systematic nodal dissection for right-sided tumors. There are few series, however, describing the surgical technique in its entirety, and most operations involve the use of a 4.5- to 5-cm anterior incision that enhances visibility, yet in expert hands subcarinal lymph node dissection is possible.²²⁴ It is generally concluded that VATS is used by a small group of surgeons in lung cancer mediastinal staging, and its chief use involves the assessment of pleural effusions associated with lung cancer adenopathy and the documentation of discontinuous pleural disease by direct visualization and roentgenographically negative pleural involvement.

Intraoperative Staging at the Time of Resection There is controversy whether complete ipsilateral mediastinal nodal

dissection as opposed to minimal or more-extensive hilar and mediastinal lymph nodes sampling has greater efficacy in determining intraoperative stage and whether the degree of the dissection influences prognosis. A number of investigators have evaluated the extent of mediastinal biopsy necessary to obtain accurate staging information. Bollen et al. found that systematic sampling of mediastinal lymph nodes was as successful as mediastinal lymph node dissection in identifying N2 disease (discovery ratio, 2.7; CI, 1.04–4.2).²²⁵ Bollen described more injuries to the recurrent nerve with lymph node dissection when compared to historic controls and that lymph node dissection lengthens the operation. Izbicki et al.²²⁶ conducted a randomized prospective trial with 182 patients comparing systematic mediastinal lymph node sampling to mediastinal lymph node dissection, and found that the number of N2 positive levels was greater in the patients who underwent complete dissection, although the percentage of patients found to have N1 or N2 disease was not significantly different between the two study arms; there was no difference in blood loss or blood replacement.²²⁶ A similar study was conducted by Sugi et al. in 115 patients with clinical T1N0 tumors that were less than 2 cm in diameter; mediastinal metastases were found in 13% of each group.²²⁷ From these data, it appears that systematic lymph node dissection is no more accurate than mediastinal dissection for staging NSCLC.

Whether regional lymph node sampling or complete ipsilateral lymphadenectomy affects long-term survival is unclear. There has been no long-term study of the effects of a complete mediastinal lymphadenectomy. However, the retrospective study by Funatsu et al. has shown that 5-year survival was significantly better in 64 patients who underwent a lymph node sampling, when compared to 61 patients who underwent a radical mediastinal lymphadenectomy.²²⁸ Conversely, in a series of 151 patients at Memorial Sloan-Kettering Cancer Center who had positive mediastinal lymph nodes, a 30% 5-year survival was observed as one of the highest in the literature today with mediastinal lymphadenectomy.²²⁹ In Izbicki's randomized trial comparing mediastinal node sampling with mediastinal lymphadenectomy, no increase in morbidity or mortality was noted for lymphadenectomy, and there were no differences in survival. This trial, however, was underpowered to show differences in locoregional recurrence or survival.²²⁶

The Intergroup Trial 0115 of adjuvant therapy in patients with completely resected stages II and IIIA NSCLC had the patients stratified by the type of lymph node dissection before participation (dissection versus sampling). Of 373 eligible patients accrued to the study, 187 underwent sampling and 186 had dissection. Although no significant difference in stage distribution was observed between the two surgical procedures, complete dissection identified significantly more levels of N2 disease and was associated with improved survival with right-sided NSCLC compared to systematic sampling.²³⁰

Wu et al. recently presented the results of the largest randomized trial to date that compared the two techniques.²³¹ In this study of 471 eligible patients with stages I to IIIA NSCLC followed up for up to 10 years after resection, complete dissection was associated with significant improvement in survival: 59 months versus 34 months median survival. Significant differences in survival were present for all patho-

logic stages of disease and, on multivariate analysis, the type of lymph node dissection was found to be an independent predictor of survival.

Sentinel Lymph Node Mapping and Mediastinal Staging

The first draining node from a primary lesion is known as the sentinel node, and determination of the sentinel node (SN) has been used to individualize lymph node dissection for melanoma and breast cancer, as well as to target those nodes for which thin-section immunohistochemical analysis of micrometastases is warranted. For patients with lung cancer with small tumors and clinically negative lymph nodes, SN mapping could be most beneficial because this group has a 15% and 20% incidence of occult nodal metastatic disease. The safety and efficacy of the SN technique have already been documented in patients with lung cancer. Liptay et al.^{232,233} established the feasibility of this technique by defining the SN in 82% of patients with lung cancer intraoperatively with technetium colloid, reporting that upstaging from NO to N1 could occur in as high as 7% of patients. Schmidt,²³⁴ Nomori,²³⁵ and Sugi²³⁶ achieved an identification rate for sentinel lymph nodes of more than 80%, 87%, and 63%, respectively. Although most of the SN were identified at station 12, the rate of mediastinal sentinel lymph nodes (skip metastases) was 20% to 35%. These detection rates had a false-negative rate of 2% to 5%, and may be influenced by the degree of the patient's chronic obstructive pulmonary disease with loss of lymphatic channels due to emphysema and/or the presence of large necrotic tumors.

The implications and utility of SN mapping will become more clear as greater experience with the technique is published to determine the appropriate isotope, timing, and intraoperative or preoperative injection, as well as the ability to intraoperatively determine nodal status using molecular techniques. By selecting only those lymph nodes with a high probability of metastases, molecular or protein identification of these occult metastases could radically stage shift these patients and have implications for therapy, either intraoperatively or postoperatively.

Restaging of the Mediastinum After Induction Therapy

Patients with documented mediastinal lymph node disease will be found at surgery after multimodality therapy to be downstaged to NO in approximately 45% of the cases,²³⁷⁻²³⁹ and a recent report using docetaxel-cisplatin induction therapy described mediastinal nodal sterilization in 65% of patients.²⁴⁰ Mediastinal clearance and complete resection of disease in these patients has been associated with 3-year survival of 53% to 61%, compared to 11% to 18% for those without mediastinal clearance. These studies suggest that surgical resection should be avoided in patients after induction therapy who have definite, biopsy-proven residual tumor in the mediastinal nodes.

As mediastinal status after therapy appears to be a strong predictor of survival, the ability to restage the mediastinum in the least invasive fashion could guide therapeutic decisions with regard to (1) feasibility of surgical resection and (2) modification of nonsurgical strategies such as changing chemotherapy regimens if a response is not being achieved. Radiographic techniques are not reliable in the restaging of the mediastinum unless there is a complete disappearance of disease [potential complete response (CR)] or if the disease is obviously progressing.²⁰² Hence, one should histologically

define the status of treated mediastinal adenopathy using less-invasive techniques than thoracotomy, with mediastinal lymph node dissection and intraoperative frozen section assessment of mediastinal disease clearance. There are controversial data to suggest that remediastinoscopy is feasible and may supply information in selected populations of patients. In a study by Mateu-Navarro et al.,²⁴¹ 24 patients underwent remediastinoscopy after receiving neoadjuvant chemotherapy with mitomycin, iphosphamide, and cisplatin or cisplatin and gemcitabine. In 12 (50%), remediastinoscopy was positive. The 12 remaining patients were operated on, and residual disease in mediastinal lymph nodes was detected in 5 patients (pN2) and hilar lymph nodes in 1 patient (pN1). The other 6 patients were free of nodal disease. The sensitivity, specificity, and accuracy of remediastinoscopy were 0.7%, 1%, and 0.8%, respectively. In a similar study by Van Schil et al., 27 of 31 identified candidates had remediastinoscopy without major technical difficulties after neoadjuvant therapy.²⁴² Remediastinoscopy was positive in 11 patients (40.7%) and negative in 16 (59.3%). Of these 16, 4 turned out to be false negatives, for a sensitivity of 71%, specificity of 100%, and accuracy of 84%. These data, although promising, do not establish remediastinoscopy as the gold standard for histologic verification of mediastinal restaging and do not address the issues that may occur with remediastinoscopy after induction chemoradiotherapy.

PET Scanning After Induction Chemo/Radiotherapy

The role of PET scanning after both induction chemotherapy and chemoradiotherapy with regard to the status of the mediastinum has been reported by various groups with mixed degrees of enthusiasm, and there are recent reports that FDG-PET scanning can be performed as early as 4 to 12 weeks after radiotherapy with or without chemotherapy and is a better predictor of survival in these patients than CT.²⁴³ In addition, survival and time to progression in Stage IIIB and IV are longer in patients who have a 46% to 60% reduction in standard uptake value (SUV) as early as 21 days after commencing therapy. Nevertheless, these studies do not involve surgical verification of the lymphadenopathy after therapy, and do not comment on nodal basin SUV as a separate region of interest.

One of the initial reports evaluating PET after induction therapy involved 15 surgically staged N2-NSCLC patients who underwent a first PET before three cycles of platinum-based induction chemotherapy.²⁴⁴ After induction, a second PET was performed and locoregional therapy consolidated with surgery in 9 and radiotherapy in 6. Correlation with pathology of the 9 resection specimens revealed that the accuracy of PET in predicting mediastinal lymph node downstaging was 100% (6 true negatives; 3 true positives). Survival was significantly better in patients with mediastinal clearance ($P = 0.01$) or with a greater than 50% decrease in the SUV of the primary tumor ($P = 0.03$) after induction chemotherapy. A study from the Massachusetts General Hospital²⁴⁵ investigated PET restaging in 26 patients with histologically confirmed stage III NSCLC [21 with stage IIIA (N2) NSCLC and 5 patients with a highly selected subset of stage IIIB] who were treated with preoperative chemoradiotherapy. All patients had an initial FDG-PET and another performed 2 weeks after completion of preoperative therapy. The FDG-PET images were evaluated qualitatively for uptake at the

primary tumor sites and mediastinal lymph nodes. When a value of 3.0 was used as the SUV cutoff, sensitivity and specificity were 88% and 67%, respectively, for the primary tumor site restaging. The sensitivity and specificity of FDG-PET for mediastinal restaging were 58.0% and 93.0%. These results indicated that FDG-PET may be useful for monitoring the therapeutic effect of neoadjuvant chemoradiotherapy in patients with stage III NSCLC. For the primary lesions, SUV-based analysis has high sensitivity but limited specificity for detecting residual tumor. In contrast, for restaging of mediastinal lymph nodes, FDG-PET is highly specific but has limited sensitivity. In a study from Memorial Sloan Kettering Cancer Center,²⁴⁶ FDG-PET was accurate in the detection of the presence or absence of disease in the primary site (positive and negative predictive values of the FDG scan were 98% and 29%, respectively) of 56 patients restaged postinduction therapy with FDG-PET. Most of the errors in tumor staging were related to understaging T4 disease. In predicting the presence of residual mediastinal nodal disease, however, the positive predictive value, the negative predictive value, sensitivity, and specificity for PET in all assessable patients were 46%, 79%, 67%, and 61%, respectively. This study, however, was limited by the absence of a majority of preinduction FDG-PET scans. More promising data for regional accuracy of lymph node prediction was reported by Cerfolio et al.²⁴⁷ in a small group of 11 patients with N2 disease in whom repeat FDG-PET scans correctly predicted the absence or presence of cancer in all the N2 paratracheal lymph nodes in all patients. FDG-PET scanning was not as accurate in the other N2 stations, however, including levels 5, 6, and 7.

Future prospective trials of the utility of FDG-PET scanning to predict nodal clearance after induction therapy must be validated by histologic confirmation of disease either by intraoperative mediastinal dissection or by combining PET scanning with targeted positive nodes for remediastinoscopy²⁴⁸ or EUS.²⁴⁹

Preoperative Evaluation

Based on the literature for more than 14,000 patients reported, the operative mortality rates for resection of lung cancer average 4% (lobectomy, 3%; pneumonectomy, 7%–9%), and the most common causes of death include pneumonia and respiratory failure (41%), myocardial infarction (14%), empyema and bronchopleural fistula (11%), hemorrhage (7%), and pulmonary embolus (6%).²⁵⁰ Surgical selection should be defined by correlation of the functional cardiopulmonary reserve with the age of the patient instead of the chronologic age alone. In a recent review of the literature, the mortality of pulmonary resection for lung cancer in patients 70 to 79 years or more than 80 years was 6% and 8%, respectively.²⁵⁰ For patients in their seventh decade or older, the mortality for lobectomy is 4% to 7%, and for pneumonectomy it is approximately 14% to 16%.²⁵¹ These rates may be more a function of comorbidity than age alone.

In a literature review of more than 9,000 patients, the overall operative morbidity for patients having lung cancer surgery is 34%, with the leading causes of major morbidity being pneumonia (6%), respiratory failure (5%), empyema/bronchopleural fistula (4%), cardiac failure (4%), hemorrhage

(2%), myocardial infarction (1%), and pulmonary embolus (1%).²⁵⁰ The most common minor morbidity is supraventricular tachyarrhythmia (12%).

Preoperative Pulmonary Assessment

The major parameters that have been used to predict postoperative mortality on preoperative studies include blood gas studies while breathing ambient air, and the forced expiratory volume in 1 second as an absolute number or as a percentage of predicted value. Preoperative arterial oxygen saturation less than 90% has been associated with an increased risk of postoperative complications.²⁵² Hypercapnea (PaCO₂ greater than 45 mmHg) cannot be used as an independent risk factor for increased complications but does call for further evaluation of pulmonary reserve.^{253,254} The generally accepted guidelines for preoperative FEV₁ for lobectomy and pneumonectomy are values greater than 1.5 and 2L, respectively, and in all cases the maximum voluntary ventilation (MVV) should be greater than 50% of predicted.²⁵⁵ Preoperative diffusing capacity of the lung for carbon monoxide (DLCO) has also been linked to postresection morbidity and mortality. For pneumonectomy and lobectomy, a preoperative DLCO of greater than 60% and 50% are recommended for pneumonectomy and lobectomy, respectively. The risk of pulmonary complications also increases if the DLCO% is less than 80%.²⁵⁶ In general, patients with an FEV₁ more than 80% predicted, a DLCO more than 80% predicted, and no significant cardiac history are suitable for pneumonectomy.²⁵³

Postoperative Prediction of Lung Function

The prediction of postoperative lung function after resection by using nuclear medicine perfusion scans and recently quantitative CT further defines pulmonary risk. A quantitative radionuclide perfusion scan measures the relative function of each lung.^{257–259} In general, the threshold for postoperative FEV₁ for surgical resection is between 0.7 and 0.8L.^{260,261} It is difficult to predict the absolute cutoff for surgical resection and predicted postoperative FEV₁ by percent of normal, but a group of studies have suggested increased morbidity with a postoperative FEV₁ that is less than 40% of normal.^{258,262} Moreover, a predicted postoperative DLCO less than 40% is also associated with increased morbidity.^{258,263,264}

Exercise Testing

Stair climbing has been used historically to gauge an individual's cardiopulmonary conditioning. In general, lobectomy candidates were expected to climb three flights of stairs, and indeed this correlates with an FEV₁ greater than 1.7L. Pneumonectomy patients who could climb five flights of stairs have an FEV₁ above 2L.^{265,266}

Formal cardiopulmonary exercise testing (CPET) with the measurement of oxygen consumption has also been used to stratify for the risk of perioperative complications. Patients with a preoperative oxygen consumption greater than 20mL/kg/min are not at increased risk of complications or death,^{255,267,268} whereas those with measurements less than 10mL/kg/min are at high risk for postoperative complications.^{267,269,270}

Specific Management of Lung Cancer Stages

Screen-Detected Central NSCLC

Occult lung cancers (those without radiographic or bronchoscopic findings) are usually detected in sputum screening programs of high-risk asymptomatic individuals and in patients who have had a previous aerodigestive malignancy. The majority of these sputum detected lesions are squamous cell carcinomas, and synchronous lung cancers occur in 7% to 10% and as high as 22% in some studies.²²¹ Occult lung cancers are usually carcinoma in situ or microinvasive cancer, and the “gold standard” for these lesions is pulmonary lobectomy. The use of autofluorescence bronchoscopic techniques has improved the detection of these occult lesions,^{270,271} and 5-year survival with surgery approaches 90%.^{272,273}

The depth of invasion of these lesions and the risk of lymphatic permeation can be derived from bronchoscopic evaluation of their size and shape (i.e., less than 10mm, superficial lesions have invasion in only 5% or less, whereas those that are polypoid lesions invade up to 27% of the time).²⁷⁴ For the smaller lesions with less of a chance of invasion and for patients who will not tolerate a pulmonary resection, lung-preserving endobronchial therapies may be considered including photodynamic therapy, brachytherapy, electrocautery, cryotherapy, and neodymium-yttrium-garnet (Nd-Yag) laser therapy.^{275,276,277} Photodynamic therapy of lesions less than 1 cm can ablate these lesions in 75% of the cases with a recurrence rate of approximately 30%.²⁷⁶ Similar results are achieved with electrocautery,²⁷⁸ endobronchial iridium-based brachytherapy,²⁷⁷ and, most recently, cryotherapy.²⁷⁹

Stage I Lung Cancer (T1, T2N0M0)

Patients who are medically fit for surgery with lung cancers limited to the hemithorax without lymph node involvement, and with tumor extension no further than the visceral pleura (stage IA and B), should have complete surgical excision by a Board-certified general thoracic surgeon. In the event of positive pathologic margins, additional local therapies should be considered, including reoperation or radiation therapy. The use of adjuvant and induction therapies, specifically for the T2 subset, is discussed in another section of this chapter.

The 5-year survival rates of pathologic stage IA and IB disease after surgical resection are 70% and 55%, respec-

tively, independent of the histology of the tumor.^{280,281} The T status of the tumor is clearly important in the prognosis. A literature review of more than 1,600 cT1 tumors versus 1,800 cT2 tumors revealed a 5-year survival of 70% versus 47%,²⁸² while a review of more than 11,000 pT1 and pT1 tumors revealed survival differences of 71% and 55%, respectively. On average, about a third of the patients with stage I lung cancer will recur, with two-thirds of these recurrences being systemic and one-third local. Approximately 5% of patients with stage I lung cancer will develop a second primary at the rate of 2% per year.²⁸²

Primary Radiation Versus Surgery for Stage I NSCLC

There have been no randomized trials of surgery versus primary radiation therapy for stage I non-small cell lung cancer. In general, however, radiation therapy is only delivered to early-stage patients who refuse surgical management or who are deemed physiologically unable to undergo resection. A review of 978 patients from various studies of patients with poor performance statuses varying from 0% to 16% and radiation doses ranging from 50 to 80Gy reveals a cancer-specific survival of 23% for clinical stage I non-small cell lung cancer (versus the generally accepted 5-year survival of 51% for surgically resected clinical stage I lung cancer).²⁸³⁻²⁸⁹ A meta-analysis evaluating the role of primary radiation therapy in stage I NSCLC patients receiving at least 40Gy in 20 fractions over 4 weeks revealed a cancer-specific survival of 13% to 39% at 5 years.²⁹⁰

Limited Resection and Early Lung Cancer

The controversies regarding the surgical management of stage IA and IB lung cancer include whether an anatomic resection should be preferred as opposed to wedge resection or less than a lobar anatomic resection, that is, segmentectomy, and the role of lymphadenectomy at the time of resection. Limited resection as a compromise procedure in patients with poor pulmonary reserve has a 5-year survival of 50%.²⁸² A 6% to 24% risk of local recurrence has been reported in earlier studies using wedge or segmental resection for stage I non-small cell lung cancer along with a 5-year survival of 55% to

TABLE 37.5. Lobectomy versus limited resection for lung cancer: nonrandomized trials.

Author	Year	Lobectomies (n)	Limited resections (n)	Survival (5 year)	Recurrence rates	Comments

93% when performed in noncompromised individuals.^{291–295} In more-recent studies that compare efficacy in single institutional series of lobectomy versus limited resection (Table 37.5), lobectomies were generally similar, especially for smaller lesions, yet the risk of recurrence was significantly increased for lesser resections. There has been one randomized prospective trial comparing limited resection to lobectomy for T1-2N0 non-small cell lung cancer. The study, performed by the Lung Cancer Study Group with 247 patients assigned either lesser resection or lobectomy, revealed that the lung cancer recurrence rate was 75% greater in the limited resection due to a tripling of local tumor recurrence and that there was a 50% increase in cancer death.²⁹⁶

One must conclude at present that survival is better after lobectomy than after limited resection, and there is a two- to fourfold-higher local recurrence rate in limited resection. Nevertheless, the role of limited resection for lesions less than 1 cm and for lesions that are part solid or nonsolid (i.e., ground-glass opacities) remains under investigation.

The issues regarding mediastinal node dissection and nodal sampling have been described in the “staging” portion of this chapter. Table 37.6 reviews the issue of node positivity as a function of lesion size, showing that even small lesions less than 1 cm can have lymph node metastases if they are adenocarcinomas.

Stage II Lung Cancer

T1–T2N1M0

The majority of patients with pathologic stage II lung cancers (80%) have N1 disease involvement whereas the rest have T3N0 disease.^{280,281} N1 nodal disease refers to involvement either by metastasis or direct extension to the subsegmental, segment, and lobar lymph nodes (stations 14, 13, 12) or to the interlobar (11) and hilar lymph nodes (10). The 5-year survival of patients with pathologic stage II (N1) disease is 40%, and the survival of T1N1 disease is approximately 15% higher than that for T2N1 patients.^{189,297–300} Squamous stage II lung

cancers have improved 5-year survival compared to adenocarcinoma,²⁹⁸ and the site of recurrence in all N1 is usually systemic rather than local sites.³⁰⁶ Although evaluated in few studies,^{298,301,302} involvement of lobar lymph nodes has approximately a 15% survival advantage over the involvement of extralobar/hilar lymph nodes.

The major surgical issues regarding management of N1 disease involve whether sleeve resections (preservation of lung tissue using bronchoplastic reconstruction techniques) are as efficacious as pneumonectomies and the role of induction/neoadjuvant therapy. The risk of recurrence as well as the operative mortalities are equivalent for the two operations in the setting of sleeve lobectomy for NSCLC (Table 37.7). There are really no data that suggest that pneumonectomy for N1 disease is superior to sleeve resection in terms of survival.³⁰³ The theoretic advantages of sleeve resection also include lung preservation in anticipation of a second primary lung cancer, as well as the increased risk of a cardiopulmonary death with pneumonectomy. The role of induction and postoperative adjuvant therapy for N1 involved patients is discussed elsewhere in this chapter.

TREATMENT OF STAGE II NSCLC: T3 CATEGORY

T3 tumors usually present without lymph node involvement, and this subset represents approximately 10% of all resected non-small cell lung cancers or 5% of all NSCLC.^{281,282} T3 tumors invade the chest wall or diaphragm, the mediastinum (mediastinal pleura, pericardium, phrenic nerve, azygous vein, or right or left pulmonary artery), or have proximity (less than 2 cm) to the carina and involve the mainstem bronchus. Mediastinoscopy should be performed in patients with T3 central tumors before resection for reasons of occult N2 metastases, and the survival of T3N2 NSCLC with a primary surgical resection is low.

CHEST WALL T3 DISEASE

Chest wall muscle, involvement of the parietal pleura, or rib invasion constitute 40% of T3 tumors, and with a complete

TABLE 37.7. Sleeve resections versus pneumonectomies.

Author	Sleeve lobectomies vs. pneumonectomies (n)	Five-year survival	Recurrence	Operative mortality
Gaissert ⁶⁷¹	72 vs. 72	42% vs. 44%	14% vs. NA	4% vs. 9%
Okada ³¹⁸	60 vs. 60	48% vs. 29%	8% vs. 10%	2%
Suen ⁶⁷²	58 vs. 142	38% vs. 35%	NA	5.2 vs. 4.9

resection, the 5-year survival is approximately 50% to 60%. The prognosis of resected chest wall T3 disease depends on completeness of resection, nodal involvement, and depth of invasion.^{304,305} If on exploration of the chest, the tumor is found to invade the parietal pleura or deeper, an en bloc resection of the tumor with chest wall with a minimum of 2 cm of normal chest wall in all directions beyond the tumor is the preferred surgical technique, and the morbidity of en bloc resection is similar to that of operations where an extrapleural resection is performed.^{304,306,307} The decision to reconstruct the chest wall with prosthetic material will depend on the location of the tumor, the preoperative pulmonary status of the patient, and the extent of the resection. The few studies that address postoperative radiotherapy in patients who have undergone either a complete or an incomplete resection of T3 (chest wall) NSCLC have not identified a survival advantage.^{305,308}

Pancoast (Superior Sulcus) Tumors

The symptoms arising from a tumor in the apex of the lung, with invasion of the first rib and associated involvement of the brachial plexus and stellate ganglion, create the classic Pancoast syndrome (rib erosion, shoulder pain radiating down the arm, Horner's syndrome). These are usually adenocarcinomas, and fine-needle aspiration has greater than 90% success rate in establishing a diagnosis. Poor prognostic factors for a superior sulcus tumor include mediastinal nodal involvement, the presence of a Horner's syndrome, vertebral body invasion, and great vessel involvement (T4 involvement). In the absence of mediastinal nodal involvement, the overwhelming problem with these tumors is local control. Preoperative radiation therapy of 3,000 to 4,500 cGy followed by en bloc resection of the involved lung, chest wall, and frequently the T1 nerve root has been the standard of care until recently, resulting in complete resection in approximately 66% of patients and a 5-year survival for completely resected patients of 40%. A minority of patients in the surgical series have mediastinal nodal involvement or have evidence of T4 disease.³⁰⁹ Approximately 45% of resected patients recur locally, and another 25% recur systemically, chiefly in the brain.

The new standard of care for Pancoast tumors involves concurrent chemoradiation therapy followed by surgical resection. Initial results for 95 patients eligible for surgery in the Southwest Oncology Group Trial 9416 (Intergroup Trial 0160) using this approach revealed an operative mortality of 2.4% and a 92% complete resection rate. A pathologic complete response or minimal microscopic disease was seen in 65% of thoracotomy specimens. The 2-year survival was 55% for all eligible patients and 70% for patients who had a complete resection.³¹⁰ Presently a Phase II trial that evaluates the role of consolidation chemotherapy after this regimen is under way.

Mediastinal T3 Disease

If mediastinal invasion of the pleura, pericardium, or fat seen by an en bloc resection of the mediastinal tissue is over a small area and discovered only at the time of surgery, resection can usually be accomplished. The average 5-year survival of such patients is 25%.²⁰⁵ The patients with

mediastinal invasion usually have other major structures involved or concomitant mediastinal lymph node disease.^{311,312}

Proximal Airway Involvement T3 Disease

Tumors within 2 cm of the carina can be resected by pneumonectomy, but in most of the series reported, especially with those tumors arising from the upper lobes and extending into the main bronchus, a sleeve resection is performed with preservation of the normal distal lung. In fact, patients with mainstem bronchial involvement are usually reported in series of sleeve resections, often mixed in with other stages (Table 37.7). The range of 5-year survival in reported series varies from 12% to 40%.³¹³⁻³¹⁶ No randomized trials comparing sleeve lobectomy with pneumonectomy have been reported in the literature. In single-institution reports comparing pneumonectomy with sleeve resection, the complication rate and mortalities were increased in the pneumonectomy patients, but survival of the two techniques was equivalent. The survival of patients with proximal airway disease is influenced by the ability to perform a complete resection (35% 5-year survival versus 18%, complete versus incomplete resection) and the presence of mediastinal nodal involvement (45% 5-year survival for N0 versus 37% for N1 and 0% for N2).^{205,317,318} Although these studies are limited by their retrospective method and small numbers of patients, the authors agree with the conclusions of these articles that sleeve lobectomy is preferred over pneumonectomy whenever a complete pathologic resection can be obtained using bronchoplastic techniques.

Locally Advanced Lung Cancer: Stages IIIA and B

STAGE IIIA (N2) DISEASE

Stage IIIA disease includes a T3N1 tumor or N2 nodal spread. The 5-year survival of T3N1 patients is approximately 22%, and the finding of T3N1 (4% of all lung cancers) disease is usually confirmed after resection of suspected T3N0 disease.

The role of surgery for N2 disease is much more complicated because of the heterogeneity of N2 scenarios in clinical presentation, treatment, and prognosis.

SURGERY FOR INCIDENTAL N2 DISEASE

Despite careful preoperative staging including CT scan, PET, and mediastinoscopy, as many as 25% of patients will be found at thoracotomy to have metastases to mediastinal N2 lymph nodes, either intraoperatively or on the final pathologic examination of the surgical specimen. In others, metastases will be found intraoperatively at the time of a thoracotomy with frozen section examination of unsuspected, enlarged mediastinal nodes. In patients with an occult single-station mediastinal node metastasis that is recognized at thoracotomy and when a complete resection of the nodes and primary tumor is technically possible, most thoracic surgeons will proceed with the planned lung resection and a mediastinal lymphadenectomy. This is the best possible prognostic category for these patients because they are classified as clinical N0, microscopic N2, single station, and, according to Andre et al., have 5-year survivals of approximately 35%

to 40%.²⁰³ If a complete resection is not possible or there is multistation or bulky, unresectable extracapsular nodal disease, then the planned lung resection should be aborted as the 5-year survival rate in this situation is only 5% to 10%. These patients can then be considered for induction therapies and potentially reexploration at the conclusion of their chemotherapy with or without radiation therapy. Although incomplete resection rarely results in long-term survival, collected results of surgery alone in stage IIIA (N2 disease) provides a 14% to 30% 5-year survival, with the best survival seen in cases with minimal N2 disease and complete resection.^{191,192,194,195,215,319-321} However, if before thoracotomy metastatic disease is found in the N2 nodes at mediastinoscopy, further surgery at that time should be avoided.³²² If appropriate, induction therapy first is more advantageous (see later), followed later in selected patients by definitive surgical resection of the primary lung cancer along with as complete a mediastinal lymphadenectomy as possible.

PROGNOSTIC FACTORS RELATED TO N2 DISEASE

Extracapsular tumor spread, multiple levels of involved lymph nodes, bulky enlarged nodes, and the size of the primary tumor have negative prognostic significance in stage III A disease.¹⁸⁸⁻¹⁹² Metastatic disease to the subcarinal lymph nodes adversely affects prognosis compared to other lymph nodes¹⁹²⁻¹⁹⁸ and, as mentioned earlier, multistation nodal disease has a somewhat worse prognosis than single-station disease.

POTENTIALLY RESECTABLE N2 DISEASE

The poor survival rate with surgery alone in N2 disease, even with adjuvant postoperative chemotherapy or radiotherapy, has led to efforts at giving initial nonsurgical (radiotherapy and/or chemotherapy) therapy first, often to convert the unresectable tumor to resectable and, as well, to improve long-term survival. Patients considered for such approaches include those with enlarged (more than 1.0-cm short-axis diameter) N2 nodes (IIIA) on chest CT. Tissue confirmation of nodal involvement must be performed in this setting to document that these nodes actually contain metastatic tumor, as approximately 40% of moderately enlarged nodes may be benign, especially if there is an associated recent pneumonitis.

Preoperative Chemotherapy in Early-Stage NSCLC

There remains a significant chance for recurrence in patients having surgery for Stage IB–IIB. Due to the feasibility and potential efficacy of induction therapy seen in a small series of randomized trial of IIIA disease, Phase II and III trials have explored the use of induction therapy before surgery in earlier-stage lung cancer patients. One of the first large studies to demonstrate data supporting the use of induction therapy (also discussed later in this chapter) came from a subset analysis of a trial that randomized over 300 patients with stages IB, II (188 patients), and IIIA to receive induction chemotherapy with mitomycin, ifosfamide, and cisplatin before surgery compared to surgery alone.³²³ The survival benefit was primarily for patients with stages I and II, with an estimated 4-year survival of 44% for the induction group compared to 35% for the surgery-alone arm. There was a sig-

nificant decrease in distant metastases and an increase in the length of disease-free survival for the patients treated with chemotherapy. Postoperative morbidity was increased in the combined modality treatment arm (6.7% versus 4.5% for surgery alone). There was no statistically significant benefit in the stage III subgroup.

A randomized study of 212 patients with stage I–IIIA from Shanghai, China, has been reported in abstract form only.³²⁴ One hundred and three patients were randomized to one to two cycles of preoperative cisplatin based chemotherapy and 108 to immediate surgery. A response rate of 50% was seen following preoperative chemotherapy, but no survival benefit was found at 5 years (32% chemotherapy arm versus 37% surgery arm). In fact, the 5-year survival rates were significantly worse in stage II patients (20% versus 65%; $P = 0.042$). Further comments regarding this study will have to await the full publication.

The Phase II BLOT (Bimodality Lung Oncology Team) trial that evaluated preoperative paclitaxel and carboplatin established the feasibility and safety of this approach with encouraging survival.³²⁵⁻³²⁷ Eligible patients had stage T2N0, T1N1, T2N1, and T3N0-1 NSCLC. This population was selected for study based on poor survival despite operability and resection (5-year survival rates, 38%–9%).³²⁷ The study had two cohorts: 94 patients who received two induction and three postoperative paclitaxel/carboplatin cycles³²⁷ and a second cohort of 39 patients who were treated with three induction and two postoperative cycles.³²⁵ The response rate for the induction chemotherapy was 56%, and 94% of the patients underwent resection (86% had a complete resection). The pathologic CR rate was only 6% and the 5-year survival was 46%. An update on the BLOT trial that includes 40 additional patients reveals a 3-year survival of 63%. As seen with many adjuvant lung cancer studies, only 45% of the patients received the postoperative treatment. Forty-six percent of patients had relapsed at the time of the last analysis. The majority of these were distant (44%), with 13 (21%) occurring in the brain only. A combination of local and distant failure was seen in 18%, and 15% recurred locally only. This pattern of failure did not differ from historical controls.

The promising survival from this Phase II trial led to the development of the Phase III North American Intergroup trial S9900. This Southwest Oncology Group (SWOG)-led trial was a prospective, randomized trial that compared three cycles of induction chemotherapy with paclitaxel and carboplatin followed by surgery to surgical resection alone in patients with early-stage NSCLC. However, with the announcement of marked survival advantage to adjuvant chemotherapy as previously described in this chapter, the surgery-alone arm was no longer acceptable as the control, and S9900 was closed to accrual as of July 2004. Nevertheless, all the approximately 350 patients randomized to that point will be followed and the study will still yield valuable information.

The concern that induction chemotherapy given to patients with early-stage disease may increase operative morbidity and mortality³²⁸ should be diminished by data from large surgical series as well as the trials already reviewed here. For example, at the M.D. Anderson Cancer Center, no significant increases in operative morbidity or mortality were found based on clinical stage, pathologic stage, extent of resection, or protocol enrollment. Investigators at Memorial Sloan-Kettering Cancer Center reported similar findings, with

the exception that patients undergoing right pneumonectomy following induction therapy had increased operative risk.³²⁹ Other international investigators also examined operative morbidity and mortality rates and found them acceptable following preoperative chemotherapy.^{330,331}

Ongoing Early-Stage Induction Trials

Currently, there are randomized trials that compare preoperative chemotherapy to surgery alone in early-stage NSCLC ongoing in Europe. The NATCH trial in Spain is a three-arm study comparing three cycles of paclitaxel/carboplatin chemotherapy given before surgery or after surgery to surgery alone, and data should soon be available from this trial. In Italy, the CHEST study is comparing three cycles of gemcitabine/cisplatin chemotherapy before surgery to a surgery-alone control arm. The LU22 study in Great Britain compares three cycles of platin-based induction chemotherapy to a surgery-only control arm. Finally, the current French study administers chemotherapy to all early-stage NSCLC patients, with randomization to one of two different chemotherapy regimens (gemcitabine/cisplatin or paclitaxel/carboplatin).

Induction Chemotherapy and/or Radiotherapy in Stage IIIA

The modern era of induction regimens for higher-stage NSCLC began with a series of first-generation Phase II trials conducted utilizing cisplatin-based chemotherapy with or without radiotherapy as induction treatment before surgery.³³²⁻³³⁶ Response rates from the induction therapy were 39% to 82%, resection rates (percent of original number accrued) were 14% to 88%, and the survival rates were highly variable. Staging and volume of tumor differences within these trials preclude conclusions about efficacy or comparisons across trials; however, these pivotal studies demon-

strated the general safety of surgery after induction therapy and, in some instances, provided intriguing survival data and leading to a series of second-generation induction chemotherapy studies.³³⁷⁻³⁴¹ Although all second-generation studies required pathologic documentation of N2 disease, tumors with a wide range of disease bulk were accrued. Moreover, radiotherapy was variably given (intraoperative, postoperative, or not at all), and information on why radiotherapy was either given or withheld was not provided in detail for some of the studies. Thus, lack of concordance on the disease bulk and radiotherapy utilization variables makes comparison of results among the studies difficult. Resection rates for second-generation studies were 51% to 68%, and postoperative mortality, predominantly from pulmonary or cardiopulmonary toxicities, ranged from 0% to 18%.

The other major category of second-generation induction studies utilized concurrent chemoradiotherapy (chemoRT) induction therapy (Table 37.8.^{237,342-345} The RT varied in schedule, all induction chemotherapy was cisplatin based, but the treatment prescribed after surgical resection was not uniform among these five studies. Biopsy documentation of N2 disease or T4 status (see later) was required only in the SWOG, Lung Cancer Study Group (LCSG), and Cancer and Leukemia Group B (CALGB) trials, and stage IIIA (N2) accounted for 47% to 87% of patients per trial. Two studies included T3N0 or T3N1 (21% and 20% in the Rush Presbyterian and CALGB studies, respectively), whereas all patients with stage IIIA disease in the SWOG 8805, LCSG 852, and Tufts trials had N2 nodal involvement. The stage IIIB subsets of T4 and/or N3 were allowed in all trials except the CALGB study and accounted for 6% to 53% of patients per trial.

Response or "response plus stable" (one study) rates were 56% to 92%, and 52% to 76% of the total number of patients accrued to each study had a complete resection at thoracotomy. The pathologic complete response (pCR) rates were 16%, 21%, and 27% in the LCSG, SWOG, and Rush Presby-

terian trials, respectively.^{237,342,343} Postinduction assessment of nonresponse by CT scan was often misleading, because 46% of the 26 patients with resectable stable disease in the SWOG study had pCR or only rare microscopic foci.²³⁷

The operative mortalities were predominantly pulmonary related, as observed in the induction chemotherapy trials. The cause of death often resembled the adult respiratory distress syndrome (ARDS).

Long-term survival data were reported in several of the trials of induction chemotherapy and induction chemoRT (Table 37.9). Long-term follow-up of several of the trials suggested that a plateau emerged on the tails of the survival curves, and 5- to 7-year survivals of 17% to 34% were reported. Favorable outcome predictors included postinduction pCR, complete resection, T3N0 or T3N1 disease, T4N0 or N1 disease, and pathologic clearance of initial N2 or N3 involvement (nodal downstaging). The SWOG 8805 trial analysis showing that nodal downstaging was an independent favorable prognostic impact of intermediate (2- to 3-year) survival is of interest, and was the only significant factor in a multivariate model that included complete resection rate, pCR, and multiple other factors.²³⁷ This variable was also the most important univariate discriminant of 6-year survival, although complete resection emerged as a long-term survival predictor as well.³⁴⁶ The survival rates 3 and 6 years after thoracotomy for patients with uninvolved nodes at surgery were 41% and 33%, respectively, versus only 11% and 11% if there was persistent mediastinal disease.

Following on the aforementioned chemoRT trials came three Phase II induction trials [Massachusetts General Hospital (MGH), West German Cancer Center (WGCC), and the German Lung Cancer Cooperative Group (GLCCG)] using platinum-based chemotherapy and hyperfractionated radiotherapy either with a planned break (1) or with radiation intensification by delivering it in an accelerated fashion (2)³⁴⁷⁻³⁴⁹ (Table 37.10). Treatment-related mortality was 7%, 6%, and 9% and postoperative mortality 5%, 7%, and 8% (of patients who underwent thoracotomy) in the MGH, WGCC, and GLCCG trials, respectively. The main perioperative

complication seen in both WGCC and GLCCG trials was bronchial stump insufficiency, most often after right-sided resections. After both groups started reinforcing bronchial stumps with tissue later in each trial, the incidence of this problem dropped to zero. A complete resection with negative margins was accomplished in 81% of all patients in the MGH trial, and the median survival was 25 months with an overall survival of 66%, 37%, and 37% at 2, 3, and 5 years, respectively. Five-year survival was 79% if the nodes were downstaged to N0; 53% of the patients had complete resection with negative margins on the West German Cancer Center study and 26% had a complete pathologic response. Median survival was 20 and 18 months and 3-year survival rates were 36% and 31% for stages IIIA and IIIB, respectively (no statistical difference). A complete resection with negative margins was achieved in 63% of patients enrolled on the GLCCG trial, and over 50% of these exhibited a major histological response, defined as necrosis or fibrosis of more than 90% of tumor cells. Seven (13%) had pathologic complete response. The median survival for the whole group was 20 months, with 2- and 3-year survival of 40% and 30%, respectively. Median survivals for stages IIIA and IIIB (25 versus 17 months) showed no statistical significance, as did 2- and 3-year survivals (52% and 35% versus 30% and 26%).

Randomized Trials of Surgery Alone Versus Induction Therapy Followed by Surgery in Mixed-Stage, Resectable Disease

Several small randomized studies and one large Phase III trial of induction chemotherapy for NSCLC were conducted for patients with low-volume or "minimal" N2 disease and with a surgery-alone arm as the control (Table 37.11).^{238,350-353} The NCI trial was the most homogeneous in the stage subsets accrued, whereas the treatment groups of the small M.D. Anderson and Spanish studies had heterogeneous stage subset distributions. The same stage mix issues existed in the large French Thoracic Cooperative Group (FTCG) trial, with some imbalance of stage subsets between the two arms ($P = 0.07$).³⁵³

Furthermore, in the FTCG study, clinical staging alone was accepted and documentation of N2 status was not required. The induction chemotherapy regimens for the five trials were cisplatin based and were also variably given after surgery depending on the study design.

Three of the four trials closed before the target accrual goal was met. The National Cancer Institute (NCI) trial was halted due to slow accrual, whereas the M.D. Anderson and Spanish studies were stopped early because of large survival differences by data monitoring committees due to strongly positive results in favor of the induction chemotherapy arms.^{354,355} With additional follow-up of the M.D. Anderson trial cohort (median follow-up, 81 months), 32% of patients were alive in the induction chemotherapy group versus 16% in the surgery-alone arm ($P = 0.06$).³⁵¹ The P value became significant if only deaths caused by cancer were considered. The update of the Spanish trial has revealed that no patients survived in the surgery group, whereas 16% were long-term survivors in the induction chemotherapy arm.³⁵²

These M.D. Anderson and Spanish trials generated extensive discussion and debate with a consensus that these results were provocative but not definitive. Suffice it to say that the major concerns were the marked substage heterogeneity within these two trials, and that the surgical control arms fared poorly, possibly because of substage imbalances.

The largest randomized Phase III trial of chemotherapy alone for induction was the French Thoracic Cooperative Group Trial, which enrolled patients with stage IB to IIIA disease.^{323,353} The 1-, 2-, 3-, and 4-year survivals were 77%, 71%, 59%, and 44%, respectively, in the induction chemotherapy arm and 73%, 52%, 41%, and 35% in the surgery-alone arm. The difference did not reach statistical significance ($P = 0.15$). Stage-adjusted relative risk of death was 0.80 in the chemotherapy arm ($P = 0.089$). In a subset analysis, there was a benefit to induction for patients with N0-1 disease [relative risk (RR), 0.68; $P = 0.027$], but not for patients

with N2 (RR, 1.04; $P = 0.85$). There was a nonsignificant excess of mortality (10% versus 5%) in the induction chemotherapy arm, consisting of pneumonia, emphysema, fistula, and pulmonary embolism.

The North American Intergroup trial 0139, chaired by RTOG, is the largest Phase III trial to date that addressed the potential value of surgery in stage IIIA(N2) NSCLC³⁵⁶ (Table 37.12). The entry criteria for this study included T1-3 primary tumor, pathologically confirmed N2 disease, feasible resection from a surgical standpoint, and medical ability to undergo resection. The induction regimen was identical in both arms: 45 Gy of external radiotherapy given in once-daily fraction, concurrent with day 1 of induction chemotherapy, which was cisplatin, 50 mg/m² on days 1, 8, 29, and 36, and etoposide, 50 mg/m² days 1–5 and 29–33. Patients were reevaluated by a CT scan 2 to 4 weeks after completion of the induction regimen in the surgical arm, and in the RT arm, 1 week before completion of treatment. Those patients with no progression proceeded with their assigned treatment. In the surgical arm, the treatment consisted of resection of all known disease and mediastinal nodal sampling. In the RT arm, the radiotherapy continued to 61 Gy without a break. In both arms, consolidation chemotherapy (two cycles of cisplatin and etoposide) was given to all patients. At a median follow-up of 69 months, 392 patients were analyzable. Induction treatment was delivered as per the protocol equally in both arms. In the surgical arm, a thoracotomy was performed in 96%, and a complete resection was accomplished in 88% of patients for whom the data were available. There were 18% pathologic complete responses (TON0) and 46% with pathologic nodal clearance. The chemoRT toxicity was similar in both arms, with the exception of esophagitis, which was more common in the chemoRT-alone arm. Consolidation chemotherapy was not administered to 42% of patients undergoing surgery, and 21% of those not having undergone surgery (P less than 0.001), reiterating the difficulty of deliv-

ering chemotherapy after “definitive” surgical treatment for lung cancer. Conversely, RT was delivered according to protocol in 81% on the chemoRT arm versus 97% on the surgery arm ($P = 0.002$). Three patients (1.6%) in the chemoRT arm and 14 (7%) patients in the chemoRT-surgery arm died of treatment-related toxicity. In the latter group, 10 of these deaths were caused by postoperative complications. Most of the deaths occurred in patients who underwent pneumonectomy (especially right-sided), and the most frequent cause of death was the adult respiratory distress syndrome (ARDS).

Median progression-free survival was 14.0 months and 11.7 months in the chemoRT-surgery arm and chemoRT arm, respectively. Three-year progression-free survival was 29% in the chemoRT-surgery arm versus 19% in the chemoRT arm (log rank, $P = 0.02$). The median overall survival was 22.1 months versus 21.7 months and the 3-year survival was 38% versus 33% in the chemoRT-surgery and chemoRT arms, respectively (log rank, $P = 0.51$). The overall survival curves cross over and begin to separate at 22 months. By 3 years, there was a 5% absolute survival benefit in the surgical arm, but the confidence intervals are wide and overlap. More patients died of treatment complications in the surgical arm, but more are alive without progression in the same treatment arm. Sites of relapse were also analyzed: 13% of patients in the chemoRT-surgery arm had locoregional relapse only versus 21% in the chemoRT arm ($P = 0.07$). Relapse in the primary site was three times more common in the nonsurgical arm. Brain was common site of first relapse in both arms (10% versus 18% in the chemoRT and chemoRT-surgery arm, respectively; $P = 0.08$). Pretreatment factors predictive of favorable outcome were lower T stage, less than 5% weight loss, and younger age. Female sex and normal LDH did not reach statistical significance. After the induction treatment, patients who achieved complete response in the mediastinal nodes had median survival of 36.7 months and 3-year survival of about 50%, regardless of the response in the primary tumor.

The Stage IIIB Subgroup in Second-Generation (and Subsequent) Studies of ChemoRT Induction Trials

From a subset of these second-generation ChemoRT trials, data are available regarding the role of induction therapy followed by surgery in selected stage IIIB subsets. The SWOG 8805 trial was unique among the other chemoRT trials in that it included stage IIIB disease. Pathologic documentation of T4 or N3 disease was required and outcome was analyzed separately for this subset.^{237,256} The median, 2-year, and 3-year survivals were identical for the IIIA(N2) versus the IIIB group in the SWOG 8805 study (27%, 24%).²³⁷ Of note, in the SWOG 8805 study, the T4N0-1 subset had an outcome identical to the T1N2 substage and achieved a 2-year survival of 64%. This substage variable was the only independent predictor of favorable outcome from the time of registration to the study in a multivariate analysis.²³⁷ Exploratory survival analyses were conducted within the N3 subset of the SWOG trial, of which 27 patients were accrued. The 2-year survival for the contralateral nodal N3 subgroup was zero, whereas it was 35% for the supraclavicular N3 subset. However, the resection rate in this latter group was only 39%. An update of SWOG 8805 provided 6-year survival statistics: IIIA (N2), 20%; T4N0-1, 49%; and N2 or N3, 18%.³⁵⁷

Subsequent studies have commented on the role of induction therapy for stage IIIB disease. Grunewald et al. prospectively studied 40 patients with IIIB disease, of whom 30 had T4 disease and 18, N3.³⁵⁸ Five patients had T4N0 tumors and 1 had T4N1. All patients underwent pretreatment surgical staging. Induction treatment consisted of 5-fluorouracil (5-FU), cisplatin, and vinblastine for two cycles. A total of 42 Gy of external radiotherapy was given split in two 21-Gy courses, 1.5 Gy bid, with 10 days of rest between the courses. Patients who responded to the induction regimen underwent thoracotomy. A clinical response was obtained in 73% of patients, and in 60% resection was performed. The resection was com-

plete in all but 1 patient who underwent thoracotomy. Four patients (10%) had complete pathologic response and 30% had complete mediastinal clearance. There were 5 treatment-related deaths, and 7 additional patients suffered serious morbidity. Median survival was 15 months and 5-year overall survival was 19%. Thirty percent of the overall patient number had locoregional relapse and 50% had distant relapse. Pathologic mediastinal nodal downstaging was the only significant favorable prognostic factor in a multivariate analysis (5-year survival, 42% for postinduction N0/1 versus 12% for postinduction N2/3 for resected patients). All long-term survivors had persistent viable tumor cells in the primary tumor but 6 of 7 were postinduction N0-1.

Pitz et al. treated patients with stage IIIB NSCLC with neoadjuvant gemcitabine and cisplatin without radiotherapy, followed by surgery in responding patients. There was a response rate of 66%, resection rate of 44%, and perioperative mortality of 2.4%. Median survival for all patients was 15.1 months and 3-year survival was 15%. The investigators found no difference in outcome between T4N0 and N2/N3 subsets. However, only patients with a response after induction chemotherapy were considered for surgical resection.³⁵⁹ These trials highlight that the T4N0/1 substage as a group does particularly well with trimodality therapy.

INDUCTION WITH THIRD-GENERATION CHEMOTHERAPY AGENTS

Third-generation chemotherapy agents have been tested in Phase II induction therapy protocols in stage III disease (Table 37.13). The Swiss Group for Clinical Cancer Research (SAKK) enrolled 90 potentially operable stage IIIA patients with biopsy-proven ipsilateral mediastinal nodal involvement.²⁴⁰ The induction regimen consisted of cisplatin 40mg/m² on days 1–2 plus docetaxel 85mg/m² on day 1 for three cycles. All patients except those with progressive disease underwent thoracotomy. No postoperative chemotherapy was given, and postoperative RT to 60Gy was reserved for patients found to have a positive resection margin and/or involvement of the uppermost mediastinal lymph node. There were 2 treatment-related deaths (3%). The overall clinical response was 66%, and complete resection was accomplished in only 48% of the entire patient group. An additional 43% underwent incomplete resection with positive margins and/or positive highest mediastinal lymph node, and their overall cisplatin dose intensity was less than that in patients with negative resec-

tion margins (80 versus 96mg/m²/cycle; $P = 0.034$). There were 14 patients (16%) with a complete pathologic response, and 45 (60%) had pathologic nodal clearance. The median survival was 27.6 months and 3-year survival was 33%. Mediastinal downstaging was the most powerful independent favorable prognostic factor ($P = 0.0003$), and patients with mediastinal downstaging had a 3-year survival rate of 61% as compared to 11% for those who did not. Complete resection was also predictive of favorable outcome ($P = 0.006$).

In another recent trial, three preoperative cycles of gemcitabine, paclitaxel, and cisplatin were delivered to 49 biopsy-documented N2 disease patients.³⁶⁰ Patients with at least stable disease after the induction regimen underwent attempted surgical resection. Patients whose disease did not respond received RT alone, and the patients whose disease responded but did not undergo thoracotomy, received three more cycles of the same chemotherapy followed by RT. Postoperative RT was delivered for patients with persistent N2 disease or incomplete resection. There was 1 death during the induction. A response rate of 73.5% based on radiographic criteria was recorded, and a complete resection was performed in 55% of patients. Mediastinal nodal disease clearance occurred in 35% of cases and complete pathologic response in 16%. Median and progression-free survival were 23 and 18 months, respectively, and the brain was the most common metastatic site (16%). The Italian Lung Cancer Project completed a Phase II trial in 129 unresectable, locally advanced stage IIIA and IIIB NSCLC patients.³⁶¹ The induction regimen consisted of four cycles of gemcitabine 1,000mg/m² on days 1 and 8 and cisplatin 70mg/m² on day 2. The response rate was 80%, but the resectability rate was only 29%. There was no perioperative mortality and minimal morbidity. Postoperative RT was given for positive mediastinal lymph nodes and was continued to 60Gy if the disease was unresectable. The median progression-free survival was 11 months and median survival was 20 months.

The European Organization for Research and Treatment of Cancer (EORTC) is conducting a Phase III trial (EORTC 08941) of induction chemotherapy followed by either radiotherapy or surgery for those patients with at least partial clinical response to induction (see discussion in section to follow).³⁶² The trial design allows a menu of induction combination chemotherapy so long as it includes cisplatin at 100mg/m² or carboplatin at 400mg/m². Two reports of feasibility and toxicity have been published to date of induction approaches, while the Phase III trial is ongoing.^{363,364} The first

pilot study was reported by Van Zandwijk et al. in which gemcitabine 1,000 mg/m² and cisplatin 100 mg/m² were used.³⁶⁴ The dose of gemcitabine had to be reduced or omitted in more than half of the patients, mainly due to thrombocytopenia. Responses were observed in 70%. O'Brien et al. reported the use of induction paclitaxel, 200 mg/m², and carboplatin, AUC of 6. Over 90% of patients were able to complete all induction treatment per protocol. The response rate was 64%. One patient died of postoperative complications.³⁶³ In the two studies, resection rates of 71% and 80%, respectively, were reported.

MORTALITY AFTER INDUCTION THERAPY

Although the use of neoadjuvant chemotherapy and/or radiotherapy appears to have potential advantages in the treatment of locally advanced lung cancer, concern has been raised in numerous publications about the perceived and real increase in morbidity and mortality of the subsequent lung resections. So far, there has been no difference in overall postoperative mortality rates compared to the surgery-alone control arms in trials with induction chemotherapy for early, more minimal bulk disease.^{323,328,351} Pulmonary complications and deaths from pulmonary causes during the postoperative time period are the greatest concern after induction therapy, and collectively rates are probably greater than reported in the literature after surgery alone. In particular, events such as extensive pneumonitis, usually culture negative, ARDS, and bronchopleural fistula have a high mortality in the postoperative period. Pulmonary morbidity and mortality rates are often quoted to be greater after induction regimens with chemoRT than after induction chemotherapy alone. However, a careful review of all the literature available discloses great variability. Postoperative mortality rates from 3.1% to 17% were reported after mitomycin/vinblastine/cisplatin (MVP)- or VP16/cisplatin (VP)-containing induction chemotherapy (including some cases of ARDS), from 4% to 15% after second-generation induction chemoRT, and 5% to 7% after induction chemoRT with hyperfractionation. The specific type of mortal postoperative event may differ according to whether RT was included with induction chemotherapy or not, although this issue is not fully resolved. Moreover, the degree of pulmonary resection, that is, pneumonectomy, especially on the right, is associated with a higher morbidity and mortality.³²⁹

Adjuvant Radiotherapy

Randomized trials examining adjuvant radiotherapy for resected NSCLC are shown in Table 37.14, including four trials of greater than 100 patients that were incorporated into the 1998 PORT meta-analysis (see following).³⁶⁵⁻³⁶⁹ None of these trials demonstrated a beneficial effect of postoperative radiotherapy on overall survival. However, findings from the LCSG 773 trial are notable for detecting a significant reduction in local recurrence (41% versus 3%) for patients receiving adjuvant radiotherapy.³⁶⁶ Dautzenberg et al. detected inferior efficacy outcomes and an increased rate of intercurrent deaths in their large randomized trial; the intercurrent deaths were largely caused by cardiorespiratory failure and prompted concern regarding the utility of adjuvant radiotherapy in patients with resected stage I and II disease.³⁶⁸

The PORT meta-analysis encompassed updated data on 2,128 patients from nine randomized studies of adjuvant radiotherapy in resected NSCLC, approximately one-third of whom were enrolled in the trial of Dautzenberg et al.³⁶⁸ The PORT meta-analysis found that radiation exerted a harmful effect, especially for N0-N1 patients, with a hazard ratio of death of 1.21. This translated to an absolute detriment of 7% at 2 years, reducing overall survival from 55% to 48%. Subgroup analyses revealed that adjuvant radiotherapy exerted no harmful effect on patients with N2 disease. Criticisms of this meta-analysis include its dependence on older studies that used outmoded radiation techniques such as lateral portals and the use of cobalt-60 units.³⁷⁰ It is anticipated that modern radiotherapy procedures, relying on three-dimensional (3-D) conformal planning and using doses no greater than 45 Gy in fraction sizes less than 2.0 Gy, will reduce morbidity and mortality associated with adjuvant radiation, especially radiation pneumonitis.³⁷¹

Interim analyses from a more recent investigation, incorporating modern radiotherapy techniques, did not detect deleterious effects of adjuvant radiation therapy.³⁶⁹ Adjuvant radiation, administered using 50.4-Gy linear accelerator radiotherapy in 1.8-Gy fractions with 2-D and 3-D imaging support, was associated with a decline in local recurrence but exerted no effect on estimated 5-year overall survival. Preoperative and postradiation pulmonary function tests were not significantly different in this study population. Final results of this study are eagerly awaited as this trial tests the hypothesis that more modern radiation techniques will reduce the

number of treatment-related, intercurrent deaths in the setting of adjuvant radiotherapy for NSCLC patients.

Published reports of adjuvant radiotherapy have failed to demonstrate improvements in overall survival in resected NSCLC patients, and have, in fact, raised the question of possible harmful effects for N0 and N1 treated patients. Although no survival benefit has been observed in patients with resected N2 disease, the preponderance of randomized evidence demonstrates improved local control in resected N2 patients who receive adjuvant radiotherapy. Off-study use of postoperative radiation cannot be recommended for completely resected NSCLC patients with N0 or N1 disease.

Adjuvant Chemotherapy

Table 37.15 demonstrates results from randomized trials investigating the role of adjuvant chemotherapy in resected NSCLC.³⁷²⁻³⁸³ Until very recently, the clinical trial experience of adjuvant chemotherapy has been hampered by an inability to administer adequate dose intensity because of treatment-related toxicities. The Lung Cancer Study Group (LCGS) conducted three trials in the United States investigating the role of adjuvant cyclophosphamide, doxorubicin, and cisplatin (CAP) in patients with resected stage I-III disease.³⁷²⁻³⁷⁴ Systemic adjuvant therapy did not improve overall survival in any of the three studies, or in two European trials (although treatment was associated with a positive impact when rates of pneumonectomy were controlled for in the trial of Niiranen et al.).^{375,376}

Japanese investigators instituted a series of adjuvant trials with oral uracil-tegafur (UFT), an oral agent consisting of tegafur, a 5-fluorouracil derivative, and uracil at a 1:4 molar ratio. Tegafur is gradually converted to 5-fluorouracil in vivo. Treatment with UFT results in sustained concentrations of

intratumoral 5-fluorouracil.³⁷⁹ Results of these trials have been mixed (see Table 37.15), with only one trial conducted by the Japan Lung Cancer Research Group in patients with resected stage I (T1N0 or T1N1) adenocarcinomas being clearly positive.³⁸³ However, subgroup analyses revealed that the survival benefit seen with UFT was restricted to the 269 patients with T2 lesions (improving 5-year survival from 73.5% to 84.9%; $P = 0.005$), and that no improvement was seen in the T1N0 subgroup. Other studies involving postoperative chemotherapy plus or minus UFT have been negative, although subgroup analysis^{380,381} after controlling for baseline T or N stage,^{381,382} or for baseline prognostic factors and the extent and completeness of surgery,³⁸⁰ have suggested a possible role for UFT in very early stage disease. Confirmatory studies are certainly warranted.

In 1995, the Non-small Cell Lung Cancer Collaborative Group published a meta-analysis using updated data on individual patients from 52 randomized clinical trials.³⁸⁴ One of their analyses examined randomized trials of adjuvant chemotherapy versus surgery alone in patients with resected NSCLC. Data were available from 14 trials, of which 5 used alkylating agents, 8 used cisplatin-based chemotherapy, and 3 used other combinations. Alkylating chemotherapy was associated with a hazard ratio of 1.15, or a 15% increase in the risk of death, translating into an absolute detriment of alkylating chemotherapy of 5% at 5 years. For regimens containing cisplatin, the overall hazard ratio was 0.87, or a 13% reduction in the risk of death, translating into an absolute benefit from chemotherapy of 5% at 5 years. This result was of borderline statistical significance ($P = 0.08$).

A number of randomized trials have examined the role of adjuvant chemotherapy in patients undergoing postoperative radiation for resected NSCLC (Table 37.16).³⁸⁴⁻³⁹¹ Investigators from the LCGS, Memorial Sloan Kettering, the Groupe d'Etude et de Traitement des Cancers Bronchiques, the U.S. Intergroup, and investigators from Germany did not detect

improvements in survival using cisplatin-based regimens in trials of adjuvant chemoradiation.^{386–390}

The 1995 Non-small Cell Lung Cancer Collaborative Group meta-analysis examined seven trials randomizing patients to adjuvant chemoradiation versus radiation alone.³⁸⁴ Radiation treatment doses ranged from 40 Gy in 10 fractions to 65 Gy in 33 fractions. They concluded that there was no benefit or adverse effects of adjuvant combined therapy for patients with resected NSCLC compared to postoperative radiotherapy alone.

Two large, recently completed international trials yielded conflicting results in terms of the efficacy of postoperative chemoradiation in patients with completely resected NSCLC. Results from the Adjuvant Lung Project Italy (ALPI)/EORTC study confirmed the lack of benefit in adding systemic cisplatin-based chemotherapy.³⁹¹ In this trial, 1,209 patients with stages I–IIIA NSCLC received postoperative radiotherapy (50–54 Gy over 5 to 6 weeks) at the investigator's discretion. As such, radiotherapy was planned in 4%, 60%, and 76% of stage I, II, and IIIA patients, respectively, and randomization was stratified accordingly. Patients were randomized to either three cycles of mitomycin, vindesine, and cisplatin adjuvant treatment or no chemotherapy. The study was designed to detect a 7% improvement in overall survival at 5 years, from 50% to 57% (or a 20% reduction in the relative risk of death). At over 5 years of follow-up, no statistically significant difference in progression-free or overall survival was detected between the two treatment arms. Comparison of the Kaplan–Meier curves for overall survival gave a hazard ratio of 0.96 (95% CI, 0.81–1.13; *P* = 0.589). This impact translated into an absolute increase in 5-year survival of 1%. There was an excess of early deaths (within 12 months after randomization) in the chemotherapy arm (90 patients), compared to the control arm (69 patients); this was attributable to cancer progression in 11 patients and to cardiopulmonary events in 7 patients. Rates of grade 4 neutropenia and nausea/vomiting for the patients receiving chemotherapy were 12% and 4%, respectively.

However, positive results were recently seen in the large randomized International Adjuvant Lung Trial (IALT) of adjuvant cisplatin-based chemotherapy.³⁸⁵ Although patients were allowed to undergo postoperative radiotherapy at their physician's discretion, this study was primarily designed to assess the value of adjuvant chemotherapy in a large, heterogeneous sample of patients, and 1,867 patients were randomized in the

late 1990s from 148 centers in 33 countries to observation or to undergo three or four cycles of cisplatin-based systemic treatment. The total dose of cisplatin was predetermined to be in the range of 300 to 400 mg/m². Most of the patients received etoposide as the second agent in the chemotherapy doublet (56%), while others received vinorelbine (27%), vinblastine (11%), or vindesine (6%). Patients were balanced in terms of pathologic stage, histology, and type of surgical procedure. At a median follow-up of 56 months, both disease-free and overall survival at 5 years was improved in patients treated with adjuvant chemotherapy (39.4% and 44.5% for the chemotherapy patients, and 34.3% and 40.4% for the control patients, respectively; *P* less than 0.03 for overall survival). No significant interaction between response to adjuvant chemotherapy was observed with respect to age, gender, performance status, type of surgery, pathologic stage, histology, cisplatin dose, choice of the second chemotherapy agent, and the addition of radiotherapy. Twenty-three percent of the chemotherapy-treated patients experienced at least one grade 4 toxicity, and the treatment-related mortality was 0.8%.

The authors of the IALT trial concluded that cisplatin-based adjuvant chemotherapy exerts a statistically significant positive impact on survival in resected patients, thereby potentially saving 7,000 lives worldwide annually. Why was the IALT trial positive in the face of so many prior negative studies of adjuvant chemotherapy? The IALT investigators were the first to design the statistical analyses of their outcomes to reflect the findings of the 1995 meta-analyses, in which an absolute survival advantage of 5% was seen with treatment. In contrast, earlier studies hypothesized a larger difference in the primary outcome of overall survival.³⁹¹ In addition, more than 70% of patients in the IALT trial received at least 240 mg/m² total of cisplatin during the course of their adjuvant treatment, a substantially higher dose intensity than had been delivered in most of the previous studies of postoperative chemotherapy.^{372–374} Last, a lower percentage of patients in the ALPI/EORTC trial underwent pneumonectomy, in comparison to the IALT study (25% in ALPI/EORTC versus 35% in the IALT), possibly improving the survival of the control arm in the ALPI/EORTC sufficiently to mask a beneficial impact of chemotherapy, as was seen in the IALT.^{385,391}

In conclusion, although the majority of trials of adjuvant therapy in resected NSCLC have been negative, recently published evidence points to the possible efficacy of UFT,

particularly in early-stage disease, and cisplatin-based chemotherapy, especially when administered at doses of at least 240mg/m².

Management of Locally Advanced Stage IIIB

The role of radiation therapy (RT) in management of patients with unresectable locally advanced NSCLC became accepted when the VA study in the late 1960s showed a survival benefit at 1 year (18.2% versus 13.9%) for those patients who received 35Gy in 5 weeks of RT versus no RT.³⁹² This study's conclusions were confounded by inadequate dose of RT, inadequate techniques, and inclusion of patients with small cell histology. The role of RT was further refined by a randomized study by the Radiation Therapy Oncology Group (RTOG 73-01), which showed that response rate improved with higher dose of RT (60Gy versus 40 and 50Gy) and led to improved local tumor control and 3-year survival. Furthermore, inclusion of a split-course arm revealed that the standard fractionation led to a better outcome.³⁹³ RR was 51% with 40Gy, 66% with 50Gy, and 61% with 60Gy. Local control was inversely proportional to dose received: 77% at 3 years for the 60-Gy arm, 58% for the 50-Gy arm, and 48% for those treated with 40Gy ($P = 0.02$).³⁹³ However, although these trials indicate a role for high-dose thoracic RT in patients with NSCLC, the overall survival with this modality alone still left much to be desired [2-year overall survival (OS), 19%].³⁹⁴ Meanwhile, the issue of whether thoracic RT was indicated as a single modality despite these studies continued to be a subject of debate. In the 1980s, a randomized trial designed to readdress this issue was reported by Johnson et al.³⁹⁵ This trial randomized 319 patients to three arms: experimental chemotherapy (vindesine) arm, RT-alone arm (60Gy/6 weeks), and vindesine and thoracic RT arm. The overall response rate was superior in the RT arms: 30% (RT alone),

34% (RT + chemo), and 10% (chemo alone) (P less than 0.001). However, there was no significant difference in median and overall survival. Median survival for vindesine arm was 10.1 months, for RT alone was 8.6 months, and 9.4 months for those receiving RT + vindesine ($P = 0.58$). It is important to note that 37% (36/98) of the vindesine-alone arm crossed over to the RT arm, and of these, 22% had response. Conversely, 25 patients crossed over to the vindesine arm from the RT arm, and of these patients, the response rate was 4%. The authors concluded that immediate radiation may not confer survival advantage to patients with locally advanced (LA) NSCLC, despite a statistically significant improvement in response rate. However, in retrospect, in view of our current knowledge that combined modality therapy improves survival compared to RT alone, and with up to one-third of the chemo-alone arm crossing over to RT in this study, it is possible that this arm, in reality, was partially a sequential chemo-RT arm. Regardless of the controversies, these and other studies clearly pointed to a need for improvement in the therapy of LA NSCLC patients.

SEQUENTIAL COMBINED MODALITY THERAPY (CMT) DEFINED FOR LOCALLY ADVANCED NSCLC

NEGATIVE STUDIES

In the 1980s, several important Phase III studies conducted at various countries around the world helped to determine the role of combined modality therapy (CMT) for inoperable locally advanced NSCLC patients. Chemotherapy in these studies was administered mostly before (induction) or after (consolidation) the administration of thoracic RT.

The trial from Finland randomizing 238 patients to RT versus CMT, revealed no statistically significant difference in local and distant control and overall survival (Table 37.17).³⁹⁶ In retrospect, their thoracic RT regimen was suboptimal in

TABLE 37.17. Sequential combined modality therapy (CMT) trials in the 1980s.

<i>Study</i>	<i>N</i>	<i>Median survival</i>	<i>Two-year survival</i>	<i>P</i>
Finnish Trial ³⁹⁶				
CAP (induction, mid, consolidation) + split course RT 55 Gy/2.5–3 Gy/fx	119	11 months	19%	
RT alone	119	10.3 months	17%	$P = \text{ns}$
Italian Trial (Trovo et al.) ³⁹⁷				
RT 45 Gy/15 fx	62	11.74 months		
RT + CAMP × 12 cycles	49	10.03 months		$P = \text{ns}$
NCCTG (Morton et al.) ³⁹⁸				
MACC × 2 induction/consolidation + RT 60-Gy conventional fx	56	10.4 months	21%	
RT 60Gy/2 Gy/fx	58	10.3 months	16%	$P = 0.69$
CALGB (Dillman et al.) ³⁹⁹				
PV × 2 cycles induction + RT 60Gy/2 Gy/fx	78	13.7 months	26%	
RT alone	77	9.6 months	13%	$P = 0.012$
French Trial (Le Chevalier et al.) ⁴⁰⁰ ; included follow-up that showed statistical significance				
VCPC × 2 cycles + RT 65 Gy/26 fx	176	12	21%	
RT alone	177	10	14%	$P < 0.02$
Italian trial (Crino et al.) ⁵⁴³				
PE × 3 cycles + RT 56 Gy	33	14 months	30%	
RT alone	33	11 months	14%	$P = 0.056$

terms of total dose (55 Gy), fractionation (split course with 3-week break after 2 weeks, 30 Gy), nonstandard fractionations used [2.5 Gy/fraction (fx), 3 Gy/fx, and 4.5 Gy/fx], and technique (posterior cord block used during second course of RT). Therefore, the true value of combined modality was difficult to assess in this setting.

A group from Italy also published reports on CMT versus RT alone for locally advanced NSCLC.³⁹⁷ In this study, chemotherapy was administered 4 weeks after completion of RT (sequential/consolidation) rather than as an induction phase. RT dose was 45 Gy in 15 fractions (fx) delivered in 3 weeks, which in retrospect is also a suboptimal dose; 111 patients were randomized to RT alone ($n = 62$) or RT + chemotherapy ($n = 49$). Response rate was 56.4% for RT alone versus 38.8% for RT + chemotherapy, which was not statistically significant ($P = 0.9$). Time to progression was 5.93 months for RT versus 7.02 months for RT/chemo ($P = ns$). Important to note was also the high cross-over rate: patients progressing on RT alone were allowed to be started on CAMP, and of the 54 patients who progressed in the RT-alone arm, 29 patients received CAMP. Median survival was 11.74 months in the RT arm versus 10.03 months in the RT/CAMP arm; however, there was a high cross-over rate (47%) in the RT arm, which makes this study difficult to analyze.

The North Central Cancer Treatment Group (NCCTG) also reported on their Phase III randomized study, which was also a negative trial for CMT.³⁹⁸ Median survival times were equivalent between the chemo/RT arm versus the RT-alone arm (317 days versus 313 days, respectively), and 2-year survival showed a trend toward improved survival with CMT (16% versus 21%), but failed to reach statistical significance, and did not hold true on long-term follow-up at 5 years (7% for RT alone versus 5% for CMT). Unlike the Finnish study, their RT regimen was based on the RTOG 73-01 regimen, and patients received 60 Gy over 6 weeks. Furthermore, in both the Finnish and the NCCTG studies, patients with poor prognostic factors (poor performance status, liberal weight loss criteria, and presence of supraclavicular disease) were enrolled in the trials, which may have led to worse outcome.

POSITIVE STUDIES

Meanwhile, two important randomized Phase III studies conducted by CALGB (Dillman et al.³⁹⁹) and the French group (Le Chevalier et al.⁴⁰⁰) both showed statistically significant improvement in OS with CMT (see Table 37.17).

In an attempt to clarify the issue of CMT versus RT alone, several groups performed meta-analysis and reported improvement of survival, albeit modestly so, favoring addition of chemotherapy to thoracic RT.^{384,401,402} Marino et al. performed meta-analysis on 14 randomized trials from 1980–1994, comprising a total of 1,887 patients.⁴⁰¹ As expected, the studies involved used a variety of radiation regimen and a variety of chemotherapy regimen (10 of 14 were platinum based). This analysis reported a reduction in mortality of 18% at 2 years for the non-cisplatin-based group, and 30% for the cisplatin-based group. However, this improvement did not persist at 3 and 5 years.

Similarly, the Non-Small Cell Lung Cancer Collaborative Group also performed a meta-analysis, which was published in the *British Medical Journal* in 1995.³⁸⁴ This was a larger meta-analysis comparing four treatment modalities including surgery versus surgery plus chemotherapy, and surgery

plus radiotherapy with or without chemotherapy for early-stage disease, and RT versus RT + chemotherapy for locally advanced NSCLC. For the scope of this review, we briefly summarize their findings for unresectable locally advanced NSCLC. Altogether, data from 52 trials with 9,387 patients were used for analysis. For locally advanced NSCLC, data from 22 trials with 3,033 patients were available with varying CT regimens and various RT regimens. Results showed significant benefit of chemotherapy with a hazard ratio of 0.9 ($P = 0.006$), or a 10% reduction of risk of death, corresponding to a 2% benefit at 5 years (3% at 2 years). Cisplatin-based chemotherapy once again showed strongest benefit with a hazard ratio of 0.87 ($P = 0.005$), or a 13% reduction in risk of death, which equals a 4% benefit at 2 years and 2% at 5 years.

Finally, a similar meta-analysis by Pritchard et al. was published the next year in the *Annals of Internal Medicine*.⁴⁰² The main difference was that this group's analysis included trials by Sause and Jeremic and excluded trials by Wils and Crino.⁴⁰² They also had more updated data, as it was analyzed later, and the trials included were from 1987 to 1995. The main exclusion criteria difference was that they did not include any studies that have only been presented in abstract form or were in preliminary publications only. Fourteen studies were analyzed for total of 2,589 patients. In their analysis, they reported a reduction in risk of death up to 3 years using combined modality therapy of 10% to 20%. Mean gain in life expectancy was calculated to be approximately 2 months at the end of 3 years. Interestingly, cisplatin-based sequential chemotherapy had a RR of 0.77 (CI, 0.68–0.87), compared to 0.83 (CI, 0.77–0.9) for any chemotherapy. Median survival was improved from 10.3 months to 12.0 months with the addition of any chemotherapy.

As with all meta-analyses, one must be wary of the publication biases (i.e., negative trials tend not to be reported), but as the author interestingly points out in Pritchard's paper, 10 of 14 were initially published as negative trials. Furthermore, different agents were used for chemotherapy, different radiation regimens were also used, and sequencing of chemotherapy was not uniform in all studies. However, despite all these potentially confounding issues, these studies pointed toward a role for chemoradiation therapy. If anything, the meta-analysis may have underestimated the potential benefit of combined modality therapy in an appropriately selected patient population.

Therefore, these pivotal trials and the follow-up meta-analysis led to a new paradigm for therapy of unresectable NSCLC: that the addition of appropriate chemotherapy (particularly cisplatin based) to the optimal RT regimen would improve survival. These studies led the way to investigation of some very important issues that pertain to optimizing combined modality therapy that include questions aimed at defining the optimal sequencing of the chemotherapy with radiation, the optimal agent or agents to be used with radiation, and the optimal dose and fractionation of RT that can be safely delivered with chemotherapy.

CONCURRENT ADMINISTRATION OF CHEMOTHERAPY WITH RT FOR LOCALLY ADVANCED NSCLC

As the trials in the 1980s indicated that addition of chemotherapy appears to confer significant survival benefit,

likely secondary to decrease in metastasis rate, as alluded to by several studies,^{400,401} sequential chemo/RT became the standard of care. However, local control was not always shown to be improved by this approach. Importance of local control in improving survival was first indicated by previous work by Perez et al.³⁹³ This finding was further strengthened by the EORTC trial, which was the first randomized Phase III study comparing concurrent chemo/RT versus RT alone.¹⁰⁵ This study randomized 331 patients to three treatment arms: RT alone, RT + weekly cisplatin (30mg/m²), and RT + daily cisplatin (6mg/m²) during thoracic RT. RT was administered in split-course regimen: 3Gy × 10 daily fractions, followed by 3 weeks of break, followed by 2 more weeks of 2.5Gy × 10 fractions for a total of 55Gy. Significant survival advantage and disease-free survival (DFS) were noted for patients treated with cisplatin, despite a split-course RT regimen. Local recurrence-free survival was also significantly improved with the addition of cisplatin. Interestingly, with the split-course regimen, the typical acute and late toxicities, including esophagitis and delayed lung injury (pneumonitis, fibrosis, and respiratory symptoms), were not significantly worsened by the addition of concurrent cisplatin.

The major trials addressing the efficacy of concurrent administration of chemotherapeutic agents with thoracic RT are outlined in Table 37.18 in chronologic order. The first reported trial that specifically compared head to head concurrent versus sequential chemo/RT was reported by the West Japan Lung Cancer Group.⁴⁰³ This was a Phase III study randomizing 314 patients to concurrent versus sequential

chemotherapy with RT. In the sequential arm, RT was delivered to 56Gy and 2Gy/fx without a break. Statistically significant improvement in response rate was achieved (84% versus 66.4%; $P = 0.002$). Overall median survival was 16.5 months versus 13.3 months ($P = 0.04$) favoring the concurrent arm, with 5-year OS at 15.8% versus 8.9%. On further analysis, local control was found to be directly impacted by the use of the concurrent approach, which found survival without local relapse was 30 months versus 11 months ($P = 0.0221$), which persisted on long-term follow-up of 5 years. Time to distant failure was not statistically different between the two arms ($P = 0.8$; log rank test), suggesting that local control was an important determinant of improved survival. Toxicity profile, in particular grade 3+ esophagitis, was not worse in the concurrent arm (4% concurrent versus 3% sequential), likely because of the split-course regimen employed in this study. This was the first published report of improvement of survival with concurrent chemoRT versus sequential chemoRT.

The GLOT-GFPC NPC 95-01 study was reported in ASCO 2001 by Pierre et al.⁴⁰⁴ This randomized, multicenter, Phase III trial from France also addressed the issue of sequential versus concurrent administration of chemo/RT: 212 patients were randomized to sequential versus concurrent arms. Median survival was 13.8 months in the sequential and 15 months in the concurrent arm ($P = 0.41$), which was a trend for the concurrent arm. Two-year OS was 23% in the sequential and 35% in the concurrent arm, also indicating a trend toward increased survival for the concurrent regimen.

TABLE 37.18. Schema of major concurrent versus sequential CMT to date.

<i>Trial</i>	<i>Schema</i>	<i>Median survival</i>	<i>Grade 3+ esophagitis (acute)</i>
West Japan LC Group ⁴⁰³	Sequential:	13.3 months	3%
	MVP × 2 → Conventional RT Day 50	16.5 months	4%
RTOG 9410 ⁴⁰⁹	Concurrent:	$P = 0.04$	
	MVP × 2/Split course RT Day 1		
	Sequential:		
	Vinb/CisP × 2 → Stn RT day 50		
French Trial ⁴⁰⁴	Conc standard RT:	14.6 months	4%
	Vinb/CisP × 2/Stn RT day 1	17 months	25%
	Conc hyperfractionated RT:	($P = 0.046$ vs. sequential)	46%
	CisP/Eto × 2/BID RT day 1	15.2 months	
Czech Trial ⁴⁰⁵	Sequential:	13.8 months	0%
	CisP/Nav → Stn RT day 50	15 months	26.1%
	Concurrent:	$P = 0.41$	
LAMP ^{406,407}	CisP/Etop × 2/RT → CisP/Etop		
	Sequential:	13 months	4.2%
	Cisp/Nav × 4 → RT	20.2 months	17.6%
BROCAT ⁴⁰⁸	Concurrent:	$P = 0.0216$	
	Cisp/Nav/RT → Cisp/Nav		
	Sequential:	13 months	4%
	Paclitaxel/Carbo → RT	12.8 months	20%
	Induction → Conc:	16.1 months	28%
LAMP ^{406,407}	Paclitaxel/Carbo → p/c/RT	$P = ns$	
	Conc. → Consolidation:		
	p/c/RT → Paclitaxel/Carbo		
BROCAT ⁴⁰⁸	Sequential:	14.6 months	7.6%
	Paclitaxel/Carbo × 2 → RT alone	19.2 months	15.8%
	Concurrent: Paclitaxel/Carbo × 2 → weekly paclitaxel/RT		

In ASCO 2002, two important trials addressing this same issue were highlighted. One study was presented by Zatloukal et al., for the Czech Lung Cancer Group.⁴⁰⁵ This study employed vinorelbine and cisplatin, and 102 patients were enrolled and randomized to the two arms. Median survival time was 619 days in the concurrent arm and 396 days in the sequential arm ($P = 0.0216$). Time to progression was 366 days in the concurrent arm, and 288 days in the sequential arm ($P = 0.0506$). The concurrent arm had significantly higher grade 3/4 toxicities, including leukopenia (52.9% versus 18.8%), neutropenia (64.7% versus 39.6%), and esophagitis (17.6% versus 4.2%). Pulmonary toxicity was equivalent (3.9% versus 2.1%) between the concurrent and sequential arms.

The locally advanced multimodality protocol (LAMP) trial is a randomized Phase II study whose preliminary results have been presented at ASCO 2001 and 2002.^{406,407} One of the unique aspects of this trial was its liberal weight loss criterion, up to 10% before enrollment (most recent studies require less than 5% weight loss to be eligible). Three arms were as follows: arm 1 was a sequential arm where patients were administered two cycles of paclitaxel with carboplatin, followed by daily RT to 63 Gy. The second arm was the induction/concurrent arm, where patients were given induction chemo, as in arm 1, followed by weekly paclitaxel and carboplatin with RT for 7 weeks, also to 63 Gy. Finally, arm 3 consisted of a concurrent/consolidation mode in which patients were treated with concurrent RT as in arm 2, but followed by adjuvant chemo for two cycles (same as induction regimen). When all patients were considered, median survival was 13 months for sequential, 12.8 months for induction/concurrent, and 16.1 months for concurrent/adjuvant arm. When a subset analysis of patients with better weight criteria was conducted, the median survival and 2-year OS were 13 months/28%, 14.4 months/24%, and 17.2 months/35% for arms 1, 2, and 3 respectively. Both the total and subset analyses showed a trend toward the concurrent/consolidation arm but did not reach statistical significance on short-term follow-up. Toxicity profile showed grade 3/4 esophagitis to be 4%, 20%, and 28% on arms 1 to 3, respectively. The interesting result from this study was that delay of concurrent chemo/RT with induction chemotherapy appeared to have a negative impact on outcome, whether this was due to underpowering of this study ($n = 69$) or to the true impact of delaying initiation of concurrent chemo/RT is difficult to assess with certainty but is worth further investigation.

Most recently, in ASCO 2003, two trials were presented that gave further credence to concurrent chemo RT as the modality of choice over sequential CMT. One study was a long-term mature update of the RTOG 9410, which was first presented in ASCO in 2000. The other was a study from Germany reported by Huber for the BROCAT group.⁴⁰⁸

The BROCAT group schema involved initiation with two cycles of induction paclitaxel and carboplatin chemotherapy for 3 weeks.⁴⁰⁸ After the induction, patients were analyzed, and if patients did not have progressive disease, they were randomized to the sequential arm (RT alone to 60 Gy), or the concurrent arm (weekly paclitaxel + RT as in sequential arm); 303 patients enrolled, and 262 patients were able to complete the induction chemotherapy. Median survival time was 14.6 months for sequential versus 19.2 months for concurrent arm. With this short follow-up, however, statistical significance was not reached.

RTOG 9410 is a Phase III randomized three-arm study ($n = 610$) that compared sequential chemotherapy followed by RT versus concurrent administration of hyperfractionated (69.9 Gy bid in 1.2 Gy/fx) or daily RT and chemotherapy.⁴⁰⁹ Chemotherapeutic agents used were cisplatin and vinblastine; when given sequentially, two cycles were administered before RT (start on day 50), whereas in the concurrent arms, RT began on day 1 with the chemotherapy. In ASCO 2003, the long-term results of the trial were reported, with median survival for the sequential arm being 14.6 months, 17 months for the concurrent qd arm, and 15.2 months for the concurrent bid arm. This survival benefit was maintained on long-term follow-up with 4-year OS for the sequential arm being 12%, versus 21% for the concurrent qd arm and 17% for the concurrent bid arm. The difference between the sequential and concurrent qd arms reached a statistically significant difference with a P value of 0.046. There were significant acute toxicity issues with the concurrent and hyperfractionated arms. The concurrent arm had 25% grade 3 or 4 esophagitis and the hyperfractionated arm had 46% grade 3 or 4 esophagitis, whereas the sequential arm had 4% grade 3 or 4 esophagitis. There was no significant difference in acute grade 3 or 4 lung toxicity (within 90 days) of RT initiation, which was approximately 9% for the sequential arm, versus 4% for the concurrent arm and 4% for the hyperfractionated arm. There was no significant difference in late toxicities including esophagitis and pneumonitis.⁴⁰⁹

OPTIMAL SEQUENCING FOR COMBINED MODALITY THERAPY: SUMMARY OF MAJOR TRIALS

In summary, when all these trials are evaluated together, a total of 709 patients were treated with one of the foregoing concurrent regimens and 716 on the sequential arm. Median survival of these studies summed together show a difference of 3 months: 17 months versus concurrent, and 14 months for sequential arms (P less than 0.05 Kruskal–Wallis test). Furthermore, these trials appear to validate the earlier sequential trials of the 1980s in that addition of chemotherapy appears to improve median survival. The most impressive and convincing data that are now beginning to emerge are that the benefits conferred by the concurrent regimen appear to be durable on long-term follow-up. Long-term follow-up of two important trials, WJLCG and RTOG 9410,^{403,409} both show a significant long-term survival advantage to the concurrent arm. Similar data were seen on long-term follow-up of three sequential Phase II studies of concurrent chemo/RT by Choy et al., as reported in ASCO 2003.⁴¹⁰

TOXICITY OF CONCURRENT CHEMO/RT

Although the benefit of concurrent chemoRT appears to improve survival outcome in patients with LA NSCLC, the question of the cost or risks of this modality remained. The most apparent cost, however, is that of increased acute toxicities, mainly esophagitis and pneumonitis. A review of the data from multiple RTOG concurrent chemoRT trials (90-15, 91-06, 92-04, and 94-10), all involving cisplatin given concurrently with standard 60 Gy or hyperfractionated 69.6 Gy bid RT, was performed (personal communication, Werner et al.). Analysis included a total of 585 patients. Acute esophagitis of grade 3 or higher occurred in 37% of these patients,

peaking and plateauing by 2 months after initiation of therapy.

When a similar analysis was performed to evaluate grade 3 or 4 esophagitis rates, the results showed that a 19.5% esophagitis rate was observed in the concurrent arm versus 4% in the sequential arm. Therefore, it appears that the concurrent arm does lead to superior survival at the expense of increased acute esophageal toxicity.

Similar to the foregoing analysis, Werner-Wasik et al. performed analysis on the same 585 patients from the various RTOG trials looking at late pneumonitis incidence.⁴¹¹ Incidence of late pneumonitis of grade 3 or higher toxicity occurred in 20% of these patients. Time course of incidence showed that this could occur as late as 18 months after therapy, with 50% of these grade 3 or higher pneumonitis patients having symptoms at 6 months posttherapy. A majority of patients had pneumonitis occur between 6 and 12 months posttherapy.

In the RTOG 9410 trial, there appears to be no difference in the rate of pneumonitis in the three arms on long-term follow-up. For example, pneumonitis rate (grade 3 or 4) was 14% in the sequential arm, 12% in the concurrent arm, and 16% in the hyperfractionated arm (personal communications). Furthermore, although there was increased esophagitis acutely in the concurrent and the hyperfractionated arms as noted above, this appears to resolve on long-term follow-up, and the rate of esophagitis among the three arms became equivalent at 0.5%, 2.6%, and 4% for the sequential, concurrent, and hyperfractionated arms, respectively. It appears that the major disadvantage of concurrent arm, which is esophagitis, is not a sustained toxicity, and without significant evidence for undue late toxicity with this regimen, the survival advantage should convince us that concurrent strategy is superior to the sequential combined modality therapy. In lieu of a further confirmatory, larger randomized trial, the next important analysis would be to perform a meta-analysis of all studies comparing sequential versus concurrent therapy to improve the power to detect a significant difference in outcome and toxicities between these two approaches.

A variety of strategies for decreasing the toxicity of chemoRT treatment has been suggested. These include improvements in technology of RT delivery and utilization of pharmacocytotoxic strategies to decrease normal tissue toxicity. Technical innovations include usage of intensity modulated radiation therapy (IMRT) or 3-D conformal planning strategies, novel fractionation schemes, improved functional imaging to deliver therapy to a smaller target volume, and new strategies for RT delivery (i.e., determining for which patients mediastinal nodes could be omitted to decrease target volume). The more biologic approach includes suggestions of usage of agents such as keratinizing growth factor, tumor necrosis factor- β (TGF- β), melatonin, glutamine, gene therapy (intratumoral injection of manganese superoxide dismutase plasmid/liposome, SOD2-PL), and use of amifostine, an organic thiophosphate compound that has been shown to protect normal tissue selectively against both radiation and chemotherapeutic agents.

Delivery of Radiotherapy: Hyperfractionation

Another brewing question in the field of treatment of unresectable NSCLC was regarding how RT should be adminis-

tered. As previously mentioned, pioneering works by Perez et al. helped to clearly establish the appropriate dose and helped to establish that a split-course regimen was not as efficacious as the conventional continuous course RT. Investigation into hyperfractionated regimen dates back to the 1970s when RTOG 77-04 indicated that in treatment of squamous cell carcinoma of upper respiratory tract and esophagus, 1.5Gy bid produced severe mucositis requiring treatment interruptions, where as with 1.25Gy/fx bid, therapy could be carried to 60 Gy.

RTOG 81-08 was a feasibility study that helped to establish that 1.2Gy bid fx to 69.6Gy could be administered without significant acute toxicities in NSCLC.⁴¹² RTOG 83-11 was performed as a randomized dose-escalation Phase I/II trial of hyperfractionated RT with total doses ranging from 60 to 79.2Gy for stage III NSCLC patients.⁴¹³ The study had five arms, each involving 1.2Gy bid to total doses of 60.0, 64.8, 69.6, 74.4, and 79.2Gy. Their conclusion was that equal survival benefit was seen in the 69.6-Gy and above arms (median survival, 10 months versus 8.7 months versus 10.5 months for the 69.6-Gy, 74.4-Gy, and 79.2-Gy arms, respectively). However, significantly higher life-threatening pneumonitis occurred in the 79.2-Gy arm versus the 69.6-Gy arm (8.1% versus 5.7%). Median survival at 69.6Gy was superior to the lower doses of 60 and 64.8Gy, which was even more markedly pronounced when a subset of patients with the CALGB 84-33 good prognosis criteria were evaluated (median survival, 13 months in the 69.6-Gy arm versus 10 and 7.8 months for 60- and 64.8-Gy arms, respectively; $P = 0.07$). Furthermore, there was a dose-survival relationship in the CALGB group (i.e., dose received versus survival), with patients receiving 69.6Gy surviving longer than those who received less [median survival for 69.6Gy (± 2.4 Gy) dose received was 13.7 months versus those who received 64.8Gy (± 2.4 Gy) was 12.7 months, and those who received 60Gy (± 2.4 Gy) was 8.9 months ($P = 0.02$)]. These results led to a Phase III trial (RTOG 88-08) investigating the role of hyperfractionated RT in this population of patients. The major hyperfractionation trials are listed and summarized in Table 37.19.

NEGATIVE HYPERFRACTIONATION TRIALS

A Phase III trial comparing (1) RT alone, (2) induction chemotherapy followed by RT, or (3) hyperfractionated RT (1.2Gy bid to 69.6Gy) was conducted by the U.S. intergroup.⁴¹⁴ In this trial, 452 patients were enrolled and eligible, with 149, 151, and 152 patients, respectively, in arms 1 to 3. Initial results showed median survival of 11.4 months, 13.8 months ($P = 0.03$ for chemoRT versus RT alone), and 12.3 months for arms 1 to 3 respectively, which validated the Dillman data.³⁹⁹ Toxicity profile was reported as being acceptable, with similar grade 3 or 4 nonheme toxicity profile for the three patient groups who were followed to 18 months. Grade 4 toxicity related to RT was reported in 4 patients in the hyperfractionated arm, versus 1 on the standard and sequential arm; 2/4 grade 4 toxicity on the hyperfractionated arm was esophagitis. Updated reports published in 2000 reported similar findings with median survival of 11.4 months, 13.2 months, and 12 months, respectively, in arms 1 to 3.⁴¹⁵ The 5-year survival rates were 5%, 8%, and 6%, once again showing mild benefit to the sequential arm, but not in the hyperfractionated arm. There was an indication that in

TABLE 37.19. Comparison of hyperfractionated (tid, bid) versus conventional (qd) RT either with or without concurrent chemotherapy.

Study	Median survival	Three-year OS	Five year OS	P value	Acute esophagitis (grade 3 or 4)
RTOG 8808 ⁴¹⁵					
Daily RT (no chemo)	11.4 months	9%	5%		Not available
BID RT	12 months	14%	6%	<i>P</i> = ns	Not available
RTOG 9410 ⁴¹⁶					
Concurrent chemo + daily RT	17 months	35%	21%		25%
Concurrent chemo + bid RT	15.2 months	34%	17%	<i>P</i> = ns	46%
CHART ^{418,419}					
Daily RT	13 months	21%	12%		3%
TID RT	16.5 months	30%	7%	<i>P</i> = 0.008	19%
HART ⁴²⁰					
Induction chemo + conventional RT	13.7 months	33%			16%
Induction chemo + tid RT	22.2 months	48%		<i>P</i> = NS	25%

squamous cell cancer histology, the hyperfractionated arm had a durable response of 5-year survival of 9% compared to 2% in the other two arms (*P* = ns).^{414,415} However, as a whole, this was a negative trial for the hyperfractionated regimen, contrary to what was indicated by the RTOG 83–11 study. It did prove to be a confirmatory trial for the sequential arm with very similar median survival results as the Dillman study.

RTOG 94–10 also had a hyperfractionated arm as previously noted. The difference was that, in this study, chemotherapy was administered concurrently with the hyperfractionated regimen as described above, and as was the case in RTOG 88-08, the hyperfractionated arm failed to provide survival advantage over the concurrent or the sequential arm⁴¹⁶ (see Table 37.19). It is also quite clear that the acute toxicity was significantly higher in the hyperfractionated arm. Therefore, hyperfractionation using 1.2Gy bid to 69.6Gy does not appear to be a reasonable therapeutic option for this group of patients. However, this does not necessarily imply that hyperfractionation is not a good strategy in this setting.

POSITIVE HYPERFRACTIONATED TRIALS

CONTINUOUS, HYPERFRACTIONATED, ACCELERATED RADIOTHERAPY (CHART)

CHART was introduced in the mid-1980s and has a strong biologic rationale.⁴¹⁷ The goal for CHART is twofold: (1) to attempt to improve tumor control of cancer cells, which can proliferate and repopulate rapidly, by using more-frequent fractions, and (2) to minimize long-term normal tissue morbidity by using smaller fractions.⁴¹⁷ CHART employs a 1.5-Gy fx three times a day in 12 consecutive days. Saunders et al. reported on their trial, which randomized 563 patients to CHART (*n* = 338) versus conventional RT (*n* = 225) which was administered to 60Gy in 30 daily fractions. Promising survival advantage with CHART, particularly in patients with SCCA histology, was demonstrated on short-term

follow-up.⁴¹⁸ Results from long-term follow-up confirmed a significant reduction in death, with 2-year survival being 30% for CHART and 20% for the conventional arm (*P* = 0.008). This benefit was extended at 5 years, with OS being 12% for CHART and 7% for standard RT. There was also a 21% reduction in risk of local progression (*P* = 0.033). This benefit was more pronounced for patients with SCCA histology in terms of survival (20% versus 33%), and improvement in local control was substantial and statistically significant in this group.⁴¹⁹ Interestingly, there was also a significant 25% reduction in relative risk of metastasis (*P* = 0.043) and 27% reduction in risk of local progression (*P* = 0.0012) in the SCCA histology. Considering no chemotherapy was used in these patients, one could potentially argue that in the squamous histology, improvement of local control may be critically linked to inhibition of further metastatic progression. As one would expect, the rate of acute toxicity with CHART was higher than that of conventional, with the esophagitis rate being 19% in CHART versus 3% in the conventional arm (see Table 37.19). The late complications were not significantly different between the two groups, however. Interesting to note was that 81% of patients in the CHART trial were of squamous histology, and this trial included patients with stage IA, IB, and II disease (36% of enrolled patients), which may explain the significantly higher survival data even with conventional RT alone compared to historical controls. Is it also possible that CHART may have been more effective in patients with early-stage disease for whom ultimate local control has been the primary mode of therapy (i.e., surgery)? Despite these and other potential issues, the data from CHART are encouraging and worthy of further pursuit.

HYPERFRACTIONATED ACCELERATED RADIOTHERAPY (HART)

Therefore, based on this, ECOG set forth to clarify this issue with a randomized Phase III multiinstitutional trial comparing standard thoracic RT to hyperfractionated accelerated radiotherapy (HART) (Table 37.19). The results of ECOG 2597 were recently presented at ASCO 2003.⁴²⁰ They reported that

119 eligible patients were randomized to either standard RT or HART following two cycles of induction chemotherapy consisting of carboplatin (AUC = 6) and paclitaxel (225 mg/m²) on day 1 of each 3-week cycle. The HART regimen was similar to CHART, consisting of 1.5 Gy tid over 2.5 weeks to a total of 57.6 Gy (no weekends). Standard RT involved 64 Gy in 2 Gy/day fractions. Only stage III patients were enrolled. The study was closed prematurely due to poor accrual. The results, nevertheless, are provocative. Median survival time for conventional RT is similar to historical control at 13.7 months. The HART regimen, meanwhile, conferred a trend toward survival benefit, with median survival at 22.2 months, and the 2-year survival was 33% for conventional and 48% for HART ($P = 0.20$). Grade 3 or 4 esophagitis was higher for the HART (14 patients, 25%) arm than the conventional arm (9 patients, 16%).

Role of Prophylactic Cranial Irradiation in Locally Advanced NSCLC

Chemotherapy combined with thoracic radiotherapy improves survival for patients with locally advanced NSCLC,^{384,404,421} but the systemic relapse, including brain metastasis, remains a major problem (Table 37.20). Central nervous system (CNS) metastasis is a common and devastating problem for patients with NSCLC with reported incidence up to 54%.^{100,422-430} The median survival of patients diagnosed with brain metastasis in NSCLC is less than a year.⁴³¹⁻⁴³³ Gaspar and colleagues reported a retrospective review of the SWOG database of stage IIIA/B NSCLC patients who underwent combined modality therapy on four SWOG protocols (S8805, S9019, S9416, and S9504).⁴³⁴ There were a total of 422 patients enrolled on the SWOG trials, and 20% of the patients experienced isolated brain metastasis after primary therapy; 46% of the patients who had brain as the site of first relapse developed brain metastasis within 16 weeks of completion of therapy. The Radiation Therapy Oncology Group (RTOG) also showed that NSCLC patients with locally advanced disease with longest survival are at significant risk for developing CNS metastases.^{435,436} The improvement in the treatment of locally advanced NSCLC with combination chemotherapy, radiotherapy, and surgery has shown that CNS metastases remains a major site of relapse with up to 33% of patients experiencing CNS as the first site of metastasis.^{423,437} Similarly, the Lung Cancer Study Group (LCSG) reported that 21% of patients developed brain metastasis after undergoing neoadjuvant chemoradiotherapy followed by surgery for stage III NSCLC.⁴³⁸ Martini et al. also reported that 28.5% of patients developed isolated brain metastasis after undergoing chemotherapy (cisplatin, vindesine or vinblastine, and mitomycin) followed by surgery.⁴³⁹

Three published prospective randomized trials investigated the role of prophylactic cranial irradiation (PCI) in patients with NSCLC. One of the early studies was from the Veterans Administration Lung Group (VALG) reported by Cox and colleagues in 1981.⁴²⁵ The study reported the results of treatment for 281 inoperable NSCLC patients enrolled between 1975 and 1978. The treatment consisted of thoracic radiotherapy alone with dose up to 50 Gy in 25 daily fractions with or without PCI (20 Gy in 10 fractions); 6% of patients (7/136) who received PCI relapsed in the brain compared to 13% (16/145) of patients who did not receive PCI ($P = 0.38$). The reduction in brain relapse was not significant for squamous cell histology and addition of PCI did not alter the median survival of patients in the study. Umsawasdi and colleagues from the M.D. Anderson Cancer Center reported the results of a randomized trial testing the role of PCI in 1984.⁴²⁷ The study included 100 patients with locally advanced NSCLC who were clinically free of lung cancer after combined modality therapy. Patients received two cycles of induction chemotherapy (cyclophosphamide, adriamycin, cisplatin) followed by thoracic radiotherapy administered concurrently with the same chemotherapy. Patients in the PCI group received 3,000 cGy in 10 daily fractions to the whole brain. PCI reduced the incidence of brain metastasis dramatically from 27% to 4% ($P = 0.002$). However, no survival benefit was seen with PCI because of the negative impact of frequent extracranial relapses. Finally, RTOG conducted a study that investigated the role of PCI in 187 patients with unresectable or inoperable adenocarcinoma or large cell carcinoma of the lung. Russell and colleagues reported the results of the randomized study that incorporated thoracic radiotherapy with or without PCI (30 Gy/10 daily fractions).⁴²⁶ The dose to the chest was 60 Gy in 30 treatments for patients without prior surgery and 50 Gy in 25 treatments for those who had prior thoracotomy. Eighteen patients (19%) developed brain metastasis without PCI and 8 patients (9%) with PCI developed brain metastasis ($P = 0.10$). There was no survival difference seen due to the significant extracranial systemic (81%) and thoracic (61%) relapses (see Table 37.20).

Unresectable Locally Advanced NSCLC: Decades of Progress

Despite all the controversies that may persist in the field of locally advanced NSCLC therapy, the advancement of this field in the past 20 years has been substantial and noteworthy. The median survival, using standard of care therapy in the 1980s, was less than 10 months. In the 1980s, with the advent of sequential chemotherapy with improved RT techniques and conventional dosing, the survival was improved to the order of 14 months. Currently, utilizing concurrent

TABLE 37.20. Prophylactic cranial irradiation (PCI) for NSCLC: randomized trials.

Study	N	PCI dose (dose/fraction)	Median survival		Brain metastasis

VALG, Veterans Administration Lung Group; RTOG, Radiation Therapy Oncology Group.

chemoRT or CHART or sequential chemo-HART regimens, one can expect that patients with unresectable LA NSCLC would have median survival of the order of 17 to 18 months. Between 15% and 20% of patients with this disease may now expect to have survival of the order of 4 to 6 years (or more; longer follow-up not yet available) as seen in the WJLG, RTOG 9410, and Lun-27/56/63 studies. This prognosis is in contrast to 5-year survival of less than 5% in the 1980s, and translates to almost a threefold improvement in long-term survival for this cohort of patients. However, it is true that lung cancer is a disease that continues to humble us, as a majority of our patients with locally advanced NSCLC will succumb to this disease. Therefore, much more clinical, translational, and basic science research still needs to be devoted to this field.

Metastatic NSCLC

CISPLATIN-BASED CHEMOTHERAPY VERSUS BEST SUPPORTIVE CARE

Through the 1980s, cisplatin formed the backbone of systemic treatment in metastatic NSCLC, demonstrating single-agent response rate activity of 10% to 17%.⁴⁴⁰ Other active agents included mitomycin C, vinblastine, ifosfamide, and vindesine. However, the impact on patient survival using these agents remained in doubt, as multiple trials comparing cisplatin-based chemotherapy with best supportive care (BSC) drew conflicting conclusions (Table 37.21).^{441-447,677}

Although conclusive prolongations in survival were not consistently seen with the use of chemotherapy in the advanced disease setting in the 8 studies compared to BSC, its use was frequently associated with symptom relief and improvements in quality of life.^{448,449} For example, investigators in the Big Lung Trial found that the use of chemotherapy was associated with less grade 3 and 4 breathlessness and less pain, but worsened peripheral neuropathy, compared to patients receiving supportive care only.⁴⁵⁰ In addition, quality

of life as assessed by the EORTC QLC-LC13 questionnaire at 6 weeks confirmed an improvement for patients receiving cisplatin-based chemotherapy.⁴⁵¹ This randomized experience confirmed that seen in prior Phase II studies, in which rates of symptom relief often exceeded that of objective antitumor response, in that patients with stable disease experienced lessening of disease-related symptoms.^{452,453}

Because of discrepant survival results in BSC trials, meta-analyses of chemotherapy versus BSC trials have been helpful in determining the role of systemic treatment in these patients. A 1993 analysis of 6 randomized trials concluded that the use of chemotherapy in this setting was associated with a statistically significant 24% reduction in the risk of death at 1 year, and that treatment was associated with a lengthening of overall survival from 16.7 weeks to 27.4 weeks.⁴⁵⁴ A 1994 meta-analysis of published literature results and individual patient data confirmed the benefit of treatment, determining an odds ratio of death of 0.44 and an increase in estimated median survival from 3.9 months for BSC to 6.7 months for patients with advanced disease receiving chemotherapy.⁴⁵⁵ The largest meta-analysis of individual patient data was compiled from 11 studies from 1965 to 1991 and was reported in 1995.³⁸⁴ Findings from this analysis of more than 1,100 patients revealed that the use of cisplatin-based regimens was associated with a 27% reduction in the risk of death for patients with advanced NSCLC, translating into an absolute improvement in survival at 1 year of 10% (from 5% to 15%). The use of nonplatinum-containing regimens was not beneficial in the setting of advanced disease.

NEWER AGENTS VERSUS BEST SUPPORTIVE CARE

Clinical testing of newer, so-called “third-generation” chemotherapeutic agents in the treatment of NSCLC was active in the 1990s, with resultant improvements in the therapeutic index.⁴⁵⁶⁻⁴⁶⁰ The antimicrotubule agent, paclitaxel, was administered over 1 hour, 3 hours, and 24 hours, at various doses and schedules, with response rates ranging from 21% to 56% in untreated patients.^{461,462} Another taxane,

docetaxel, demonstrated a 35% response rate in Phase II testing, while antitumor response rates of 25% and 32% were seen in early clinical trials of gemcitabine and irinotecan, respectively.^{455,459,460}

The advent of these more-active agents prompted a renewal of BSC comparison trials, using these newer agents⁴⁶³⁻⁴⁶⁶ (Table 37.22). These trials more consistently demonstrate statistically significant prolongations in survival (approximating 2 months), as well as frequently detecting improvements in quality of life due to symptom relief. No comparative study detected a detriment in quality of life associated with the use of palliative chemotherapy with these newer agents, and in the one study in which the survival was not lengthened with treatment, symptom improvement was statistically sustained with chemotherapy.⁴⁶⁶ These trials provide the foundation for the use of palliative chemotherapy in metastatic NSCLC, with the expectation from single-agent therapy of an antitumor response seen in approximately one of five patients, and an average improvement in overall survival from 5 to 7 months, coincident with symptom improvement.

COMBINATION CHEMOTHERAPIES VERSUS CISPLATIN ALONE

The next challenge was to improve upon these single-agent results by combining chemotherapeutics, based upon the experience of combination chemotherapy in other disease settings. Prior combinations, using cisplatin with less-active drugs, yielded response rates similar to that seen with newer single-agent third-generation agents, namely in the 20% range, with median survivals of 5 to 6 months.^{448,467} As such,

no single combination could be recommended as first-line therapy for patients with advanced NSCLC.

Table 37.23 demonstrates the results from four randomized trials, comparing cisplatin alone versus cisplatin combinations using a newer, third-generation agent.^{449,468-470} This table provides evidence that doublet, platinum-based chemotherapy combined with a newer active, third-generation agent positively impacts survival in most studies, without significantly worsening toxicity. Large cooperative groups, therefore, selected one of these doublets as their reference arm for treatment in subsequent comparative trials. Carboplatin appears to be able to insert for cisplatin with no consistent loss in efficacy, and with an improvement in tolerability (please see following), such that it has often replaced cisplatin as the platinating agent of choice for treatment doublets.

CISPLATIN VERSUS CARBOPLATIN

Cisplatin, however, has been associated with a significant number of side effects, most notably nausea and vomiting. Although this toxicity has become much more manageable with the advent of the HT3 antiemetics, concerns remain regarding the renal toxicity, neuropathy, ototoxicity, and generalized fatigue and asthenia. To alleviate some of these side effects, clinicians have turned toward the platin analogue carboplatin. Although carboplatin has a relatively low single-agent response rate, data from most, but not all, randomized trials supports equivalent clinical benefit between cisplatin and carboplatin.⁴⁷¹ An EORTC study from the late 1980s demonstrated similar survival curves for cisplatin and carboplatin when each drug was combined with etoposide.⁴⁷²

TABLE 37.23. Randomized trials of cisplatin alone versus newer cisplatin-based combinations.

Study	N	Therapy	Overall response rate (%)	Median survival (months)	One-year overall survival (%)	P value
Wozniak ⁴⁴⁹	432	Cisplatin Cisplatin/vinorelbine	12 26	6 8	20 36	0.0018
Sandler ⁴⁶⁸	522	Cisplatin Cisplatin/gemcitabine	11.1 30.4	7.6 9.1	28 39	0.004
von Pawel ⁴⁶⁹	446	Cisplatin Cisplatin/tirapazamine	13.7 27.5	6.9 8.7	22.5 34	0.0078
Gatzemeier ⁴⁷⁰	414	Cisplatin Cisplatin/paclitaxel	17 26	8.6 8.1	36 30	NS

Another more-recent study compared carboplatin and gemcitabine to cisplatin and gemcitabine and showed similar survival from treatment with cisplatin- and carboplatin-based regimens.⁴⁷³ In ECOG 1594, four different chemotherapy doublets were compared to each other; the comparator arm involved cisplatin and paclitaxel, while one of the experimental arms included carboplatin and paclitaxel.⁴⁷⁴ Although the dose and infusion rate of the paclitaxel differed between the two arms (135 mg/m² over 24 hours in the cisplatin arm, and 225 mg/m² over 3 hours in the carboplatin arm), the overall response and median survival did not differ significantly (22% and 7.8 months in the cisplatin/paclitaxel arm, and 17% and 8.1 months in the carboplatin/paclitaxel arm, respectively). A Phase III trial by a Yugoslavian group found an improved survival by log rank analysis when carboplatin was substituted for cisplatin in combination with vindesine and mitomycin C, whereas a European trial comparing cisplatin/paclitaxel to carboplatin/paclitaxel, in which the dose and schedule of paclitaxel was identical between the two arms, found a statistically significant improvement in median survival (9.8 months) in the cisplatin arm, compared to 8.5 months in the carboplatin arm.^{475,476} Another study reported by Fossella and colleagues compared docetaxel/cisplatin and docetaxel/carboplatin with vinorelbine/cisplatin, 75 mg/m² of docetaxel being given in both arms.⁴⁷⁷ Although the study was not designed to compare the two docetaxel arms, the investigators reported a trend toward improved survival in the docetaxel/cisplatin arm (11.3 months) compared to the docetaxel/carboplatin arm (9.4 months). Essentially all these studies found decreased toxicity in the carboplatin arm. Thus, although it could be debated as to whether carboplatin produces exactly the same efficacy outcomes as cisplatin in advanced NSCLC, results appear to be roughly similar, and with improved tolerability seen with the use of carboplatin. Given the paramount importance of limiting toxicity and optimizing quality of life in the advanced disease setting, it certainly seems reasonable to incorporate carboplatin as the platinating agent of choice in first-line doublet therapy.

However, in earlier-stage disease such as in the postoperative setting, where curability is defined as the treatment goal, the results of Rosell et al. and Fossella et al. raise the important question of whether cisplatin is superior to carboplatin in terms of disease activity.^{476,477} Randomized trials comparing cisplatin and carboplatin in earlier-stage NSCLC are needed to address this question.

NEW SINGLE AGENTS VERSUS NEW COMBINATIONS

Table 37.24 shows randomized trials comparing a newer single agent versus a newer platinum-based combination.⁴⁷⁸⁻⁴⁸⁴ On the whole, these trials show that antitumor response is improved with doublet treatment, and that combination therapy potentially improves median survival by 2 months, although at higher rates of hematologic toxicity.

NEW COMBINATIONS VERSUS OLDER COMBINATIONS

Table 37.25 displays the results of nine randomized trials that compared an older cisplatin-based doublet with a platinum-based combination using a newer second agent.^{478,484-491} In these trials, the newer agents, including paclitaxel, gemcitabine, docetaxel, and irinotecan, add the toxicities of myalgias/arthralgias/sensory neuropathy, nonclinically significant thrombocytopenia, edema, and diarrhea, respectively, without consistently exacerbating neutropenia. Statistically significant prolongations in overall survival are seen in nearly half of the trials.^{478,488,489,491} Quality of life measures were improved for patients receiving the combinations with the newer agents, despite the absence of a corresponding survival benefit, in the trials of Giaccone et al. and Belani et al., revealing a clinically meaningful effect from the third-generation agents.^{485,486} Although marked improvements in overall survival were not seen in all these trials, the bulk of evidence pointed to the fact that the newer combinations resulted in 1-year overall survival rates consistently exceeding 30% to 35%, and that an efficacious doublet could be individualized to match a patient's comorbidities contingent upon the newer

agent's toxicities. As such, practice has progressed from the "one size fits all" recipe for a platinum-based doublet for patients with advanced NSCLC, therefore expanding the number of patients eligible to receive therapy.

DOUBLET COMBINATION COMPARISONS

Comparisons of platinum-based doublets incorporating third-generation agents have demonstrated improvements in treatment activity and overall survival in patients with a good performance status, but have yet to identify one clinically superior regimen.^{473,474,476,477,492-495} Table 37.26 demonstrates that treatment with these combinations yields antitumor response rates of at least 30%, median survival times of 8 to 10 months, 1-year overall survival rates exceeding 30%, and, for the first time, 2-year survival rates exceeding 10%. These advances are measured against median survivals of 5.3 to 5.8 months and 1-year survival of less than 20% seen with platinum-based doublets combined with older, second-generation agents.^{448,467} The therapeutic plateau achieved with the use of these newer doublets clearly speaks to the need to incorporate newer treatments, most notably the use of targeted agents, into clinical trials of new treatment combinations.

Selecting a regimen based upon comparisons across trials is fraught with potential error, given differences in sample populations and treatment plans (for example, ECOG 1594 enrolled patients with brain metastases and a lower percentage of patients with stage IIIB disease, compared to TAX 326, whereas the dosing of paclitaxel was lower in ECOG 1594, compared to the study of Rosell et al.).^{474,476,477} Overall, clinical efficacy within trials appears to be roughly similar using

platinum-based doublets that incorporate a newer, third-generation agent. In addition, toxicity with the newer combinations is manageable, and therefore, selection of a platinum-based doublet for therapy in advanced NSCLC may be individualized in terms of the toxicity profile of the particular doublet, as well as convenience and cost, as efficacies of the newer combinations are largely equivalent. The therapeutic plateau achieved with the use of these newer doublets clearly speaks to the need to incorporate newer treatments, most notably the use of targeted agents, into clinical trials.

Quality of life analyses were conducted in four of the trials from Table 37.26, with consistent, significant differences seen most strongly with the use of docetaxel in the Fossella trial.^{476,477,493,495} Using the EuroQoL global health scale (EuroQoL) and the Lung Cancer Symptom Scale (LCSS), these investigators showed that treatment with docetaxel/cisplatin (DC) or docetaxel/carboplatin (DCb) was associated with significant improvements in quality of life, compared to treatment with vinorelbine/cisplatin (VC): [for DC versus VC, $P = 0.064$ (LCSS) and $P = 0.016$ (EuroQoL); for DCb versus VC, $P = 0.016$ (LCSS) and P less than 0.001 (EuroQoL)]. Declines in performance status and weight were mitigated with docetaxel therapy.⁴⁷⁷ It has been noted in a discussion of these results that the cisplatin dose administered to patients in the vinorelbine arm was higher per treatment (at 100 mg/m², compared to 75 mg/m² in the docetaxel arms). Also, a higher dose of corticosteroids was given to patients receiving docetaxel. Both these factors may have contributed to an improvement in symptoms in patients in the docetaxel arms.⁴⁹⁶ Regardless, in light of the efficacy plateau reached with the platinum-based doublets shown in Table 37.26, it remains paramount to incorporate quality of life and symptom management out-

comes into the decision making of selecting treatments for patients in this palliative setting.

TWO VERSUS THREE DRUGS

Table 37.27 shows the results of 13 trials randomizing patients with advanced NSCLC to treatment with two or three cytotoxic agents.^{99,497-510} However, in 8 of the 13 trials, the comparison three-agent arm contains at least one single agent that is older and would not be used presently as a single agent for treatment (i.e., mitomycin C or ifosfamide).^{497,500,501,503-507} In one of the remaining five trials, Sculier et al. combined the two platinating agents, cisplatin and carboplatin, in the three-drug arms, in an effort to maximize platinum exposure. The similar mechanisms of action of the two platinating agents confounds interpretation of the impact of these three-drug combinations.⁵⁰⁵ The remaining 4 studies utilize newer, third-generation agents into their triplets; however, final results for 3 of the remaining 4 trials have yet to be published.^{498,499,502} Although the three-agent combination of cisplatin/gemcitabine/navelbine was found by the Southern Italian Cooperative Oncology Group (SICOG) investigators to be superior to treatment with cisplatin/navelbine, the doublet arm in this study was surpris-

ingly toxic, and was associated with two toxic deaths, and higher rates of chemotherapy discontinuation, severe neutropenia, and vomiting, compared to the other arms. This unexpected rate of toxicity with this doublet may have been related to the treatment schema of administering 120mg/m² of cisplatin on day 1 of each 4- to 6-week cycle.⁴⁹⁸ The Spanish Lung Cancer Group 98-02 study detected higher rates of hematologic toxicity with no corresponding improvement in efficacy outcomes for treatment with their three-drug combination.⁹⁹ In contrast, preliminary results from a second SICOG study yielded improved survival with only a modest increase in toxicities with the use of either of two three-drug regimens.⁴⁹⁹ Final results from this SICOG trial are anticipated.

In summary, the consensus of evidence and opinion, including the preliminary publication of two meta-analyses recently, conclude that treatment of good performance status patients with advanced NSCLC with two cytotoxic agents is better than with one (see Tables 37.23, 37.24), whereas the addition of a third agent likely only exacerbates toxicity.^{508,509} However, the majority of these findings result from studies incorporating rather inactive, older agents into the three-agent arm. Favorable results with the use of three-drug regimens from the SICOG investigators and Paccagnella et al.

require confirmation before their findings would impact practice patterns.⁵⁰² Nonetheless, incorporation of agents with novel, targeted mechanisms of action into new treatment regimens, administered to patients preselected based upon the molecular characteristics of their tumors, will likely bear better outcomes, rather than continuing to explore combinations of cytotoxic agents administered to patients without genomic preselection. The recently released results of SWOG 0003, revealing no improvement in efficacy outcomes for patients with advanced NSCLC receiving the three-drug regimen carboplatin, paclitaxel, and tirapazamine, confirms the need to consider incorporating molecular preselection criteria into study designs.⁵¹⁰

NONPLATINUM COMBINATIONS

Investigators have tested nonplatinum combinations in an effort to reduce treatment-related toxicity and extend therapy to more symptomatic patients. Table 37.28 illustrates nine recent studies comparing a platinum-based doublet with nonplatinum-containing regimens.^{99,505,511-517} None of the

trials detected a statistically significantly worse response activity or overall survival with use of the nonplatinum-containing regimens. However, in the seven trials for which there are data, median and/or overall survival at 1 year is numerically inferior when platinum is not employed.^{99,505,511-516} Although the use of nonplatinum-containing regimens is sometimes associated with lower rates of grade 3 and 4 toxicities, especially related to nausea, vomiting, myelosuppression, and ototoxicity, consistent trends suggesting inferior efficacy have precluded widespread acceptance of these combinations as the treatment of choice for good performance status patients with metastatic NSCLC. Furthermore, a large study from Italy and Canada failed to identify a significant improvement in quality of life for patients treated with the nonplatinum regimen of gemcitabine plus vinorelbine, despite more frequent rates of severe myelosuppression, vomiting, alopecia, and ototoxicity seen in patients receiving either of the two platinum-containing regimens in this trial, cisplatin plus vinorelbine or cisplatin plus gemcitabine.⁵¹³ As such, first-line treatment of advanced NSCLC with a third-generation nonplatinum doublet remains the exception rather

than the rule but may prove beneficial in patients less able to withstand platinum-related toxicities. Although no study has confirmed a statistically significant inferiority in terms of efficacy outcomes, reductions in treatment-related toxicities may not translate into meaningful improvements in quality of life.

DURATION OF THERAPY

Three trials have examined the question of duration of first-line therapy in advanced NSCLC.⁵¹⁷⁻⁵²⁰ The investigators determined that optimal treatment outcomes, in terms of efficacy and quality of life, are achieved with three to four cycles of therapy, as opposed to prolonged treatment. These recent studies have guided practitioners in limiting the number of front-line cycles of chemotherapy, as nearly all patients who respond to treatment do so within the first three to four cycles (all in the Socinski trial and 48/58 patients in the Smith study), and administering additional cycles only serves to expose patients to additional toxicities.

SPECIAL POPULATIONS

CHEMOTHERAPY IN THE ELDERLY

Patients over the age of 65 comprise a large fraction of patients with advanced NSCLC. Their treatment tends to be complicated by increased medical comorbidities and multiple concurrent medications. Moreover, therapeutic treatment decisions in the elderly are complicated by their significant underrepresentation in clinical oncology trials.⁵²¹ However, a recent review from the National Cancer Institute in Naples found that elderly patients with lung cancer do not appear to have different characteristics at disease presentation, especially related to disease stage, performance status, and his-

tology, compared to younger patients.⁵²² Moreover, when asked, elderly patients are as likely as their younger counterparts to accept chemotherapy for both curative and palliative purposes.⁵²³

Multiple retrospective reviews of cooperative group trials in advanced NSCLC that examined subsets of elderly patients (usually defined as 70 years of age) have shown that the "fit" elderly are as likely to benefit in terms of improvements in survival and quality of life as are younger patients, albeit at the expense of a slightly higher rate of the most severe toxicities.⁵²⁴⁻⁵²⁸

Prospective data regarding the experience of elderly patients with advanced NSCLC receiving chemotherapy were provided by Italian investigators who compared treatment with single-agent vinorelbine to best supportive care in patients over 70 years of age.⁴⁶³ As shown in Table 37.29, vinorelbine-treated patients scored better than control patients on quality of life scales and had fewer lung cancer-related symptoms. Furthermore, there was a statistically significant survival advantage for elderly patients receiving vinorelbine, with median survival increasing from a baseline of 21 weeks to 28 weeks. Clinical research is active with this group of patients, as practitioners have come to accept that age alone should not preclude consideration of systemic treatment of advanced NSCLC. The combination of both gemcitabine with vinorelbine together appears only to increase toxicity without a corresponding improvement in efficacy or quality of life parameters.⁵²⁹ The slightly lower response rates and survival in the study by Frasci et al. may point to the fact that this trial, in contrast to the MILES study, permitted patients with brain metastases.⁵³⁰ Investigations of single-agent docetaxel or gemcitabine at varying doses and schedules for the treatment of the elderly with advanced NSCLC are ongoing.^{531,532}

Treatment of fit elderly patients with NSCLC should now include consideration of at least single-agent therapy, and possibly consideration of doublet therapy, in an attempt to improve quality of life, reduce symptoms, and prolong survival, as the studies in Table 37.29 demonstrate that age alone should not disqualify patients from consideration of treatment.^{533,534} Further investigation of the pharmacokinetics and pharmacodynamics of chemotherapies in the elderly are needed to clarify the impact on chemotherapy-related toxicities of reduced renal function and hematopoietic reserve of the elderly.⁵³⁵

CHEMOTHERAPY FOR PATIENTS WITH PERFORMANCE STATUS 2

Advanced NSCLC tends to be a highly symptomatic disease, often impairing one's ability to perform activities of daily living. Poor functional capability, or poor performance status, consistently appears as a negative prognostic factor in treatment trials.^{96,474} In a recent review of a large ECOG trial comparing platinum-based systemic therapies, Eton et al. determined baseline physical well-being, as assessed by the FACT-L scale, to be the strongest predictor of both response to therapy, as well as survival duration.⁵³⁶ Most (although not all) clinical trials suggest that these patients do not derive substantial benefit from chemotherapy and thus should probably not be treated off a clinical protocol.⁴⁵¹ The increased number of deaths in the PS 2 population (7.35%) enrolled in ECOG 1594 was related to the worsened incidence of medical comorbidities in these patients, rather than being strictly a consequence of treatment-related toxicity.⁴⁵² Efficacy was poor in these patients, with response rate, median survival, and 1-year overall survival all worse in the PS 2 patients compared to the better performance status cohorts (14% versus 19%, 4.1 months versus 7.9 months, and 19% versus 33%, respectively). ECOG is actively enrolling patients onto a PS 2-dedicated trial to further assess the utility of systemic cytotoxic treatment in this symptomatic population. For now, chemotherapy cannot be recommended as a means to prolong survival for patients with advanced NSCLC who are PS 2. However, chemotherapy may improve quality of life in these symptomatic patients and, as such, may be a reasonable consideration.⁴⁵¹ This patient group appears especially appropriate for further investigation of novel, molecularly targeted therapy, as many of them have a reduced toxicity profile because of their inherent selectivity, compared to cytotoxic chemotherapy.

SECOND-LINE TREATMENT

Approximately one-quarter to one-half of patients with advanced NSCLC go on to receive second-line therapy.^{477,513,518} Cytotoxic chemotherapy with docetaxel has been shown in two large international trials to confer a survival and quality of life/symptom control benefit in this setting.^{537,538} Based on these studies, patients receiving docetaxel for relapsed disease can expect about a 5% to 10% rate of antitumor response, about a 35% to 45% incidence of stable disease, and an improvement in survival, compared to best supportive care, of about 3 months. These findings extended to patients who had received prior first-line treatment with paclitaxel and were confirmed to be cost-effective.⁵³⁹

Clinical research of second-line treatment of advanced NSCLC is proceeding at a robust pace, comparing new cytotoxics, combinations, and administration schedules, and incorporating novel, targeted agents (please see next section). Hanna et al. recently presented preliminary findings comparing second-line docetaxel with pemetrexed, the novel multitargeted antifolate that inhibits thymidylate synthase, dihydrofolate reductase, and glycinamide ribonucleotide formyltransferase.⁵⁴⁰ Response rates, time to progressive disease, and survival were similar in both treatment arms, but therapy with pemetrexed produced a significantly more favorable toxicity profile, with less myelosuppression and fewer hospitalizations from febrile neutropenia. Comparisons of weekly versus the standard every-3-week schedule of administration with second-line docetaxel have revealed slightly higher rates of grades 3 and 4 nonhematologic toxicities with the weekly schedule, in contrast to worsened hematologic toxicities with the standard schedule.^{541,542} Docetaxel combinations have also been investigated, as have other cytotoxics, including weekly paclitaxel, gemcitabine, and irinotecan.^{543,544} Although docetaxel represents standard second-line treatment for advanced NSCLC at the present time, this recommendation will likely revise repeatedly in the near future, with the expected U.S. Food and Drug Administration (FDA) approval of pemetrexed, as well as continued application of novel, targeted agents into clinic protocols.

NOVEL TARGETED AGENTS IN THE TREATMENT OF NSCLC

A very exciting and quickly paced field of lung cancer research is the continuing clinical application of novel, molecularly targeted therapies. By definition, these agents specifically interfere with the molecular and biochemical pathways

that contribute to the malignant phenotype. The specificity of these agents, directed against pathways that are often abnormally activated or overexpressed in the malignant cell and not in the normal cell, should result in reduced toxicity.

Gefitinib is an oral small molecule that serves as the prototypic molecularly targeted agent, disrupting the tyrosine kinase activity of the epidermal growth factor receptor (EGFR), which is frequently overexpressed on the surface of lung cancer cells. Single-agent response rates of 11.8% to 18.4% and a median survival measuring 6.1 months resulted in international Phase II studies of heavily pretreated NSCLC patients, using the 250-mg daily dose.^{545,546} Stable disease was observed in 31% to 36% of patients. Of critical importance was the finding that symptom improvement was achieved by more than 40% of patients, occurred promptly, and was often experienced by patients who lacked an objective radiographic response. Drug-related toxicities were limited in this large Phase II experience, consisting primarily of mild to moderate rash and diarrhea, such that less than 2% of patients discontinued treatment due to side effects. Based upon these Phase II findings, gefitinib was recently approved by the FDA for administration in patients who have previously received platinum and docetaxel chemotherapies. Somewhat surprisingly, concurrent administration of gefitinib with platinum-based doublets in patients with advanced NSCLC did not yield improved efficacy outcomes.^{547,548} Toxicity was not worsened by administration of this novel agent with chemotherapy, but the reasons for an absence of clinical benefit are not clear, given the promising preclinical experience with the combination.⁵⁴⁹ Questions regarding the impact of sequencing and scheduling of administration of gefitinib, which blocks cells in the G₁ phase, with cytotoxic agents, are of intense research interest, as are means to better preselect patients who may respond to these EGFR-blocking agents.⁵⁵⁰ In contrast to the targeted therapy experience with anti-estrogen agents and the erbB-2 blocking monoclonal antibody, trastuzumab, the intensity of EGFR overexpression in tumor cells does not appear to correspond with clinical outcomes following treatment with EGFR inhibitors.⁵⁵¹ As such, further preclinical and clinical studies are needed to clarify pretreatment patient and/or tumor characteristics that may predispose a patient to respond to this well-tolerated agent. In that regard, work done by Clark et al. is of interest, in that in their Phase II study of the EGFR small molecule inhibitor, erlotinib, rash occurred more frequently in patients whose tumors responded to treatment, compared to nonresponders.⁵⁵² Although molecular characteristics obviously differ considerably between skin and tumor cells, further understanding of, and potential correlation with, the effects of EGFR blockade on surrogate tissue and corresponding tumor cells will hasten the clinical development of these targeted medications.

Erlotinib (Tarceva) is another oral tyrosine kinase inhibitor that targets EGF. Multiple Phase II trials have demonstrated striking responses in females, patients from Japan, never smokers, and patients with adenocarcinomas. In a randomized, double-blind, placebo-controlled trial, 731 patients were randomized 2:1 to receive either erlotinib, 150mg/day, or placebo. The primary endpoint showed that erlotinib did significantly prolong survival (median, 6.7 versus 4.7 months for erlotinib versus placebo). Patients receiving Erlotinib also exhibited a statistically significant tumor response (8.9% versus 0.9%). The IRESSA Survival Evaluation in lung cancer (ISEL) trial was a similar double-

blinded, placebo-controlled, parallel group, multicenter, randomized Phase III survival study of 1,692 patients who were followed for a median of 7 months. The study compared survival data in patients receiving gefitinib, 250mg/day, plus best supportive care to placebo plus best supportive care in patients with advanced NSCLC who had received one or two prior chemotherapy regimens and were refractory or intolerant to the most recent regimen. The primary endpoint revealed that gefitinib did not significantly prolong survival in the overall population (median, 5.6 versus 5.1 months for gefitinib versus placebo), or for patients with adenocarcinoma (median, 6.3 versus 5.4 months for gefitinib versus placebo). Studies have found that the EGFR gene is mutated in a cohort of non-small cell lung cancers and that these mutations are associated with increased sensitivity to gefitinib or erlotinib.^{553,554} Recent studies have found that EGFR gene mutations are more common among females, patients from Japan, never smokers, and patients with adenocarcinomas, the same groups that have the highest response rates to tyrosine kinase (TK) inhibitors. In lung cancer patients, mutations in the TK domain of the EGFR gene are more common in never smokers than in smokers (51% versus 10%), adenocarcinomas versus other types of lung cancer (40% versus 3%), in patients of East Asian ancestry than in other ethnicities (30% versus 8%), and in females versus males (42% versus 14%). Mutation status is not associated with age at diagnosis, clinical stage, the presence of certain histologic features, or overall survival, and mutations are not found in any normal tissue or tissue from other cancer types. EGFR TK domain mutations are the first known mutation to occur in never smokers. Moreover, KRAS mutations, which also are involved with the EGFR signaling pathways gene, is mutated in about 8% of lung cancers but not in any that had an EGFR gene mutation.⁵⁵⁵

Antiangiogenic treatment, as a means to inhibit tumor-related neovascularization, also represents an active area of clinic research. RhuMAB-VEGF (Bevacizumab; Avastin; Genentech, Inc.) is a recombinant human monoclonal antibody that targets the VEGF protein and sequesters VEGF-A inhibiting signal transduction. Both *in vitro* and *in vivo* data indicate that endothelial cell proliferation is inhibited and tumor growth is reduced with administration of this antibody.⁵⁵⁶

A Phase II, three-arm, multicenter trial randomized 99 patients with stage IIIB or IV NSCLC to standard therapy with carboplatin/paclitaxel or one of two experimental arms: carboplatin/paclitaxel with rhuMAB VEGF (7.5 mg/kg) or carboplatin/paclitaxel with rhuMAB VEGF (15 mg/kg).⁵⁵⁶ Because the endpoints of the study were safety, response, and time-to-tumor progression, the control group was allowed to cross over to the antibody-alone arm if disease progression was witnessed. Addition of rhuMAB VEGF led to an increase in response rates by about 10% and prolongation of the time-to-tumor progression by about 3 months (4.5–7.5 months) in the high-dose antibody group. Six patients developed severe hemoptysis (four episodes were fatal). Assessment of the potential risk factors for this adverse event indicated that squamous histology and rhuMAB treatment were the only factors associated with hemoptysis. Trials with this drug were then limited to those patients with nonsquamous cell histology in NSCLC.⁵⁵⁷ Given the positive impact on survival seen with this agent in patients with advanced colon cancer,⁵⁵⁶ the results of an ECOG Phase III trial in which patients with

advanced NSCLC were randomized to receive chemotherapy with or without bevacizumab were eagerly awaited. The data were presented at the ASCO 2005 meeting. In a recent elegant example of the potential ability to combine targeted, molecularly directed agents, which comes from investigators at Vanderbilt University, erlotinib and bevacizumab are combined.⁵⁵⁸ This important work illustrates the capability to potentially disable multiple intracellular pathways that are interacting to stimulate tumor growth and spread; further studies of this type are needed to optimize the clinical application of these agents.

Other molecularly targeted agents undergoing clinical assessment in the treatment of NSCLC include treatment with inhibitors of cyclooxygenase (COX)-2,⁵⁵⁹ adenovirus replication-deficient p53 gene replacement,⁵⁶⁰ vaccination with the whole tumor cell vaccine GVAX,⁵⁶¹ the farnesyl-transferase inhibitor R115777,⁵⁶² treatment with BAY 43-9006, an inhibitor of the raf kinase pathway,⁵⁶³ use of the thrombospondin 1 mimetic peptide ABT-510,⁵⁶⁴ the RXR selective retinoid bexarotene,⁵⁶⁵ and treatment⁵⁵⁹ with the ubiquitin proteasome pathway inhibitor, bortezomib.⁵⁶⁶ Additionally, the emerging field of pharmacogenomics will enhance the ability to optimize treatment outcomes by individualizing chemotherapy to match a patient's pharmacodynamic makeup.⁵⁶⁷ Rosell et al. recently used quantitative PCR to analyze the expression of beta-tubulin III, stathmin, RRM1, COX-2, and GSTP1 in mRNA isolated from paraffin-embedded tumor biopsies of 75 patients with advanced NSCLC who were treated as part of a large randomized trial.¹¹⁴ Their findings showed that patients with low beta-tubulin III levels had a better response to carboplatin/paclitaxel, whereas patients with low RRM1 levels showed a tendency to respond better to treatment with cisplatin/gemcitabine. Similarly, low levels of gene expression of ERCC1, critical in the repair of cisplatin-related adducts, corresponded to longer survival in patients treated with cisplatin/gemcitabine.¹¹² These examples of integration of patient-specific

molecular information and the corresponding individualization of therapy should result in improved treatment outcomes for patients with advanced NSCLC.

Small Cell Lung Cancer Therapy

Limited-Stage Small Cell Lung Cancer

COMBINED MODALITY TREATMENT OF SMALL CELL LUNG CANCER

Small cell lung cancer (SCLC) accounted for approximately 18% to 25% of the estimated 169,500 cases of lung cancer in 2001.^{59,568} Most patients present with metastatic disease because of the aggressive nature of SCLC. Limited-stage disease (LD) accounts for approximately 40% of all SCLC cases. The VALG classified limited-stage disease as tumor limited to one hemithorax and its regional lymph nodes that can be encompassed by one radiation port. Extensive-stage disease (ED) is tumor spread beyond these boundaries.⁵⁶⁹ Radiation therapy's main role is in the treatment of limited-stage disease. Because radiation only offers locoregional control, chemotherapy is necessary to destroy the micrometastatic disease that invariably is present. Multiple cooperative group trials have been performed to establish the role of radiation therapy in SCLC.⁵⁷⁰⁻⁵⁷³

In the early 1960s, surgery was the treatment of choice for patients with resectable SCLC. However, a trial performed in the United Kingdom that compared patients with limited disease treated with thoracic radiation alone versus surgery alone showed the 10-year survival for the surgery-alone arm was zero, but the 10-year survival for the radiation-alone arm was 5%.⁵⁷⁴ In the 1970s and 1980s, multiple cooperative group trials were performed to test the role of adding thoracic radiation therapy to chemotherapy (Tables 37.30, 37.31). These trials randomized patients with LD-SCLC to chemotherapy

TABLE 37.30. Studies of chemotherapy versus chemotherapy and radiation in patients with limited diseases-small cell lung cancer (LD-SCLC).

alone versus chemotherapy with radiation. The schedule of radiation and type of chemotherapy used varied between trials, but all the trials used prophylactic cranial irradiation (PCI). The combination of radiation therapy and chemotherapy decreased the locoregional recurrence rates compared to the use of chemotherapy alone in the treatment of LD-SCLC (see Table 37.31). All the trials except the SWOG trial reported statistically significant improvements in survival. As a result of these studies, thoracic radiation therapy became a standard part of the therapy for patients with LD-SCLC.

RADIATION THERAPY

The optimal dose of radiation therapy for patients with limited-stage disease is unknown. Full-dose radiation therapy is critical to achieve the therapeutic gain of local tumor control.⁵⁷⁵ Effective chemotherapy may allow a decrease in the radiation dose needed for local control. In the presence of chemotherapy, the radiation dose theoretically can be reduced 20% to control the tumor. Thus, the dose for complete response, approximately 70Gy, can be decreased to 55Gy.⁵⁷⁵ Local recurrence is still about 40% to 50%.⁵⁷⁶ Retrospective trials revealed that doses less than 40Gy were not adequate for local control.⁵⁷⁷

Fractionation of radiation therapy is another important factor affects the biologically effects radiation dose. Pignon et al. performed a meta-analysis and included 13 randomized trials.⁵⁷⁸ The fractionation dose varied between 2 and 4Gy. The analysis revealed that as the fraction became larger, the toxicities increased.⁵⁷⁸

Hyperfractionated radiation decreases the fraction size but is repeated hours later. Theoretically, twice-daily radiation therapy decreases the repopulation of tumor cells. The CALGB trial by Choi et al. established the maximum tolerated dose of hyperfractionated radiation therapy given twice daily as 45 Gy in 30 fractions over 3 weeks, and the maximum tolerated conventional dose was 70Gy in 35 fractions over 7 weeks.⁵⁷⁹

An intergroup randomized Phase III study compared daily versus hyperfractionated radiation therapy.⁵⁷⁹ Patients were randomized to twice-daily radiation therapy (45 Gy over 3 weeks) or conventional radiation therapy (45 Gy over 5 weeks). Radiation therapy was started day 1, cycle 1, with four cycles of cisplatin and etoposide (CE). Local control trended better in the twice-daily arm. After a complete response, the recurrence rate was 75% in the daily radiation

versus 42% in the twice-daily radiation arm. Local recurrence only rates were 52% versus 36%, respectively ($P = 0.058$). Median survival for the conventional radiation was 19 months and for the hyperfractionated radiation was 23 months. Five-year survival was 16% for conventional daily fractions and 26% for hyperfractionated radiation ($P = 0.04$). However, grade 3 or greater esophageal toxicity was higher for the twice-daily radiation (25.7% versus 10.9%, respectively).

Optimal radiation volume is still not well defined at this point. Several studies have tried to address the question of encompassing pre- versus postchemotherapy tumor volume.^{569,571,580-582} Studies have been limited because of small patient numbers. The Mayo Clinic performed a retrospective analysis comparing radiation ports encompassing the prechemotherapy or the postchemotherapy tumor volume. No marginal failures occurred. Locoregional failures occurred in 10 of 31 patients treated with a prechemotherapy port versus 9 of 28 patients treated with a postchemotherapy radiation port.⁵⁸⁰ Locoregional recurrences occurred within the radiation port. SWOG performed a randomized study evaluating this same question.⁵⁸¹ Patients were randomized per their tumor response to induction chemotherapy. Those patients who achieved a complete response after chemotherapy were randomized to either a wide-volume port followed by chemotherapy or chemotherapy alone. A wide-volume port was defined as the prechemotherapy tumor volume plus mediastinal adenopathy and a surrounding margin. Local recurrence rate of the patients treated with the wide volume was 50% versus chemotherapy alone was 72% ($P = 0.01$). The median survival of the group of complete responders was 18.5 months. Local recurrence rate of the group given wide-field radiation therapy was 32% versus 28% for the reduced-field radiation (not statistically different). In conclusion, there is no difference in locoregional recurrence when the volume of the port size is varied between pre- versus postchemotherapy tumor volume or margin size. Thus, larger volumes do not necessarily mean better control. If combined chemotherapy and radiation therapy is used, only postchemotherapy tumor volumes need to be included within the radiation port. However, prophylactic radiation of regional lymph nodes is still a subject to be evaluated.

COMBINING CHEMOTHERAPY WITH RADIATION THERAPY

Several randomized studies have demonstrated that the combination of chemotherapy and radiation therapy improves overall survival compared to chemotherapy alone. The optimal timing and sequence of combining chemotherapy and radiation therapy is unknown for the treatment of limited-stage small cell lung cancer. Radiation can be combined with chemotherapy sequentially, alternating, or concurrently. When combined concurrently, radiation can be started early in the treatment or later during the treatment schedule.⁵⁸²

Three randomized Phase III studies have been performed evaluating sequential chemotherapy followed by radiation therapy versus chemotherapy alone in patients with LD-SCLC (Table 37.32). Carlson et al. randomized patients who responded to chemotherapy to chemotherapy only or radiation therapy.⁵⁸³ No difference in overall survival was detected. A French group randomized 53 patients who achieved a complete response after chemotherapy to radiation of 46.5Gy or no radiation therapy until disease relapse.⁵⁸⁴ The median survival was 10.5 months for the radiation therapy group and

16.5 months for the group who received radiation therapy at the time of relapse. The SWOG cooperative group randomized 93 patients who achieved complete responses after induction chemotherapy to split-course radiation therapy or chemotherapy alone.⁵⁷¹ The radiation therapy did improve local control compared to chemotherapy alone. The local recurrence rate was 50% versus 72%, respectively.

Two studies evaluated the alternating schedule, which is defined as chemotherapy given conventionally with radiation given in between the chemotherapy cycles for LD-SCLC. The Southeastern Cancer Study Group (SECSG) trial randomized patients to chemotherapy alone or chemotherapy alternating with radiation therapy.⁵⁶⁹ The addition of radiation therapy improved local control and 2-year survival (64% versus 48% and 24% versus 16%, respectively).⁵⁶⁹ A French trial randomized patients between alternating and concurrent schedules.⁵⁸⁵ The median survival for the concurrent arm was 13.5 months and for the alternating arm was 14 months. The 3-year survival for the concurrent arm was 6% versus 11% for the alternating schedule arm. The differences were not statistically different.

A Japanese trial compared sequential delivery of chemotherapy and radiation therapy to concurrent delivery of chemotherapy and radiation.⁵⁸⁶ Patients were randomized to receive concurrent hyperfractionated radiation therapy (day 2 of cycle 1 of chemotherapy) or to sequential chemotherapy followed after the fourth cycle by hyperfractionated radiation therapy. The radiation dose was 45 Gy given in 1.5-Gy fractions twice daily for a total of 30 fractions in 3 weeks. The chemotherapy given was cisplatin and etoposide. The median survival for the concurrent schedule was 29 months and for the sequential schedule was 19 months. The 2-year survival was 50% for the concurrent therapy and 40% for the sequential therapy.⁵⁸⁷ These results favored concurrent therapy and are the best results to date for patients with LD-SCLC.

Other studies evaluated the question of whether early delivery of radiation concurrently with chemotherapy was better than late delivery. A study performed by the CALGB randomized patients to early (day 1, cycle 1), late (day 64, cycle 4), or no radiation therapy. The radiation therapy dose was 50 Gy over 6 weeks. Chemotherapy used in this trial was cyclophosphamide, etoposide, and vincristine. The local recurrence rate for the early, late, and no radiation therapy arms was 49%, 68%, and 82%, respectively. The 2-year progression-free survival rate was 15% for the early schedule arm

versus 25% for the late schedule ($P = 0.078$). The 5-year survival rate for the early, late, and no radiation therapy arms was 6.6%, 12%, and 3%, respectively ($P = 0.007$). The poor 5-year survival rate for the early schedule was thought to be due to the significant decrease in chemotherapy dose needed for the early schedule group.^{570,587}

The NCIC randomized patients to radiation therapy started either early or late with concurrent chemotherapy (cyclophosphamide, doxorubicin, and vincristine alternating with cisplatin and etoposide).⁵⁷² In the early arm, radiation was started on day 21 of cycle 2 (after the first cycle of cisplatin/etoposide). In the late arm, radiation was started on day 106 (cycle 6) with the third cycle of cisplatin and etoposide. The 5-year survival in the early delivery and late delivery arm was 20% and 11%, respectively ($P = 0.006$). The early delivery arm also had a decreased incidence of brain metastasis (18% versus 28%; $P = 0.042$), which could explain the improved 5-year survival.⁵⁷²

A Danish trial randomized 199 patients to either early radiation therapy or late radiation therapy given concurrently with chemotherapy.⁵⁸⁸ The 5-year survival and local recurrence rate were not statistically different. The 5-year survival for the early arm was 10.8% versus 12% for the delayed radiation therapy arm. The local recurrence rate for the early radiation arm was 76.6% versus 72.8% for the delayed arm.⁵⁸⁸

The EORTC randomized patients to either start radiation therapy during week 6 (early) or after the chemotherapy during week 14 (late). No significant differences were noted for local recurrence (50.5% for early radiation versus 45.5% for late radiation) or 3-year survival (14% for both early and late radiation therapy).⁵⁸⁹

Another CALGB study randomized patients to early versus late delivery of hyperfractionated radiation given with carboplatin and etoposide chemotherapy.⁵⁹⁰ In the early radiation arm, patients received radiation with chemotherapy during weeks 1 through 4. In the late radiation arm, patients received radiation with chemotherapy during weeks 6 through 9. The radiation dose for both arms was 54 Gy given in 36 fractions over 4 weeks. The radiation dose was also hyperfractionated, with 1.5 Gy given twice daily for 5 days per week. The locoregional recurrence rate for the early and late radiation was 42% and 65%, respectively. The median survival for the early radiation group was 34 months compared to 26 months in the late radiation group ($P = 0.052$). The 5-year survival for the early radiation group was 30% versus

15% for the late radiation group ($P = 0.027$). The results favored the early delivery of radiation therapy concurrently with platinum-based chemotherapy.⁵⁹⁰

Current data support the use of concurrent over sequential or alternating chemotherapy and radiation therapy. The optimal delivery of concurrent chemoradiation is still under study. Early delivery of radiation therapy may decrease dissemination by killing the chemoresistant tumor cells before their distant seeding. Late delivery of radiation therapy possibly reduces toxicities, and full chemotherapy doses can be delivered. However, even with increased toxicity, improved survival rates help establish as standard early delivery of concurrent radiation with platinum-based chemotherapy.

PROPHYLACTIC CRANIAL IRRADIATION FOR SCLC

Prophylactic cranial irradiation (PCI) use for SCLC began in the 1970s. The CNS is a sanctuary from most chemotherapy agents, and for patients with SCLC, relapse in the CNS is common. At diagnosis, 10% of patients with SCLC have brain metastasis, and 20% to 25% of patients with SCLC are diagnosed later with brain metastasis.⁵⁹¹ PCI is thought to decrease disease relapse in the CNS. Several studies have randomized patients after receiving definitive therapy for their systemic disease and achieving a complete remission to PCI versus no PCI. Of three randomized trials, PCI improved overall relapse rate and brain-only relapse rate (Table 37.33). A trend toward improved survival was also demonstrated.⁵⁹²⁻⁵⁹⁴ A meta-analysis of PCI was performed including seven randomized trials.⁵⁹⁴ A total of 847 patients with LD-SCLC and 140 patients with extensive disease SCLC were included in the meta-analysis. These patients were in complete remission and then randomized to PCI or observation. A 16% decrease in mortality was observed in those patients who received PCI. Also, a 5.4% increase in the 3-year survival was demonstrated (15.3% controls versus 20.7% PCI). From these data, PCI should be considered for patients who achieve a complete remission or near complete remission after initial therapy. The optimal dose and fractionation for PCI is unknown. The most commonly used dose for PCI is 25 Gy given over 10 fractions.

The randomized trials reported very few or no late neurologic complications from PCI for NSCLC. However, there are more data available regarding the late toxicity of PCI from SCLC patients who underwent PCI. In these trials of PCI for patients with SCLC, dementia was not commonly seen,⁵⁹⁵⁻⁵⁹⁷ but attention deficit, memory changes, and changes in visual perception were noted.^{595,598,599} Some investigators noted changes in the white matter in T₂-weighted MRI of the brain.^{423,597,598} Most of the patients exhibiting these changes did not show significant deterioration in clinical status. In

TABLE 37.33. Summary of prophylactic cranial irradiation (PCI) for SCLC patients.

Study	PCI dose	Brain Metastasis		P value
		+PCI	-PCI	
Arriagada ⁵⁸²	24 Gy/8 Fx	41%	59%	$P < 0.0001$

	24 Gy/12 Fx			
	8 Gy/1 Fx			

+ Carboplatin.

addition, the changes rarely affected daily life functions.⁶⁰⁰ Recent data of prospective studies incorporating PCI in SCLC did not demonstrate a profound effect on neuropsychologic function.^{592,593,600,601} In addition, recent studies have reported a significant portion of the patients with SCLC had cognitive dysfunction even before PCI,^{600,601} and these patients did not have significant changes in their neuropsychologic status after PCI. This finding implied that neuropsychologic abnormalities seen with SCLC might have been the result of either systemic therapy or SCLC itself. Cecile Le Pechoux and colleagues reported follow-up data on 57 patients followed for more than 36 months in a randomized PCI trial.⁶⁰² There was no severe, late-onset neurotoxicity. However, memory loss and mood changes were believed to be more attributable to PCI. Memory loss was seen in 21% (7/33) of patients who received PCI versus 4% (1/24) of patients who did not receive PCI. Mood changes such as anxiety were seen in 18% (6/33) of the patients who received PCI versus 4% (1/24) of patients who did not receive PCI. Highest rates of toxicity have been seen when PCI was combined with concurrent chemotherapy or when high dose per fraction was used.⁶⁰³

Extensive-Stage Small Cell Lung Cancer

CISPLATIN/EPOPOSIDE (EP) VERSUS ANTHRACYCLINE-BASED CHEMOTHERAPY

Cisplatin has been used frequently in the first-line treatment of patients with extensive SCLC in the United States and Japan since the 1980s, whereas anthracycline-based therapy cyclophosphamide, doxorubicin, vincristine (CAV), cyclophosphamide, epirubicin, vincristine (CEV) has been used more commonly in Europe.⁶⁰⁴ In one of the few randomized clinical trials demonstrating the superiority of a combination regimen in patients with extensive SCLC, Evans et al. detected a statistically improved response rate (80% versus 63%), median survival (9.6 versus 8 months), and overall survival ($P = 0.03$) for patients receiving six cycles of the alternating regimen of cisplatin/etoposide (EP) and CAV, compared to patients receiving six cycles of CAV alone.⁶⁰⁵ In contrast, no improvement in either antitumor response or survival was seen with either EP or CAV alternating with EP, compared to CAV, in a randomized trial of 437 patients with extensive disease published by the Southeastern Cancer Group Study.⁶⁰⁶ A meta-analysis of nine trials comparing cisplatin-based treatment versus chemotherapy not containing cisplatin for all patients with SCLC yielded an odds ratio of 1.35 (95% CI, 1.18-1.55; P less than 0.00005) in favor of obtaining a response after receiving cisplatin. Patients treated with a cisplatin-containing regimen benefited from a significant reduction of risk of death at 12 months (odds ratio, 0.80, 95% CI, 0.69-0.93; $P = 0.002$), corresponding to a significant increase in the probability of survival of 4.4% at 1 year.⁶⁰⁷ Additionally, a comprehensive meta-analysis of randomized chemotherapy treatment trials in patients with extensive disease only recently reported that the median survival time of patients receiving a cisplatin-based regimen was 9.5 months, compared to patients treated with a noncisplatin-containing combination (7.1 months).⁶⁰⁸ Last, investigators from Norway recently published their 5-year results of a trial comparing five courses of EP to CEV for patients with both extensive and limited SCLC.⁶⁰⁹ Median survival was improved for all

patients who received EP (10.2 months), versus patients in the CEV arm (7.8 months; $P = 0.0004$). This trial was not powered to detect a statistical difference in survival for patients with extensive disease only, but the numerical superiority of the results with EP, combined with the findings from the above meta-analyses, confirms the clinical experience that treatment of patients with extensive SCLC is no worse than anthracycline-based treatment and may be better tolerated.

REFINEMENT OF EP: REPLACING ETOPOSIDE WITH IRINOTECAN

In an effort to improve the stagnation in the treatment of extensive SCLC, Noda et al. replaced etoposide with irinotecan, in combination with cisplatin in a randomized Japan Clinical Oncology Group (JCOG) trial of 154 patients.⁶¹⁰ A survival advantage was experienced by patients receiving the investigational treatment (median survival, 12.8 months for the cisplatin/irinotecan group versus 9.4 months for patients receiving cisplatin/etoposide; $P = 0.002$). This survival advantage exceeded that seen in any of the 21 randomized trials reviewed by Chute et al. and prompted termination of accrual after two interim analyses (the first was planned and the second was early).⁶⁰⁸ Use of irinotecan also yielded a significantly higher antitumor response rate (84.4 % versus 67.5% for patients receiving the standard EP). Treatment was fairly well tolerated in this study, with the exception of grade 3 and 4 diarrhea occurring more frequently in the irinotecan group.⁶¹⁰ Two multicenter randomized trials in the United States are attempting to confirm these impressive results.

REFINING EP: ADDING AGENTS CONCURRENTLY

Other investigators have attempted to improve upon the standard treatment of EP by adding concurrent additional active agents (Table 37.34).⁶¹¹⁻⁶¹³ In all three trials, toxicity was exacerbated with the addition of the third agent, such that platinum-based doublet therapy remains the standard of care for extensive SCLC.

REFINING CISPLATIN-BASED CHEMOTHERAPY:

ADDING MAINTENANCE CHEMOTHERAPY

Prior trials assessing the utility of maintenance chemotherapy added sequentially to induction treatment demonstrated a 2-month prolongation in time to progression, but no improvement in overall survival.^{614,615} Two studies assessing the possible role for sequential maintenance treatment in nonprogressing patients with extensive SCLC have been pub-

lished recently. The Eastern Cooperative Oncology Group trial 7593 attempted to exploit the potential synergistic antitumor effects of administering topoisomerase II and I inhibitors in sequence in randomizing patients to four cycles of topotecan or observation after their received cisplatin and etoposide.⁶¹⁶ Addition of the topotecan did not impact overall survival (8.9 months in the topotecan arm versus 9.3 months in the observation arm; $P = 0.53$), nor did it improve quality of life in the topotecan recipients per the FACT-L questionnaire. However, progression-free survival was statistically improved (3.7 months in the treated patients versus 2.3 months; P less than 0.001), confirming a trend seen in older studies of mixed populations.^{614,616} Hanna et al. confirmed these findings after randomizing 144 patients to observation or three courses of oral daily etoposide following their initial treatment with etoposide, ifosfamide, and cisplatin.⁶¹⁷ Maintenance therapy again prolonged progression-free survival, from 6.5 to 8.23 months ($P = 0.0018$), but resulted in only a trend toward improving overall survival, from 11.2 to 12.2 months ($P = 0.0704$). Without a clear-cut improvement in overall survival from the addition of maintenance cytotoxic agents, it appears more prudent to investigate the utility of augmenting cytotoxic therapy with molecularly targeted agents, which often do not exacerbate toxicity to the same extent.

HIGH-DOSE CHEMOTHERAPY

The administration of high-dose chemotherapy, using late intensification chemotherapy with autologous bone marrow transplantation, did not improve overall survival in the single randomized trial to date that tested this paradigm.⁶¹⁸ Using higher doses of both cisplatin and etoposide in cycles 1 and 2 of a total of four cycles of treatment did not improve antitumor response or overall survival in a sample of 90 patients with extensive disease, despite increasing the dose intensity by 46%.⁶¹⁹ Investigators attempted to increase the dose intensity of cyclophosphamide, 4'-epidoxorubicin, etoposide, and cisplatin by giving higher doses over a shorter number of cycles in a 1997 study from France.⁶²⁰ Due to worsened toxicity in the high-dose arm, cumulative dose delivered was actually higher in the standard dose group. Use of the higher-dose treatment yielded a significantly shorter survival, suggesting that higher doses over fewer courses is not an advantageous route to dose intensity.⁶²⁰ Last, the EORTC

increased the dose intensity with accelerated CDE (cyclophosphamide, doxorubicin, and etoposide) by 70% with every-2-week administration (with growth factor support, for four cycles), compared to every-3-week treatment for five cycles.⁶²¹ Grade 3 and 4 anemia and thrombocytopenia, as well as stomatitis/mucositis, were not unexpectedly significantly worse with the accelerated treatment. Median survival times were equivalent (54 weeks on the standard arm and 52 weeks on the intensified arm; $P = 0.885$). These multiple negative results demonstrated that efforts to increase dose intensity that utilize fewer cycles of treatment should be abandoned.

DOSE DENSITY

In their recent review of dose-intensified chemotherapy in the treatment of SCLC, Tjan-Heijnen et al. point out that dose densification is the most effective means to improve efficacy outcomes with this paradigm, citing four studies (three with mixed populations of patients with extensive and limited disease) that, on average, yielded a prolongation of median survival of 2.7 months by reducing the treatment interval, but keeping the doses administered, the number of treatment cycles, and hence the cumulative dose, equivalent.⁶¹⁴ However, three recent negative studies argue against this method.⁶²²⁻⁶²⁴ Weekly administration of the cisplatin, vincristine, doxorubicin, etoposide (CODE) regimen yielded a higher toxic death rate (8.2%) and no improvement in overall survival (0.98 years), compared to standard every-3-week alternating CAV/EP (0.9% and 0.91 years, respectively) in a Canadian/ SWOG trial of 220 patients with extensive SCLC.⁶²⁴ The European Lung Cancer Working Party confirmed the absence of a survival benefit, despite an improved antitumor response rate, when accelerating chemotherapy from every 3 weeks to every 2 weeks, using epirubicin, vindesine, and ifosfamide.⁶²² Moreover, recently announced results from British investigators again detected no improvement in response rate or survival, despite nearly doubling the dose intensity of ICE (ifosfamide, carboplatin, and etoposide) for six cycles by administering it every 2 weeks [with granulocyte colony-stimulating factor (G-CSF) support and transfusions of autologous blood], compared to every 4 weeks.⁶²³ As such, despite the optimistic conclusions of Tjan-Heijnen et al., the use of dose-intensified treatment via treatment acceleration cannot be recommended.⁶¹⁴

EXPERIENCE WITH CISPLATIN AND PROLONGED ORAL ETOPOSIDE

Oral etoposide has been examined as a potentially less toxic regimen that might be suitable for patients with an impaired performance status. The CALGB combined oral etoposide for 21 days with intravenous cisplatin, while investigators from the Medical Research Council and the London Lung Cancer Group examined the use of 21 days of oral etoposide as a single agent (Table 37.35).⁶²⁵⁻⁶²⁷ These results indicate that oral etoposide yields significant myelosuppression and, even when used as a single agent in untreated, symptomatic patients, inferior efficacy outcomes, compared to intravenous doublet therapy.

TREATMENT OF THE ELDERLY PATIENT WITH SCLC

Treatment of elderly patients with extensive SCLC is, again, complicated by their increased rate of medical comorbidities and relative underrepresentation in clinical oncology trials.^{521,628} Nonetheless, multiple groups have retrospectively reviewed treatment outcomes with elderly patients and determined from subset analyses that survival is not limited by advanced age alone, despite the reduced dose intensity often administered to elderly patients.⁶²⁹⁻⁶³¹

Prospective data reporting the experience of chemotherapy in the treatment of elderly patients with extensive SCLC is limited to small Phase II studies. Investigators from the British Columbia Cancer Agency in Vancouver treated 66 SCLC patients over the age of 65, 41 with extensive-stage disease, with four cycles of cisplatin (30mg/m²), doxorubicin (40mg/m²), vincristine (1.0mg/m²), and etoposide (100mg/m²), repeated every 3 weeks (PAVE).⁶³² All four cycles of PAVE were delivered to 64% of the patients treated with chemotherapy only; only 27% of such patients required dose reductions. Of the extensive-stage patients, 15% required hospitalization for supportive care of toxicities, namely, febrile neutropenia. Antitumor response with this regimen measured 87% (24% with a complete response), and median survival was 11.5 months. However, chemotherapy efficacy outcomes are confounded by the fact that half the patients with extensive-stage disease also received radiotherapy as a part of their treatment.⁶³²

Multiple groups have used the combination of carboplatin and etoposide in their treatment of elderly SCLC patients

Evans et al. ⁶⁸¹	36	Cb: 150 mg/m ² day 1 E: 100 mg/m ² × 7 days po	67	11.3	NR
Matsui et al. ⁶⁸²	22	Cb: Egorin's formula E: 760 mg/m ² po over 14 days	71	8.6	NR
Okamoto et al. ⁶⁸³	20	Cb: AUC 5 day 1 E: 100 mg/m ² po days 1–3	85	10.1	47
Quoix et al. ⁶⁸⁴	26	Cb: AUC 5 day 1 E: 100 mg/m ² IV days 1–3	60.5	8.6	26.3
Larive et al. ⁶⁸⁵	28	Cb: AUC 5 day 1 E: 100 mg/m ² po days 1–5	59	9.3	21

(Table 37.36). The Phase II experience is certainly broadest using the combination of carboplatin and etoposide for the treatment of elderly patients with extensive SCLC. At present, it represents the most reasonable combination regimen to consider for this population; however, hematologic toxicity can be significant.⁶²⁹ It is imperative that future clinical trials in this population incorporate improved methods to assess geriatric functional status and extent of comorbidities to assist in the selection of patients who may benefit from systemic treatment.⁶³³

SECOND-LINE TREATMENT

Although the majority of patients with extensive SCLC respond to first-line chemotherapy, relapse is virtually inevitable, usually within 8 months.^{610,611,624} Approximately 45% to 60% of patients who receive combination first-line treatment proceed to second-line therapy.^{611,634} Patients who receive best supportive care at relapse typically survive 2 to 4 months. Although comparative data are lacking, treatment at relapse with chemotherapy appears to positively impact survival.⁶³⁵ A critical predictive marker of antitumor response with second-line treatment is the duration of the time to

relapse, in that patients with primary refractory disease or those who relapse within 2 to 3 months of completing their first-line treatment (refractory relapse) are less likely to respond to salvage chemotherapy than patients who recur later following initial therapy (sensitive relapse). For instance, response rates of 6.4% and 11% and a median survival of 5 months were seen in studies of patients with refractory relapse treated with topotecan.^{636,637} In contrast, response rates of 15% to 38% and a median survival of up to 7 months resulted from the use of topotecan in patients with sensitive relapse.^{636,638,639} Uncontrolled trials with small numbers of patients suggest that repeat treatment with the same regimen that was used in the patient's initial therapy may offer clinical benefit, given a sufficiently long progression-free interval.^{640,641} Clinical investigators more recently have used the somewhat arbitrary time to relapse of 90 days to distinguish those patients with refractory versus sensitive relapse. Data regarding the impact of systemic treatment at relapse on quality of life are sparse.^{638,642}

Table 37.37 demonstrates recent examples of clinical trials examining second-line systemic treatment in SCLC. von Pawel et al. compared intravenous topotecan, dosed at

TABLE 37.37. Second-line systemic treatment in SCLC.

(s), sensitive relapse; (r), refractory or resistant relapse; QOL, quality of life.

1.5 mg/m² daily times 5 days every 21 days, versus CAV in 107 patients with sensitive relapsed extensive SCLC.⁶³⁸ Response rates (24.3% for topotecan and 18.3% for CAV), median times to progression (13.3 and 12.3 weeks, respectively, for topotecan and CAV), and median overall survivals (25 weeks for topotecan and 24.7 weeks for CAV) were virtually superimposable. Differences between the two salvage treatments were seen with respect to worsened myelotoxicity and improved symptom control in patients receiving topotecan.⁶³⁸ Oral topotecan offers more convenient administration while maintaining similar efficacy in the relapsed setting.⁶³⁹ Toxicity profiles and FACT-L quality of life measurements were comparable between the intravenous and oral forms of this agent.⁶⁴²

Median survivals between 6 and 7 months and acceptable toxicities were seen in two Phase II trials of salvage gemcitabine.^{643,644} Additional cytotoxics that appear to exert antitumor activity as second-line single agents include irinotecan, vinorelbine, and docetaxel.^{635,645,646} Compared to the single-agent experience, rates of moderate to severe hematologic toxicities, including febrile neutropenia, are higher in recent Phase II trials using combination regimens in the setting of relapsed SCLC, with no improvement in survival.⁶⁴⁷⁻⁶⁴⁹ Clearly, systemic treatment of refractory and relapsed SCLC remains fertile ground for clinical investigation examining the incorporation of novel anticancer agents, in an effort to improve patient survival, symptom control, and quality of life.

NOVEL AGENTS IN THE TREATMENT OF SCLC

As with NSCLC, incorporation of novel, molecularly targeted therapeutics for patients with SCLC attempts to disrupt over-expressed or inappropriately activated cellular pathways that may be stimulating tumor cell growth, proliferation, invasion, and protection from apoptosis. As an example, blocking the antiapoptotic activity of Bcl-2 with antisense technology is under active investigation in SCLC. Bcl-2, a prototypical antiapoptotic protein, is expressed frequently in SCLC samples and has been shown to correlate negatively with prognosis.⁶⁵⁰ G3139, an 18-base antisense oligonucleotide complementary to the bcl-2 mRNA, is thought to inhibit Bcl-2 mRNA translation and result in RNase H-mediated mRNA degradation, and thereby result in augmented chemosensitivity.⁶⁵¹ G3139 has been combined with carboplatin and etoposide in untreated patients with extensive SCLC in the Phase I setting, and a comparative randomized trial of this doublet, with or without G3139, will be conducted by the CALGB.^{651,652}

Treatment of patients with SCLC using STI571 (Gleevec) is intended to inhibit the tyrosine kinase activity of the kit receptor, which is part of an autocrine growth loop in SCLC. Four of 19 patients (21%) with untreated or sensitive relapsed SCLC were found in a Phase II study of STI571 to have kit (CD117) positivity per IHC staining.⁶⁵³ Treatment of all 19 patients with STI571 yielded no antitumor responses, although 1 patient had prolonged stabilization of disease. Future studies with this agent will incorporate kit (CD117) preselection, in an effort to target the patient population who may benefit from this agent.

Additional examples of molecularly targeted agents under investigation in the treatment of SCLC include adjuvant

therapy with the BEC2 vaccine, which mimics the ganglioside GD3, use of the tyrosine kinase inhibitor SU11248, which is targeted at the platelet-derived growth factor receptor, kit, and FLT3 receptors, treatment with the ubiquitin proteasome pathway inhibitor bortezomib, and treatment with 2A11, a monoclonal antibody directed against gastrin-releasing peptide.⁶⁵⁴⁻⁶⁵⁶

Therapy for Malignant Pleural Mesothelioma

Harvey I. Pass, Nicholas Vogelzang,
Steven Hahn, and
Michele Carbone

Malignant mesotheliomas, highly aggressive neoplasms arising primarily from the surface serosal cells of the pleural, peritoneal, and pericardial cavities, are caused primarily from exposure to asbestos fibers.^{1,2} Recent investigations have also implicated simian virus 40 (SV40) and genetic predisposition in the etiology of some malignant mesothelioma.¹⁻³ The disease is characterized by a long latency from the time of exposure to asbestos to the onset of disease. Early evidence provided by karyotypic analysis supports the theory that multiple somatic genetic events are required for tumorigenic conversion of a normal mesothelial cell. Although a specific chromosomal change is not shared by all malignant mesotheliomas, several prominent sites of chromosomal loss have been identified in this malignancy. Tumor suppressor genes (TSGs) residing in these deleted chromosomal regions may be responsible for the tumorigenic conversion of mesothelial cells, and recent studies have begun to identify the specific TSGs that contribute to the development and progression of malignant mesothelioma. Here we review the clinical aspects of this malignancy, focusing on etiology, pathology, epidemiology, symptoms, diagnosis, imaging methods, and treatment.

Genetic Predisposition to Mesothelioma

Recent evidence indicates that genetic predisposition plays an important role in determining individual susceptibility to mineral fibers carcinogenesis and to the development of mesothelioma. In the 1970s, asbestos was the only known causative agent for mesothelioma. In three small villages in Turkey, Karain (population ~600), Tuzkoy (population ~1,400), and Sarihidir (this village was abandoned) in Cappadocia, 50% or more of deaths are caused by malignant mesothelioma.⁴⁻⁸ These villages, similar to most other villages in the region, were built with stones mined from the nearby natural caves. Studies in Cappadocia concluded that in this region, asbestos is almost everywhere, as it is a natural component of the volcanic terrain, and asbestos-tremolite-based stucco was widely used in building construction in all Cappadocian villages.⁵⁻⁹ However, it was concluded that asbestos could not account for the unique high incidence of

mesotheliomas in these three villages.⁵⁻⁹ Another type of mineral fiber, erionite, a type of fibrous zeolite commonly found in the stones of the houses of Karain, Sarihidir, and Tuzkoy,^{2,8-10} had been detected in the lungs of several villagers and was suspected as a possible causative agent.⁵⁻⁹ Erionite was injected intrapleurally into animals, causing mesothelioma,¹¹ and it was concluded that erionite was the cause of mesothelioma in these villages.^{8,9,12} Erionite, therefore, appeared much more potent than asbestos in causing mesothelioma.¹⁰ Studies tried to link erionite to other human tumors. With the exception of mesotheliomas, there is no significant difference in the incidence of any other tumor types in these two villages compared with the rest of Turkey.²

Homes in these areas of Turkey are inhabited by multiple generations and passed down. Closer observation revealed that mesotheliomas only occurred in certain homes and not in others, although all homes contained similar amounts of erionite according to recent mineralogic analysis.^{2,13} Furthermore, in the nearby village of Karlik, where homes are built from the same materials and contain the same types of erionite fibers, only one mesothelioma had been known to occur, which was in a woman who had migrated from Karain.^{2,13} Further analysis of pedigrees of families who lived in homes where mesotheliomas occurred showed that these mesotheliomas appeared to be inherited in an autosomal dominant pattern. About 50% of descendants of affected parents developed mesotheliomas. When members of unaffected families married into affected families, 50% of their descendants also developed mesotheliomas.^{2,13} Whether genetics alone or in conjunction with erionite are responsible for these mesotheliomas remains unknown, but clearly genetics is a key factor, because mesotheliomas do not develop in nonaffected families regardless of environmental exposure.

Familial malignant mesothelioma has been occasionally described in the United States and in Europe.^{2,14} These families, however, were too small to prove genetic transmission. Furthermore, in these families, mesothelioma may also have been linked to asbestos exposure or/and SV40 infection.² It is hoped that isolation of this putative mesothelioma susceptibility gene will lead to future preventative and therapeutic approaches.

Pathology of Mesothelioma

Benign Mesotheliomas

True malignant mesothelioma is an aggressive malignancy with a dismal prognosis. There are, however, a number of benign mesothelial proliferations that must be distinguished from malignant mesothelioma, such as multicystic mesothelioma, also called multilocular peritoneal inclusion cyst. Multicystic mesothelioma is a benign mesothelial lesion, characteristically formed by multiple cysts arranged in grape-like clusters. Adenomatoid mesotheliomas are benign mesothelial lesions of the genital system. Mesothelioma of the atrioventricular node is neither a mesothelioma nor a tumor but a congenital heterotopia of the endodermal sinus in the atrioventricular node.

Well-differentiated papillary mesothelioma (WDPM) is found more often in the abdominal cavity of young women. Histologically, it is formed by multiple papillary structures covered by cytologically benign mesothelial cells. The lesion is benign, but there have been occasional cases in which several years after diagnosis the patient developed a true mesothelioma. Consultation with a pathologist who sees numerous mesothelial lesions and malignant mesothelioma is highly recommended to rule out a well-differentiated epithelial malignant mesothelioma, based mostly on the absence of invasion in these benign lesions. Patients with WDPM may be more likely to die of the complication of therapy for a misdiagnosed malignant mesothelioma compared to the risk of dying of WDPM if left untreated.¹⁵

Localized fibrous tumor of the pleura (FTP), often referred to as localized mesothelioma, is thought to originate from the submesothelial cells, but it is unclear what submesothelial cells are. More than 700 FTPs have been reported in the literature and, on presentation, are frequently confused with pleural mesothelioma. These tumors are similar to other fibrous tumors found elsewhere in the body; the cells have a benign appearance, and are usually immersed in a fibrous and characteristically vascular stroma. FTP is characteristically negative for cytokeratin, a mesothelial cell marker, and positive for CD34, suggesting that these cells are not of mesothelial origin. Occasionally, localized FTPs are histologically and cytologically malignant and until recently were called hemangiopericytomas. These tumors are the more cellular and histologically aggressive tumors; however, they are still FTPs and should be called fibrous tumors (of the pleura if in the pleura). They are characterized by multiple recurrences after resection and, often, a poor prognosis. The most important predictive factor in the prognosis of FTP is whether the tumor can be completely resected. Thus pedunculated tumors have a much better prognosis than tumors that grow over a broad pleural area. Tumor array studies may in the future provide us with tools to identify rare "benign malignant mesothelioma" from classical epithelial malignant mesothelioma; however, the majority of the markers that have been found to be significant in the expression arrays are already used as part of the standard immunohistochemical panel.¹⁶

Malignant Mesothelioma

The diagnosis of malignant mesothelioma, in contrast to common belief, is usually straightforward, provided that the

pathologist has extensive experience with this malignancy. Histologically malignant mesothelioma can show an epithelial morphology (malignant mesothelioma epithelial type), the most common, about 50% to 60% of cases; a fibrous morphology (malignant mesothelioma fibrous type, also called sarcomatoid type), 10% of cases; or a combination of both (mixed type or biphasic malignant mesothelioma), about 30% to 40% of cases. Tumors with a prevalently sarcomatous morphology are quite resistant to therapy and have median survivals less than 1 year from diagnosis. They are difficult to diagnose because they show a morphology that can be essentially identical to other primary or metastatic pleural sarcomas. Immunohistochemistry showing positive staining for pankeratin may be considered confirmatory. Only a fraction, which varies depending on the study, of sarcomatoid malignant mesothelioma stain positive for calretinin, and some of them are positive for WT-1. Thus, negative staining for these two mesothelial markers does not rule out the diagnosis of malignant mesothelioma, but should prompt the pathologist to consider other differentials. Electron microscopy (EM) has a limited role in diagnosing sarcomatoid malignant mesothelioma because these cells do not have the diagnostic long branching microvilli of the epithelial type. However, EM can identify characteristics of other sarcomatoid tumors besides microvilli that can help to rule out the diagnosis of sarcomatoid malignant mesothelioma.

Mostly epithelial-type tumors, especially well-differentiated variants, are associated with prolonged survivals up to 2 years from diagnosis. Epithelial malignant mesothelioma typically shows large and well-differentiated epithelioid cells, with centrally placed nuclei, lack of atypia, abundant cytoplasm, and often form glandlike spaces or tubular-like spaces, although some epithelial mesotheliomas instead grow forming sheets of epithelioid cells. To be classified as biphasic, assume that at least 10% of the tumor must have a fibrous (or epithelial) component for the malignant mesothelioma. In fact, most malignant mesothelioma could be considered biphasic, as most mesothelioma show both morphologies if in a very tiny fraction, which is the characteristic histologic feature of this malignancy. Unusual morphologic variants exist, but are rare. In addition, some malignant mesotheliomas cannot be subcategorized histologically and should be called poorly differentiated malignant mesothelioma.¹⁵

The experienced pathologist will recognize these tumors as mesothelial in origin; however, occasionally a carcinoma with a typically more aggressive and atypical histology can look very much like a malignant mesothelioma, or a malignant mesothelioma can look so atypical that it resembles a metastatic carcinoma. Therefore, to rule out these rare mimics, confirmatory immunohistochemistry should be completed. Epithelial-type mesothelioma tumor cells are positive for pankeratin, keratin 5/6, calretinin, and WT-1 and negative for the epithelial markers carcinoembryonic antigen (CEA), LeuM1, B72.3, Ber-EP4, Moc-1, TTF-1, etc. Positive staining for pankeratin and calretinin and negative staining for three epithelial markers is considered sufficient for diagnosis; however, some carcinomas may stain positive for calretinin or negative for some of the epithelial markers and therefore additional testing may be required. In these difficult cases, EM showing the classic long branching microvilli of human mesothelial cells compared to the short nonbranch-

ing microvilli of carcinomas can still be considered the gold standard for a correct diagnosis.

Clinical Presentation of Malignant Pleural Mesothelioma

Classically, mesothelioma affects older men in their fifties, sixties, and seventies because of the aforementioned 25- to 40-year latency period between occupational asbestos exposure and the development of the tumor. Latency periods between first exposure to asbestos and a diagnosis of mesothelioma vary by occupation, intensity, and duration of exposure, with shorter latencies for insulators and dock workers and longer intervals for shipyard and maritime workers, as well as for domestic exposures. Table 38.1 lists the most common industries identified in 1,048 cases of histologically confirmed mesothelioma cases reviewed by Roggli et al.¹⁷

Women and children can have the disease but the male to female ratio is approximately 3–5:1.¹⁸ There are many reports of childhood mesothelioma; however, on review of the pathology, the diagnosis is erroneous in as many as 50% of the cases, and there does not seem to be a relationship in these pediatric cases with asbestos, radiation, or isoniazid.¹⁹

SYMPTOMS

The majority of patients (~60%) present with nonpleuritic chest pain, classically located posterolaterally and low in the thorax. The pain typically has increased over time and may be severe enough to warrant narcotics for pain management. Intractable chest pain often indicates chest wall invasion beyond the endotheracic fascia. Approximately 5% of patients also have metastatic disease at presentation, usually to the lungs. The right side is affected more than the left side

(60% versus 40%), most likely due to its greater volume. Dyspnea is present in 50% to 70% of the cases, and some 80% of the patients present with dyspnea and effusion. In some series the symptoms of shortness of breath and chest pain are seen either singly or in combination in 90% of the cases.²⁰ The presence of a pleural effusion will be documented at some time in the course of the disease in 95% of patients with malignant pleural mesothelioma. Cough, fever, fatigue, and weight loss occur in approximately 30% of the patients, and a minority of cases present with hoarseness, hemoptysis, Horner's syndrome, superior vena caval syndrome, or paralysis from invasion of the spinal canal.

The duration of symptoms varies; however, the range can extend from 2 weeks to 2 years, with most series having a median time to diagnosis from symptoms of 2 to 3 months. Unfortunately, as many as 25% of patients with the disease have symptoms for 6 months or more before seeking medical attention.

PHYSICAL EXAMINATION

Physical examination usually reveals signs associated with a pleural effusion with decreased breath sounds, dullness to percussion, or decreased motion of the involved chest wall. In patients with severe dyspnea, the effusion may occupy the entire chest, resulting in mediastinal shift and compromise of the opposite lung volumes. Dyspnea continuing after thoracentesis may be an indication of fixation of a nonexpanding, contracted, and trapped lung (i.e., failure to expand after fluid removal). In the late stages of the disease there is often dramatic cachexia, marked contraction of the involved chest with narrowed interspaces, and hypertrophy of the contralateral hemithorax. A chest wall mass occurs in up to 25% of patients, often at the site(s) of prior thoracentesis, thoracotomy, or thoracoscopy wounds. Lymph node examination should concentrate on the cervical, supraclavicular, and axillary basins, and any externally palpated asymmetrically enlarged nodes should be biopsied. The abdomen must be inspected for signs of ascites.

LABORATORY EXAMINATION

The most striking laboratory abnormality is thrombocytosis (more than 400,000), which is seen in 60% to 90% of patients,²¹ and elevated platelet counts (more than 1,000,000) in approximately 15% of patients. In addition, nonspecific laboratory findings including hypergammaglobulinemia, eosinophilia, and/or anemia of chronic disease may be seen. It has been recently noted that 14% to 15% of patients have elevated homocysteine levels reflecting folic acid deficiency, 17% have biochemical evidence of B₁₂ deficiency and 32% have biochemical signs of B₆ deficiency.²²

At present, validated serum markers that are both sensitive and specific for mesothelioma do not exist. Hyaluronic acid is elevated in the mesothelioma pleural effusions in approximately 60% of the patients^{23,24}; however, this is only seen in the serum in advanced cases and has not proven to be a reliable marker. Measurement of low molecular weight cytokeratins has been reported to aid in the diagnosis of mesothelioma when combined with other pleural effusion markers including CEA but prospective validation studies are lacking.²⁵ Serum CEA should be less than 5 ng/mL in more than 95% of cases. Recently, a dual monoclonal forward

sandwich enzyme-linked immunosorbent assay (ELISA) for the measurement of soluble members of the mesothelin/megakaryocyte potentiating factor (MPF) family of proteins expressed by mesothelial cells has been reported to predict the development of mesothelioma in high-risk individuals as well as to reflect the influence of therapeutic efficacy in mesothelioma.²⁶

RADIOLOGIC EXAMINATION/IMAGING STUDIES

Malignant mesothelioma can have a diverse radiographic appearance. Many of the early changes are associated with a previous exposure to asbestos, consisting of both pleural and parenchymal changes, including pleural plaques or parenchymal pulmonary fibrosis.

CHEST RADIOGRAPHY

The presence of a pleural effusion, diffuse pleural thickening, and nodularity are the most common features associated with progression and symptoms. The involved hemithorax can eventually have smooth, lobular pleural masses that infiltrate the pleural space and fissures²⁷⁻²⁹ in 45% to 60% of patients with contraction and fixation of the chest. The lung becomes encased, and the mediastinum shifts because of volume loss. The apex may appear to have minimal pleural thickening on the chest radiograph, which may be better visualized with computerized tomography (CT). The effusion can completely obscure a view of the diaphragm, lower lobes, and pericardium indicative of complete collapse. One must assess the contralateral chest for effusion, which could raise the possibility of two-cavity involvement, or reveal worrisome nodularity or evidence of asbestos involvement that may impact on the functional ability of the patient to undergo diagnostic or therapeutic interventions.

Usually the chest radiograph adds little to the staging of mesothelioma; however, it may guide the workup toward a thoracoscopy if fluid is present.

COMPUTERIZED TOMOGRAPHY

CT imaging allows for density resolution that is not available with chest radiography, and these characteristics are useful not only in the evaluation of the patient with mesothelioma but also with asbestos-related diseases.³⁰ Such asbestos-induced parenchymal changes on CT frequently include subpleural lines and parenchymal bands, prominent pulmonary arcades, subpleural dependent densities, reticulation, and parenchymal honeycomb patterns. Pleural changes seen on CT include pleural plaques, diffuse pleural thickening, and pleural effusion. Up to 10% of pleural plaques are calcified, and they appear characteristically on the posterolateral aspect of the lower parietal pleura or diaphragm.

The patient with mesothelioma may have all the previously mentioned findings in addition to the abovementioned circumferentially lobulated, soft tissue mass with lower-zone predominance. Additional CT features of mesothelioma include localized nodular or plaque-like pleural thickening possibly associated with pleural effusion. The lobulated pleural encasement frequently causes lower lobe collapse. Intrapulmonary nodules can occur in 60% of patients, and infiltration into fissures along with enlarged hilar and mediastinal lymph nodes may be seen. CT allows a better view of the involved pericardium, which is irregularly thick-

ened and associated with infiltration to the pericardial fat pad. Chest wall involvement is still difficult to assess with CT and, unfortunately, this finding is an important aspect in the staging of the disease. Occasionally CT will demonstrate focal chest wall invasion at a previous biopsy site, surgical scar, or chest tube tract.³¹ CT signs of chest wall invasion include distortion of the intercostal spaces, infiltration of extrapleural soft tissue and ribs, and undefined densities infiltrating the chest wall musculature. A clear fat plane between the inferior diaphragmatic surface and the adjacent abdominal organs as well as a smooth inferior diaphragmatic contour may imply resectability.³² CT may reveal a hemidiaphragm encased by a mass or poor definition between the liver, stomach, and inferior diaphragmatic surface.

Volumetric estimates of tumor volume using three-dimensional reconstruction have also been investigated for the staging of mesothelioma.³³ Tumor volumes associated with mesothelioma patients who are found to have no spread to lymph nodes are significantly smaller than in those patients with positive nodes. Moreover, progressively higher stage is associated with higher median preoperative solid volume of tumor in these patients.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) is appealing because of the differential signal intensity, depending upon the sequence used, and the ability to image in the coronal, sagittal, and transverse planes. Tumors are found to have intermediate signal intensity on the T₁-weighted image, whereas on T₂-weighted images there is an increase in signal intensity, fluid is clearly seen as high signal intensity and there are focal areas of very high signal intensity. More recent studies have suggested gadolinium contrast enhancement MRI can improve tumor detection and extension. Detection of diaphragm invasion and invasion of endothoracic fascia or a single chest wall focus may be better with MRI compared to CT.³¹

POSITRON EMISSION TOMOGRAPHY

There are a number of studies of positron emission tomography (PET) and the radionuclide imaging agent [¹⁸F]fluorodeoxyglucose (FDG) in mesothelioma. Four studies have reported that FDG-PET is accurate in the diagnosis of pleural malignancies, specifically mesothelioma, and that it may be superior to CT for defining mediastinal lymph node involvement.³⁴⁻³⁷ Moreover, the ability to define extrathoracic, otherwise occult disease in newly diagnosed patients can be as high as 10% to 11% and 45% in those followed after therapy. One of the more intriguing aspects of the technology is quantitative prognostication using the standardized uptake value (SUV). The data suggest that patients with higher SUVs have tumors that are more metabolically active and have a shortened median survival compared with those with a lower SUV. In the most recent report, the SUV of the tumor before resection was significant in discriminating longer- versus shorter-surviving patients and was able to stratify very good risk versus very bad risk patients: those with low SUV and epithelial histology had the best prognosis whereas those with high SUV and nonepithelial histology did the worst.³⁸

FOLLOW-UP RADIOLOGIC ASSESSMENT

After thoracoscopy or thoracentesis, a postprocedure X-ray can be done to determine whether the patient has trapped lung. The failure of the lung to expand should alert the clin-

ician that the lung may require decortication in addition to parietal pleurectomy if surgical therapy is required. Such a situation implies that the lung has been trapped for a considerable amount of time and may point to the use of a ventilation perfusion scan to assess functional contribution of that lung. The discovery of a trapped lung rules out the ability to successfully palliate the effusion with a talc pleurodesis, although the patient may still be a candidate for insertion of a Pleurex catheter (see Supportive Care section).

The standards for postoperative radiographic follow-up for patients having mesothelioma surgery are undefined; however, CT should be performed at regular intervals after extrapleural pneumonectomy (EPP) or pleurectomy decortication to monitor for progressive disease. After EPP, CT scanning of the resected hemithorax will reveal a smooth-walled, well-defined postoperative membrane lining the pneumonectomy space that is usually concentrically smooth, but as the interval from operation to follow-up lengthens, the membrane may actually get thicker. Unexplained irregular focal thickening at the base of the chest should alert the clinician to a recurrence of disease. This finding is especially pronounced in the pleurectomy patient in whom the recurrent mesothelioma may start to thicken rapidly and infiltrate the underlying lung. Other presentations of recurrence include the development of new mediastinal adenopathy or ascites otherwise undetectable by physical examination. The development of asymptomatic abdominal fluid after EPP is an ominous sign and calls for paracentesis. CT will usually reveal diaphragmatic thickening or diffuse mesenteric infiltration in these cases.

Without recurrence, however, the space is smooth walled, especially on the parietal pleura and mediastinal surfaces. The prosthetic Goretex diaphragm eventually becomes radiopaque and the diaphragmatic surface requires close inspection, for at the lower sulci the initial appearance may not be smoothly contoured.

Another important role of follow-up or sequential CT scanning is in the assessment of the response of mesothelioma to chemotherapy. Multicenter protocols now require measuring the thickness of the pleural rind at one to three locations on the rind on three separate slices of the CT every 6 to 9 weeks. If the total thickness has decreased by 30% or more, the patient has shown a response to treatment whereas 20% or greater increase in thickness equals progressive disease.³⁹ This method of response assessment correlated with outcome in Phase II trials and in an international trial, which showed that cisplatin plus pemetrexed was superior to cisplatin alone. Research is still needed to validate the three-step process: (1) selection of the CT sections in which the disease is most prominent, (2) identification of specific sites within these sections that demonstrate the greatest extent of tumor, and (3) the actual measurement of tumor thickness at these sites that generate these measurements.

The role of PET imaging to follow response or progression to chemotherapy is also under evaluation.

Diagnosis

Thoracentesis and Closed Pleural Biopsy

Patients who present with a large, unexplained pleural effusion and minimal or moderate evidence of pleural thickening

should have initial thoracentesis and pleural biopsy. Multiple closed pleural biopsies to avoid sampling error are able to aid in the diagnosis in 30% to 50% of cases.⁴⁰ Using both histochemical and immunohistochemical staining techniques along with EM analysis of a preserved pleural fluid cell block, the diagnosis of mesothelioma can be obtained from pleural effusion in as high as 84% of suspected cases.^{41,42}

Thoracoscopy

Patients at risk for mesothelioma who develop a large effusion and who do not have malignant cells on thoracentesis and pleural biopsy or who recur with effusion after initial thoracentesis should have a video-assisted thoracoscopy⁴³⁻⁴⁵; this allows evaluation of specific areas for guided biopsy and assessing the ability of the lung to expand. Thoracoscopy can be invaluable for estimating extent of disease with regard to the diaphragm, pericardium, chest wall, and nodes. The compulsive use of thoracoscopy led to the finding that exclusive involvement of the diaphragmatic pleura and parietal pleura (stage IA) has a median survival of 31.2 months whereas involvement into visceral pleura led to a median survival of 6.75 months.⁴⁶ There is a 10% chance of later development of chest wall masses from seeding of the biopsy site or surgical scar from any diagnostic procedure, but this can usually be avoided by radiotherapy to the scar if appropriate,⁴⁷ although this is controversial (see Radiation Therapy section).

Open Pleural Biopsy

Open biopsy is indicated when there is no free pleural space as a result of previous treatment and the bulk of the disease in the hemithorax is solid. Such a biopsy should be infrequent and carefully planned such that the scar could be incorporated into the incision if a major resection is planned after definitive diagnosis. Bronchoscopy may be necessary to rule out carcinoma of the lung until unequivocal pathologic confirmation is reported. Mediastinoscopy should generally be performed when enlarged mediastinal lymph nodes are detected by imaging and to rule out contralateral disease.⁴⁸ This step may, however, underestimate the extent of nodal involvement because the majority of mediastinal nodal involvement in mesothelioma is below the subcarinal level.⁴⁹

Natural History

Most patients with pleural mesothelioma will die of complications of their local disease; these include increasing tumor bulk causing progressive respiratory compromise, pneumonia or myocardial dysfunction with arrhythmias, narcotic usage leading to pulmonary complications and cachexia, and/or occasionally dysphagia from tumor compression of the esophagus. Small bowel obstruction from direct extension through the diaphragm develops in approximately one-third, and 10% die of pericardial or myocardial involvement.⁵⁰ Extrathoracic metastases occur late in the course of disease and are not usually the direct cause of the patient's death.

Prognostic Indicators

Although the overall prognosis for patients with mesothelioma is poor, there are some patients who do not conform to

the norm and live with their disease for a considerable period of time. Retrospective analysis of prognostic variables to define these outliers is difficult for reasons of nonuniformity of pathologic staging and reporting criteria. Recently, however, larger studies have been published that give insight into potential prognostic variables in mesothelioma.

The most important predictor of survival in nonsurgical studies of mesothelioma is performance status. The Cancer and Leukemia Group B conducted 10 clinical trials in which patients were required to have a performance status of 0–2 at entry. Analysis of survival of 337 patients in these studies showed that overall median survival was 7 months; however, in the subgroup of patients with a performance status of 0, median survival was 13 to 14 months.⁵¹ In addition, chest pain, dyspnea, platelet count greater than 400,000/ μ L, weight loss, serum lactate dehydrogenase level greater than 500IU/L, pleural involvement, low hemoglobin level, high white blood cell count, and increasing age over 75 years predicted shorter survival.⁵¹

The European Organization for Research and Treatment of Cancer (EORTC) studied 204 adults with malignant pleural mesothelioma. The median survival was 13 months from diagnosis and 8 months from trial entry. Poor prognosis was again associated with a poor performance status as well as a high white blood cell count, male gender, and the sarcomatous histologic subtype⁵² in the multivariate analysis.

The molecular prognostication of mesothelioma has been explored by two groups. These data require further validation in larger prospective analyses but imply that gene expression data in mesothelioma at the time of initial biopsy may predict clinical outcome.^{53,54}

Staging

The commonly used American Joint Committee on Cancer (AJCC) staging system for mesothelioma (Table 38.2) was adopted from that proposed by the International Mesothelioma Interest Group (IMIG) in 1995 and has been validated in a number of surgical-based trials.^{55–58} There was a redefinition of the T categories from the original Butchart system dividing T1 lesions into involvement of the parietal pleura only (T1a) and involvement of the visceral pleura (T1b), creating stage IA and IB from stage I. T3 is defined as a locally advanced but potentially resectable tumor and T4 is defined as a locally advanced, technically unresectable tumor. The AJCC system classifies any nodal involvement, either intrapleural or extrapleural, as stage III disease. The Brigham and Women's Staging System has also been proposed for pleural mesothelioma and differs from the AJCC by defining intrapleural adenopathy as stage II disease and extrapleural adenopathy as stage III disease.^{59–62}

Treatment

Overview

No standards exist for the management of resectable pleural mesothelioma, and treatment decisions are influenced by the functional evaluation of these often-elderly individuals and the philosophy of the treating physician. Treatment of mesothelioma can consist of supportive care only, surgery,

radiotherapy, chemotherapy, and/or combinations of these modalities. Geographic locale can dictate the type of treatment given. In the United Kingdom, less than half of mesotheliomas are treated by radical resection (E.G. Butchart, personal communication). Currently however, a randomized trial of EPP compared with nonsurgical treatment is under way.⁶² In the United States, a cohort of cancer centers using Phase I/II protocols are defining the use of surgery in mesothelioma with or without intraoperative and/or postoperative innovative adjuvant therapies and, in general, innovative, multimodality protocols that incorporate surgery as part of the package are being explored in larger numbers of patients.

Supportive Care

The median survival of patients who select active symptom control only for mesothelioma ranges from 4 months⁶³ to 13 months⁵⁰ because of variations in tumor biology, host response to tumor, detection bias, lead time bias, and the use of ad hoc or unreported treatments by some patients and physicians. Factors predictive of survival were poorly defined when many of the "natural history" series were published; therefore, survival data can only be used for historical comparisons if the prognostic factors of that group are taken into account.

Control of pleural effusion can be accomplished with repeated thoracenteses, talc pleurodesis, pleuroperitoneal shunting, or placement of a Pleurex catheter. Success rates in effusion control with talc, used either via thoracoscopy or via slurry, approach 90%.^{64,65} Failure of these techniques is usually associated with the standard reasons for poor prognosis. In such cases, the Pleurex catheter can be implanted under local anesthesia into the fluid collection and the patients can drain themselves at home,⁶⁶ or internal drainage from the pleura to the abdomen may be accomplished using the Denver pleuroperitoneal shunt.

Pain management frequently requires narcotics and consultation by a dedicated pain management team to optimize the patient's quality of life. Insertion of subcutaneous epidural catheters for long-term outpatient use has also been used in selective cases.

In 2002, the British Thoracic Society (BTS) proposed a Phase III clinical trial to compare the use of ACS with ACS plus two different chemotherapeutic regimens to measure overall survival, symptom palliation, performance, quality of life, and other endpoints.⁶⁷ The chemotherapeutic regimens mitomycin, vinblastine, cisplatin (MVP) and vinorelbine (N) were chosen because of their record of symptom control. More recently, in 2004, a study was conducted to determine if this study was feasible and it was concluded to be.⁶⁸ This study is now under way and will be the first to indicate if ACS alone or ACS plus chemotherapy is more effective in symptom control in mesothelioma patients.

Surgery

Aggressive therapy of pleural mesothelioma often entails a multimodality approach of which surgery is only a part. Surgical procedures include pleurectomy/decortication or EPP, and the indication for each of these operations depends on the extent of disease, performance, and functional status of the patient and the philosophy and experience of the treating

TABLE 38.2. International staging system for diffuse malignant pleural mesothelioma.

Stage	T	N	M
Stage I	T1	N–Lymph nodes	M–Metastases
Ia	T1a	NX Regional lymph nodes cannot be assessed	MX Distant metastases cannot be assessed
T1aN0 M0	Tumor involves ipsilateral parietal (mediastinal, diaphragmatic) pleura No involvement of the visceral pleura	N0 No regional lymph node metastases	
Ib	T1b		M0 No distant metastasis
T1bN0 M0	Tumor involves ipsilateral parietal (mediastinal, diaphragmatic) pleura, with focal involvement of visceral pleura		
Stage II	T2		
T2 N0 M0	Tumor involves any of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following features: —confluent visceral pleural tumor (including fissure) • invasion of diaphragmatic muscle • invasion of lung parenchyma		
Stage III	T3		
Any T3 M0	Describes locally advanced but potentially resectable tumor. Tumor involves any of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura), with at least one of the following: • invasion of the endothoracic fascia • invasion into the mediastinal fat • solitary focus of tumor invading the soft tissues of the chest wall • nontransmural involvement of the pericardium		
Any N1 M0		N1 Metastases in the ipsilateral bronchopulmonary and/or hilar node(s)	
Any N2 M0		N2 Metastases in the subcarinal and/or the ipsilateral internal mammary or mediastinal lymph node(s)	
Stage IV	T4		
Any T4	Describes locally advanced technically unresectable tumor Tumor involving all the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following: • diffuse extension or multifocal invasion of soft tissues in the chest wall —any involvement of rib • invasion of the diaphragm to the peritoneum • invasion of any mediastinal organ • direct extension of the contralateral pleura —invasion into the spine • extension to the internal surface of the pericardium —pericardial effusion with positive cytology —invasion of the brachial plexus		
Any N3		N3 Metastases in the contralateral mediastinal, internal mammary, or hilar lymph nodes, and/or ipsilateral, or contralateral supraclavicular or scalene lymph nodes	
Any M1			M1 Distant metastasis present

institution. Operative intervention in mesothelioma fall into one of three categories: (1) primary effusion control as described for supportive care purposes, (2) cytoreduction before to multimodal therapy, or (3) to deliver and monitor innovative intrapleural therapies. Currently studies are under way to determine the benefits of aggressive therapy using surgery as part of a multimodality approach.

Most mesothelioma patients are older individuals with a long latency period between asbestos exposure and tumor development. A detailed physiologic and functional evaluation assessing cardiac and pulmonary status must be performed before any surgical intervention. The degree of asbestos exposure, smoking history, trapped lung, and patient age all influence pulmonary function. Fiber-related fibrosis and reduced CO₂ diffusion capacity increases dyspnea in these patients, and abnormal chest wall motion resulting in reduced lung volumes on the affected side will influence the patient's respiratory functional reserve and the extent of surgery.

Patients without objective evidence of cardiac injury require nuclear medicine studies to rule out reversible perfusion defects indicative of myocardium at risk. Patients with a left ventricular ejection fraction (LVEF) less than 45% or who have sustained a myocardial infarction within the past 3 months are not candidates for EPP. Patients who undergo angioplasty before operative intervention for their disease may be better candidates after such interventions if a multimodality approach is being contemplated.

In addition, before surgery, any drugs that could impact platelet function or anticoagulant therapies must be halted. If a multimodality program utilizing drugs with potential renal toxicity (i.e., cisplatin) is planned, a preoperative creatinine clearance should be performed.

Staging and Operative Therapy

The goal of a surgical resection in mesothelioma is to leave only microscopic residual disease, that is, a near-complete cytoreduction. Eligibility includes all patients who are clinically IMIG stages I–III, although there is increasing skepticism whether patients with stage III mesothelioma are benefited by surgery. No guidelines exist that can assure the patient preoperatively which operation will be necessary to accomplish tumor removal. A large effusion with minimal bulk disease may call for pleurectomy decortication, whereas the presence on CT of irregular, bulky disease that infiltrates into the fissures probably dictates that an EPP should be performed. Hence, stage II mesothelioma may indeed be an absolute indication for EPP as opposed to pleurectomy. Moreover, some surgeons reserve EPP for those patients with bulk disease that prevents simple pleurectomy, whereas others believe that the greatest chance for complete gross excision is via EPP performed in the patient with minimal disease. This important factor, preoperative quantitative bulk of disease, may not only influence the choice of resection but may be an important preoperative prognostic factor in any patient with mesothelioma. The final decision as to whether pleurectomy and decortication or EPP is to be performed, given these caveats, becomes an intraoperative decision unless a protocol calls specifically for one operation or the other.

The influence of nodal status and eligibility for surgery is not well defined because only 30% to 40% of nodes involved from resected mesothelioma patients are accessible to routine

mediastinoscopy.⁵⁶ The involvement of any nodes, making the patient Stage III, is an ominous prognostic sign; however, it is unclear whether the prognostic importance of mediastinal nodal involvement in mesothelioma is equivalent to the prognostic importance of the nodes within the visceral envelope of the lung which may reflect disease at a later time point. It is possible that FDG PET scanning as previously discussed will help to at least define those patients with node involved mesothelioma in the future. Until then, without routine thoracoscopic sampling of multiple nodal stations in mesothelioma before definitive resection, mediastinoscopy may be justified in those patients with obvious (i.e., larger than 1.5 cm) nodal involvement in levels 7, 4R, 4L, 5L, or 6L, or in patients with a suspicion for contralateral nodal involvement on presentation.⁴⁸

Pleurectomy

Most diffuse malignant mesotheliomas cannot be surgically removed en bloc with truly negative histologic margins. A minority of patients have a margin-free resection, and because those patients who have margin-free resections usually have less-bulky disease, it may be justifiable to spare functioning lung if the visceral pleura is minimally involved; this can be accomplished by performing a radical parietal pleurectomy instead of EPP. "Minimal visceral pleural disease" is an undefined entity and there are no criteria for how many sites should be involved, the size of these involved sites, or whether involvement of the fissure is worse than non-fissural involvement. In general, patients who have pleurectomy decortications for mesothelioma have lesser disease and live longer.

Pleurectomy and decortication are very effective in controlling malignant pleural effusion. Effusion control has been reported in 88% of patients having decortication, 98% of patients having pleurectomy,⁶⁹ and 86% of patients having partial decortication and pleurectomy.⁷⁰ When performed routinely, pleurectomy for mesothelioma has few major complications, the most common of which is prolonged air leak lasting longer than 7 days occurring in 10% of the patients. The modern-day mortality for pleurectomy for mesothelioma is generally considered to be 1.5% to 2% with death from either respiratory insufficiency or hemorrhage.^{71,72}

Many of the published series using pleurectomy for palliative management have added therapies postoperatively in an uncontrolled, institution-related fashion (Table 38.3). The overall median survival for patients having pleurectomy alone is approximately 13 months. The patients who receive pleurectomy and decortication usually have early effusive disease with minimal bulk tumor. If these patients have epithelial mesothelioma, and are not found to have nodal involvement, survival rates can be significantly longer than that quoted above. For additional discussion of pleurectomy and multitherapy, see the Multimodality section.

EXTRAPLEURAL PNEUMECTOMY

Although a minority of patients have margin-free resections, in one of the largest series of EPPs performed for mesothelioma, 66 of 183 patients were defined as having negative resection margins after surgery. Patients with negative margins at resection, without nodal involvement, and epithe-

lial histology were found to have 2- and 5-year survival rates of 68% and 46%, respectively.⁶⁰

EPP is a more-extensive dissection and a more-complete resection than a pleurectomy, chiefly in the diaphragmatic and visceral pleural surfaces. For EPP, pericardiectomy and partial pericardiectomy are performed during the resection because this maneuver aids in the exposure of the vessels and allows intrapericardial control to prevent a surgical catastrophe. Some surgeons include diaphragmatic resection and pericardial resection with their pleurectomies also to accomplish removal of all gross disease.

EPP should only be performed at those centers that have specialized expertise in the surgical management of mesothelioma, loosely defined as having a caseload of 20 or more EPPs per year. Moreover, expansion of surgical eligibility criteria should occur only at those institutions that are conducting institution-based, human investigation committee-approved physician-initiated surgical protocols for the disease or who are participating in consortium-based surgical mesothelioma protocols through cooperative groups or other mechanisms.

Often, during exploration, a cohort of patients planned for EPP are found to be unresectable at the time of the operation. Eligibility for EPP ranged from 50% to 63% at three different institutions,^{60,73,74} and in a study in the 1980s it was reported to be as low as 24%.⁷¹

EPP has significantly greater risk than pleurectomy, and major complication rates range from 20% to 40% with arrhythmia requiring medical management being the most common complication. Morbidity of some type has been reported to be as high as 60.4%.⁷⁵ In addition, rates for some morbidities such as bronchopleural fistula is greater with right-sided EPPs, with an overall fistula rate of 3% to 20%. The bronchopleural fistula can be handled for the most part with open thoracostomy drainage with or without muscle flap interposition.

Median survival ranges from 9.3 to 17 months, with longer survival shown in a series heavily weighted in stage I patients (see Table 38.4).^{56,60,72,75–78} Mortality rates have declined over the last 30 years and range from 3.8 to 8%, death occurring chiefly in older patients from respiratory failure, myocardial infarction, or pulmonary embolus.^{75,77,78} The pattern of recurrence following surgery has been reported as chiefly local progression after pleurectomy and systemic failures after EPP.⁷²

Currently, a unique multimodality pilot study is underway in the UK (Treasure, unpublished data) to determine if EPP is useful in the management of mesothelioma; this is described in detail in the Induction Chemotherapy followed by Surgery Section.

Radiotherapy for Mesothelioma

Palliation Using Radiation Therapy

Palliation with radiotherapy in mesothelioma involves the management of dyspnea and chest pain and is most commonly used to palliate pain in patients with advanced mesothelioma and to treat painful chest wall metastases. Palliation was improved with the use of 400-cGy fractions compared with 300-cGy fractions (50% to 72% rate of symptom improvement); however, pain recurrence within the treated field remained a significant problem.^{79,80} These investigators reported that short courses of radiation (2,000 cGy in 5 fractions) were as efficacious for symptom relief as more protracted courses of radiation (3,000–4,000 cGy in 10–15 fractions). There is some evidence that total doses greater than 4,500 cGy are the most efficacious,⁷⁰ as reported in the results of palliative radiation therapy in 85 patients with mesothelioma.⁸¹ However, in a study with 1,100 patients, 71 of 1,100 patients were treated with radiation for symptoms and more than 60% of patients had some symptomatic benefit from radiation therapy with no dose response.⁸² Therefore, the standard approach is to offer patients short courses of treatment (2,000 cGy in 5 fractions) rather than longer courses of radiotherapy.

Curative Radiation Therapy as a Single Modality

Administration of "curative" radiotherapy for malignant pleural mesothelioma adds the risk of severe toxicity to surrounding normal tissue from the large treatment volumes, typically in the 5,000 to 5,500 cGy range. Survival in patients receiving 5,000 to 5,500 cGy to the pleural space using a rotational technique⁸³ ranged from 3 to 10 months, with one patient who was alive and well 4 years after the completion of treatment. In additional studies, median survival ranged from 9.8 to 17 months.^{70,80,84} Patients receiving palliative therapy only had a median survival of 7 months. Selection bias may explain these differences, with those fit enough to undergo a full course of radiation likely to have a greater survival regardless of treatment given. The median survival is 4 to 5 months^{79,83} when only local radiotherapy has been delivered solely for chest wall pain or chest wall nodules.

Radiotherapy to Prevent Malignant Seeding

As noted in the thoracoscopy section, there is a 10% chance of later development of chest wall masses from seeding of the biopsy site or surgical scar from any diagnostic procedure. In a recent study designed to determine if a single 9-MeV electron treatment following invasive thoracic procedures would eliminate tract metastasis, 58 patients were randomized to single-dose treatment or no treatment. No significant differences were seen between the two treatments.^{85,86}

The best evidence for prevention of malignant seeding by the use of radiotherapy following invasive diagnostic procedures comes from a 1996 study in France.⁴⁷ Investigators enrolled 40 patients with histologically proven malignant pleural mesothelioma who had undergone thoracoscopy. Half of the subjects (20) were given 2,100 cGy over 3 days in

700-cGy fractions within 10 to 15 days of the procedure. The other 20 patients were given no additional treatment to the thoracoscopy site. In the radiotherapy arm of the study, not 1 patient developed metastasis at the entry tract, compared with 8 of 20 (40%) who did in the other study arm. These findings support the use of early local radiation therapy at appropriate doses following procedures such as thoracoscopy, needle biopsy, and chest tube placements in eliminating malignant seeding.

Combined Surgical Resection and Definitive Radiotherapy

Surgical resection, when feasible, is the desired treatment for patients with malignant pleural mesothelioma. After an EPP, radical radiotherapy can be administered without concern for damage to the underlying ipsilateral lung because it has been removed surgically. However, radical radiotherapy after a pleurectomy continues to place the ipsilateral lung at risk for substantial loss of function.

No difference in survival was reported in two series when decortication or EPP was followed by radiation therapy for a total dose of 5,000 to 5,500 cGy in 12 and 8 patients, respectively, with pleural mesothelioma.^{70,83} Toxicities from this regimen were minimal and included nausea, malaise, transient radiation hepatitis, and mild esophagitis.

Some investigators have used brachytherapy or intraoperative external-beam radiation in combination with surgery. In a study of 41 patients with pleural mesothelioma, parietal pleurectomy resulted in residual disease being left in the majority of patients. Either brachytherapy or radioisotopes were used to eradicate gross residual disease.⁸⁷ Measurable gross residual disease was treated with permanent ¹²⁵I brachytherapy implants, for diffuse residual disease, temporary ¹⁹²Ir implants were placed 3 to 5 days after the pleurectomy, and for gross disease on the lung surface, a ³²P solution was instilled into the pleural cavity 5 to 7 days after thoracotomy. External-beam radiation to a dose of 4,500 cGy was delivered to the pleural surface 4 to 6 weeks after surgery via a combination of photons and electron. There was no mortality and minimal toxicity from this treatment strategy. Six patients (15%) developed complications from treatment: subcutaneous emphysema ($n = 2$), pneumonitis ($n = 1$), pulmonary fibrosis ($n = 1$), pericardial effusion ($n = 1$), and esophagitis ($n = 1$). The median survival was 21 months, with 1-year and 2-year survivals of 65% and 40%, respectively. Local failure occurred in 17% of the patients, perhaps because of the aggressive local therapy. It was concluded that although aggressive surgical resection is an essential portion of treatment, it is often very difficult to remove all sites of disease. The results of this study showed that intraoperative brachytherapy followed by external-beam radiation therapy was effective in controlling local recurrence.

In a Phase II trial at Memorial Sloan Kettering Cancer Center, 67 subjects with malignant pleural mesothelioma received postoperative radiotherapy.⁷⁷ Most patients ($n = 62$) underwent an EPP, followed by 5,400 cGy given through anterior and posterior fields in 30 fractions of 180 cGy. Five patients were treated with a pleurectomy, during which 1,500 cGy was given intraoperatively using a high-dose iridium applicator; this was followed by 5,400 cGy to the hemithorax via anterior and posterior fields, in the same fractionation schedule as

those who underwent EPP. Not all patients were able to complete the radiation therapy. There were 7 postoperative deaths from pulmonary complications in patients who had undergone an EPP. A total of 33 patients had some complications, the most common being atrial arrhythmias ($n = 17$), respiratory failure ($n = 6$), pneumonia ($n = 5$), and empyema ($n = 5$). In general, radiation was well tolerated, with grade 3 toxicities mainly related to fatigue, nausea, and esophagitis. There were five grade 4 toxicities, the most serious being an esophago-pleural fistula. Survival analysis was completed for the 62 EPP patients. Median survival was 17 months, with an overall survival of 27% at 3 years. Locoregional recurrence was 13%, primarily the result of distant metastases. The results of the study showed aggressive surgery with EPP followed by high-dose radiation to the entire hemithorax provided a favorable outcome for those patients who were able to complete the therapy compared with historical data. It should be noted that almost 25% of the enrolled patients were unresectable and were not included in the survival analysis, perhaps introducing a bias in the reported results.

In a recent retrospective review of the efficacy and toxicity of surgery with intraoperative radiotherapy followed by chemotherapy, 24 patients underwent pleurectomy/decortication and intraoperative radiotherapy consisting of 4 to 9 MeV electrons for a median dose of 1,500 cGy (range, 500 to 1,500 cGy).⁸⁸ Following surgery, external-beam conformal radiation was given to 14 patients and intensity-modulated radiation therapy (IMRT) was completed in 10 patients. The goal of this radiation therapy was to treat the affected tissue while sparing the underlying normal tissue. The median dose of radiation delivered was 4,140 cGy (range, 3,010–4,880 cGy). Chemotherapy consisting of cisplatin, doxorubicin, and cyclophosphamide was administered to selected patients beginning 1 to 2 months after radiation was completed. There were no deaths, and postoperative complications consisted of atrial fibrillation ($n = 3$) and a persistent air leak ($n = 1$). Radiation was also well tolerated; pneumonitis occurred in 4 patients and pericarditis in 1 patient. All symptoms resolved with conservative management. The median overall survival was 18.1 months and the median progression-free interval was 12.2 months. Locoregional relapse was the most common site of failure. It was concluded that this approach was a potential treatment option for adjuvant radiotherapy in patients who were unable to tolerate an EPP.

IMRT offers the potential for administering higher doses of radiotherapy to the hemithorax while minimizing normal tissue toxicities. In a study of 28 patients given IMRT after EPP, the hemithorax was treated with doses totaling 4,500 to 5,000 cGy in most cases, with some regions getting boosted to a total dose of 6,000 cGy.^{89,90} Radiation dose homogeneity to the entire hemithorax was excellent. Side effects included nausea, vomiting, dyspnea, and esophagitis. The median follow-up was 9 months, the local control rate was 100%, and 1-year survival was 65%. These early results are encouraging and are worthy of additional study.

Adjuvant Therapy For Surgically Cytoreduced Mesothelioma Patients

Although there are no published Phase III trials of adjuvant therapy in mesothelioma, patients treated with surgery followed by postoperative adjuvant therapy have an apparent

improved survival compared with palliative therapy alone in consecutively treated patients from single institutions. These results may be explained by selection bias or by a number of other factors, yet the possibility remains that surgery and adjuvant therapy changes the course of the disease. Mesothelioma is characterized by chemotherapy resistance and infrequent surgical cure, yet an EPP dramatically reduces the amount of visible cancer. The importance of the cytoreduction has been quantified by Pass et al.,³³ and in patients who have a more complete cytoreduction, the time to progression as documented by CT and survival time is longer. In a comparison of patients treated at the National Cancer Institute (NCI), Bethesda, from 1990 to 1993 who did not receive adjuvant therapy and patients treated from 1993 to 1996 and who received cytoreduction followed by adjuvant immunochemotherapy with cisplatin, interferon, and tamoxifen, the addition of postoperative adjuvant therapy influenced postoperative survival.^{91,92} These data have been corroborated by Rusch et al.⁹³ Strong consideration should be given to treating patients with postoperative chemotherapy (if pleurectomy was performed) and/or radiotherapy (if EPP was performed)⁹⁴ as Phase III trials are rare and unlikely in this disease.

Multimodality Treatment

Pleurectomy/Intraoperative Brachytherapy and Postoperative Radiation

The Memorial Sloan Kettering Cancer Center has been the leading proponent of this technique, which includes as complete debulking by parietal pleurectomy as possible followed by permanent (¹²⁵I) or temporary (¹⁹²Ir) implantation to deliver 3,000 rads in 3 days to a 1-cm distance from the implant plane. Radioactive ³²P is selectively instilled intrapleurally 5 to 7 days after thoracotomy, and external-beam radiation therapy commences 4 to 6 weeks postoperatively using electrons and photons to deliver 4,500 rads in 4.5 weeks. In a series from 1984 there was minimum morbidity in 41 patients, and median survival was 21 months at the time of their report.⁹⁵ Most patients (54%) recurred at distant sites with or without local recurrence. There have been no subsequent publications on this novel approach; however, the use of intraoperative radiotherapy has been explored recently. Radical pleurectomy/decortication has been combined with intraoperative radiotherapy and postoperative three-dimensional conformal radiation therapy or with IMRT. The study resulted in a median survival of 18 months and median time to progression of 12 months but requires greater maturation. Moreover, the adjuvant therapy did not seem to have an impact on patterns of recurrence after pleurectomy.⁹⁶

Pleurectomy/Intrapleural Chemotherapy and Postoperative Chemotherapy

There has been interest in combining debulking surgery with intracavitary treatment of pleural mesothelioma since the first reports of intrapleural chemotherapy alone for malignant mesothelioma. Rusch et al. used intrapleural chemotherapy with cisplatin and cytarabine after surgical debulking fol-

lowed by systemic chemotherapy in 10 patients.⁹⁷ A subsequent report used an even more aggressive regimen of pleurectomy, immediate intracavitary cisplatin, and mitomycin C with two cycles of systemic cisplatin and mitomycin C.⁹⁸ In the initial trial there was one postoperative death and the chemotherapy complications were reversible, making such an approach feasible. The most recent trial revealed an overall survival rate of 68% at 2 years and 44% at 2 years in the 27 patients who received the therapy, with a median survival of 17 months.^{97,98} Recurrences, however, were chiefly locoregional. A very similar regimen combining pleurectomy or EPP with cisplatin and mitomycin C resulted in a disappointing median survival of 13 months, and only 50% of the chemotherapy treatments were delivered adjuvantly. In an Italian study of 20 patients, pleurectomy and diaphragmatic or pericardial resection, combined with intrapleural chemotherapy with cisplatin and cytarabine for 4 hours immediately after pleurectomy, followed by systemic chemotherapy with epirubicin and mitomycin C, revealed a median time to disease progression of 7.4 months and median survival of only 11.5 months.⁹⁹

The intrapleural route with standard agents or radiation therapy remains intriguing but unanswered with regard to its efficacy. Phase II studies with the following design principles continue to be needed: (1) a tolerable regimen without chronic side effects, (2) a standard debulking approach with definition of the extent of residual disease, and (3) careful documentation of recurrence patterns.

Extrapleural Pneumonectomy/Intravenous Chemotherapy and Postoperative Radiotherapy

A multimodal approach to malignant mesothelioma using EPP, postoperative chemotherapy, and targeted postoperative radiotherapy has been ongoing since 1980 at the Brigham and Women's Hospital in Boston.¹⁰⁰ The adjuvant therapy presently includes two cycles of paclitaxel and carboplatin with concurrent radiation to a dose of 4,050 cGy. Over a 19-year period, 183 patients have been treated with a perioperative mortality of 3.8%. The median survival in this group of patients is approximately 17 months, which is a significant improvement over other trials. Favorable subgroups include those with no mediastinal nodal involvement and epithelial histology.¹⁰⁰

A large nonrandomized series from Germany has also demonstrated apparent increased survival with multimodal treatment compared to best supportive care.¹⁰¹ The treated patients, however, were younger, had a better performance status at presentation, and had no medical contraindications to surgery. These 93 patients chose either best supportive care or multimodal treatment. Surgery consisted of pleurectomy decortication or EPP followed by systemic chemotherapy with doxorubicin, cyclophosphamide, and vindesine. Patients in remission at the end of the chemotherapy (16 of the 57 accrued) received 4,500 to 6,000 cGy of radiation therapy to the hemithorax. Median survival was 13 months compared to 7 months for those receiving best supportive care.

In a series of 32 patients from Italy, Maggi et al.¹⁰²⁻¹⁰⁴ used the Brigham and Women's protocol of EPP followed by adjuvant chemotherapy and concurrent hemithoracic radiation up to a total dose of 5,500 cGy. The results were encouraging with only a 6.25% operative mortality rate. However, a

median survival of only 9.5 months was reported as 50% of the patients were found to be in stage III after the procedure.

Induction Chemotherapy Followed by Surgery

Induction or neoadjuvant therapy for pleural mesothelioma followed by surgery has been patterned after such therapy with non-small cell lung cancer. Results have been disappointing due to the inability of the patients to tolerate both the cytotoxic chemotherapy and the surgery. There also appeared to be difficulty in performing the surgical dissection after induction chemotherapy with doxorubicin because of the dense adhesions, perhaps caused by fibrosis following cancer kill by chemotherapy. With the improved efficacy of doublet chemotherapy (gemcitabine/cisplatin or pemetrexed/cisplatin), there is renewed interest in investigating a neoadjuvant approach for mesothelioma. A Swiss neoadjuvant study used three cycles of cisplatin 80 mg/m² on day 1 and gemcitabine 1,000 mg/m² on days 1, 8, and 15 every 28 days followed by surgery. Radiation therapy was considered after EPP to areas at risk. In all, 30 patients entered thus far have been reported. After chemotherapy, 22 (73%) underwent EPP. Histology after surgery revealed epithelioid (10), mixed (11), and sarcomatoid disease (3). There was 1 postoperative fatality. The median overall survival was 20 months and the 1-year survival rate was 77%.¹⁰⁵ A similar trial performed by de Perrot et al. involved induction chemotherapy, surgery, and postoperative hemithorax radiation therapy with a 6% operative mortality and 74% 1-year survival.¹⁰⁶ A neoadjuvant approach is presently being investigated in the United States as a multicenter trial of four cycles of pemetrexed and cisplatin followed by EPP and postoperative hemithorax radiation therapy.

Currently, a pilot feasibility study of neoadjuvant chemotherapy followed by EPP and postoperative radiotherapy is under way in the United Kingdom (unpublished). The mesothelioma and radical surgery (MARS, unpublished) trial is intended to help determine the usefulness of EPP in the management of mesothelioma. In this clinical trial, 670 patients will be enrolled over 3 years. Before randomization, the patients will have histologically proven mesothelioma with no distant metastases, with resectable disease, and have undergone three cycles of cisplatin-based chemotherapy. Following their chemotherapy, each patient will be randomized to the EPP + radiotherapy arm or the no further intervention arm of the study. Follow-up for the patient is expected to be 5 years.

Novel Intrapleural Approaches: New Techniques with New/Old Agents

Intrapleural Photodynamic Therapy

Photodynamic therapy involves the light-activated sensitization of malignant cells⁹² using a photosensitizer such as Photofrin II that is retained by malignant tissue *in vivo* in comparison to normal tissue. The sensitizer is activated by 630-nm light and then interacts with molecular oxygen to produce an excited reactive oxygen species. After a series of Phase I and II trials, a group of 63 patients with localized mesothelioma were randomized to surgery, with or without

intraoperative photodynamic therapy (PDT). All patients received postoperative immunochemotherapy with cisplatin, tamoxifen, and interferon. There were no differences in median survival (14.4 versus 14.1 months) or median progression-free time (8.5 versus 7.7 months), and sites of first recurrence were similar. Thus, aggressive multimodal therapy incorporating PDT can be delivered for patients with higher-stage mesothelioma, but first-generation PDT does not prolong survival or increase local control for mesothelioma. Other Phase II trials of photodynamic therapy and mesothelioma have not demonstrated therapeutic efficacy,^{107–109} and most recently preliminary results using intrapleural PDT with meta-tetrahydroxy-phenylchlorin after EPP have revealed significant toxicities without survival benefit¹¹⁰ (Table 38.5).

Pleural Perfusion

Hyperthermic chemoperfusion of the pleura after resection of mesothelioma is based on the hypothesis that the treatment will provide increased local control and avoid systemic chemotherapy toxicity. Ratto et al. delivered cisplatin to the pleural space after pleurectomy or EPP in 10 patients¹¹¹ and

recorded the pharmacokinetics but did not comment on survival or recurrences. Other small Phase II studies using cisplatin or doxorubicin with cisplatin have recorded morbidity rates of 33% to 65% using temperatures of 40° to 42°C without impacting on survival^{112,113} (Table 38.6). Sugarbaker et al. presented a Phase I/II trial using hyperthermic cisplatin (42°C) to perfuse both the abdomen and the pleura after pleurectomy/decortication. Operative mortality was 11%, and survival of all patients was 10.5 months; however, in the group of patients surviving surgery who received 225 mg/m² of cisplatin, the median survival was 22 months and disease-free survival was 20 months.¹¹⁴

Novel Gene and Cytokine-Related Therapies

By transferring the herpes simplex virus (HSV-tk) thymidine kinase gene to a tumor by infecting it with an adenovirus construct containing the TK gene (AdHSVtk), one essentially kills the tumor with the addition of gancyclovir. A Phase I trial of intrapleural suicide gene therapy has been reported that delivered a replication-deficient adenovirus encoding HSV-tk (Ad.HSV-tk) which, in preclinical studies, was found to transduce mesothelioma cells and treat human mesothe-

lioma xenografts in SCID mice.¹¹⁵ Gene transfer was demonstrated in 17 of 25 evaluable patients and was dose dependent. There was 1 partial response, 3 of the first 18 patients remained stable for up to 2 years following treatment, and 1 early-stage patient was tumor free for more than 31 months. The median survival of all patients was 11 months.

Immunomodulatory gene therapy is also being investigated for mesothelioma by transfecting tumors with cytokine genes that can activate CD4 T cells or stimulate CD8 T cells. The IL-2 gene has been inserted into a replication-deficient vaccinia virus, and six patients have been treated with one to three weekly injections of vaccinia virus-IL-2 (VV-IL-2) intratumorally. No clinical responses were seen, although expression of VV-IL-2 mRNA was detected in tumor biopsies and a T-cell infiltrate was detected in 50% of tumor biopsies at the site of injection.¹¹⁶⁻¹¹⁸ Preclinical trials of the transfection of interferon- β ,^{119,120} interleukin 4, and p14^{121,122} into mesothelioma are ongoing. An approach that combines suicide gene therapy and vaccination strategies uses genetically modified allogeneic irradiated ovarian cancer cells transduced with the HSV-tk gene followed with systemic gancyclovir treatment.^{118-120,123-125} In *in vitro* mixing experiments, gene-modified ovarian tumor cells killed both mouse and human mesothelioma cells in a dose-dependent manner. Use of the ovarian HSV-TK ovarian cells also prolonged survival of mice with mesothelioma in a dose-dependent fashion. These data have served as the basis for an ongoing Phase I clinical gene therapy trial to determine the maximum tolerated dose of HSV-TK-transduced ovarian cancer cells infused into the pleural cavities of mesothelioma patients followed by systemic gancyclovir.

Intrapleural and Systemic Cytokine Therapy

The use of intrapleural cytokine therapy by infusional techniques has chiefly been investigated in earlier-stage mesothelioma, and the effectiveness of interferon- γ by this route has been documented by Boutin et al.^{126,127} Interferon was administered at a dose of 40 million units twice a week for 8 weeks intrapleurally via a catheter or an implantable port for 89 patients over 46 months. Thoracoscopic or surgical biopsy was performed if CT scan 2 weeks after the end of treatment demonstrated a reduction in tumor size. Eight histologically confirmed complete responses and 9 partial responses with at least a 50% reduction in tumor size were obtained. The overall response rate was 20%. The response rate for patients with stage I disease was 45% with the main side effects being hyperthermia, liver toxicity, neutropenia, and catheter-related infection.

Intrapleural interleukin-2-based regimens have also been exploited in mesothelioma.¹²⁸ Intrapleural IL-2 (21×10^6 IU/m²/day for 5 days) was given to 22 patients with mesothelioma. Patients had stage IA ($n = 3$), stage IB ($n = 1$), stage II ($n = 16$), stage III ($n = 1$), or stage IV ($n = 1$) disease (Butchart classification). Histology comprised epithelial ($n = 19$), mixed ($n = 2$), and fibrosarcomatous ($n = 1$) mesothelioma. Patients were evaluated for response 36 days after treatment by CT scan and thoracoscopy with biopsies. There were 11 partial responses and 1 complete response. Stable disease occurred in 3 patients and disease progression in 7 patients. The overall median survival time was 18 months, and the 24-month and 36-month survival rates for responders were 58% and 41%,

respectively. Surprisingly, no confirmatory trials of this promising approach have been published.

Chemotherapy And Newer Agents

The rarity and dismal survival of pleural mesothelioma has precluded, until recently, Phase III trials. It was not surprising, therefore, that early studies with single-agent chemotherapeutics were tested in 20 to 40 patients^{21,129-133} with the hope that a major therapeutic advance would be discovered with limited numbers of patients. The most common single-agent drugs used for mesothelioma have been the anthracyclines, platinum agents, and antimetabolites.¹³⁴ The anthracyclines have had response rates of 0% to 15%, with median survivals of 4.4 to 9.5 months. Cisplatin or carboplatin have had response rates of 7% to 16%, with median survivals of 5 to 8 months. Antimetabolites as single agents have had response rates from 0% to 37%, the highest observed in methotrexate (37%) and gemcitabine (31%).¹³⁴ Typically, tumor regression of short duration associated with symptomatic improvement occurred in 15% of patients treated with chemotherapy but the median survival remained at about 7 to 9 months. Recently, however, a clinical benefit in up to 40% to 50% of patients was seen with single-agent vinorelbine.¹³⁵

In general, combination regimens have had higher response rates and longer median survival times. Anthracycline-based combinations had response rates from 11% to 32% and median survivals from 5.5 to 13.8 months, and those with platinum have had response rates of 6% to 48% with median survivals of 5.8 to 16 months.¹³⁴

A 1998 report from the U.K. suggested that clinical benefit as measured by reduction in pain and dyspnea occurred in up to 40% to 50% of patients treated with a regimen of mitomycin C, vinblastine, and cisplatin (MVC).¹³⁶ Therefore, a study is under way that will randomize more than 800 patients with mesothelioma to single-agent vinorelbine, the MVC combination, or supportive care to determine whether chemotherapy improves either quality of life or length of life in this disease.¹³⁷

A role for the antifolates has been suggested since it was reported that methotrexate induced regressions in 37% of patients.¹³⁸ Other antifolates had consistent but low activity as well¹³⁹⁻¹⁴³ (Table 38.7). A novel antifolate, pemetrexed, binds with high affinity to folate transport proteins,¹⁴⁴ is extensively polyglutamated, inhibits dihydrofolate reductase (DHFR), thymidylate synthase (TS), and glycinamide ribonucleotide formyltransferase (GARFT), and demonstrated broad antitumor activity in Phase I and II trials.¹⁴⁵ In Phase I studies, the combination of cisplatin and pemetrexed induced regressions in 5 of 12 (38%) of pleural mesothelioma patients in one study¹⁴⁶ and significant radiologic improvements in approximately 40% of patients in another.¹⁴⁷ These two trials led to a Phase II trial of pemetrexed as a single agent in the treatment of mesothelioma¹⁴⁸ in which 14% of patients responded. A comprehensive multivariate analysis of ongoing Phase II and III trials revealed that elevated serum homocysteine and methylmalonic acid (MMA) levels indicated folic acid and vitamin B₁₂ deficiency states were the major contributors to grade 3 and 4 toxicity of pemetrexed.¹⁴⁹ Subsequently, the enforced initiation of folic acid therapy (400-1,000 μ g/day) and B₁₂ injections every 9 weeks reduced myelosuppression and

TABLE 38.7. Single-agent antifolate studies.

Drug	Author and year of report	No. of patients	Response rate

Pemetrexed	Scagliotti and Novello 2003	64	15%

gastrointestinal toxicity while preserving and possibly enhancing efficacy.

Encouraging results in Phase I and II trials prompted a Phase III trial with 448 evaluable patients comparing every-3-week single-agent cisplatin (75 mg/m²) versus pemetrexed (500 mg/m² IV bolus over 10 minutes) plus cisplatin (75 mg/m²). Median survival time was clearly superior with combination therapy (12.1 months versus 9.3 months, respectively). An average 30% reduction in the thickness of the pleural rind measured by CT scan was 41.3% in the combination arm versus 16.7% in the cisplatin-alone arm. Time to disease progression, pulmonary function, and quality of life also improved in a statistically significant manner in the pemetrexed/cisplatin-treated patients.

Treatment with the combination regimen had resulted in more serious adverse events including drug-related death, grades 3 and 4 neutropenia, thrombocytopenia, and nausea and vomiting compared with cisplatin alone; however, supplementation with folic acid and vitamin B₁₂ significantly reduced the incidence of these toxicities and was associated with longer survival (*P* less than 0.01) in the pemetrexed/cisplatin arm only. Sustained improvement in quality of life and symptom relief (including pain, dyspnea, fatigue, anorexia, and cough) were also seen in the combination arm when compared with cisplatin alone.¹⁵⁰ These results suggest treatment with pemetrexed and cisplatin, supplemented with folic acid and vitamin B₁₂, provides an improved risk-to-benefit ratio in the treatment of mesothelioma.

Powerful predictors of increased survival and decreased survival were consistent with those reported previously in this chapter. Pulmonary function tests (PFTs) before each cycle of therapy in both treatment arms were improved in both the responder and stable-disease patients.¹⁵¹ Changes in slow vital capacity (SVC), forced vital capacity (FVC), or forced expiratory volume in 1 second (FEV₁) all correlated significantly with tumor response status. Therefore, the commonly used objective measurement with PFTs may be helpful and more sensitive than CT scanning in detecting treatment efficacy for patients with a response.

An additional two drug regimens containing a platinating agent (cisplatin, carboplatin, and oxaliplatin) have been studied in Phase II trials and appear to be associated with response rates and median survivals similar to that of the pemetrexed/cisplatin-treated patients. The combination of the older chemotherapeutic agent cisplatin combined with the antimetabolite gemcitabine showed a 30% or greater reduction in the thickness of the pleural rind and improvement in symptoms in 10 of 21 (47%) of patients in one study¹⁵²; in another, a 26% rate of activity was seen but median survival was only 7.5 months.¹⁵³ Other multicenter Phase II studies have shown promising activity with combi-

nation chemotherapy using gemcitabine/carboplatin, leading to widespread use of this regimen.¹⁵⁴⁻¹⁵⁶

Following an encouraging Phase II experience with ranpirase, a ribonuclease derived from frogs' eggs,¹⁵⁷ a Phase III trial compared the median survival of 154 patients randomized to treatment with either single-agent doxorubicin or ranpirase (Onconase). No difference in the median survivals of 7 to 8 months in each group was seen. Poor-risk patients were heavily weighted in the ranpirase arm, and elimination of those patients from the analysis showed median survival for ranpirase was 11 months. The trial has now been extended to compare doxorubicin to doxorubicin plus ranpirase and will accrue a total of up to 300 patients. Ranpirase has recently been granted orphan drug status for the treatment of mesothelioma by the European Union.

In a 3-year period from November 1999 to January 2003, 250 patients were randomized into a Phase III study of cisplatin alone or cisplatin plus raltitrexed, a thymidine synthase inhibitor. Previously, Phase I and Phase II studies had shown an overall response rate of 20% to 35% in the combination arm and 21% with cisplatin alone. Patients must have had histologically confirmed mesothelioma that was unresectable, had not been pretreated with chemotherapy, and a performance status of 0 to 2. Cisplatin (80 mg/m²) or cisplatin (80 mg/m²) plus raltitrexed (3 mg/m²) was given every 3 weeks until progression, unacceptable toxicity, or patient refusal occurred. The population was 80% male, median age 58 years, and mostly histological subtype epithelial (68%). Most patients had a performance status of 1 (62%). Grade 3 and 4 toxicities were roughly double in the combination arm for neutropenia, thrombocytopenia, fatigue, nausea, and emesis. Interestingly, more patients with greater pleuritic pain were in the cisplatin-alone arm when compared with combination therapy (*n* = 10 versus 6, respectively), and dyspnea was equivalent in the two treatment arms. There were 207 patients with measurable disease who were followed by RECIST criteria during the study. Partial response was seen in 14 cisplatin-alone patients compared with 24 in the combination arm. In addition, 1 patient in the combination arm achieved completed response. Overall response rates and median and 1-year survivals were better for the combination therapy compared with cisplatin alone, showing a trend toward improved survival in combination (23% versus 14%, 11.2 versus 8.8 months, and 45% versus 40%, respectively); however, these results were not statistically significant.

In spite of these modestly heartening results, chemotherapeutic agents have historically had little effectiveness against mesothelioma. Most of the larger studies require unresectable patients; therefore, the benefit of these drug regimens in early-stage mesothelioma is not well studied. However, in the studies reported, newer agents seem to be

somewhat more effective and the pemetrexed and cisplatin combination alters the natural history of mesothelioma. Second-line chemotherapy may also alter the natural history of mesothelioma, but Phase III trials using a placebo-control population are needed. Effective agents with unique mechanisms of action against mesothelioma are still desperately needed. Vascular endothelial growth factor (VEGF) signal transduction inhibitors are being tested and have clinical activity. To optimally test the many newer agents, referral of fit patients with no prior exposure to systemic therapy to clinical trials is strongly encouraged.

Malignant Peritoneal Mesothelioma

Presentation

Peritoneal mesotheliomas account for 25% to 33% of all mesotheliomas. Similar to pleural mesothelioma, it is diagnosed later in life (median age, 60 years), and there is a male to female ratio of 3:1. The relationship between mesothelioma and heavy exposure to airborne asbestos fibers is statistically proven, and pleural plaques are seen in approximately 50% of patients with peritoneal primaries.¹⁵⁸

Presentation commonly includes increased abdominal girth from ascites (49%), pain (43%), and weight loss (22%) and includes a pain-predominant or ascites-predominant clinical type,¹⁵⁹ with concomitant abdominal distension and abdominal pain in 14% of the patients. A tumor mass is seen in 6% of patients with localized abdominal pain with little or no ascites, and the abdominal mass usually represents omental caking.¹⁶⁰ Most patients have had symptoms for 6 months to 2 years before diagnosis. Men can present with an inguinal or umbilical hernia, and women can present with a pelvic mass. Some patients present with a new-onset hernia. Other signs of advanced disease include fever, leukocytosis, and thrombocytosis, and are associated with poor prognostic signs.¹⁶¹

Diagnosis

RADIOGRAPHY AND TISSUE PROCUREMENT

The workup of the patient with a peritoneal mesothelioma usually includes abdominal ultrasonography,¹⁶² CT of the abdomen,¹⁶³⁻¹⁶⁵ MRI,^{166,167} and most recently PET scanning.¹⁶⁸ On routine endoscopy, the appearance of mesothelioma is consistent with metastatic tumors with nodules, plaques, and masses that will involve the parietal and visceral peritoneum. The absence of hepatic parenchymal metastases should alert the physician to the possibility that the pathology is mesothelioma. Patients may present with massive ascites without demonstrable solid disease, ascites with infiltration of the mesentery leading to mesenteric thickening, peritoneal studding with masses of varying sizes, and/or hemorrhage within a dominant tumor mass.^{169,170} Peritoneal fluid from malignant ascites may be a watery transudate or a viscous fluid rich in mucopolysaccharides. Cytology establishes the diagnosis in only 5% to 10% of cases; however, viscous ascites with high fluid hyaluronidase levels may suggest the diagnosis. Definitive diagnosis requires CT-guided core biopsy of tumor masses or infiltrated omentum,¹⁷¹ paracentesis with cell block for

immunohistochemical staining, or preferably adequate tissue sampling from a laparoscopy with biopsy^{172,173} or an open directed biopsy. Laparoscopy, in addition to evaluating the extent of disease, should carefully examine the ovaries and the bowel to rule out nonmesothelioma neoplasms. Sufficient tissue must be obtained to perform immunohistochemical staining to differentiate an abdominal mesothelioma from other more-common causes of peritoneal carcinomatosis.

Peritoneal mesotheliomas must be differentiated from papillary tumors of the peritoneum (WDPM) because these tumors have a completely different natural history (see Benign Mesotheliomas). Although the ability to diagnose cystic mesotheliomas of the peritoneum before or at the time of exploratory laparotomy is limited, there has been advocacy for the avoidance of treatment unless there is evidence of progressive disease.¹⁷⁴ Differential diagnosis from ovarian cancer or true mesothelioma, however, may be possible only after the surgically resected ovaries and tumor are examined pathologically to document that there is no minimal or superficial invasion of the ovarian cortex or through immunohistochemical methods.¹⁷⁵ Because the amount of residual disease may be a prognostic factor, all such patients should be debulked to no macroscopic disease. Nevertheless, despite initial surgical resection, approximately one-half recur locally, and outcome is not associated with lesion size or proliferation.¹⁷⁶ There are recent anecdotal reports of an aggressive approach to these tumors either by adding adjuvant platinum-based chemotherapy after resection or primary treatment with cytoreductive surgery, and heated chemoperfusion may prove worthwhile.¹⁷⁷

Staging and Natural History of Malignant Peritoneal Mesothelioma

There is no staging system for peritoneal mesothelioma. The tumor is typically confined to the abdomen until late in the course and usually spreads to one or both pleural cavities rather than disseminating hematogenously. Most patients die without metastases or involvement of the chest. Involvement of the serosa overlying the small and large bowel, the liver, the spleen, and other organs leads to encasement of these organs in tumor tissue and repeated bowel obstructions. The median survival of untreated patients is 5 to 12 months.^{178,179}

Treatment

A multidisciplinary aggressive approach has evolved at specialized centers for treating peritoneal mesothelioma. Complete surgical resection is rarely, if ever, feasible and has not shown a survival benefit in the absence of additional therapy. Nevertheless, in the absence of clear evidence-based data, it may be that effective local therapy has a substantial effect on the survival of patients with this disease, and peritonectomy and cytoreduction is an integral part of multimodality therapy for the disease. Because of the low response rates of systemic chemotherapy, novel approaches involving either induction therapy followed by surgery, or postoperative intraperitoneal drug delivery after surgical debulking, were explored. Intraperitoneal chemotherapy with a variety of agents including cisplatin, mitomycin C, doxorubicin, epidoxorubicin, etoposide, and cytarabine used either singly or

in combination has been reported with responses up to 50% in small Phase II studies.¹⁸⁰⁻¹⁸⁴ Whole abdominal radiotherapy as an adjunct to intraperitoneal chemotherapy and surgery was first described in 10 patients with peritoneal mesothelioma in which 6 of the 10 patients received the multimodality approach between 1968 and 1985. The 6 patients remained free of disease at 19+ to 78+ months after diagnosis whereas the 4 patients not treated with this multimodality approach died of the disease.¹⁸⁵ The intraperitoneal infusion of radioisotopes for peritoneal mesothelioma remains of historical interest only^{186,187}; however, intraperitoneal chemotherapy is of continued interest.

INTRAPERITONEAL CHEMOTHERAPY

Intravenous chemotherapy results in patients with malignant mesothelioma have been disappointing. Given the tendency of the disease to remain confined to the peritoneum, interest has focused on the use of intraperitoneal chemotherapy. The primary theoretical obstacle to this form of treatment is the shallow depth of drug penetration into tumor nodules. Advantages include greatly enhanced drug concentrations in the peritoneal cavity and decreased systemic toxicity. In addition, substantial intravenous drug concentrations are obtained from peritoneal absorption of some drugs such as cisplatin. Thus, the combination of free surface diffusion and intracapillary drug flow may be potentially more efficacious than intravenous treatment alone.

The use of intraperitoneal chemotherapy for mesothelioma has been extensively reviewed.^{188,189} Intraperitoneal cisplatin and intravenous thiosulfate protection have resulted in a 59% complete response rate. However, many patients in this study relapsed quickly after treatment, implying incomplete eradication of tumor using cisplatin alone.¹⁹⁰ Intraperitoneal cisplatin was given to 18 of 19 patients and cisplatin alone was given to 1, resulting in 2 patients (10.5%) being disease free more than 5 years after therapy.¹⁹¹ The combination of cisplatin and etoposide resulted in 1 complete response in 5 patients with measurable disease.

Another study showed a response for two of four patients receiving cisplatin-based intraperitoneal therapy, one of which was a complete response. A 2-year follow-up laparotomy revealed only adhesions.¹⁹² Additionally, a case report noted continuing complete response at 53 months in a patient treated with intraperitoneal cisplatin and cytarabine.¹⁹³

COMBINED MODALITY APPROACHES

Several institutions have researched combined modality, which typically involves surgery with cytoreduction, intraperitoneal intraoperative treatment with cytotoxic chemotherapy, and postoperative chemotherapy and/or radiation therapy,^{194,195} and many of these reviews are reported next in this section. In a retrospective review of 15 women with peritoneal mesothelioma, it was reported that the response rate to first-line chemotherapy regimens was 30% overall but 67% to paclitaxel and cisplatin.¹⁹⁶ The median survival of all patients was 12 months; however, survival was longer for patients who underwent cytoreductive surgery versus biopsy only (14 versus 6 months, $P = 0.24$) and chemotherapy versus none (29 versus 1 month, $P = 0.03$).

Three sequential series of patients reported by Taub et al.¹⁹⁵ (1980 to 1982, 1982 to 1985, 1986 to 1988) were

treated at the Dana Farber Cancer Institute and Joint Center for Radiation Therapy. In the initial trial, 1 of 9 patients treated with surgery and intravenous cyclophosphamide, doxorubicin, and dimethyltriazenoimidazole carboxamide (DTIC), before and after whole abdominal radiotherapy, survived more than 10 years after diagnosis. In the second Phase I trial between 1982 and 1985, 6 of 13 patients having a debulking resection of all lesions of more than 1 cm in size were treated with intraperitoneal doxorubicin (6 to 50 mg/m²) and cisplatin (60 to 100 mg/m²) for a total of 8 to 12 treatments. At the time of the second laparotomy for removal of the access device, all 6 patients had a minimum decrease of 50% in the size of the tumor. The complete treatment package of surgical resection and chemotherapy followed by whole abdominal irradiation was completed in 4 patients. Four of the 6 patients, including 3 of the 4 who received irradiation, remained disease free for at least 36, 48, 60, and 61 months after diagnosis. In the third Phase II series, patients were treated with surgical debulking and intraperitoneal cisplatin and doxorubicin every 2 weeks for 20 weeks. Patients with no visible disease at second-look laparotomy received whole abdominal external-beam radiotherapy, and patients with macroscopic residual disease were treated with intravenous cyclophosphamide and doxorubicin and then radiation therapy. Thirteen patients had responded to therapy (partial response, $n = 7$; complete response, $n = 6$; although random biopsies were positive in all patients). Three patients with partial responses relapsed at 8, 24, and 25 months. At the time of reporting, all 6 patients with complete responses had remained in remission from 9 to 30 months (median, 25 months). Toxicity was generally mild, including nausea, vomiting, transient elevation in creatinine, and mild to moderate hematologic toxicity, and there were no discontinuations due to toxicity. Two episodes of small bowel obstructions in responding patients resolved without surgical intervention.

In a series of 17 early-stage patients between 1984 and 1999¹⁹⁵ who underwent cytoreductive surgery followed by five cycles of intraperitoneal doxorubicin (25 mg/m²) and cisplatin (75 mg/m²), 11 patients responded (65%) as assessed by second-look laparotomy or CT scan and received total abdominal radiation (3,000 cGy, $n = 3$), intravenous chemotherapy ($n = 3$), or both ($n = 4$). Ten patients completed all planned treatment. Toxicity included nausea, fatigue, and myelosuppression. Median survival for this group was 27.6 months (range, 3.6–66 months), and 8 patients were alive at the 24-month median follow-up (range, 3–49 months).

Taub et al.¹⁹⁷ also pioneered the use of surgery, intraperitoneal chemotherapy, and postoperative radiotherapy for peritoneal mesothelioma. Ten symptomatic patients were registered to be surgically debulked and receive five courses of intraperitoneal cisplatin and doxorubicin postoperatively, weekly over 10 weeks via the laparotomy-placed catheter. After reexploration to document disease status and to resect residual disease, patients were to receive 3,080 cGy to the abdomen and pelvis. Of the 10, 5 patients underwent surgical debulking and intraperitoneal chemotherapy but did not receive planned radiotherapy and 4 completed all three modalities of treatment. Three patients died of disease progression. The remaining 7 patients survived longer than 9 months; 4 had minimal or undetectable stable disease, and 3 had detectable intraabdominal disease.

Other investigators have combined hyperthermia to 42°C with the chemotherapy at the time of the cytoreduction.¹⁹⁸⁻²⁰⁰ As part of three consecutive Phase I trials conducted at the National Cancer Institute, 18 patients (13 had associated ascites) underwent tumor debulking followed by a 90-minute continuous hyperthermic peritoneal perfusion with cisplatin. Results showed symptomatic, multiply recurrent, benign, cystic peritoneal mesothelioma ($n = 1$), reperfusion due to recurrence after 6 months or more, a progression-free interval following continuous hyperthermic peritoneal perfusion ($n = 3$), superficial wound infections ($n = 2$), and atrial fibrillation, pancreatitis, fascial dehiscence, ileus, line sepsis, and *Clostridium difficile* colitis ($n = 1$ for each). No toxic deaths occurred. Renal toxicity occurred at cisplatin doses above the recommended Phase II dose. Postoperative resolution of ascites occurred in 9 of 10 patients. Three patients with recurrent ascites at 10, 22, and 27 months after initial treatment had resolution of their ascites with ongoing responses at 4, 6, and 24 months after reperfusion. The median progression-free survival was 26 months, and the overall 2-year survival was 80% at early follow-up.

In the series of Loggie,¹⁹⁸ 12 patients underwent exploratory laparotomy with cytoreduction followed by a 2-hour hyperthermic chemoperfusion using mitomycin C. One patient died 50 days postoperatively from complications relating to small bowel perforation. Hematologic toxicity of the procedure was minimal. Ascites was controlled in all patients and permanently in 86% of patients presenting with ascites. To date, median survival is 34.2 months with median follow-up of 45.2 months; however, long-term follow-up is lacking, and whether any of these patients had cystic mesothelioma must be determined. The Sugarbaker et al. series of 51 patients reports an encouraging median survival of 50 to 60 months using cytoreduction and heated chemotherapy with adriamycin and cisplatin followed by paclitaxel²⁰¹; however, further delineation of the histology of the patients is needed.

Malignant Mesothelioma of the Tunica Vaginalis Testis

Fewer than 100 cases of gonadal mesothelioma have been reported in the literature, and although most patients are 50 years of age or older, approximately 10% of the patients are younger than 25 years.²⁰² Asbestos exposure is documented in approximately one-half of the more recently reported cases.²⁰³ Patients generally present with a hydrocele or hernia. An accurate preoperative diagnosis has been reported in only two cases.²⁰⁴

All patients with a suspected testicular malignancy should undergo a radical or high inguinal orchiectomy. Local resection of the tumor or hydrocelectomy is associated with a high recurrence rate compared with high inguinal orchiectomy. Because preoperative diagnosis of gonadal mesothelioma is difficult, management should be as for any testicular tumor. The inguinal approach avoids interruption of the scrotal lymphatics, which would alter the metastatic pathway of the tumor, and also allows complete removal of the spermatic cord up to the internal ring. Patients with evidence of disease extending into the retroperitoneal nodes should undergo a retroperitoneal lymphadenectomy.

The overall recurrence rate (local and disseminated) for gonadal mesothelioma can be as high as 52%, with 38% of patients dying of disease progression.²⁰⁵ Local recurrence is seen in 36% of patients who undergo local resection of the hydrocele wall, 10% after scrotal orchiectomy, and 12% after inguinal orchiectomy.²⁰⁵ More than 60% of recurrences developed within the first 2 years of the follow-up. The overall median survival is 23 months. There are few data regarding the use of adjuvant therapy after resection of gonadal mesothelioma.

Malignant Mesothelioma of the Pericardium

A recent review of the primary pericardial mesothelioma has been published.²⁰⁶ It is a rare neoplasm with a reported incidence of 0.0022% in an autopsy series of 5,000,000 case studies²⁰⁷ and a calculated annual incidence of 1 in 40 million in a Canadian epidemiologic survey.²⁰⁸ An antemortem diagnosis was made in less than one-third of 150 reported cases in the literature. Pericardial mesotheliomas can occur at any age, but people in the fourth to seventh decades of life are most likely to be afflicted, and there is a 2:1 male to female ratio.^{209,210} Patients generally present with a pericardial effusion,²¹¹ congestive heart failure, an anterior mediastinal mass, or tamponade.²¹² Presentation is usually nonspecific, and chest radiography may demonstrate only an enlarged cardiac silhouette, making diagnosis difficult. Echocardiography can reveal evidence of an effusion, thickening of the pericardium, or mass involvement of the myocardium.²¹³ CT scanning or MRI can show a thickened pericardium and may help determine invasion into myocardium.^{214,215} Currently, surgical excision is the treatment for primary pericardial mesothelioma primarily to palliate symptoms of constriction or tamponade.

Mediastinum

Alexander S. Krupnick
and Joseph B. Shrager

Because tumors of the mediastinum make up only a small portion of thoracic oncology and the cases are relatively few, treatment-based outcomes of only a few mediastinal diseases processes have been evaluated by powerful level I data consisting of randomized, controlled trials.^{1,2} The majority of the data guiding treatment of mediastinal tumors, therefore, come from level II data.

Anatomy and Embryology

The mediastinum comprises an anatomic space located between the thoracic inlet and the diaphragm and bordered on the left and right sides by the pleural cavities. This central anatomic location houses or borders upon vital structures of almost every major organ system: the thymus of the immune system, the heart and great vessels of the circulatory system, the esophagus and major airways of the aerodigestive tract, and important nerves such as the phrenic and vagus. The oncologist or operating surgeon treating mediastinal disease must be familiar, therefore, with both the anatomic configuration and the pathophysiologic derangements that may occur in each of these systems.

By the fourth week of gestation, the intraembryonic coelom, or primordial body cavity, is separated into several body cavities that will ultimately form the boundaries of the mediastinum. These cavities are the pericardial cavity, the peritoneal cavity, and two pericardioperitoneal canals that connect the two cavities. Growth of the lung buds as well as mesenchymal tissue into the pericardioperitoneal canals further divides these cavities and creates the mesothelial lining, which will ultimately form the pleura and serve as the lateral borders of the mediastinum. The primitive mediastinum, consisting of solid mesenchymal tissue, becomes a true entity by the seventh week of gestation as the pericardioperitoneal membranes fuse with the mesoderm ventral to the esophagus. At approximately the same time, the primitive bilobed thymus, derived from the third pharyngeal pouch epithelium, descends into the mediastinum. By this time in gestation, all adult structures are present in the primitive mediastinum, but they begin to function only at different points in development or even at birth.³

Despite the complex developmental relationships between what are to become the mediastinal structures, postnatal anatomic divisions can be organized on the basis of simple radiographic anatomy. The most anatomically appropriate model for organization of the mediastinum is a modi-

fication of the three-compartment model as refined by Shields.⁴ According to this system, the mediastinum is divided into what are essentially anterior, middle, and posterior compartments based on the borders of anatomic structures as seen on a lateral radiograph (Figure 39.1). The anterior compartment that Shields terms the *prevascular zone* is bordered anteriorly by the sternum and posteriorly by the pericardium and the great vessels. It contains the thymus, variable amounts of fat and lymphatic tissue, and the internal mammary arteries and veins. The middle mediastinum (Shield's *visceral compartment*) extends from the anterior to the posterior pericardium and contains the heart, great vessels, trachea, main bronchi, and esophagus, along with all associated lymph nodes. It is bordered by the main segments of the phrenic nerves. The posterior mediastinum or *paravertebral sulci* is bounded anteriorly by the posterior pericardium and extends posteriorly to the chest wall. It contains the descending thoracic aorta, inferior vena cava, and sympathetic chain and is variably deemed to include the esophagus with associated vagi. One of the main advantages of this system is the ability it confers to generate a differential diagnosis for a mediastinal mass based on the structures naturally contained within the compartment in which it arises (Table 39.1). Such a classification thus allows the thoracic surgeon or oncologist to proceed systematically to the appropriate diagnostic or therapeutic approach depending on this differential diagnosis.

Signs and symptoms of mediastinal tumors can vary widely at presentation and usually offer only nonspecific clues to the nature of the underlying disease process. Although more than 60% of patients do present with symptoms, it is not uncommon for an asymptomatic mass to be detected on a routine screening examination.⁵ As a rule, two-thirds of all mediastinal masses are benign, and more than three-fourths of asymptomatic patients with mediastinal lesions have a benign lesion. The majority of patients who present with symptoms, however, have an underlying malignant process.⁵ The presenting symptoms vary widely based on anatomic location. Although anterior mediastinal masses can present with symptoms of anatomic impingement such as cough, chest pain, or dyspnea, the presence of systemic symptoms such as fevers and night sweats heightens the suspicion for lymphoma whereas new-onset myasthenic symptoms are suggestive of thymoma. Posterior mediastinal tumors, which are most commonly benign and neurogenic in nature, are usually asymptomatic at presentation.⁶

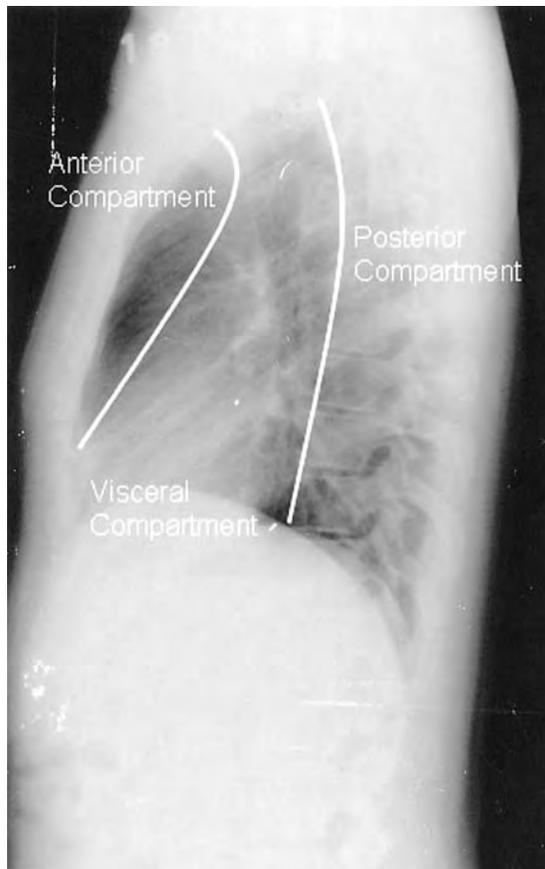

FIGURE 39.1. Traditionally, the mediastinum has been divided into anterior, middle, and posterior compartments based on the lateral radiograph.

Anterior Mediastinal Masses

Differential Diagnosis

Fifty percent of all mediastinal masses are located in the anterior mediastinum, and the majority of all malignant mediastinal lesions occur in this compartment.^{5,7} In descending order of frequency, the common malignant lesions here consist of thymic tumors, lymphoma, and germ cell tumors (see Table 39.1).

History and Physical Examination

After the initial chest radiograph, a history and physical examination focusing on factors that suggest one of these diagnoses is performed. Lymphomas and germ cell tumors should be high on the differential diagnosis in patients under 40 years of age. Symptoms such as fevers, night sweats, and weight loss can further enhance the suspicion for lymphoma. Lymphoma symptoms are classified as A, if there are no systemic symptoms, and as B, if fevers are above 38°C, drenching night sweats occur, and weight loss is greater than 10% body weight. The presence of remote, palpable lymphadenopathy also raises the likelihood of lymphoma and may simplify tissue diagnosis via superficial lymph node excisional biopsy.

Thymoma usually affects adults over 40 years of age.^{7,8} Nearly one-half of patients with thymoma suffer from one or more of the paraneoplastic symptoms associated with this disease.⁸⁻¹⁰ Myasthenia gravis is the most common such parathymic syndrome, and 30% to 50% of patients with thymoma concurrently have this disease. A careful history focusing on weakness and fatigability with repeated activity and a detailed neuromuscular examination may suggest this diagnosis and the diagnosis of thymoma.

Germ cell tumors account for only 1% to 4% of mediastinal tumors.¹¹ The majority of patients present with symptoms caused by the mass lesion of the anterior mediastinum, including chest pain, dyspnea, and cough. A small portion of patients presents with constitutional symptoms such as fever, night sweats, and malaise similar to patients with systemic lymphoma. Asymptomatic cervical lymphadenopathy has also been reported as the initial presenting sign of both lymphoma and malignant germ cell tumor.¹² Finally, germ cell tumors can rarely be associated with testicular masses in men, so a thorough testicular examination is important in this population.

Serum Studies

Serologic evaluation plays an important role in the diagnosis of mediastinal tumors and is the next step after history and physical examination. It is now widely accepted that the neuromuscular abnormalities of myasthenia gravis are caused by an antibody-mediated process, and 90% of patients with myasthenia have detectable serum levels of antibodies to the acetylcholine receptor (anti-AChR Ab), even if asymptomatic.¹³ Although serum titers do not necessarily correlate

TABLE 39.1. Normal anatomic and pathologic content of the mediastinum.

<i>Anterior mediastinum</i>	<i>Middle mediastinum</i>	<i>Posterior mediastinum</i>
Thymus	Heart	Sympathetic chain
Thyroid (if ectopic)	Ascending and transverse aortic arch	Esophagus
Parathyroid (if ectopic)	Superior and inferior vena cava	Descending aorta
Lymphatic tissue	Pulmonary arteries and veins	Inferior vena cava
Internal mammary artery and vein	Lymph nodes	
Thymic neoplasms	Pericardial cyst	Neurogenic tumor
Lymphoma	Bronchogenic cyst	Esophageal disease
Germ cell tumors	Enteric cyst	
	Metastatic cancer	

with the magnitude of the disease,¹⁴ the presence of such antibodies is diagnostic of the disease. Detectable anti-Achr Ab combined with radiographic features of thymic enlargement or a discrete thymic mass render the diagnosis of thymoma likely and allow the clinician to proceed directly to surgical therapy. As only 40% to 50% of thymomas are associated with myasthenia, however, the absence of detectable anti-Achr Ab does little to eliminate thymoma from the differential diagnosis of an anterior mediastinal mass.

Serum tumor markers play a critical role in the diagnosis, treatment, and follow-up of patients with mediastinal tumors. β -Human chorionic gonadotropin (β -HCG) and alpha fetoprotein (AFP) are two of the most common markers used in this diagnosis, and all patients with anterior mediastinal masses should undergo serum evaluation for these proteins. Alpha fetoprotein is synthesized by the fetal liver with structural and functional similarities to albumin, whereas β -HCG is normally produced by the placenta and most likely functions to maintain uterine integrity during pregnancy. In adults, both AFP and β -HCG levels remain exceptionally low except in pregnancy and certain disease states such as cirrhosis, hepatic and gastrointestinal cancers, and malignant germ cell tumors.

An elevation in AFP is diagnostic of a nonseminomatous component of a malignant germ cell tumor and is elevated in 80% to 90% of patients. β -HCG is also elevated in the majority of nonseminomatous germ cell tumors. Primary mediastinal seminoma, on the other hand, does not result in an elevation of AFP, but 10% of tumors may show a slight elevation (less than 100 ng/mL) of β -HCG.¹⁵ This small amount of protein does not originate within the seminomatous tumor itself but rather from the syncytiotrophoblasts scattered throughout the tumor. Thus, the presence of elevated AFP and β -HCG in patients with a known mediastinal mass is suggestive of a germ cell tumor, and pure AFP elevation is most likely the result of a mediastinal seminoma whereas a pure elevation of β -HCG makes the discrimination slightly more difficult. High levels of AFP and β -HCG (more than 600 ng/mL) are virtually diagnostic of a malignant nonseminomatous germ cell tumor. Although no definitive data exist, a large number of thoracic oncologists would initiate therapy for nonseminomatous germ cell tumor without tissue diagnosis in this scenario. In addition to the initial diagnostic value of these markers, they also play a critical role in assessing the response to therapy and detection of recurrence of malignant germ cell tumors. Benign germ cell tumors such as mature teratoma do not elaborate AFP or β -HCG.

Imaging

The plain chest radiogram provides only limited information necessary to tailor diagnostic options. It is therefore important to proceed to either computerized tomography (CT) or magnetic resonance imaging (MRI) for cross-sectional imaging.¹⁶⁻¹⁸ With few exceptions, CT can provide all the data necessary to either diagnose or select the appropriate further diagnostic workup for a mediastinal mass. The initial question that must be answered by cross-sectioning imaging is whether the mass truly arises from the mediastinum or may be involving the mediastinum secondarily from the contiguous lung, pleura, or chest wall. The lungs must be examined for pathology, as mediastinal lymphadenopathy secondary to

metastatic disease, most commonly from primary lung cancer, is more common than primary neoplasms of the mediastinum.¹⁹ A primary pulmonary malignancy itself, however, can be confused with a mediastinal mass if it arises adjacent to the mediastinal pleura. A mass with its broadest base in the mediastinum and a smooth edge, however, is usually mediastinal in origin. Masses with irregular or spiculated edges rarely arise in the mediastinum.¹⁶ If clinical suspicion is high for lymphoma, support for this diagnosis is often obtained by a CT showing lymphadenopathy within the chest that is remote from the main anterior mediastinal mass.

After determination that the mediastinal mass does not arise from a contiguous structure, the location within the three-compartment model is confirmed by CT. The mass is next evaluated for its major components—fat, calcium, and higher-density soft tissue—and it is classified as solid or cystic. Fat can be recognized due to its low Hounsfield units (70–130), whereas calcification is best seen in the unenhanced series of images. For the most part, the discovery that the mass has a large fatty component suggests that it is benign. A caudad, anterior mediastinal mass could represent omental fat in a foramen of Morgagni hernia, and mediastinal lipomatosis has been reported in Cushing's disease or steroid therapy.²⁰ Lipomas or liposarcomas can present in the mediastinum, but they are very rare, and fat may no longer be present in undifferentiated tumors.²¹

Most mediastinal masses in the adult consist primarily of nonfatty soft tissue. Spontaneous hyperattenuation, or a CT finding of tissue that is brighter than muscle on unenhanced CT, is uncommon. This finding usually restricts the differential diagnosis to intrathoracic thyroid goiters, which are bright as a result of the high iodine content, or fresh hematoma, reflecting the high hemoglobin content of fresh blood. Masses that strongly enhance with intravenous contrast are usually vascular tumors such as hemangiomas, thymic carcinoids, medullary cancers of the thyroid, or metastatic tumors. Such tumors, however, are rare, and most tumors of the thymus mimic the CT density of normal young thymus. The intensity is slightly lower than that of muscle because of the presence of some fat, and enhancement does increase with administration of contrast.

Noninvasive thymomas can appear as round or oval masses growing either within or adjacent to the thymus. These tumors can also present as diffuse enlargement of the thymus rather than as a discrete mass.^{17,21,22} An invasive thymoma may appear as an irregularly shaped mass growing to or through the pleural surface or invading adjacent great vessels. *Drop* metastases separate from the main mass, usually on the parietal or visceral pleural surface of the adjacent hemithorax, may be seen in 15% of the cases. Diagnostic criteria for aggressiveness of thymic tumors have classically been based on gross evidence of invasion at the time of surgical resection (see following section on Masaoka staging system, under Histology and Classification Systems). CT diagnosis of an aggressive thymoma or thymic carcinoma according to these traditional criteria must thus rely on the demonstration of direct invasion into adjacent structures or obliteration of peritumoral fat planes and direct apposition of tumor to mediastinal structures. However, caution should be exercised in both overdiagnosing and underdiagnosing aggressive behavior based on radiographic findings, as absence of cleavage planes is not a strictly reliable criteria of invasion.

The differentiation between noninvasive and invasive thymoma is a pathologic diagnosis. Although thymic carcinoma behaves more aggressively than thymoma and frequently invades the pleura or other mediastinal structures, distinguishing the two disease processes on CT scan is unreliable.^{23,24}

The CT features of malignant germ cell tumors are similar to those of other malignant tumors of the anterior mediastinum. As for thymic malignancies, invasion of adjacent structures is difficult to determine radiographically. The benign germ cell tumor, mature teratoma, contains a mixture of solid, fatty, and calcified components. Occasionally, diagnostic features such as the presence of fat–fluid level or spherical calcifications of dental material may render the diagnosis of benign teratoma nearly certain. None of these features, however, is entirely specific for benignity.^{25,26} These benign radiographic features, along with normal AFP and β -HCG, however, only very rarely turn up anything other than a benign teratoma.

Although MRI does offer some advantages over CT, including lack of iodinated intravenous contrast, multiplanar imaging, and excellent soft tissue and tissue–vessel contrast, in clinical practice MRI provides little beyond CT in the diagnosis and workup of mediastinal tumors.^{18,21} Compared with CT, MRI offers less spatial resolution and does not show calcification, both of which can be critical to the diagnostic workup of mediastinal masses. MRI characteristics of malignant mediastinal tumors such as thymoma and germ cell tumors are similar to skeletal muscle, with intermediate to low signal intensity on T_1 -weighted images and high signal intensity on T_2 -weighted images. The multiplanar imaging capability and high-contrast resolution of MRI may facilitate staging by demonstrating local invasion of a mediastinal tumor not apparent on CT, but the clinical value of this finding is still uncertain.²⁷ The finding of a fat–fluid level by MRI in a mediastinal mass has been reported to be diagnostic of teratoma, but these benign tumors possess classic CT characteristics as well, so MRI adds little to the diagnosis.²⁵ Similar limitations are encountered when imaging both mediastinal lymphomas and lymphadenopathy, as there is a significant overlap in both T_1 -weighted and T_2 -weighted images of benign and malignant lymphadenopathy.²⁸ It is more common for MRI to be used as a problem-solving study further evaluating abnormalities detected by CT, such as suspected great vessel or chest wall invasion, rather than as a primary imaging modality during the workup of an anterior mediastinal mass.

Positron emission tomography using the 2-deoxy-2-fluoro[^{18}F]-D-glucose analogue of glucose (FDG-PET) has a developing role in the diagnosis and staging of many malignancies.²⁹ Several groups have attempted to apply this imaging modality for a similar purpose to tumors of the mediastinum. Kubota and colleagues³⁰ performed both preoperative FDG-PET and CT scans on 22 patients with primary mediastinal tumors, and FDG-PET added little diagnostic information to the CT scan. Although biopsy-proven malignant lesions such as invasive thymoma and thymic carcinoma did show higher levels of FDG uptake than benign lesions, the relatively wide distribution of radioisotope uptake and the inability to differentiate lymphoma from primary thymic malignancy put the clinical utility of this imaging modality in question. Some benign inflammatory

masses such as mediastinal sarcoidosis demonstrated FDG uptake similar to malignant lesions, further hampering the diagnostic value of FDG-PET. Further evaluation of this imaging modality by other groups, including larger studies as well as case reports, reached nearly the same conclusions.^{31–33} The rapid advancement of this technology does hold future diagnostic potential, but its current role in diagnostic evaluation of a mediastinal mass is not established.

Diagnostic Biopsy Versus Resection

A preresectional tissue diagnosis is often not indicated in the management algorithm of anterior mediastinal masses. In a patient over 40 years of age, with negative tumor markers, absence of systemic *B* symptoms or remote lymphadenopathy, and a well-circumscribed anterior mediastinal mass, most surgeons would proceed with surgical resection for both diagnosis and cure. The presumed diagnosis for such a clinical scenario is thymoma, and resection without prior biopsy avoids violation of the capsule and potential seeding of surrounding tissues with thymic tumor cells that are known to have a propensity for local dissemination. Myasthenic symptoms or serum antiacetylcholine antibodies increase the suspicion of this diagnosis further.

This direct excisional approach is also recommended if the presumed diagnosis is benign, mature teratoma with typical appearance on imaging and normal serum AFP and β -HCG. Most oncologists would also be willing to initiate treatment with cisplatin-based multidrug chemotherapy for presumed malignant, nonseminomatous germ cell tumors based on extreme elevation of AFP and β -HCG and a typical CT appearance.

A perhaps equally large group of patients, however, requires tissue diagnosis before initiation of therapy. This group includes those in which lymphoma is the leading diagnosis, metastatic lung or esophageal cancer is thought to be a possibility, or a germ cell tumor is suspected but serum markers are not sufficiently high to be pathognomonic. Tissue diagnosis is also useful in cases of unresectable-appearing mediastinal tumors by imaging studies with negative serum tumor markers, as such a neoplasm could represent lymphoma, aggressive thymoma that might benefit from neoadjuvant treatment, or germ cell tumor. Tissue diagnosis is necessary in such a case because of the differing treatment of these tumors.

Techniques of Diagnostic Biopsy

A tissue diagnosis from an anterior mediastinal mass may be best obtained by either open surgical or percutaneous techniques, depending upon the circumstances.

PERCUTANEOUS NEEDLE BIOPSY

CT-guided percutaneous fine-needle biopsy or aspiration (FNA) represents the least invasive modality that may be used to diagnose a mediastinal mass. Several anatomic approaches have been used for CT-guided FNA. The transpulmonary approach requires that the needle transverse the lung as well as both the visceral and mediastinal pleura. The risk of pneumothorax with this technique is 11% to 19%.^{34,35} The parasternal, extrapleural approach has been reported as a

useful modality to sample a mediastinal mass and can be performed under either CT or ultrasound (US) guidance avoiding violation of the pleural space.^{35,36} Although this approach minimizes the risk of pneumothorax, the potential risk of accidental injury to the mammary vessels is high and has been reported to result in life-threatening hemorrhage.^{37,38} The transsternal approach for needle access to mediastinal masses has been described in several series with a low reported complication rate. Although this technique has been used to sample lesions in all areas of the mediastinum, it is most appropriate for anterior mediastinal masses, which are located in the prevascular space immediately beneath the sternum.³⁹ Aside from the transthoracic approach for biopsy, the recent introduction of endoscopic ultrasound (EUS) in the diagnosis and staging of esophageal cancer has resulted in numerous reports describing the success of transesophageal EUS-FNA in the diagnosis of mediastinal masses.⁴⁰ Other studies report similar success rates of FNA in the diagnosis and treatment stratification of mediastinal masses.

Not all investigators, however, have had equally positive experience with FNA in the evaluation of mediastinal masses, and its appropriate application remains controversial. In a series from the Memorial Sloan-Kettering Cancer Center, 48 patients with operatively proven thymoma were evaluated by a preoperative biopsy: 26 patients underwent an open biopsy and 22 an FNA. The FNA diagnosis was accurate in only 59% of patients compared with an 81% accuracy by open biopsy. This issue is even more controversial due to reports describing the shedding of tumor cells into the mediastinum after capsule violation by preoperative biopsy.^{41,42} Based on such reports, it is currently our policy to proceed with surgical excision in good surgical candidates in whom thymoma is thought to be the likely diagnosis, without a preoperative biopsy, either percutaneous or open.

The role of FNA in the clinical management of presumed mediastinal lymphoma is even more unclear. While FNA combined with immediate cytologic analysis may sometimes provide a rapid and cost-effective diagnosis, cytology alone plays only a small role in the initial diagnosis of mediastinal lymphoma. As stratification and proper clinical treatment usually involves subtyping lymphoma by flow cytometry and architectural pattern, FNA can rarely provide enough tissue for this entire workup. A large multiinstitutional study evaluated the role of FNA in the diagnosis and management of anterior mediastinal masses; over half the lymphomas identified by FNA required more tissue for further subclassification and confirmation of the diagnosis. A portion of the lymphomas were also misclassified as thymoma or metastatic melanoma based on FNA diagnosis.⁴³ As such mistakes can have disastrous consequences in proper patient management, it is rare in our practice to base the diagnosis and therapy of mediastinal lymphoma on FNA, and we most often perform a chamberlain procedure (anterior mediastinotomy; see following) in patients with anterior mediastinal masses thought to be most suspicious for lymphoma. FNA may, on the other hand, be appropriate as the sole diagnostic modality in identifying a relapse of mediastinal lymphoma when surgical tissue is available from the initial diagnosis to confirm FNA-based cytology.

Lymphoblastic lymphoma may represent the sole exception to the otherwise limited role of FNA in the initial diagnosis of lymphomas. This tumor has a characteristic

TABLE 39.2. Representative studies evaluating fine-needle aspiration (FNA) in diagnosis of mediastinal masses.

Representative sample of studies reporting success of FNA in the diagnosis of a mediastinal mass	vanSonnenberg et al. ¹⁷⁵ Morrissey et al. ¹⁷⁶ Catalano et al. ⁴⁰ Wakely et al. ⁴⁴
Representative sample of studies reporting failure or misdiagnosis of FNA for mediastinal masses	Gossot et al. ⁴⁸ Blumberg et al. ⁴¹ Powers et al. ⁴³

cytologic appearance and lacks the architectural organization and extracellular fibrosis common to other mediastinal lymphomas. As this high-grade malignancy can present with rapidly progressing obstructive symptoms in the anterior mediastinum, the rapidity of FNA with immediate cytologic analysis can allow earlier initiation of therapy. Some small series have documented the success of FNA as the sole diagnostic modality for initiation of treatment for lymphoblastic lymphoma.⁴⁴

Core needle biopsy or aspiration using a large 14- or 18-gauge needle may overcome some of the limitations of percutaneous biopsy for lymphoma by providing a larger volume of tissue with preserved architectural integrity for diagnosis. While large studies evaluating the value to core needle biopsy in patients with systemic lymphoma report a high rate of success in diagnosis, these results do not necessarily apply to isolated mediastinal lymphoma.^{45,46} Because of the large size of the needle and high risk of pneumothorax, the transpulmonary approach is rarely chosen.^{34,47} The direct mediastinal parasternal approach is favored for core needle biopsy but is limited by the potential damage to and bleeding from the mammary vessels.^{37,38} Based on these inherent difficulties, only limited data are available regarding the success of this diagnostic modality for mediastinal lymphoma (Table 39.2).

VIDEO-ASSISTED THORACOSCOPIC BIOPSY

Video-assisted thoracoscopy (VATS) can be a cumbersome means for accessing the mediastinum and is potentially associated with a higher morbidity than other methods of mediastinal sampling.⁴⁸ Most importantly, there is a real concern that biopsy of a thymoma, in particular, is not prudent from this approach given the propensity of loose thymic cells to seed the pleural space even in cases in which transpleural biopsy has not been done.

CHAMBERLAIN PROCEDURE

Anterior mediastinotomy, also known as the Chamberlain procedure, is in our opinion the optimal approach to the biopsy of most anterior mediastinal masses for which biopsy is indicated. This procedure is carried out through a 5-cm transverse skin incision made directly over the second costal cartilage.

MEDIASTINOSCOPY

Cervical mediastinoscopy in trained hands is a safe procedure, but as originally described and most widely applied, it allows access to the middle mediastinum and not the anterior mediastinum.

EXTENDED MEDIASTINOSCOPY

The *extended* cervical mediastinoscopy allows for full staging of these areas through a single cervical incision by creating a tunnel to the aorticopulmonary window between the origins of the innominate and carotid arteries.⁴⁹ This technique requires considerable experience and carries a significant risk of bleeding due to the proximity to the great vessels. Few are trained in its use.

TRANSCERVICAL, STERNUM-LIFTING APPROACH

A final approach to the anterior mediastinum that can be of use in certain circumstances is the transcervical, sternum-lifting approach that is used for transcervical thymectomy. Cooper described a device that, by lifting the sternum, allows an extended transcervical thymectomy to be performed with excellent visualization of the entire anterior mediastinum.⁵⁰ This technique has been adopted by the authors' group to biopsy of a wide variety of anterior mediastinal masses.⁵¹

Thymoma

A variety of tumors can arise from the thymus, but thymoma, derived from the thymic epithelial cells, is the most common neoplasm. Interest in thymomas developed secondarily to early investigations into autoimmune disease. Several independent investigators in the late 19th and early 20th centuries described the association of myasthenia gravis with thymic neoplasms.⁵² Based on this evidence, Blalock pioneered the use of thymectomy as a therapy.^{53,54} Advances in the use of positive-pressure ventilation increased the acceptability of thymectomy.⁵⁵ A major barrier to the diagnosis and treatment of thymic neoplasms throughout the 1900s was the lack of a standardized system for subclassification of these tumors. In 1999 the World Health Organization recognized this problem and developed a standardized system of nomenclature derived from the cellular origin of thymic neoplasms⁵⁶ (Table 39.3).

TABLE 39.3. Classification of thymic tumors.

Epithelial tumors: thymoma, thymic carcinoma
Neuroendocrine tumors: carcinoid, small cell carcinoma, large cell neuroendocrine carcinoma
Germ cell tumors
Lymphomas
Stromal tumors: thymolipoma, thymoliposarcoma, solitary fibrous tumor
Tumor like lesions: thymic hyperplasia, lymphoid hyperplasia, thymic cyst
Neck tumors of thymic or related branchial pouch derivation: ectopic hamartomatous thymoma, ectopic cervical thymoma, spindle epithelial tumor with thymus-like differentiation, carcinoma showing thymus-like differentiation
Metastatic tumors
Unclassified tumors

Histology and Classification Systems

Histologically, a thymoma is composed of a mixture of thymic epithelial cells with bland, benign-appearing histologic features as well as lymphocytes. Unlike other solid tumors that contain mature lymphocytes derived from the peripheral immune system, the majority of lymphocytes in a thymoma are immature and can be found in various stages of development, thus mirroring lymphocytes found in the normal thymus. Despite this histologic appearance, it has become accepted that the neoplastic cell of origin is the thymic epithelial cell and not the lymphocyte⁵⁷ (Figure 39.2A,B).

Determining the aggressive potential of a thymoma is of critical importance for proper therapy, because early-stage "noninvasive" tumors are associated with an excellent prognosis after surgical resection alone, whereas "malignant" tumors may benefit from neoadjuvant and/or adjuvant

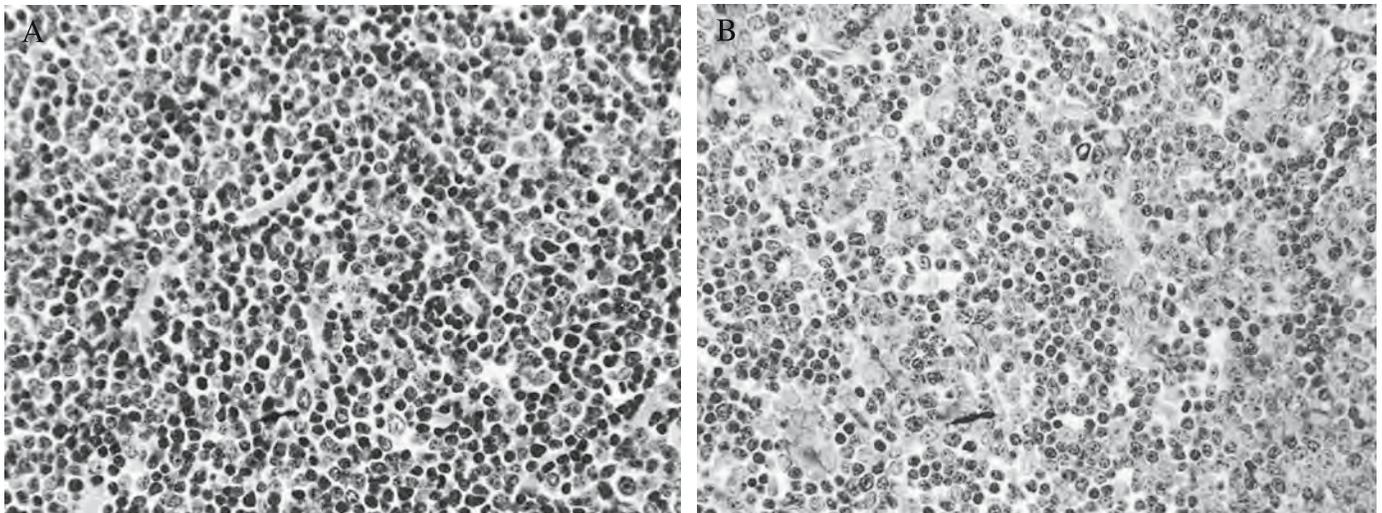

FIGURE 39.2. (A) Histologically thymoma is composed of various combinations of thymic epithelial cells and immature lymphocytes. (B) Immunohistochemical staining for cytokeratin can be used to dif-

ferentiate lymphocytes from thymic epithelial cells. [Courtesy of Dr. Leslie A. Litzky, Department of Pathology, Hospital of the University of Pennsylvania.]

TABLE 39.4. Clinical staging of thymoma according to Masaoka et al.⁶¹

Stage I	Macroscopically completely encapsulated and microscopically no capsular invasion
Stage II	Macroscopic invasion into surrounding fatty tissue or mediastinal pleura, or microscopic invasion into the capsule
Stage III	Macroscopic invasion into neighboring organ, i.e., pericardium, great vessels, or lung
Stage IVa	Pleural or pericardial dissemination
Stage IVb	Lymphogenous or hematogenous metastasis

therapy. A 1961 paper from the Mayo Clinic proposed a histologic grading system classifying thymoma based on the lymphocyte to epithelial cell ratio⁵⁸: lymphocytic, mixed, epithelial, and spindle. Predominantly epithelial cell tumors were considered more aggressive and carried a worse prognosis.^{8,59} Not all investigations, however, supported this view.⁶⁰

In 1981 Masaoka and colleagues, recognizing the difficulty of pure histologic criteria for stratification, developed clinical staging criteria.⁶¹ After excluding other tumors of thymic origin, they staged epithelial thymomas based on their local invasiveness. Stage 1 tumors were completely encapsulated without gross or microscopic capsular invasion, stage 2 tumors showed microscopic invasion into the capsule or macroscopic invasion into surrounding fat or mediastinal pleura, stage 3 tumors showed gross local invasion into neighboring organs, and stage 4 tumors had evidence of pleural, pericardial or hematogenous dissemination (Table 39.4). The clinical stage both was prognostic⁶² and allowed stratification for adjuvant therapy. A difficulty with this system is that staging is based on findings at surgical resection, thus preventing its use for triage to neoadjuvant therapies (Figures 39.3, 39.4).

Histologic classification of thymoma was revisited in 1985 by Marino and Müller-Hermelink.⁶³ who proposed a

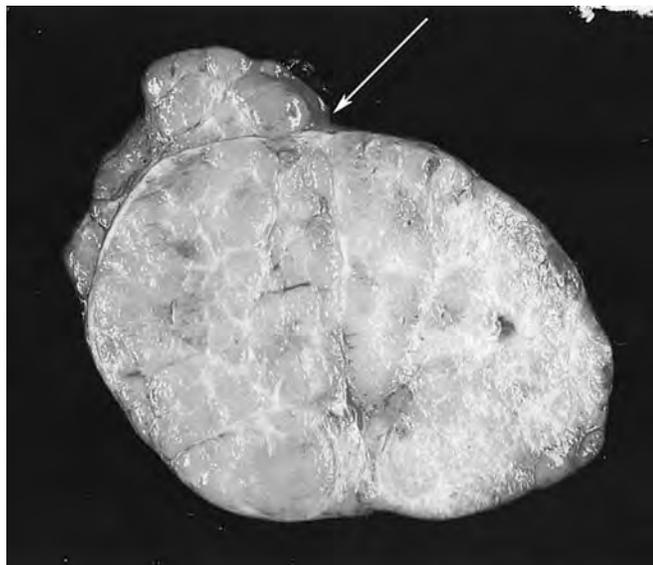

FIGURE 39.3. Stage 2 thymoma showing gross invasion past the thymic capsule (*arrow*). (Courtesy of Dr. Leslie A. Litzky, Department of Pathology, Hospital of the University of Pennsylvania.)

novel classification system dividing thymomas into different categories based on the histologic appearance of the neoplastic epithelial cells. Tumors composed of large, round, or polygonal epithelial cells were classified as cortical thymomas due to similarity of such cells to normal cortical epithelium. Medullary thymomas, on the other hand, contain smaller, spindle-shaped epithelial cells with irregular nuclei. All thymomas could thus be classified as cortical, medullary, or mixed histology. Subsequent studies indeed found that the Marino and Müller-Hermelink histologic classification reliably predicts tumor behavior and prognosis. In a large series, Pescarmona and colleagues⁶⁰ found that this histologic classification could be used to predict prognosis, with cortical thymomas exhibiting a more-malignant behavior. Of the 80 patients studied, those with medullary thymomas had essentially benign disease while patients with cortical thymomas showed evidence of invasive and malignant disease. Later studies found that both the Masaoka staging and the Müller-Hermelink grading classifications are strong and independent prognostic indicators of both overall and disease-free survival.^{62,64,65} It has now become accepted that the Müller-Hermelink classification used in combination with the Masaoka staging system provides perhaps the most accurate prognostic information for recurrence. The recently adopted World Health Organization classification system represents an effort to combine the Masaoka and Müller-Hermelink criteria⁵⁶ (see Table 39.3).

Presentation and Evaluation

Thymomas typically occur in adults over 40 years of age and are uncommon in children. They are slow-growing tumors with little propensity for hematogenous metastasis and are usually discovered incidentally on an imaging modality obtained for another purpose. Those patients who are symptomatic, with more-aggressive tumors, can present with symptoms of local obstruction or invasion, such as chest pain, cough, or even superior vena cava syndrome, or the symptoms of one of the autoimmune-related paraneoplastic syndromes associated with thymoma (Table 39.5). A standard chest radiograph is typically the initial diagnostic study, and it usually reveals an anterior mediastinal mass. Cross-sectional imaging

TABLE 39.5. Symptoms caused by or associated with thymoma.

Compressive/obstructive symptoms: cough, dysphagia, superior vena cava syndrome
Neuromuscular disorders: myasthenia gravis, myotonic dystrophy, Eaton-Lambert syndrome, myositis
Collagen vascular autoimmune disorders: rheumatoid arthritis, lupus, polymyositis
Hematologic disorders: red cell aplasia, megakaryocytopenia, pancytopenia

such as the CT scan is the best study following the chest radiography. There are no pathognomonic imaging features identifying thymoma from other mediastinal solid tumors, but the diagnosis may be strongly suggested by CT. Although it can be difficult to be certain preoperatively that one is dealing with a thymoma (see previous sections on Differential Diagnosis), ideally a noninvasive thymoma is resected directly, without preoperative biopsy (see previous section on Diagnostic Biopsy Versus Resection).

Neoadjuvant and Surgical Therapy

Although no prospective randomized trials exist, numerous groups have evaluated neoadjuvant and multimodality therapy for invasive or locally metastatic thymoma.⁶⁶⁻⁶⁸ The overwhelming majority of the studies have supported the effectiveness of this approach. Neoadjuvant therapy for unresectable tumors was used initially in the early 1990s. Several groups demonstrated the efficacy of combining cisplatin-based preoperative chemotherapy with or without radiation therapy in downstaging unresectable tumors. All 23 patients in two of these early studies demonstrated a response, and complete resection was possible in 8 patients who had been considered unresectable before treatment. Those with an incomplete resection received additional postoperative therapy. Median survival was longer than that of historical control series without neoadjuvant treatment.^{67,69} Several larger studies performed in the late 1990s confirmed these results.^{70,71} Recent data suggest that chemotherapy alone might be as effective as radiation as a neoadjuvant agent. Delaying radiation until the postoperative period eliminates the concerns that some raise about operating in a radiated field. One study showed that preoperative chemotherapy alone with cisplatin, doxorubicin, prednisone, and cyclophosphamide for stage III and IV tumors, followed by resection and adjuvant therapy, can result in 100% survival after 3.5 years.⁷² Stratification of patients with aggressive tumors to neoadjuvant therapy based on the Muller-Hermelink grade combined with the Masaoka staging system resulted in a similar increase in survival versus historical controls.⁶⁶

Despite the impressive results with neoadjuvant chemotherapy and radiation therapy, surgical resection remains the cornerstone therapy for thymoma. The accepted approach to the surgical management of thymoma has been complete resection of the mass along with all thymic tissue and the en bloc resection of adjacent structures involved by tumor. These structures most commonly include portions of lung and/or the great vessels (which, other than the innomi-

nate vein, require reconstruction if resected). This approach has been supported by several large studies showing that complete resection of all tumor is the most important prognostic factor for survival, even more important than Masaoka staging.⁷³ Simple tumor debulking, even when followed by radiation therapy, provides no survival advantage over biopsy alone.⁷⁴

Approach through a median sternotomy provides the broadest and most generally accepted access for resection of thymoma. It is generally accepted that sacrifice of one phrenic nerve can be performed in a patient with otherwise adequate pulmonary function if this maneuver will result in a complete resection. Certainly, both phrenic nerves cannot be resected, and even one should not be divided if one would still be unable to achieve complete resection.

Surgical management of vascular structures involved by tumor is also controversial.^{75,76} It is the authors' policy to resect and reconstruct involved vascular structures if this results in a complete resection.

Maximal exposure via median sternotomy for resection of thymoma is currently considered the standard of care, but a more minimally invasive approach for resection of suspected thymoma has been reported, including the transcervical approach.^{51,77,78} The use of minimally invasive techniques such as video thoracoscopy for resection of thymoma has also been described,⁷⁹⁻⁸¹ but in our opinion this approach is less likely to provide a *clean* resection.

Adjuvant Radiation

Because thymomas are sensitive to radiation, radiation has become widely accepted for unresectable stage III and IV tumors. Several small retrospective studies suggest that survival of patients with either unresectable or residual invasive thymoma after attempted surgical resection may be improved by postoperative radiation therapy.^{82,83} One study even noted that survival of stage III patients who underwent a complete resection without irradiation was identical to those who underwent incomplete resection with postoperative radiation therapy.⁵⁹ This finding, however, is controversial.⁷⁴

Although the benefits of postoperative radiation in unresectable or residual stage III-IV thymoma have been accepted, the role of postoperative radiation therapy in stage II disease, which is highly likely to have been completely resected at surgery, is still debated. Survival is no higher in those who receive postoperative radiation, and radiation also did not influence disease-free survival. Local recurrence is as prevalent in patients who receive radiation as in those who did not.^{84,85} Based on these data, we recommend that patients with completely resected stage II thymomas may be safely followed by serial radiographic examination and do not warrant postoperative radiation therapy. The role of adjuvant radiation for completely resected stage III disease, although generally accepted, is also supported by only some of the data available.

Similar to data for noninvasive and stage II disease, complete resection of invasive thymoma is the most important prognostic factor affecting survival, and postoperative radiation played no role in recurrence or survival if complete surgical resection was obtainable.⁷³ However, Curran and colleagues found a 38% local recurrence rate in patients who did not receive adjuvant radiation versus 0% for those who

did.⁸⁶ The differences between these and other studies are difficult to understand; nevertheless, most clinicians continue to “recommend postoperative radiotherapy” for invasive disease, even after complete resection.⁷³

Adjuvant Chemotherapy

Similar to preoperative neoadjuvant therapy, postoperative chemotherapy has been shown to improve survival in both retrospective and prospective studies. In a large retrospective series of patients across several French cancer centers, Cowen and colleagues reviewed the impact of platinum-based postoperative chemotherapy on survival. Multivariate analysis revealed that postoperative chemotherapy was one of the factors influencing disease-free survival. This finding was most pronounced in patients with stage III and IV disease who presented with symptoms of mediastinal compression.⁸⁷

The European Organization for Research and Treatment of Cancer Lung Cancer Cooperative group reported a prospective phase II trial of cisplatin- and etoposide-based chemotherapy for recurrent or metastatic malignant thymoma.⁸⁸ Although the trial was small and consisted of only 16 patients, the authors were able to document complete remission in 5 patients, a partial remission in 4, and no progression of disease in any of the patients while on treatment. The median survival time increased over historical controls with survival rates of 69%, 50%, and 42% at 3, 5, and 7 years, respectively. Other prospective studies support these conclusions and have shown that adjuvant chemotherapy can extend progression-free survival for patients with recurrent or unresectable disease, especially if combined with radiation therapy.⁸⁹ Based on these data, postresection adjuvant therapy is now considered the standard treatment for recurrent or unresectable disease.

Reresection

The overwhelming evidence supporting the role of complete surgical resection for curative treatment of thymoma has brought the issue of reresection for recurrent disease to the forefront. In the same study mentioned previously, Regnard and colleagues found a survival benefit for reresection of recurrent tumor. Similar to primary disease, complete reresection offered a survival advantage over incomplete reresection (53% versus 11% at 10-year survival).⁷³ Other slightly larger studies support this conclusion.^{41,84}

Prognosis

Venuta and colleagues evaluated the survival benefit of aggressive multimodality therapy.⁶⁶ These authors retrospectively evaluated 83 patients who underwent surgical resection for thymoma between 1965 and 1988, before the advent of multimodality treatment beyond surgery. Starting in 1989, all patients with newly diagnosed thymoma were preoperative stratified as having benign, invasive, and malignant disease. This stratification was based on the Masaoka staging protocols as well as biopsy-proven histology, with cortical thymomas considered more aggressive. Patients with benign disease underwent radical resection only, those with invasive disease received adjuvant chemotherapy and radiotherapy, even in cases of complete resection, and those with malignant disease received both neoadjuvant as well as postoperative cisplatin-based adjuvant chemotherapy and radiation. All patients were able to complete the multimodality treatment, and only 1 patient with stage IV thymoma had a delayed recovery because of myelosuppression. Long-term survival of patients treated by multimodality therapy after 1989 improved significantly over those in the pre-1989 era who were treated by surgery alone (Figure 39.5A,B). Improvement

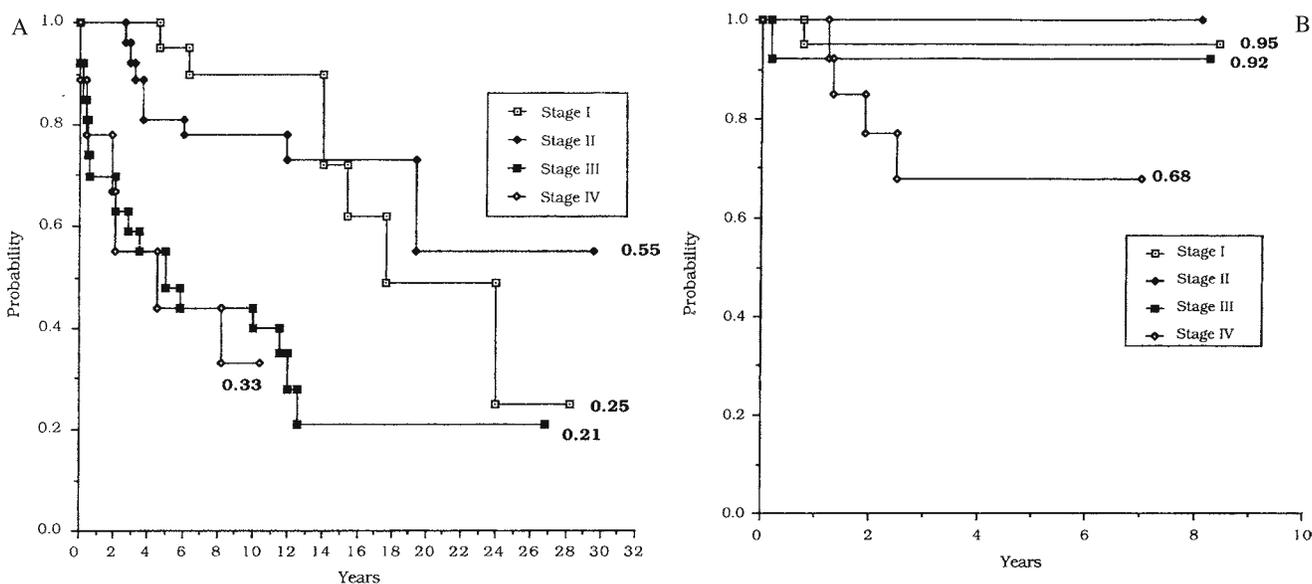

FIGURE 39.5. When grouped by Masaoka staging protocols, patients with thymoma have had an improvement in survival after the introduction of multimodality therapy: (A) patients operated on before 1989 and the introduction of multimodality therapy; (B) patients operated on after 1989. These differences were especially

prevalent for advanced disease and survival of stage III patients after the introduction of multimodality therapy approximates that of stage I and II before 1989. (From Venuta et al.,⁶⁶ by permission of *Annals of Thoracic Surgery*.)

was seen across all stages of disease but was especially pronounced for invasive disease. Survival of patients with stage III disease after multimodality therapy approached that of stages I and II in the earlier series. Further improvements in chemotherapy and radiation therapy offer the possibility of increasing survival still further.

Thymic Carcinoma

Thymic carcinoma is a highly aggressive neoplasm of thymic epithelial origin, with less than 50% of patients surviving 5 years after diagnosis.⁹⁰⁻⁹² These tumors account for only a small portion of thymic neoplasms, estimated as 20% of epithelial malignancies. The true incidence is difficult to determine as only recently have these tumors become recognized as a separate entity from aggressive thymoma, and several studies have reported treatment outcomes for thymic carcinoma along with thymoma.^{62,89} Histologically, thymic carcinomas are distinct from thymomas because of malignant cytologic features such as anaplasia, nuclear and cellular atypia, and a high number of mitosis. Whether thymic carcinoma arises from malignant degeneration of benign thymoma or is a separate entity is still undetermined. The reported finding of concomitant thymoma within specimens of thymic carcinoma as well as thymic carcinoma developing in patients with a past medical history of thymoma favors the malignant degeneration hypothesis. The possibility of a common cause for both disease processes, however, cannot be excluded.^{90,91} Unlike the classic thymoma, the infiltrating leukocytes of thymic carcinoma are usually mature.

The majority of patients with thymic carcinoma present with symptoms of local invasion or compression such as cough, chest pain, or superior vena cava syndrome.^{90,93} Traditionally, it has been thought that concomitant paraneoplastic syndromes favor the diagnosis of thymoma over thymic carcinoma, but the data supporting this are thin, only a few patients in two studies, and controversial.^{90,94}

Staging of thymic carcinoma has traditionally relied on the Masaoka staging system, similar to thymoma. The validity of this system for predicting survival in thymic carcinoma and thus establishing therapeutic options, however, has never been validated. Because thymic carcinomas, unlike thymomas, not infrequently metastasize by hematogenous as well as lymphatic routes, the use of the TNM staging system may be more appropriate.⁹⁵ In a large series, Suster and Rosai proposed a morphologic grading system for thymic carcinoma that could be used to predict clinical behavior. They discovered that patients with thymic carcinoma could be subdivided into two distinct clinical groups. Eighty-five percent of patients in group one, with aggressive tumors with high-grade histology, died of their disease, whereas all patients in group two, with low-grade histology, survived (Table 39.6). Other histologic markers such as the number of mitotic counts per high power field, lobular growth pattern, and circumscribed versus infiltrating morphology were also predictive of survival.⁹⁰ Such histologic grading criteria along with staging could be reliably used to triage patients into various treatment options.

Due to the rarity of this disease, most therapy has been based on the experience with treatment of thymoma. Thus, resection of both local and extensive disease, if possible, has

TABLE 39.6. Histologic classification of thymic carcinoma.

been the guiding principle. Ogawa and colleagues determined that complete resection was a significant prognostic factor for survival on multivariate analysis.⁹⁶ Seventy-five percent of patients treated by complete resection versus 4% of those with incomplete resection were alive at follow-up. Surgical resection is currently proposed as the primary therapy for thymic carcinoma. However, the role of complete surgical resection, especially with sacrifice of vital structures, is not as strong as that for thymoma.^{93,97,98}

Due to the aggressive nature of this tumor, more than half of patients may present with locally advanced, potentially unresectable disease.⁹⁰ The utility of both radiation and chemotherapy for neoadjuvant and adjuvant therapy has been addressed in several small studies, but standardization of treatment has been difficult to achieve because of the rarity of the disease. Yano and colleagues reported a series of patients, the majority of whom had unresectable disease, treated with both chemotherapy as well as radiation.⁹⁹ The role of chemotherapy was limited, but radiation resulted in a high response rate (seven of eight patients) and a prolonged survival over previous series. Other investigators report a similar improvement in survival in patients who received radiation therapy after complete or partial surgical resection compared to those who did not.^{97,100} Using multivariate analysis, several investigators found that the routine use of chemotherapy with or without surgical resection or radiation therapy had no impact on survival.^{94,96} Although both these groups report a relatively large number of patients, the variety of chemotherapeutic regimens used as well as combination of chemotherapy with surgery and radiation in some patients makes it difficult to reach definitive conclusions from these series alone. The reported success of multimodality therapy in the treatment of thymoma and the reported sensitivity of thymic carcinoma to radiation make it difficult to justify chemotherapy alone as the sole modality for the treatment of thymic carcinoma. One small series published in 1993 did evaluate the impact of chemotherapy alone on progression of disease after biopsy or incomplete resection of thymic carcinoma.¹⁰¹ The authors' findings were similar to those for thymoma; patients treated with the single agent of cisplatin showed a poor response whereas those treated with a multiagent regimen in addition to cisplatin demonstrated partial and even some complete responses.

The role of aggressive multimodality therapy in the treatment of thymic carcinoma has been evaluated by several groups. Lucchi and colleagues reported a series of seven patients with biopsy-proven thymic carcinoma who took part in multimodality treatment consisting of cisplatin-based multiagent neoadjuvant chemotherapy followed by surgical resection after hematologic recovery and postoperative radiation therapy to the tumor bed.¹⁰² All seven patients reported showed at least a partial response to chemotherapy, and complete surgical resection was possible in four patients. Those

with complete resection received 45 Gy to the mediastinum while those with incomplete resection received 60 Gy to the mediastinum and residual tumor areas. During the follow up period, ranging from 16 to 136 months, one patient died of metastatic disease, one patient died in a motor vehicle accident without evidence of disease at autopsy, three patients are disease free, and two patients are alive but with recurrent tumor. Both the patients with recurrence as well as the patient who died of metastatic tumor had high-grade lymphoepithelioma-like tumor. Other slightly larger retrospective series have found a similar survival advantage to multimodality treatment of neoadjuvant chemotherapy, surgical resection, and postoperative radiotherapy.^{94,96,103} Although it is unlikely that much larger series or prospective, randomized trials will be possible in the treatment of thymic carcinoma due to the rarity of this disease, these small series have made it possible to identify therapeutic regimens that can offer maximal benefit.

Other Thymic Neoplasms

Thymic carcinoid is a rare neoplasm of the thymus that has a strong association with multiple endocrine neoplasia type I^{104,105} (see Chapter 55). Unlike other carcinoids, they rarely present with carcinoid syndrome but can secrete ectopic adrenocorticotrophic hormone (ACTH), leading to Cushing's syndrome. This tumor is more frequently found in men and can present either with endocrinopathy or with a mass effect such as cough, chest pain, or superior vena cava (SVC) syndrome.¹⁰⁶ The majority of thymic carcinoids are locally invasive at presentation, and close to half of all patients have metastatic disease on presentation.¹⁰⁷

Surgery has been considered the cornerstone of therapy. As most tumors are locally invasive on presentation, complete resection is often impossible. Despite this, several small series suggest that complete resection does offer a survival advantage and propose aggressive therapy of complete resection followed by adjuvant chemotherapy and radiation therapy and resection of recurrent and metastatic disease.^{108,109} Because of the aggressive nature of this disease, radiation therapy is almost always administered, either as primary therapy for unresectable disease or even after complete resection. Numerous authors have reported good control and amelioration of paraneoplastic symptoms.¹¹⁰⁻¹¹³ Chemotherapy has been based on experience with carcinoids of the intestine; however, no standardized regimen has been established. Despite these efforts, prognosis of thymic carcinoids is overall poor, with few long-term survivors and median survival of 2 to 5 years after diagnosis.^{108,109}

Thymolipoma is a benign tumor of the thymus that consists of mature fat intermixed with normal thymic epithelium.¹¹⁴ These can reach a relatively large size, and tumors occupying the whole mediastinum and one hemithorax have been reported.¹¹⁵ Although a large number of patients are diagnosed with this tumor incidentally by an unrelated imaging study, they can present with obstructive symptoms such as shortness of breath and cough.¹¹⁴ Surgical resection is curative, and even asymptomatic thymolipoma should be resected as they can grow in size and result in obstructive symptoms.

Thymic hyperplasia is a benign condition describing a histologically normal thymus that is enlarged for the patient's

age. This condition can present as a spectrum of disease ranging from respiratory compromise to an incidental finding on an unrelated imaging study. This condition has most frequently been described as a rebound thymic hyperplasia after chronic illness or stress-related atrophy of the gland.^{116,117} The main diagnostic dilemma for the chest physician is to differentiate benign thymic hyperplasia from malignant disease.

Germ Cell Tumors

Mediastinal germ cell tumors include benign and malignant teratoma and malignant seminomatous and nonseminomatous tumors. They are a heterogeneous group of neoplasms resulting from malignant change in primordial germ cells.¹¹⁵ Collectively, they account for approximately 20% of all anterior mediastinal tumors, and this location is the most common extragonadal site for germ cell malignancies. Their origin in sites heterotopic to the gonads may result from aberrant migration of germ cells during embryonic development or as a part of normal embryogenesis.^{118,119} Based on the need for standard classification, investigators from the Armed Forces Institute of Pathology developed a reproducible histologic system of classification based on review of more than 300 cases. They concurrently proposed a clinical staging system that could help in planning therapy and defining prognosis¹²⁰ (Table 39.7).

Teratomatous Tumors

Teratomas are defined by the presence of tissue from more than one of the three primitive germinal layers.¹²¹ They are the most common of the mediastinal germ cell tumors.¹²² Mature (benign) teratomas are composed of well-differentiated mature elements such as mesodermally derived fat and cartilage, endodermal intestinal tissue, and ectodermal hair and skin with occasional formation of well-developed teeth. Immature (malignant) teratomas consist of mature elements derived from one or two embryonic layers combined with immature fetal tissue composing the remaining layer. Ter-

FIGURE 39.6. A benign cystic teratoma can be identified by the presence of a variety of tissues in an anterior mediastinal mass such as soft tissue, fluid, and calcium. (Courtesy of Dr. Wallace Miller, Department of Radiology, Hospital of the University of Pennsylvania.)

atomas may also be mixed tumors with additional malignant components derived from other germ cell tumors or nongerml cell epithelial or mesenchymal components (see Table 39.7).

Most mature teratomas are asymptomatic on presentation but may in a minority of patients present with symptoms resulting from impingement on mediastinal structures. In one of the larger series reported to date, some patients presented with nonspecific symptoms such as chest, back, or shoulder pain as well as cough and dyspnea.¹²³ Infection of a cystic component of a teratoma may result in signs of systemic infection, and erosion into the airway may lead to trichoptysis, the expectoration of hair and oily secretions, a presentation that is pathognomonic of a ruptured mediastinal teratoma.^{7,124}

Radiographic characteristics of mature teratomas have been described previously in this chapter. Chest CT provides a firm diagnosis with identifying characteristics such as the combination of calcium, fat, and fluid in a soft tissue mass in the anterior mediastinum¹²⁵ (Figure 39.6). Serum tumor markers are not elevated unless a concurrent nonseminomatous component is present.

The accepted treatment for benign mediastinal teratoma is complete surgical excision, which is curative for the disease. Radiation and chemotherapy play no therapeutic role unless concurrent malignant disease is present.^{15,123}

Seminoma

Unlike teratomas, which are equally distributed in men and women, malignant germ cell tumors, both seminomas and nonseminomatous tumors, are almost exclusively diseases of men. Seminoma is the most common malignant mediastinal germ cell tumor of single histology and usually presents in relatively young men during the third to fourth decade of life.^{15,123,126} Most patients are symptomatic on presentation, with chest pain and dyspnea present in 40% to 50% and as many as one-third of all patients showing evidence of superior vena cava obstruction.¹²³ More than 60% of patients have

metastatic disease on presentation, with intrathoracic organs being the most common site of metastasis. Widely metastatic disease to bone, brain, liver, and lymph nodes mimicking lymphoma is not uncommon.¹² As with other mediastinal masses, a chest radiograph and chest CT scan are the initial imaging studies of choice. As most seminomas reach a relatively large size before presentation, they can usually be seen on chest radiography. On CT scanning these tumors have the appearance of a bulky homogeneous anterior mediastinal mass that may obscure tissue planes or invade adjacent structures.¹²⁷ Calcification may rarely be seen in the mass, and the tumor is often surrounded by bulky lymphadenopathy. Serum tumor markers can be positive for low levels of β -HCG in about 10% of patients. Elevation of AFP is never evident in pure seminoma and indicates a nonseminomatous tumor component. Although a staging system has been proposed by some authors, it has been difficult to establish a reliable system for staging and predicting prognosis due to the rarity of this disease.^{121,128} A biopsy is usually necessary to define the diagnosis. Although it has been proposed that the diagnosis of mediastinal seminoma necessitates abdominal CT scan and testicular imaging to rule out metastatic disease from an occult gonadal primary tumor,¹⁵ one of the largest series detailing the clinical course of 120 patients with mediastinal seminoma found no evidence that mediastinal seminoma was a part of metastatic gonadal primary.¹²⁶

This tumor is highly sensitive to both radiation and chemotherapy, and successful outcomes have been achieved with both regimens. Similar to primary testicular seminoma, mediastinal seminoma responds to cisplatin-based therapy, and because most patients present with metastatic disease, chemotherapy should be considered first-line treatment. Successful therapeutic regimens reported in the literature consist of cisplatin, dactinomycin, cyclophosphamide, bleomycin and vinblastine, or cisplatin and etoposide, with an 88% remission rate and a 85% long-term survival with chemotherapy alone.¹²⁹ Most recent reports are even more encouraging and describe 100% long-term survival after cisplatin-based chemotherapy¹³⁰ (Table 39.8).

The addition of radiation therapy for locoregional control can increase the response rate even further, with 100% 5-year actuarial survival reported in one study.¹³¹ Radiation therapy alone has also been reported as a successful modality for treating patients with local mediastinal disease without extrathoracic metastasis. This approach led to a 75% 5-year rate of survival.¹⁵ The role of surgical resection in this disease is controversial. Some authors have suggested resection as primary therapy for small mediastinal seminomas,¹³² and others have proposed resection for residual masses larger than 3 cm after chemotherapy.^{133,134} None of these series showed a survival or local control advantage over radiation or salvage chemotherapy, and we do not favor surgical intervention for mediastinal seminoma.

Nonseminomatous Germ Cell Tumors

The group of malignant, nonseminomatous germ cell tumors consists of embryonal cell carcinoma, yolk cell tumor, choriocarcinoma, and mixed germ cell tumors. Some have classified teratomas with a malignant, immature component within this category as well (see Table 39.7). These tumors are rare and represent only 1% to 2% of all germ cell tumors

TABLE 39.8. Representative survival of patients with mediastinal seminoma based on therapy.

<i>Author</i>	<i>No. of patients reported</i>	<i>Primary form of therapy</i>	<i>Survival</i>
Sterchi et al. ¹⁷⁷	105	Radiation	58% at 5 years
Polansky et al. ¹⁷⁸	107	Radiation	75% at 5 years
Takeda et al. ¹²³	13	Multimodality therapy	83% survival ranging from 8 months to 19 years posttreatment
Bokemeyer et al. ¹⁴⁵	51	Chemotherapy alone, 74% of patients Radiotherapy alone, 9% of patients Chemo and radiation, 17%	88% at 5 years
Gholam et al. ¹³⁰	12	Chemotherapy only	100% at 7 years

in men,¹³⁵ with a particularly high incidence in men with Klinefelter's syndrome.¹³⁶ A primary mediastinal location of nonseminomatous germ cell tumors is considered by the International Germ Cell Collaborative Group (IGCCG) to be an independent adverse prognostic risk factor separate from tumor markers or sites of metastasis. In general, these tumors carry a worse prognosis and are more resistant to therapy than their histologic counterparts elsewhere in the body¹³⁷. Nonseminomatous malignant germ cell tumors, especially those with yolk-sac histology, are also associated with a variety of hematologic malignancies, which occur independently of the chemotherapy used to treat the tumor.¹³⁸ Similar to seminoma, the majority of patients have metastatic disease on presentation and are symptomatic due to tumor burden.¹² Reported symptoms range from chest pain, the most common, to dyspnea, hoarseness, and superior vena cava syndrome.^{123,139} Similar to seminoma, common metastatic sites include lung, liver, and regional lymph nodes.

Imaging studies typically reveal a large, irregular anterior mediastinal mass with poorly defined margins and multiple areas of central necrosis and hemorrhage.¹²⁷ In contrast to seminoma, more than 90% of patients with a nonseminomatous germ cell tumor have an elevation of either β -HCG or AFP^{15,140,141} (Figure 39.7). Although no definitive data exist,

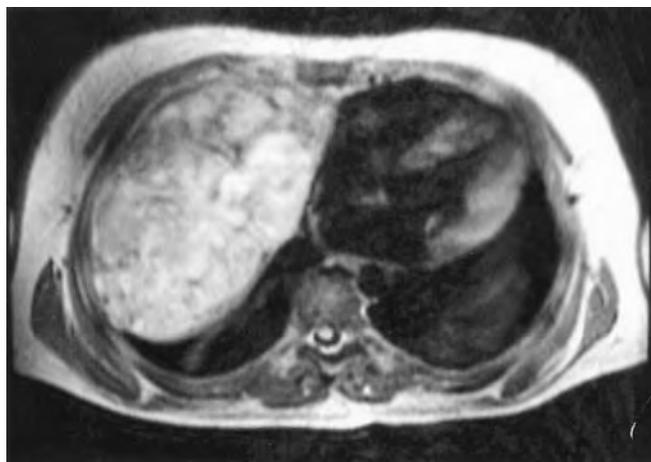

FIGURE 39.7. Magnetic resonance imaging (MRI) of embryonal carcinoma reveals a large heterogeneous mass displacing the mediastinum and replacing a large portion of the right pleural cavity. (Courtesy of Dr. Wallace Miller, Department of Radiology, Hospital of the University of Pennsylvania.)

the finding that AFP is elevated only in nonseminomatous germ cell tumors has motivated some oncologists to initiate therapy based on imaging studies and serology alone, without a tissue diagnosis.

Because most patients present with extremely bulky or metastatic disease, surgical resection is not the usual first-line treatment. Radiation therapy alone has also been unsuccessful for management of nonseminomatous germ cell tumors.¹³¹ Historically, patients diagnosed with nonseminomatous germ cell tumors had an exceptionally poor median survival of 4.0 months after diagnosis¹⁴¹; this has improved dramatically with the advent of cisplatin-based multiagent chemotherapy. One of the earlier series from Indiana University reported the results of aggressive multimodality cisplatin-, etoposide-, and bleomycin-based chemotherapy combined with salvage chemotherapy for initial failures as well as surgical resection for postchemotherapy radiographic residual masses.¹⁴² Of the 31 patients enrolled in the study, 18 (58%) obtained disease-free status after therapy, with 3 recurrences of the malignant germ cell tumors and 15 long-term disease-free survivors. These results represented a significant improvement from the 18% disease-free survival reported in the early 1980s.¹⁴¹ A follow-up series from the same Indiana University group reported an even higher 61% survival with a broader variety of multimodality therapy, including autologous peripheral stem cell transplantation after high-dose chemotherapy.¹⁴³ Similar results have been replicated by others.¹²

Current attempts to improve survival in nonseminomatous germ cell tumors (NSGCT) have involved high-dose chemotherapy combined with autologous peripheral blood stem cell transplantation. One recently published prospective trial from Germany reported the results of high-dose cisplatin, etoposide, and ifosfamide chemotherapy followed by autologous peripheral blood stem cell transplantation and granulocyte colony-stimulating factor (G-CSF) support.¹⁴⁴ Nineteen of the 28 (68%) patients enrolled obtained disease-free status after three or four cycles of therapy, with 1 patient succumbing to a relapse of nonseminomatous germ cell tumor. Two patients died of concurrent hematologic malignancies. Overall progression-free survival rates were reported as 64% at 2 years and 56% at 5 years, which compare favorably with the 46% and 42% progression-free survival rates reported with standard cisplatin-based therapy from 1979 to 1996 by the International Extragenital Germ Cell Tumor Study Group.^{145,146}

TABLE 39.9. Survival of patients with mediastinal nonseminomatous germ cell tumors based on therapy.

<i>Author</i>	<i>No. of patients</i>	<i>Therapy</i>	<i>Survival</i>
Kersh et al. ¹³¹	14	Radiation	8.8% at 5 years
Kesler et al. ¹⁴³	91	Chemotherapy and surgical resection	61% at 4 years
Bokemeyer et al. ¹⁴⁴	28	High-dose chemotherapy and autologous peripheral blood stem cell transplantation	68% at 2 years

Although surgery plays at most a diagnostic role in the initial management of NSGCT, it is a critical component of treatment after completion of chemotherapy. The M.D. Anderson Cancer Center recently reported a series of 20 patients who underwent surgical resection after completion of chemotherapy.¹² Eleven patients received no additional treatment beyond initial chemotherapy and 9 others received salvage chemotherapy after failure of the initial regimen. Of the 11 patients in the initial treatment only group, 9 survived the course of chemotherapy and all patients normalized levels of serum tumor markers after completion of chemotherapy. One patient demonstrated a complete radiographic response and did not undergo an operation, whereas 8 patients had evidence of residual mediastinal mass and underwent surgical resection. Of the 9 patients in the salvage group, there were 5 deaths during chemotherapy and 4 patients survived the course of treatment. One patient in this group had both a serologic and radiographic response and did not undergo mediastinal exploration. Three patients in the salvage group underwent surgical resection for residual mediastinal mass. Of all 11 resected tumors, 3 demonstrated complete tumor necrosis, 1 showed necrosis with mature teratoma, 3 showed mature teratoma only, and 2 showed near-complete necrosis and small microscopic rests of viable tumor. Two patients in this series had grossly viable tumor despite chemotherapy. One of these patients was the only patient in the series who had persistently elevated tumor markers after chemotherapy and succumbed to recurrent tumor, whereas the other patient with residual disease developed acute leukemia and died before restarting postresection salvage chemotherapy. At 2-year follow-up, the survival of patients treated by this aggressive multimodality therapy was 72%, with 9 of 11 patients surviving without evidence of disease. These results are the highest rates ever reported for mediastinal NSGCT. Survival of the "salvage group," or patients who had failed an initial course of chemotherapy at another institution before treatment at M.D. Anderson Cancer Center, was worse, with 4 of 9 patients (39%) alive 2 years after the initiation of treatment; 1 patient is alive with disease and 3 are free of disease.

Although this study supports previous series suggesting that resection should be undertaken in patients who have postchemotherapy residual mediastinal masses with tumor marker normalization,^{135,147} the role of surgery in the face of persistently elevated tumor markers is more controversial. Some favor salvage chemotherapy in patients with persistently elevated tumor markers and a residual mediastinal mass, but others have presented data supporting the idea that survival may be improved by postchemotherapy resection of residual masses. A retrospective 17-year review of 91 patients

treated at Indiana University showed that surgical resection after initial chemotherapy could lead to tumor marker normalization and improve survival in a subgroup of patients.¹⁴³ This finding combined with the overall poor long-term survival of patients requiring salvage chemotherapy has increased the acceptance of surgical resection for residual mediastinal NSGCT despite elevation of tumor markers (Table 39.9). Larger series will be necessary to convincingly demonstrate the efficacy of this form of treatment.

Middle Mediastinum

Although the middle mediastinum contains numerous vital structures of the aerodigestive tract, lymphoma and benign mediastinal cysts remain the most common primary middle mediastinal masses. Because the middle mediastinal lymph nodes are a frequent site of metastasis from bronchogenic carcinoma, however, metastatic carcinoma is probably the most common cause for middle mediastinal masses overall.

The diagnosis and treatment of lymphoma in the middle mediastinum does not differ from disease located primarily in the anterior mediastinum other than the fact that the diagnosis is typically made by mediastinoscopy rather than Chamberlain procedure (mediastinotomy). Congenital foregut cysts are the most common middle mediastinal cysts and represent benign, aberrant development of foregut structures. They almost never undergo malignant degeneration, but familiarity with these entities is important to distinguish them from malignant tumors of the mediastinum. Bronchogenic cysts recapitulate the structure of the tracheobronchial tree and can contain all histologic structures found in the normal airway such as respiratory epithelium, cartilage, and bronchial glands.^{148,149} Enterogenous cysts recapitulate alimentary tract structures of the foregut, although they may contain gastric mucosa or pancreatic tissue. Because many of these patients eventually develop symptoms of obstruction or cyst infection, resection of these structures is generally recommended on discovery¹⁵⁰ (Figure 39.8). Minimally invasive techniques that allow resection of these cysts with little morbidity have made resection all the more attractive.¹⁵¹ However, it is certainly reasonable to follow a simple, thin-walled, asymptomatic cyst that has all the radiologic characteristics of a benign process.

Pericardial cysts represent aberrant fusion of the anterior pericardial recess and can be located attached to the diaphragm or the pericardium. These are usually unilocular cysts filled with clear fluid, with no malignant potential, and they are resected only if symptomatic or if the diagnosis is in doubt.^{150,152}

FIGURE 39.8. Large foregut duplication cyst (*arrow*) can present with signs and symptoms of dysphagia as well as airway obstruction as a result of impingement on the aerodigestive tract. (Courtesy of Dr. Wallace Miller, Department of Radiology, Hospital of the University of Pennsylvania.)

Posterior Mediastinum

Neurogenic tumors are the most common posterior mediastinal masses. Collectively, they represent approximately 14% of all mediastinal masses in the adult.⁵ The overwhelming majority of these tumors are benign, and most patients are asymptomatic. These neoplasms are generally grouped into three categories based on the neurogenic tissue of origin. Tumors arising from the nerve sheath include schwannoma, neurofibroma, and malignant nerve sheath tumor. They are the most common neurogenic tumors in the adult. Sympathetic ganglion tumors include ganglioneuroma, ganglioneuroblastoma, and neuroblastoma. Parasympathetic ganglion tumors such as chemodectoma and pheochromocytoma have been reported to occur in the posterior mediastinum but are exceedingly rare in that location.

Esophageal duplication cysts and bronchogenic cysts also occur with some frequency in the posterior mediastinum. The approach to their management is as described previously for simple middle mediastinal cysts, but the surgical approach often involves thoracoscopic resection.

Schwannoma and neurofibroma are the most common mediastinal neurogenic tumors.¹⁵³ These are benign and slow-growing tumors. They appear as well-marginated, encapsulated masses, most commonly in the costovertebral sulci. Both tumors behave in a benign manner and most patients are asymptomatic on presentation, although symptoms of plexopathy, neurologic symptoms from the involved intercostals nerve(s) or intraspinal extension, or airway irritation are not unusual.^{150,154,155} More than one-third of patients with neurofibromas have von Recklinghausen's disease or neurofibromatosis. These patients usually have with multiple neurofibromas and tend to present at an earlier age.^{150,156} The definitive treatment of these tumors is surgical resection, although as for benign-appearing cysts, observation is not unreasonable in some patients due to the slow growth and low malignant potential. Some of the larger series have shown

that complete resection by a thoracotomy can be achieved in more than 90% of the patients, and of those with complete resection, only 5% present with local recurrence.¹⁵⁴ Thoracoscopic resection of such tumors has also been reported with favorable results,^{157,158} and this is now commonly performed. Combined thoracic and neurosurgical resection of dumbbell tumors with intraspinal extension can also be achieved with low morbidity.¹⁵⁹

The malignant version of the nerve sheath tumor, neurofibrosarcoma, is a rare malignancy arising most likely from malignant degeneration of neurofibroma.¹⁶⁰ Although it is a rare malignancy in the population as a whole, this cancer can affect as many as 29% of patients with neurofibromatosis.¹⁶¹ Unlike benign tumors, most of these malignancies are symptomatic, with pain and symptoms of nerve impingement being common at presentation.¹⁶⁰ On CT these tumors typically present as rounded masses with areas of central hemorrhage and necrosis.¹⁵⁰ Radical surgical excision is the procedure of choice. However, 5-year survival is as low as 16% in patients with neurofibromatosis, with no survival benefit derived from adjuvant therapy.^{160,162}

Sympathetic ganglion tumors represent malignant degeneration of the nerve cell, rather than the nerve sheath. These tumors tend to occur in the sympathetic ganglia and adrenal gland and probably represent a spectrum of the same tumor, with ganglioneuroma representing the most benign version of the disease. Ganglioneuromas are the most common of the thoracic sympathetic chain tumors and are composed of well-differentiated ganglion cells.¹⁶³ Most patients are asymptomatic at presentation, but symptoms related to secretory activity of catecholamines has been reported.¹⁶⁴ Complete resection is the definitive and highly successful treatment.¹⁶⁵ Ganglioneuroblastoma is a tumor that is histologically composed of ganglioneuroma-like elements as well as neuroblastoma-like features. The degree of malignant behavior is generally related to the degree of neuroblastic differentiation. Overall, these tumors have a high 5-year survival after resection.¹⁶⁶

Neuroblastoma represents the most malignant of the sympathetic ganglion tumors. This disease is almost exclusively limited to children, and 90% of the cases are reported in children less than 5 years of age.¹⁶⁷ The majority of the patients are symptomatic on presentation, and distant metastases are common. Symptoms may include chest pain, dyspnea, myelopathy from spinal canal involvement, and symptoms related to excess catecholamine production.¹⁶⁸ The International Neuroblastoma Staging System, reflecting factors such as the primary tumor size, lymph node involvement, and extent of unresectable disease, can be used to predict survival.¹⁶⁹ Amplification of the oncogene, *N-myc*, has also been shown to correlate with poor prognosis.¹⁶⁷

Localized neuroblastoma, both abdominal and thoracic, has a favorable 89% to 96% survival rate with surgery alone.^{170,171} Survival can be improved in patients with residual disease after resection and in those with positive lymph node involvement by combining chemotherapy and radiation therapy.¹⁷² Traditionally, thoracic neuroblastoma has been considered a positive prognostic factor, less likely to have *N-myc* amplification or DNA ploidy, and thus conferring a better survival rate.¹⁷³ More recent studies, however, have shown that patients with early-stage thoracic and abdominal neuroblastomas have a similar survival.¹⁷⁴

Esophageal Cancer

John D. Urschel

Esophageal cancer is a notoriously difficult cancer to treat. Locoregional therapies, such as surgery and radiotherapy, are hampered by the anatomic proximity of the esophagus to vital structures, its rich and multidirectional lymphatic plexus, and, typically, by the late stage of symptomatic disease. Currently available systemic therapies, such as chemotherapy, are effective but they leave much to be desired. Chemotherapy's effectiveness, perhaps surprisingly, relates in large measure to its synergism with radiotherapy at the locoregional level. All the major treatment modalities are hampered by the typical patient's inability to easily tolerate aggressive therapy, but this is especially so for surgical therapy. One only has to contrast the rigors of esophagectomy, especially after chemoradiation, with the tolerability of breast cancer surgery or right hemicolectomy, to see this point. Taking these factors together, esophageal cancer remains one of the most difficult cancers for an oncologist of any discipline to treat and one of the most difficult malignant illnesses that a patient can face. Sadly, it is also a cancer that is rapidly increasing in incidence, at least in the Western world.

Despite the gloomy introductory remarks to this chapter, there is some reason for optimism. Progress, albeit modest, has been made in the past several decades.¹ The stage-specific effectiveness of the major therapies—surgery, radiotherapy, and chemotherapy—has improved markedly. This change relates, in part, to real progress in each field, but better patient selection and stage migration have also played a role. Population-based statistics from several countries now show 5-year survivals in excess of 10%, instead of the consistently single-digit figures from previous eras.² Although these data largely confirm that true progress has been made, a cynic might still take exception. The disease itself has changed, at least in the Western world, and the new disease, with its predilection for the distal esophagus, is in some ways easier to treat.

Not all improvements in oncology can be measured with endpoints such as 5-year survival. Progress in the areas of imaging and staging has been particularly striking, and patients have benefited greatly from these advances. Many have been spared the exploratory operations and incomplete "palliative" resections that were so common in the past. Advances have also been made in the palliation of malignant symptoms, especially dysphagia. Endoscopic techniques have replaced surgical interventions for dysphagia, and the endoscopic methods themselves have become less morbid. Although these advances cannot be captured in survival data,

they are nevertheless very important. Progress in esophageal cancer treatment has been made, and practitioners should be excited and hopeful about the future.

This chapter is not a uniform overview of all aspects of esophageal cancer. Following the theme of this textbook, emphasis is placed on subject areas that have been studied by randomized controlled trials. The randomized controlled trials, in aggregate, provide the evidence upon which we base our clinical practices. The chapter also emphasizes the questions in clinical practice that are characterized by hard choice constraints, where we must decide between two alternatives (for example, primary surgery versus definitive chemoradiation), as opposed to soft choice constraints, where we decide if an additional intervention may be valuable [for example, computed tomography (CT) scanning versus CT and positron emission tomography (PET)]. This is not to say that soft constraints, which involve issues of cost, feasibility, and efficiency, are not important; they are. For clinicians (and by extension, patients), however, it is the choice between mutually exclusive treatment options that weigh most heavily on the mind. Finally, the chapter seeks to clarify topics that are prone to confusion, such as those relating to surgery, while avoiding duplication of topics covered elsewhere in the textbook, such as diagnostic imaging.

Problems of Data Aggregation

One of the purposes of this textbook is to help clinicians make sense of the huge body of published data on any given malignancy. In the process of aggregating data we, by necessity, ignore certain types of information in each original data source or, stated differently, we abstract the critical information from the less-important detail. It is easy to lose sight of the simplifying assumptions that we make during data aggregation, and this is especially the case for the esophageal cancer literature. The major problems in aggregating esophageal cancer data that distinguish this subject of study from others in this textbook are the following: (i) different histologies, that is, squamous carcinoma and adenocarcinoma; (ii) different classification and staging schemes for adenocarcinomas involving the esophagogastric junction; and (iii) East versus West dichotomy.^{3,4}

Squamous carcinomas and adenocarcinomas are arguably very similar in their very general features of lethality and response to treatment. However, even if this is assumed to be the case, the two histologies diverge in other important ways.

The typical patient suffering from squamous cancer of the esophagus differs from one with adenocarcinoma and poses different treatment challenges. The profile of the former includes a history of smoking and consuming alcohol, poor nutrition, a tumor in proximity to the tracheobronchial tree, involvement of lymphatics adjacent to the recurrent laryngeal nerves, difficult surgical resections that usually require a thoracotomy approach, radial resection margins that are commonly positive, and a propensity to postoperative pulmonary complications. In contrast, a typical patient suffering from adenocarcinoma is often a heavy-set nonsmoker, with a more readily resectable distal esophageal tumor (often not requiring a thoracotomy), but with lymphatic involvement of both the mediastinal and abdominal lymphatics. These generalizations, as simplistic as they are, should be kept in mind as we review aggregated patient data.

Turning to the second issue, adenocarcinomas that involve the esophagogastric junction present a major problem for the classification and staging of foregut cancers and the interpretation of published literature. These adenocarcinomas of the esophagogastric junction, or AEGs, frustrate our attempts to develop valid treatment concepts in both esophageal and gastric disease sites. Controversy abounds as how to best classify these tumors. Are they all variants of the same malignant condition, or are they very different? That question has bearing on their classification. Siewert's classification organizes tumors that involve the esophagogastric junction into three types.⁵ AEG I tumors arise in the distal esophagus from malignant transformation of Barrett's esophagus (which in turn is caused by gastroesophageal reflux), and extend to the esophagogastric junction. They are primarily esophageal tumors and should be treated as such. The surgical therapy is esophagectomy. AEG type III tumors arise in the proximal stomach and extend upward into the junction. They share a common etiology with other gastric tumors (*Helicobacter pylori* infection and nutritional risk factors) and should be treated as gastric tumors. The surgical therapy is total gastrectomy and abdominal lymph node dissection. AEG type II tumors, or true tumors of the cardia, arise at the esophagogastric junction. Their origin is hotly debated, and their optimal treatment is unclear. Siewert makes a case for treating these tumors as gastric cancers, with the surgical treatment being total gastrectomy and limited resection of the distal esophagus. Others favor operations that place the cancer at the epicenter of the resection (esophagogastrectomy).

Readers may be forgiven for thinking that the AEG classification is primarily of interest to surgeons, but they will nevertheless be mistaken. Two virtually identical AEG tumors may be classified, staged, treated, and reported in completely different fashions, depending on the point of view of the treating physicians. This practice causes tremendous confusion in the data aggregation process. For example, one center might classify an AEG tumor as an esophageal cancer, treat with chemoradiation followed by transhiatal or transthoracic total esophagectomy (based on a published randomized controlled trial), stage involved celiac nodes as stage IVA–M_{1a} (distant lymph nodes; Table 40.1) disease, and report the results accordingly. Another center may classify the same AEG tumor as a gastric cancer, proceed with staging laparoscopy followed by total gastrectomy and D2 lymph node dissection, give postoperative chemoradiation

TABLE 40.1. Definition of TNM and stage grouping for esophageal carcinoma.

<i>Primary tumor (T)</i>			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma in situ		
T1	Tumor invades lamina propria or submucosa		
T2	Tumor invades muscularis propria		
T3	Tumor invades adventitia		
T4	Tumor invades adjacent structures		
<i>Regional lymph nodes (N)</i>			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Regional lymph node metastasis		
<i>Distant metastasis (M)</i>			
MX	Distant metastasis cannot be assessed		
M0	No distant metastasis		
M1	Distant metastasis		
<i>Stage grouping</i>			
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage IIA	T2	N0	M0
	T3	N0	M0
Stage IIB	T1	N1	M0
	T2	N1	M0
Stage III	T3	N1	M0
	T4	Any N	M0
Stage IV	Any T	Any N	M1
Stage IVA	Any T	Any N	M1a
Stage IVB	Any T	Any N	M1b

(based on a published randomized controlled trial), stage the involved celiac axis nodes according to the total number of involved nodes (versus location), assign a final stage that is much more favorable than stage IV, and report the results accordingly. Both centers, arguably, have proceeded correctly. This problem frustrates rational attempts at data aggregation.

The third problem, East–West dichotomy, at first glance seems a redundant restatement of the differential histology problem. Admittedly, that is partly the case. Its importance, however, relates to the assessment of trials across time. The East–West dichotomy shows a widening trend, so as more trials are done it will be increasingly difficult to justify the inclusion of both East and West experience in a single meta-analysis or review.⁴

Epidemiology and Screening

At one time esophageal cancer was considered a single disease, squamous cancer, with its incidence varying across the world in accordance with known risk factors.⁶ Risk

factors for squamous cancer include smoking, alcohol consumption, nutritional deficiencies, and low socioeconomic status. In the United States, poor black males were commonly affected. Since the 1970s adenocarcinoma of the esophagus has increased in incidence in the West while the incidence of squamous cancer has decreased.⁷ Adenocarcinoma is now the dominant form of esophageal cancer in the West whereas squamous cancer continues to dominate in the East. Risk factors for adenocarcinoma of the esophagus include gastroesophageal reflux, obesity, and, to a lesser extent, cigarette smoking. Almost all esophageal adenocarcinomas arise in specialized intestinal metaplastic epithelium (Barrett's esophagus) and pass through a metaplasia–dysplasia–cancer sequence.⁸ Barrett's esophagus, in turn, is caused by chronic reflux. Although obesity and reflux affect males and females almost equally, adenocarcinoma typically affects males (white males). Our understanding of this disease is obviously incomplete.

Preventive strategies for squamous cancer include avoidance of smoking and excess alcohol consumption and eating a balanced diet that includes fresh vegetables. The decline in squamous cancer incidence in the West is probably (at least in part) the result of these types of behavioral change. Prevention of adenocarcinoma is more controversial. Few would take exception with recommendations to avoid obesity and cigarette smoking (although cigarette smoking is much less important in the etiology of adenocarcinoma than it is in squamous cancer). Dealing with reflux, however, is problematic. Symptoms can be controlled with medications, but the underlying reflux of harmful, usually alkaline, gastroduodenal material continues. Some have suggested a role for antireflux surgery to eliminate reflux and thereby reduce the risk of adenocarcinoma. Large-scale population-based antireflux surgery programs, while perhaps a dream in certain surgical circles, are simply not practical or warranted. Importantly, antireflux surgery has not been proven to reduce the risk of adenocarcinoma, and the surgery itself is not innocuous.^{9,10} Other areas of preventive interest include the role of *H. pylori* infection, or rather the lack thereof, and the possible protective effect of cyclooxygenase 2 (COX-2) inhibitors. There is some suggestion that *H. pylori* infection, although central to the genesis of gastric cancer, may somehow protect against esophageal adenocarcinoma. This, however, is far from clear. Interest in COX-2 inhibitors follows from their use as chemopreventive agents in other gastrointestinal sites, notably the colon.

Clinicians are very aware that the prospective for cure is greatest among patients whose esophageal cancer is detected by screening, either formal or ad hoc. However, that does not mean that screening for esophageal cancer is effective as a population-level health strategy.¹¹ The issues are not simple, as this textbook's two chapters on screening make clear. Salient problems (in the West) include the uncertainty of diagnosis of high-grade dysplasia, inability to predict progression from dysplasia to invasive cancer, and the operative mortality of esophagectomy. Readers familiar with the (apparent) success of cervical cancer screening programs should ask themselves what might have happened if cone biopsies were not really reliable and hysterectomy carried an operable mortality of 15% in nonspecialized centers. Finally, clinicians embarking on the screening of elderly or frail patients might

want to reconsider. The unfortunate combination of postesophagectomy death and a "negative" pathology report is not unknown.

Staging and Patient Assessment

Advances in the staging of esophageal cancer have greatly influenced the contemporary management of this disease.^{1,12} Many of these advances belong to the field of diagnostic imaging, and readers are referred to the chapters on thoracic and gastrointestinal imaging for detailed treatment of these subjects. The benefits of accurate staging are difficult to overstate. Once common, but futile, surgical interventions are now less frequent than in previous eras. The modern staging exercise can be stratified into three salient questions: (i) is metastatic disease present? (ii) if not, what is the precise locoregional stage? and (iii) how fit is the patient for aggressive treatments, especially surgery?

The first question is best answered with a combination of CT scanning and PET scanning. PET scanning identifies metastatic disease in approximately 20% of patients who appear to be free of metastases on other imaging studies.¹³ This accuracy in the detection of metastatic disease, along with PET's promising role in assessing response to treatment, makes PET scanning a major advance in esophageal cancer management.¹⁴ Once metastatic disease is confirmed, further detailed staging investigations are generally not needed.

Precise locoregional staging is best accomplished with endoscopic ultrasonography (EUS) and, to a lesser extent, multislice CT scanning. EUS provides the most accurate assessment of T stage, with its accuracy being especially sharp (near 90%) if clinically relevant and relatively simple discriminations, such as T1–T2 versus T3–T4 assessments are made (as opposed to T-specific measures). Newer, slimmer instruments have partly solved the problem of a tight stricture, which has previously precluded passage of the endoscopic probe. Arguably, however, failure to pass the standard EUS instrument is itself an indicator of advanced T stage. EUS also provides valuable staging information about regional lymph node involvement. Unlike CT determinations, which are mostly based on node size, EUS gives an image of both size and character (central necrosis, for example). Endoscopic transesophageal fine-needle aspiration biopsy techniques have extended the usefulness of EUS in regional lymph node staging.

The place of invasive staging, namely thoracoscopy and laparoscopy, is not well defined.^{12,15} Proponents of invasive staging hope to duplicate the success of mediastinoscopy in non-small cell lung cancer staging (one of the few established examples of surgical staging). Mediastinoscopy in lung cancer, however, provides a fairly simple outpatient assessment of the lymph nodes of interest, answers a focused and specific question, and is relatively accurate. Proficient operators can sample the relevant nodes in approximately 20 minutes. Thoracoscopy, in contrast, is much more involved, and the question or questions of interest are not as focused. One lung anesthesia is required. Dissection of relevant nodes takes time. As a rule, postoperative hospitalization and a chest tube are needed. Hospitalization can extend to several

days.¹⁵ Although thoracoscopy incisions are small, the associated pain is often out of proportion to size because of intercostal nerve trauma.

Laparoscopy is better tolerated than thoracoscopy. In gastric cancer, a malignancy known for its propensity for intraperitoneal dissemination, laparoscopy makes sense; imaging studies often miss peritoneal seeding. However, the rationale for routine laparoscopy in esophageal cancer staging is less compelling. Peritoneal metastases are not frequent. One of the alleged advantages of laparoscopy, obtaining information on celiac axis node involvement, is suspect. In many reported series the celiac nodes are simply visually inspected; fully dissecting the celiac nodes, while at the same time preserving the vessels, is not a minor undertaking. In summary, the case for routine invasive staging of esophageal malignancies is tenuous.

Assessment of fitness is an important aspect of a patient's workup, especially if surgery is considered. The preoperative assessment process has been formalized in several specialized esophageal surgery centers. Composite scoring systems have been developed that accurately stratify patients according to operative risk. One system emphasizes general status, cardiac, hepatic, and pulmonary function, while another uses age, FEV₁ (forced expiratory volume in 1 second), and performance status.^{16,17} Unfortunately, composite scoring systems do not enjoy widespread use.

Treatment: General Concepts

The treatment of esophageal cancer, similar to that of other solid tumors, is dictated by cancer stage and patient fitness.^{1,4,18,19} Although it is possible to think of treatment and develop algorithms in terms of each specific cancer stage, the process of data aggregation across clinical trials does not lend itself to this degree of precision. Rather, crude stage groupings must be used. A useful stage grouping categorizes patients into three groups: (1) early-stage disease (T1–2N0), (2) locoregional disease (more advanced than early-stage disease but no metastatic disease), and (3) metastatic disease. A few additional qualifications to this simplified scheme are helpful. Within the second category of locoregional disease, a practical subdivision can be made based on surgical considerations. The group can be divided into those patients who have a reasonable expectation of undergoing a complete, or R0, resection if primary surgery is performed and those who do not. This distinction is not always easy; considerable experience and good judgment are needed. The third category, metastatic disease, can be expanded to include frail patients who cannot tolerate aggressive, curative-intent, treatment. These patients are often treated along the same lines as those with metastatic disease, but for different reasons.

Treatment: Early-Stage Esophageal Cancer

Patients with early-stage esophageal cancer cannot be approached in an evidence-based fashion, at least not in the usual sense of the term. Large-scale randomized trials have

not been conducted in this group of patients, nor are they likely to be done in the near future. Treatment is instead based on what might be called a reason-based approach.^{18,19} Surgical resection is effective in this group of patients, so it is reasonable to deem this the standard by which other treatments are compared. Five-year survivals in excess of 50% are reported, and operative mortality is lower than that of unselected surgical patients (well below 5%). Nevertheless, it is very possible that the same results, or perhaps better, could be obtained with other treatments such as chemoradiation. Because patients with unfavorable comorbidities tend to be treated nonoperatively, fair comparisons are hard to come by.

Patients with very early disease (subgroups of T1a) may be treated with various endoscopic approaches, such as endoscopic mucosal resection, and in this way esophagectomy is avoided. However, these endoscopic treatments may have a higher cancer recurrence rate than traditional esophageal resection. Recurrence can result from underestimation of the true stage of disease (staging imprecision), inherent limitation of endoscopic treatment methods, or a combination of the two. The techniques are probably best suited for patients too frail to safely undergo esophageal resection.

Treatment: Locoregional Esophageal Cancer

This stage of esophageal cancer has generated the greatest controversy in management and, appropriately, the largest number of randomized controlled trials (RCTs). As a result of RCTs there is now broad agreement on several points: concurrent chemoradiation is superior to radiotherapy as a nonoperative treatment, preoperative radiotherapy is not effective, and the routine administration of postoperative radiotherapy is not warranted. Nevertheless, many controversies exist. One seemingly basic problem is the choice of a standard treatment (control arm) for comparison purposes. One approach is to start with treatments that have history on their side, such as surgery. This rationale is used by those who proclaim surgery as the “gold” standard. Not only does the term gold seem excessive (5-year survival is typically 20% to 25%), but the logic of using history as a criterion is questionable. Surgery is standard through precedent; other treatments require compelling evidence to become standard. The failure of a notable American intergroup trial, which tried to compare chemoradiation and surgery to surgery alone, to accrue patients suggests that, in the United States, at least, clinicians are uncomfortable with the historical surgical standard. An alternative approach is to use frequency of use as a basis for the standard. Using this argument, chemoradiation is a standard treatment for locoregional esophageal cancer in the United States.¹⁸ In this chapter two treatments, surgery alone and definitive chemoradiation (not to be confused with neoadjuvant chemoradiation), are discussed as standard treatments, and then other treatment options are measured against them. These other treatments are grouped into three categories: (1) investigational treatments of current interest, (2) investigational treatments of some interest, and (3) treatments shown to be inferior (of no current interest) (Table 40.2).

TABLE 40.2. Treatment options for locoregional stage esophageal cancer (curative intent).

I. Standard treatments, against which other treatments are compared:
1. Surgery alone
2. Definitive chemoradiation
II. Investigational treatments of current interest:
1. Neoadjuvant chemotherapy and surgery
2. Neoadjuvant chemoradiation and surgery
3. Definitive chemoradiation with possible salvage esophagectomy
III. Investigational treatments of some interest:
1. Surgery and adjuvant chemotherapy
2. Surgery and adjuvant chemoradiation
IV. Inferior treatments (of no interest):
1. Radiation alone
2. Neoadjuvant radiation and surgery
3. Surgery and adjuvant radiation

Standard Treatments

Surgery Alone

Esophagectomy for locoregional stage cancer typically cures 20% to 25% of patients (a higher percentage if patients are very carefully selected), but approximately 5% to 10% of patients succumb to postoperative complications (a lower percentage if patients are carefully selected or statistical liberties are taken).²⁰ Unlike chemotherapy and radiotherapy, surgery is difficult to standardize. The innumerable ways to remove an esophagus, and then put something in its place, provide surgeons with an endless list of topics to debate at meetings and frustrate the nonsurgeon who wishes to abstract the essential surgical concepts from the trivia. In what follows, an abstraction of the essential surgical concepts and controversies is presented (Table 40.3).

Generally Accepted Surgical Concepts

The central concept of surgery for cancer of the esophagus has changed over the past several decades.¹⁹ Surgeons once performed esophagectomy because it effectively palliated dysphagia and because a few fortunate, and largely a priori unidentifiable, patients were cured. There are now less-morbid methods to palliate dysphagia, so palliative intent esophagectomy is no longer a valid concept. The goal of

TABLE 40.3. Surgical concepts: agreement and controversies.

Agreement:
1. A complete (R0) resection is the overriding goal of surgical therapy
2. Incomplete resections are of little, if any, benefit
3. There is no place for palliative-intent surgery
4. Primary surgery should be restricted to those patients in whom there is a reasonable expectation of an R0 resection
5. There is a relationship between surgical volumes and outcomes
Controversies:
1. Operative approach (transthoracic, transhiatal, other)
2. Extent of resection (axial, radial, lymphatic)
3. Methods of reconstruction
4. Surgery as a component of multimodality therapy
5. Validity of the salvage esophagectomy concept

modern esophageal cancer resection is to perform a complete (R0) cancer resection. Microscopically (R1) and macroscopically (R2) incomplete resections provide little benefit. In fact, these incomplete resections are often harmful. Not only is perioperative mortality high in this group, but potentially curative alternatives such as definitive chemoradiation are foregone. Primary surgery should therefore only be offered to patients in whom there is a reasonable expectation of achieving a complete resection. Patients with bulky tumors that are closely apposed to vital structures (for example, the tracheo-bronchial tree and aorta) should be viewed with caution, as should those with obvious lymph node metastases. It is difficult to perform a complete resection in these patients.

How can we tell, after the fact, if a resection was complete? The pathology report is obviously critical, but so is a thoughtfully dictated operative report. The pathologist can only comment on the submitted specimens, not the tissues and lymph nodes remaining in situ; it is up to the surgeon to describe these things. We usually think in terms of resection margins, but physicians often unduly emphasize one margin (the easiest to quantify and conceptualize) while paying less attention to the other margins (the more difficult to quantify and conceptualize). There are three resection margins: axial (proximal and distal), radial, and lymphatic.^{4,19} The axial margins tend to receive the greatest attention. They are the easiest for the pathologist to measure and report and the easiest for physicians to understand. Positive proximal or distal margins indicate an incomplete resection and portend a future anastomotic recurrence. Not surprisingly, generous (many centimeters in the fixed specimen) margins give a lower risk of anastomotic recurrence than close margins (a centimeter or two).²¹ Remarkably, microscopically involved margins do not seem to increase the risk of postoperative anastomotic leakage.²² The radial margins, in contrast to the axial margins, are difficult for the pathologist to assess. Ideally, the esophagus is resected in such a way that normal mediastinal soft tissues completely envelope the area of tumor. By inking the radial margins, the pathologist can state whether the radial margin is clear and by how many millimeters (note the different scale of measurement for axial and radial margins). Often, however, the radial margin is almost nonexistent; this is the rule for a T3 tumor adjacent to the trachea. Here it is difficult for the pathologist, and the surgeon, to tell if a R0 resection has been done. Involved radial margins raise the possibility of recurrence in the tumor bed.

Finally, the lymphatic margin or, more specifically, the lymph node ratio, is often completely ignored. This concept is best described by way of an example. Imagine two seemingly similar pathology reports, each reporting an identical T-stage primary, negative axial and radial resection margins, and cancer in three lymph nodes. The postoperative TNM stage will be the same, and some might imagine a similar prognosis for the two patients. But, what if one specimen shows 3 of 30 nodes positive (lymph node ratio of 0.1) while the other shows 3 of 4 positive (lymph node ratio of 0.75)? One patient has a clear lymphatic margin and a favorable prognosis (lymph node ratio less than 0.2) while the other's R0 status is suspect, along with the prognosis.²³

Surgical treatment of esophageal cancer, as measured by survival and operative mortality, has improved markedly over the past few decades. Surgery, per se, is not more effective as

a cancer treatment than in the past. Progress in esophageal cancer surgery is instead attributable to improved patient selection (better staging), better postoperative care, and surgical experience.^{1,24} The experience factor cannot be underestimated. There is now overwhelming evidence that the results of esophageal cancer surgery are better when surgery is done at high-volume hospitals and by experienced surgeons.²⁵⁻²⁷ Specialized esophageal surgery centers consistently achieve operative mortalities of less than 5% while the comparable figure for low-volume hospitals and surgeons is closer to 15%. A final factor that may contribute to improved results, at least in the West, is the epidemiologic shift from squamous to adenocarcinomas. Infracarinal esophageal tumors are generally easier to resect, and easier to resect completely, than equivalent stage supracarinal tumors.

Controversies in Esophageal Cancer Surgery

There are five main areas of controversy in esophageal cancer surgery, but most of these controversies are linked in some way to at least one of the other controversies (see Table 40.3).⁴ For example, proponents of very radical surgery (extent of resection controversy) usually favor a transthoracic operation (operative approach controversy), and they often view surgery alone as an effective curative treatment strategy (multimodality therapy controversy). Nevertheless, this bundling of the controversies is often overstated and assumed to be present when in fact it is not. Nonsurgeons (and less-experienced surgeons), for example, often mistakenly believe that a transthoracic esophagectomy is, by definition, a more-radical operation than a transhiatal esophagectomy. This is simply not true. The clinics of the world are replete with (unsuspecting) patients who possess the unfortunate combination of a large thoracotomy scar and a pithy pathology report. Conversely, very radical infracarinal en bloc resections of distal esophageal tumors can be done through a transhiatal route.¹⁹

Operative approaches include (i) laparotomy and right thoracotomy (Ivor Lewis, or Lewis-Tanner), (ii) laparotomy, right thoracotomy, and cervicotomy (McKeown, or three-incision), (iii) left thoracoabdominal, (iv) transhiatal (laparotomy and cervicotomy), and (v) minimally invasive versions of these operations (especially iv and ii).⁴ Worldwide, the Lewis transthoracic approach is popular and broadly applicable. It offers generous exposure for dissection, but has the disadvantage of postthoracotomy morbidity, and its intrathoracic anastomosis occasionally gives rise to catastrophic complications.

The McKeown adaptation (properly called three incision, not three field) adds a cervicotomy for fashioning of a cervical anastomosis and gives a little longer proximal resection margin. The cervical anastomosis is a mixed blessing; leaks are less lethal and easier to manage, but most surgeons (not all) have noted an increased tendency for these anastomoses to leak (incidence of 10%–15% versus 5% for intrathoracic anastomoses).²² The left thoracoabdominal approach gives excellent exposure of the gastric cardia and is one valid option for treatment of type II AEG cancers but otherwise has little to recommend it. Inexperienced operators are easily seduced by its quickness and simplicity, but they often shortchange the proximal margin (the aortic arch is in the way), and the low intrathoracic esophagogastric anastomosis can produce severe reflux. Variations of this operation that take the dis-

section and the anastomosis above the aortic arch are perfectly acceptable but not popular.

The transhiatal esophagectomy is best suited to infracarinal tumors. Not coincidentally, its surge in popularity mirrors the rise of adenocarcinoma as the dominant cancer in the Western world. The main advantages of the operation are avoidance of thoracotomy (less pain and fewer pulmonary complications) and the mixed blessing of a cervical anastomosis. A radical infracarinal resection can be done (more or less under direct vision), but aggressive dissection cephalad to the carina can create unwanted surprises. In the United States, at least, some surgeons have mistakenly assumed that the lack of a thoracotomy somehow excuses the operator from having a basic familiarity with intrathoracic dissection.

Minimally invasive adaptations of the transhiatal and McKeown esophagectomies have been successfully performed at selected centers throughout the world with good results.²⁸ There is no reason to condemn these innovations. However, the operations require extraordinary skill, if they are to be done well, and this may limit their use.

Is there any evidence that one operative approach is superior to another? Many comparisons of transhiatal and transthoracic (various types) approaches have been done. Two systematic quantitative reviews of multiple nonrandomized and several underpowered randomized controlled trials (RCTs) failed to show a convincing difference between these approaches.^{29,30} However, the most recent RCT, and the only one that was adequately powered, showed lower pulmonary morbidity with the transhiatal approach,³¹ this confirms what advocates of the approach have always maintained. Nevertheless, other important outcomes, such as operative mortality and cancer survival, were not shown to be different. Proponents of the transhiatal operation point out that operative mortality was slightly lower (not significant) in the transhiatal group, whereas advocates of transthoracic operations instead dwell on the nonsignificant trend toward better cancer survival with the transthoracic approach. The RCT, as well designed and conducted as it was, still leaves room for debate.

Surgeons agree that a complete (R0) resection is needed, but they differ on how far one must go to achieve this. Both the extent of tumor resection and the extent of lymph node dissection are debated, but these two questions are virtually always bundled together into a single surgical philosophy.^{32,33} Tumor resections range from those that simply remove the involved esophagus (little attention to the radial margin), to those that remove the tumor en bloc within a sheath of normal surrounding tissues (for example, the mediastinal fat, posterior pericardium, mediastinal pleura bilaterally, and thoracic duct). En bloc resections of infracarinal tumors are easier to perform than those done for supracarinal tumors; the trachea gets in the way of an anatomically satisfying en bloc resection.

The extent of lymph node dissection ranges from a cursory sampling of regional nodes to a formal anatomic dissection across multiple body sites (abdomen, chest, neck). The term two-field suggests a formal dissection of abdominal and mediastinal nodes, while a three-field dissection adds a neck dissection (the terms two-field and three-field should be used to denote lymph node dissections, not the number of operative incisions). Is there any good evidence that the extent of tumor resection and lymph node dissection make a difference? The aforementioned RCT of transthoracic versus transhiatal esophagectomy is helpful.³¹ The transthoracic

group received aggressive resections and two-field lymph node dissections; there was a nonsignificant trend toward longer survival. Aggressive resections, although strictly of unproven benefit, may confer some modest benefit.³²⁻³⁴ The benefit, if it exists, is probably the result of better locoregional control, as opposed to a direct Halstedian impact on cure. One note of caution is in order. Skilled surgeons can perform radical esophageal operations, including a two-field node dissection, with acceptable morbidity. An analogy to the case of D2 dissections for gastric cancer is appropriate. The three-field dissection, however, is another matter. Complications, most commonly related to recurrent laryngeal nerve injury, are very frequent. Without proof of effectiveness, it is difficult to justify routine neck (three-field) dissection for esophageal cancer, especially distal adenocarcinomas.³⁵

Controversies surrounding methods of esophageal reconstruction center on the quality of neoforegut function after esophagectomy.³⁶ The issues include postreconstruction swallowing, conduit emptying, reflux, early satiety, anastomotic and conduit recurrence, and reconstruction-related postoperative mortality. Many of these issues have been studied in RCTs, but because these questions are primarily surgical in nature, interested readers are referred to other sources.³⁷⁻⁴⁰ In brief, most surgeons favor reconstruction with a gastric conduit (versus colon) placed in the posterior mediastinum (versus anterior), and a high thoracic (versus low thoracic) or cervical esophagogastric anastomosis, which can be fashioned by hand or with a stapling instrument (equivalent). A pyloric drainage procedure (pyloroplasty or pyloromyotomy) may be omitted if a narrow gastric tube is used, and care is taken to avoid kinking or twisting of the conduit. Otherwise, a drainage procedure is wise. The final two surgical controversies featured in Table 40.3, surgery as a component

of multimodality therapy and salvage esophagectomy, are discussed later in this chapter.

Definitive Chemoradiation

Definitive chemoradiation is the standard nonoperative treatment of locoregional esophageal cancer and rivals surgery as the current treatment of choice.^{18,41,42} Many RCTs have compared chemoradiation to radiation alone, the nonoperative standard treatment of the past (Tables 40.4, 40.5).⁴³⁻⁵⁷ Although many of these trials have been negative, most featured suboptimal doses of radiation or chemotherapy. Additionally, many delivered chemotherapy and radiation sequentially (versus concurrently), an approach that is now recognized as inferior. The American RTOG 8501 trial is the only major RCT to feature adequate doses of radiation (50 Gy, 2 Gy per day) and adequate doses of concurrent chemotherapy [5-fluorouracil (5-FU) and cisplatin].^{51,52} Its impressive survival results (median survival, 14 versus 9 months; 5-year survival, 27% versus 0%; $P = 0.001$) have made chemoradiation the standard nonoperative treatment throughout the world. Nevertheless, a local failure rate (persistent and recurrent disease) of approximately 45% leaves much room for improvement. Many (innumerable) modifications have since been made to both the radiation and chemotherapy protocols, but many of these apparent improvements have not been assessed in RCTs. One important modification, radiation dose escalation, has been studied in a RCT. High-dose radiation (64.8 Gy) was compared to the previous standard of 50.4 Gy; no survival or local control benefit was seen.⁵⁸ A nonrandomized study that added brachytherapy, in the hope of improving local control, was also disappointing. There was a high incidence of treatment-related esophagorespiratory fistulae.⁵⁹

Comparisons of the Two Standards: Surgery Alone and Definitive Chemoradiation

Direct comparisons of the two standard treatments for locoregional esophageal cancer, in the form of RCTs, have not been done. However, the outcomes of the two standard treatments, when compared in a very crude and unscientific way, seem roughly equivalent. Surgery typically provides median survivals of 15 to 18 months and 5-year survival rates of 20% to 25%; treatment mortality is 5% to 10%. Chemoradiation typically provides median survivals of 12 to 18 months and 5-year survivals of 15% to 20%; Treatment mortality is about 2%. Fair comparisons are difficult to find, because patients with poorer prognoses tend to be treated nonoperatively. Two nonrandomized comparative studies of surgery versus chemoradiation, as weak as this form of clinical research is, showed no difference in survival.^{60,61}

It is easy to call for a RCT comparing surgery alone to definitive chemoradiation but difficult to actually do it. Clinicians and patients often have strong preferences, even if the equipoise condition seems to be satisfied. Rather than address the question directly, it is probably more practical to pose related questions about the role of surgery, such as (i) is chemoradiation-surgery superior to chemoradiation without surgery or (ii) can we treat with definitive chemoradiation and reserve surgery for selected patients who show persistent or recurrent local disease, or patients who early during chemoradiation show a lack of response (as assessed by PET scan, or some yet to be developed discriminating test)? Some of the more interesting investigational treatments are discussed next.

Investigational Treatments of Current Interest

Neoadjuvant Chemotherapy and Surgery

Given the generally poor results of surgery alone in patients with locoregional esophageal cancer, the interest in induction or neoadjuvant therapy is not surprising. In theory, neoadjuvant chemotherapy offers early treatment of micrometastatic disease, and it can facilitate surgical resection by “down-staging” cancers. In addition, esophageal cancer patients

generally tolerate preoperative (neoadjuvant) chemotherapy better than postoperative (adjuvant) chemotherapy. However, induction therapy is not without morbidity (both independently, and after surgery), and it may cause harm by delaying definitive, albeit modestly effective, treatment with surgery.

Several RCTs have compared neoadjuvant chemotherapy and surgery to surgery alone (Table 40.6).^{62–70} Three trials are very notable. The Hong Kong study showed that there was no survival benefit to the combination of chemotherapy and surgery but that chemotherapy responders did better than nonresponders. Nonresponders actually fared worse than those treated with surgery alone.⁶⁶ In effect, the responders benefited at the expense of the nonresponders. This observation, although not sufficient to justify combined modality therapy, is nevertheless important, especially in the era of PET scanning. PET can discriminate between the two groups with impressive accuracy.¹⁴

The two largest RCTs, the U.S. and U.K. trials, are similar in many respects but markedly different in outcome. The American intergroup study showed no difference in survival for the two treatments and no difference in treatment mortality.⁶⁸ The pathologic complete response rate (no viable tumor in resected specimen) was disappointingly low (less than 10%). In contrast, the Medical Research Council (MRC) trial from the U.K. showed a significant survival advantage for the combination of chemotherapy and surgery [hazard ratio, 0.79; 95% confidence interval (CI) 0.67–0.93; *P* = 0.004].⁷⁰ This discrepancy between trials is a puzzle. One popular explanation is that the U.K. trial featured a shorter period of preoperative treatment than the American trial (two cycles of chemotherapy versus three), so nonresponders (a conceptual subgroup) in the combined therapy group moved to surgery quickly. In other words, the responders no longer benefited at the expense of the nonresponders.

Meta-analysis can be useful when individual trials show different results, but the meta-analysis process is not without difficulty and the conclusions should be considered accordingly. One meta-analysis showed no overall survival benefit for neoadjuvant chemotherapy and no difference in treatment-related mortality.⁷¹ Interestingly, the chemotherapy plus surgery patients were less likely to undergo resection but

more likely to undergo a complete (R0) resection. We can explain this observation in two ways: chemotherapy may act as a selection tool (patients with poor cancer prognoses never make it to surgery), and it may also “downstage” (this term is not without problems) tumors and make complete resection more likely. Both mechanisms are probably operational.

The interpretation of RCT evidence seems to vary according to geography. In the U.K., the MRC trial has made neoadjuvant chemotherapy and surgery a standard treatment for locoregional esophageal cancer. In the United States, however, the American intergroup trial has largely eliminated enthusiasm for neoadjuvant chemotherapy followed by surgery. The prevailing American notion is that currently available chemotherapy regimens are simply ineffective as (single-modality) induction treatments.

Neoadjuvant Chemoradiation and Surgery Compared to the Standard of Surgery Alone

Neoadjuvant chemoradiation followed by surgery is a strategy that has been formerly compared to both standard treatments, surgery alone (Table 40.7)^{63,72–81} and definitive chemoradiation (Table 40.8).^{82,83} The former implies the question: Does chemoradiation add anything to surgery? The latter asks: Does surgery add anything to chemoradiation?

Many of the concepts discussed in the previous section are transposable to the question of neoadjuvant chemoradiation and surgery versus surgery alone. The theoretical foundations, early treatment of micrometastatic disease, facilitating complete resection, and tolerance of preoperative therapy, are the same. Additionally, chemotherapy and radiation act synergistically on locoregional disease; pathologic complete response rates of 25%, as opposed to 10% with induction chemotherapy, are typically encountered. However, the issue of treat-

ment-related toxicity looms larger with neoadjuvant chemoradiation than it does for neoadjuvant chemotherapy. For example, few who argue against neoadjuvant chemotherapy justify their position with morbidity concepts; instead, they point to a simple lack of treatment effect. In contrast, it is possible to argue against neoadjuvant chemoradiation on two fronts: lack of effect and morbidity. In fact, one can even argue in favor of a positive treatment effect, but one that is offset by a negative morbidity effect. Interesting theoretical arguments aside, we now turn to the evidence.

Of the many RCTs done on this question (see Table 40.7), only one showed a benefit for chemoradiation plus surgery. Many of the other trials showed an effect directionally in favor of the combined treatment but not significantly so. The lone unequivocally positive trial, reported by Walsh, has therefore come under intense scrutiny;^{74,75} it seems that no review of this subject is complete without a few disparaging comments about the trial. The major criticisms relate to less than optimal preoperative staging and an unusually poor survival in the surgery-alone arm (less than 10% at 3 years). The first criticism cannot be completely dismissed, but the poor surgery-alone survival is partly explainable. The RCT was done at a single general hospital (a remarkable feat) and more than 70% of patients referred to the hospital unit were enrolled in the trial. Therefore, the patient selection forces at work in most RCTs involving cancer surgery, especially multicenter trials, were not present. Given that the study's population was unusually unselected (“all comers”) and that 80% of the patients in the surgery-alone arm were lymph node positive, the dismal survival rate with surgery alone is not all that surprising.

Many of the negative trials show a treatment effect that is directionally, but nonsignificantly, in favor of chemoradiation and surgery. A beneficial treatment effect, if it exists, may be too modest to detect in relatively small (underpow-

ered) RCTs. Meta-analysis can be useful here, but once again, it is not without problems. A meta-analysis showed improved 3-year survival [odds ratio (OR), 0.66; 95% CI, 0.47, 0.92; *P* = 0.016], and reduced locoregional recurrence (OR, 0.38, 95% CI, 0.23, 0.63; *P* = 0.0002), in the chemoradiation/surgery-treated patients.⁸⁴ Subgroup analysis showed that concurrent chemoradiation was beneficial but sequential chemoradiation was not. In common with the neoadjuvant chemotherapy data, there was a lower rate of esophageal resection with induction treatment, but a higher rate of complete resection. Treatment-related mortality was higher in the combined modality treatment patients, but this did not quite reach statistical significance (OR, 1.63, 95% CI, 0.99, 2.68; *P* = 0.053).

Because only one RCT shows a significant benefit for neoadjuvant chemoradiation and surgery, we cannot proclaim this treatment as proven, or standard, even if a meta-analysis is “positive.” Nevertheless, there is probably a modest survival benefit for neoadjuvant chemoradiation and surgery

over surgery alone. A cancer survival benefit may be partly negated by treatment-related mortality. This possibility was apparent in the French trial; disease-free survival was longer in the experimental arm but treatment-related mortality was higher.⁷⁶ Further RCTs are needed. However, investigative interest around the world is shifting somewhat to related clinical research questions, such as does surgery add benefit over chemoradiation?

Neoadjuvant Chemoradiation and Surgery: Compared to the Standard of Definitive Chemoradiation

Two recently completed RCTs have compared neoadjuvant chemoradiation to definitive chemoradiation, and the results are more or less consistent (Table 40.8).^{82,83} The French FFD 9102 RCT compared chemoradiation without surgery (defin-

TABLE 40.8. Definitive chemoradiation versus neoadjuvant chemoradiation and surgery: RCTs.

itive chemoradiation) to neoadjuvant chemoradiation followed by planned surgery.⁸² Four hundred fifty-five patients with T3–T4, N0–N1 squamous carcinoma or adenocarcinoma were treated with two cycles of 5-fluorouracil and cisplatin, plus radiotherapy (46 Gy). Patients showing at least a partial response, and fit for surgery (259 patients), were randomized to surgery or further chemoradiation (three cycles of chemotherapy and 15–20 Gy radiotherapy). Median survival was 17.7 months in the chemoradiation plus surgery group and 19.3 months in the chemoradiation group. Two-year survival was 34% in the chemoradiation-surgery group and 40% in the chemoradiation group ($P = 0.56$). Ninety-day treatment mortality was 9% in the patients treated surgically and 1% in patients treated with definitive chemoradiation ($P = 0.002$). After completion of treatment, 78% of patients treated with chemoradiation plus surgery, and 87% of those treated with definitive chemoradiation, had a World Health Organization performance status of 0 or 1 ($P = 0.08$). Surgically treated patients were less likely to need palliative endoscopic interventions for dysphagia (P values for stenting and dilatation, 0.005 and 0.07, respectively).

The German Oesophageal Cancer Study Group performed a similar trial.⁸³ One hundred seventy-seven patients with locally advanced squamous cancer were randomized to treatment with either (i) three cycles of chemotherapy (5-fluorouracil, cisplatin, etoposide, leucovorin) followed by chemoradiation (cisplatin, etoposide, and 40 Gy) and then surgery, or (ii) chemotherapy (same), followed by definitive chemoradiation (cisplatin, etoposide, and more than 60 Gy). Median and 3-year survival were 16 months and 28% in the chemoradiation-surgery group versus 15 months and 20% in the definitive chemoradiation group ($P = 0.22$). There was a trend toward better local control in the chemoradiation-surgery group ($P = 0.08$) but also a higher overall treatment mortality (10% versus 3.5%). Not surprisingly, responders in both treatment arms fared better than nonresponders. Although the nonresponders in the chemoradiation-surgery arm had a dismal 3-year survival, 18%, a small subgroup that could still undergo a complete resection did better (35% 3-year survival). The denominator of this group is small, and overemphasis on this point may be unwarranted.

Taken together, the French and German trials show that definitive chemoradiation, and neoadjuvant chemoradiation followed by surgery, provide equivalent overall survival in patients with locoregional esophageal cancer. The inclusion of surgery in treatment provides modest benefit in terms of local control and palliation of dysphagia, but at the cost of higher treatment-related mortality.

Definitive Chemoradiation with Possible Salvage Esophagectomy

Because definitive chemoradiation provides survival that is equivalent (or perhaps better) to that observed with chemoradiation plus surgery, but has a high local failure rate, it is logical to ask the question: Is there a role for esophagectomy as a selective salvage strategy in patients with local failures after definitive chemoradiation? This question has been implicit in much of the foregoing discussion, especially in the comparisons of definitive chemoradiation and chemoradiation-surgery; herein it is addressed explicitly. In part the ques-

tion of salvage esophagectomy is one of feasibility, and in part it is one of effectiveness. RCTs have not been done, but the U.S. Radiation Therapy Oncology Group, along with other groups, is keenly interested in this question.

The feasibility of salvage esophagectomy for local failures (persistent or recurrent disease) of definitive chemoradiation relates to two major issues: properly identifying patients for salvage surgery (true local failure, and lack of disseminated disease), and performing salvage esophagectomy with acceptable operative mortality.^{85,86} In contrast to the primary diagnosis of esophageal cancer, which is exceptionally simple, the diagnosis of persistent or recurrent local disease can be very difficult. Endoscopic biopsies can be “negative” despite the presence of viable tumor in deeper layers of the posttreatment esophagus. A persistent stricture is often the clue that malignant disease is present, but this is hardly a specific diagnostic criterion. EUS and CT scanning are also less accurate in the posttreatment setting. An apparent paradox in relation to diagnostic accuracy is noteworthy. In the context of neoadjuvant chemoradiation and planned surgery, little effort is expended in assessing the exact status of the tumor before surgery, and an absence of viable tumor in the resected specimen brings cheers from all concerned. However, in the context of salvage esophagectomy, an inherently selective approach, the lack of tumor in the resected specimen is a diagnostic failure, and a particularly difficult one should the patient die (disease free) after surgery.

Although experience with salvage esophagectomy is limited, there is little doubt that it is a more morbid operation than both esophagectomy alone and planned esophagectomy after neoadjuvant chemoradiation.^{85,87} Within the salvage esophagectomy framework there are two patient subgroups, each with different, but negative, implications. One group has persistent local disease that is apparent at the completion of definitive chemoradiation, and they promptly undergo salvage esophagectomy. This situation is very similar to planned surgery after neoadjuvant chemoradiation (although the radiation dose may be a bit higher), but being nonresponders, the anticipated survival is poor. The second group manifests local disease months after treatment. They may have a better cancer prognosis (initially responding), but the salvage esophagectomy can be technically difficult (later in the evolution of radiation tissue injury). It is not surprising that taken together these two groups of patients have a propensity for poor outcomes, but for different reasons.

Finally, a third group of patients can be considered for a slightly different form of surgical salvage. These are patients who are treated with definitive chemoradiation but early in the course of treatment show features of nonresponse. The lack of response usually portends a poor outcome irrespective of treatment, but promptly offering an operation is sensible. PET scanning holds tremendous promise as a response discriminator.¹⁴

Investigational Treatments of Some Interest

Surgery and Adjuvant Chemotherapy

Postoperative chemotherapy is an accepted therapeutic strategy for several solid tumor sites (breast, colon), but it is not very practical in postoperative esophageal cancer patients. It

TABLE 40.9. Surgery and adjuvant chemotherapy versus surgery alone: RCTs.

RCTs, randomized controlled trials; Chemo, chemotherapy; SCT, surgery and postoperative chemotherapy; S, surgery alone; 5-FU, 5-fluorouracil.

takes weeks or sometimes months for a patient to recover after an esophagectomy; temporary nutritional compromise and postoperative weight loss are the rule. Patients with squamous cancer, in particular, are often malnourished before esophagectomy, and they are especially frail after surgery. Predictably, trials of adjuvant chemotherapy after surgery for squamous cancer have been characterized by a high rate of incomplete treatments. Even patients undergoing esophagectomy for adenocarcinoma have difficulty completing postoperative chemotherapy treatment.⁶⁸

Several RCTs have studied the question of adjuvant chemotherapy, but none has shown a benefit (Table 40.9).^{88–90} Admittedly, the most recent Japanese trial showed a significant improvement in disease-free survival.⁹⁰ Although a modest beneficial effect is plausible, the current evidence does not support the routine use of postoperative chemotherapy after esophageal cancer resection.

Surgery and Adjuvant Chemoradiation

The question of chemoradiation after esophagectomy for esophageal cancer has not been studied in RCTs. Several non-randomized studies have been encouraging, but selection bias probably plays a role in these studies;⁹¹ being fit enough to be considered for postoperative chemoradiation could, in itself, be a favorable prognostic factor. Postoperative chemoradiation is even more taxing than postoperative chemotherapy, and this feasibility problem has dampened interest. However, postoperative chemoradiation was shown to be effective after gastric cancer resection in the U.S. intergroup trial (problems of inadequate surgery aside).⁹² That trial included patients who had tumors of the cardia (patients often included in esophageal cancer trials). Although adjuvant chemoradiation after esophagectomy is an interesting question for study, current investigational interest generally focuses on neoadjuvant treatment.

Treatments Shown to Be Inferior

Radiation Alone

RCTs of concurrent chemoradiation versus radiation alone are summarized in Table 40.4.^{43–52} Most researchers and clinicians have been convinced by the RTOG trial, and radiation alone is no longer a standard treatment for locoregional esophageal cancer.⁴² Critics could point to the many negative trials on this subject, or suggest that very modern radiation techniques have not been compared to chemoradiation in proper trials, but the general oncology community is not

receptive to these arguments. If a patient is fit for chemoradiation, chemoradiation is preferable to radiation alone.

Neoadjuvant Radiation and Surgery

Eight RCTs of preoperative radiation and surgery versus surgery alone have been performed (some included additional postoperative treatment).^{63,93–99} The trials are of historic interest; they are not deemed important enough to summarize in a table. The radiation regimens varied considerably, with doses ranging from 20 to 53 Gy. None of them showed a survival advantage for preoperative radiation. A published meta-analysis, based on updated individual data (1,147 patients), reported a hazard ratio of death of 0.89 (95% CI, 0.78–1.01; $P = 0.06$) for the preoperative radiation patients.¹⁰⁰ This result could be interpreted as being consistent with a very modest benefit. However, another meta-analysis that included an additional published trial found a relative risk of 1.01 (95% CI, 0.88–1.16; $P = 0.90$).¹⁰¹ The combination of neoadjuvant radiation and surgery is no longer a valid treatment.

Surgery and Adjuvant Radiation

Four RCTs of surgery and postoperative radiation versus surgery alone have been conducted (not summarized in table form).^{99,102–104} None showed a survival benefit for postoperative radiation, and in one trial the survival was actually significantly shorter.¹⁰³ Postoperative treatment impaired quality of life in another trial.¹⁰⁴ Postoperative radiation is not indicated after complete resection of esophageal cancer. Most oncologists are tempted to offer some further therapy after an incomplete resection, but not necessarily radiation alone. There is little evidence to guide therapy in this situation.

Treatment: Metastatic Disease, and Palliation of Dysphagia

The primary goal of treatment in metastatic disease is palliation of symptoms. Prolongation of life is a second objective. Chemotherapy has some palliative benefit, but it has not been shown to increase survival over supportive care, at least not in RCTs.^{105,106} Few RCTs have specifically addressed this issue in esophageal cancer. In gastric cancer, a related malignancy, some (but not all) RCTs have shown a modest survival benefit for chemotherapy (refer to Chapter 41).

Many different strategies can be used to palliate dysphagia, and there is no single best treatment. External-beam radiation is the traditional standard, but brachytherapy,

chemotherapy, and a host of endoscopic treatments are also effective. Endoscopic treatments include laser (thermal ablation) therapies, stents (plastic, expandable metal, covered expandable metal), photodynamic therapy (PDT), and ethanol (and other chemical agents) injections into the tumor. These endoscopic treatments have been compared in RCTs;¹⁰⁷⁻¹¹⁷ these are briefly summarized next.

Endoscopic PDT palliates dysphagia with fewer treatments than Nd:YAG laser treatment, but cost and photosensitivity are drawbacks.¹⁰⁷ Newer expandable metal stents have justifiably replaced older plastic stents, despite their higher per unit cost and the lack of conclusive (randomized) supporting evidence.¹⁰⁸ Higher per unit costs are usually favorably offset by reduced costs of treating complications. The slimmer introducer of the metal expandable stents minimizes the need for preliminary dilatation (so often the source of complications with plastic stents), and success rates for placement approach 100%. The multiple brands of stent are broadly equivalent.¹⁰⁹ Covered stents prevent tumor ingrowth, but they are more expensive than uncovered stents and more prone to migration.¹¹⁰

RCTs comparing laser treatment to metal expandable stenting are inconsistent.^{111,112} Because a major drawback of laser therapy, compared to stenting, is the need for repetitive treatments, combinations of laser therapy and radiotherapies (external beam or brachytherapy) have been investigated. These combinations reduce the need for repetitive laser interventions^{113,114} but they still seem inferior to stenting.¹¹⁵ Brachytherapy also effectively palliates dysphagia, but it should be used cautiously in the setting of previous chemoradiation as fistulae may result.^{59,116} Overall, brachytherapy is as effective as stenting.¹¹⁷ Stenting palliates dysphagia immediately, but the palliative effect of brachytherapy is more durable.

What should clinicians, especially those not active in endoscopy, think of this maze of RCTs on endoscopic palliative interventions? Although broad treatment themes are properly shaped by RCTs, individual patient circumstances and institutional expertise often (correctly) determine the specifics of endoscopic palliation. Proficiency with a given method is probably more important than the choice of method itself.

Future Directions

It is always difficult to predict the future direction of cancer care, but certain general themes deserve mention. Chemopreventative approaches for adenocarcinoma are interesting, as are developments in the therapy of reflux. Modern RCTs are needed to address the impact of antireflux surgery on cancer risk. An accurate way to determine cancer risk in patients with Barrett's esophagus and dysplasia is needed. In the area of treatment, a more individualized approach is desirable. Surgery, it can be argued, should be used more selectively. Perhaps its main value is in early disease, as a sole therapy, and in more-advanced disease as salvage therapy. The trend toward regionalization of surgery to specialized centers should be encouraged. PET scanning shows great promise in assessing response to treatment, predicting outcome, and generally guiding treatment decisions. Newer chemotherapeutic

agents and targeted therapies, it is hoped, will also improve the prospects for cure in the future. Finally, if we consider obesity to be an important causal (versus confounding) factor in the rise of adenocarcinoma, then the epidemic of obesity in the West, especially in the United States, desperately needs a solution, and preferably not one that surgically inflicts a new disease.

Stomach

Scott A. Hundahl, John S. Macdonald, and
Stephen R. Smalley

Neoplasms of the stomach encompass both benign and malignant tumors, with more than 95% of the latter consisting of adenocarcinomas. Until approximately 1980, gastric cancer was the most common solid organ tumor in the world, and today it is eclipsed only by lung cancer in incidence and mortality.¹

This chapter addresses the classification, epidemiology, staging, and evidence-based treatment of gastric adenocarcinoma. Less-common gastric neoplasms, such as gastrointestinal stromal sarcomas (GIST), carcinoid tumors, and gastric lymphomas, are comprehensively reviewed in other chapters. Despite the necessary emphasis on new findings and improved treatments, background items of historical significance are also mentioned, lest we underappreciate previous work and the difficulty of progress.

Gastric Adenocarcinoma

Classification

Borrmann first characterized gastric carcinoma on the basis of gross characteristics in 1926, based on a review of 5,000 European cases.² He described four macroscopic tumor growth patterns: (1) type I, nodular polypoid tumor without ulceration and usually with a broad base; (2) type II, a fungating, exophytic, circumscribed tumor with defined sharp margins, devoid of ulceration except at its dome; (3) type III, an ulcerating tumor with a penetrating, infiltrating ulcer base; (4) type IV, a diffuse thickening of the gastric wall without a discretely marginated mass or ulceration, corresponding to the “leather bottle,” nondistensible stomach termed linitis plastica. Still used today, the Borrmann classification has proved useful in guiding surgical treatment, especially the extent of gross tumor clearance necessary for reliable negative margin resection.

The histology of gastric adenocarcinoma falls into two distinct subtypes, first identified by the Finnish authors Jarvi and Lauren in 1951 and refined in 1965^{3,4}: (1) intestinal type and (2) diffuse type. Intestinal-type cancers (Figure 41.1), often found in association with chronic atrophic gastritis and intestinal metaplasia, demonstrate gland formation and locally/progressively invade the gastric wall. Diffuse-type cancers (Figure 41.2) present as a sheet of discohesive individual cells that diffusely spread within the gastric wall, often spreading considerable distances from the site of origin. Diffuse tumors elicit a particularly brisk scirrhous proliferation of fibroblasts.

Histoepidemiologically, gastric adenocarcinomas generally sort into three broad patterns, based on simple combinations of Lauren type and location within the stomach.⁵

1. Intestinal-type tumors arising in the antrum or antral–corpus junction (*Helicobacter pylori* associated)
2. Diffuse-type cancers involving the corpus (*H. pylori* associated)
3. Intestinal-type cancers of the gastroesophageal junction

In regions of high gastric cancer incidence, approximately two-thirds of the incident cancers are of the intestinal-antral type associated with chronic *Helicobacter pylori* infection, multifocal atrophic gastritis, and intestinal metaplasia. This process usually begins at the lesser curve and the antral–corpus junction, and this is the most frequent site of cancer in high-incidence regions of the world. In such areas, most of the remaining cancers are also associated with *H. pylori* infection, but not intestinal metaplasia, and afflict younger age groups (usually those under 50 years). In this presentation, the cancer is of the diffuse type involving the body of the stomach and is associated with a brisk mucosal inflammatory infiltrate related to the *H. pylori* infection. *Helicobacter pylori* (see below) is therefore associated with both the antral-intestinal and the corpus-diffuse patterns.^{6,7} Gastroesophageal junction (GE junction) tumors, on the other hand, tend to be associated with Barrett’s metaplasia of the esophagus and are proportionately far less common in high-incidence regions but are an increasingly frequent subtype in low-incidence areas.

For the sake of completeness, a somewhat less common fourth subset of gastric cancer is also seen: intestinal-type cancers of the corpus associated with chronic autoimmune gastritis, G-cell hyperplasia, and achlorhidria. This less-common subtype is usually seen in Northern Europeans.⁵

Before the development of antral–intestinal-type adenocarcinoma, antecedent histologic changes occur that can be viewed as tissue markers along the multistep path to frank neoplasia. Multifocal atrophic gastritis, literally a thinning, chronic inflammation of the gastric mucosa, is generally thought to be the result of decades of superficial gastritis associated with *H. pylori* infection (Figure 41.3) and other factors. So-called intestinal metaplasia (Figure 41.4) is the characteristic histologic feature of atrophic gastritis, and it occurs in two forms: (1) complete type intestinal metaplasia and (2) incomplete type intestinal metaplasia. Complete type intestinal metaplasia (Figure 41.4) closely duplicates the mucosa of the small intestine, with small intestine-like mucin-negative

absorptive cells and Alcian blue-positive, sialomucin-positive goblet cells. This process usually begins at the antral–corpus interface, especially along the lesser curve near the incisura.⁸ When antral-intestinal metaplasia is still of limited area and spotty, and the remaining oxyntic gastric mucosa is still pumping out acid normally, peptic ulceration of affected areas is frequent, hence explaining the historical association between gastric ulcer and gastric cancer. Incomplete intestinal metaplasia represents a more-advanced process in which absorptive enterocytes disappear in favor of columnar, brush-border-free, colon-like cells with prominent mucous droplets and sulfomucins. Additionally, in incomplete intestinal metaplasia, Paneth cells are absent.⁸ In both types of intestinal metaplasia, cells produce enzymes not normally present in the stomach, including sucrase, aminopeptidase, disaccharidases, and, most-importantly, alkaline phosphatase.⁹ The latter enzyme may be used to grossly stain and map the distribution of intestinal metaplasia within the stomach *ex vivo*.⁸

Of the many alternative histologic gastric cancer classification schemes based on morphology, such as the World Health Organization Classification,¹⁰ or histogenesis-based classifications such as that of Mulligan and Rember,¹¹ degree of differentiation such as Broder's classification¹² and the Nagayo–Komagome classification,¹³ or classifications that include growth pattern such as the Ming classification,¹⁴ none has proven of more “beyond-TNM” prognostic value than the Goseki classification.^{15,16} In the Goseki scheme, degree of tubular differentiation (well versus poor) is combined with mucin staining pattern (mucin rich versus mucin poor) to divide gastric adenocarcinomas into four groups. Although of apparent prognostic value, it has yet to find widespread use.

Epidemiology

In incidence and mortality, gastric cancer ranks as the second in the world.¹ In raw numbers, it ranks third.^{1,17} Of the estimated global cancer burden of 10 million cases in the year 2000, 876,000 are stomach cancers.^{1,17} An estimated 38% of incident cases in the world occurs in China, where it is the most common cancer in both males and females.¹⁸ In almost all registries, gastric cancer incidence for males is approximately twice that of females.¹⁹

Figure 41.5 depicts widespread variation in gastric cancer incidence in various population-based registries around the world. The registries selected for this figure reflect those with both high numbers of incident cases and relatively low death-certificate-only cases, which suggests good case-finding. The highest world standard incidence rate (91.3 cases per age-standardized 100,000) is reported from Yamagata, Japan. The lowest rates are reported from Bangkok, Thailand, as well as from England, Australia, and the United States.

Age-adjusted gastric cancer incidence rates are declining in most countries throughout the world.¹⁸ The age adjustment of such rates tends to obscure the fact that, as a result of population growth and aging, the numerical burden of gastric cancer cases is actually expected to increase by 30% in 2010, to approximately 1 million cases.¹⁸

Unifying a vast body of epidemiologic, pathologic, and biologic research, Correa in 1975 proposed a multistep, multicausal model of gastric carcinogenesis, which he refined in 1988 and again in 1992.^{20–22} Chronic gastric mucosal irrita-

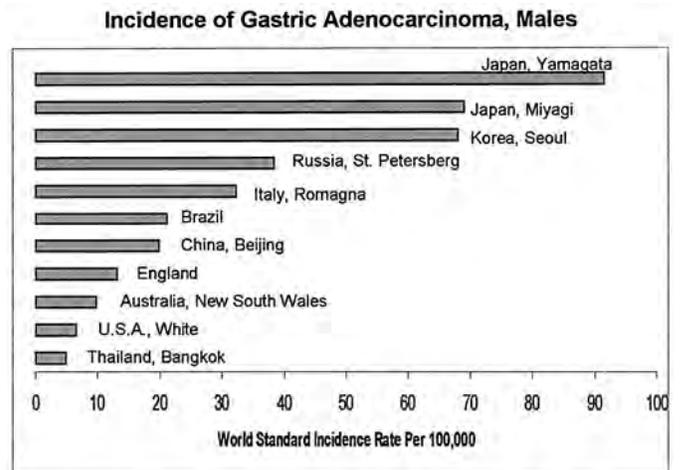

FIGURE 41.5. World Standard incidence of gastric adenocarcinoma (rate per 100,000 World Standard population, males). (Data from Cancer in Five Continents,¹⁹ vol VIII.)

tion, particularly that associated with the gastric mucosal bacterium *Helicobacter pylori*,^{23–25} initiates a superficial gastritis, which, especially in a setting of a diet rich in salt-preserved foods and high NaCl intake,²⁶ progresses to atrophic gastritis and intestinal metaplasia (first the complete type and subsequently the higher-risk incomplete type). This transformation, and the subsequent march to dysplasia and cancer, is facilitated by diminished oxyntic acid output, increasing gastric pH, bacterial growth, and high-nitrate-containing diet. In such an intragastric environment, dietary nitrates are converted to carcinogenic *N*-nitroso compounds.^{27–33} Many other carcinogenic compounds, such as polycyclic aromatic hydrocarbons, are also implicated. Certain ingested compounds, such as vitamin C, can interrupt this process.^{34–36} Additional risk factors for epidemic gastric cancer include smoking and a diet deficient in fresh fruits, vegetables, and antioxidants.^{26,37,38} Blood group A,³⁹ gastric ulcer,⁴⁰ ionizing radiation,^{41,42} family history,^{39,43–52} and previous gastric resection⁵³ are also associated risk factors.

A vast body of data now supports *Helicobacter pylori* as a key factor in epidemic gastric cancer,^{23–25} and the International Agency for Research on Cancer (IARC) has recognized it as a human carcinogen with both direct and indirect effects.⁵⁴ Strains containing the *cagA* gene appear more dangerous.^{55–57} Summarizing a large body of surveillance data, Parkin and colleagues observe that more than 80% of individuals in developing countries are infected with *H. pylori*. The figure for developed countries is approximately 50%.^{18,58} An odds ratio for *H. pylori* and gastric cancer of 2.1 has been estimated.^{18,58} Based on this, Parkin and colleagues estimate that 42% of the world total gastric cancer cases can be attributed to the impact of infection with this bacterium.¹⁸

Decades-long *H. pylori* infection, usually starting in childhood, begets superficial gastritis and chronic atrophic gastritis and intestinal metaplasia, which, once established, usually persists even after the *H. pylori* infection has disappeared because of the resulting achlohydric gastric luminal environment (the bacterium requires an acid environment to live). Atrophic gastritis and intestinal metaplasia were once believed to be irreversible. This does not appear to be entirely true, however. The pharmacologic elimination of *H. pylori*

TABLE 41.1. Hereditary Syndromes in Gastric Cancer.

Familial adenomatous polyposis (FAP) syndrome	

along with favorable dietary intervention has led to documented regression of atrophic gastritis and intestinal metaplasia.^{34,59-65} Unfortunately for the purpose of cancer prevention, however, a (somewhat underpowered) Chinese *H. pylori* elimination trial in Fujian Province has recently documented a significant decrease in gastric cancer incidence only in participants without preexisting intestinal metaplasia and no significant decrease when such metaplasia was already established.⁶⁶ Ongoing *Helicobacter* eradication trials include one in Venezuela,⁶⁴ and one in Japan, the Japanese Intervention Trial on *H. pylori*.⁶⁷

Molecular Biology

The genetics and molecular biology of gastric cancer continue to be elucidated. With each clue to understanding the biology of gastric neoplasia, both targeted prevention and targeted therapy seem more and more feasible.

Between 8% and 10% of gastric cancer cases appear to be associated with a hereditary component, and these cases provide significant clues.⁶⁸ Dominant inheritance patterns and familial clusters have certainly been documented.⁶⁹⁻⁷¹ Notably, Napoleon Bonaparte's family was afflicted by hereditary gastric cancer, and this (rather than arsenic poisoning) appears to have caused his death.⁷²

Table 41.1 summarizes recognized hereditary conditions associated with gastric cancer.⁷³ Perry Guilford and colleagues were among the first to describe germline E-cadherin mutations in a Maori kindred afflicted with diffuse-type gastric cancer,^{52,74} and such mutations have also been described in African-American and European kindreds.^{52,75} Gastric cancer is one of the neoplasms associated with the hereditary nonpolyposis colon cancer (HNPCC) syndrome, and such HNPCC-associated cancers are almost exclusively of the intestinal type.^{43,76} It is also overrepresented in those afflicted with germline p53 mutations, Li-Fraumeni syndrome.^{50,77} Asian reports of association of gastric cancer with familial polyposis coli (FAP) syndrome⁷⁸ have not been reported

for other populations,⁷⁹ and the relationship remains controversial.

Table 41.2 summarizes genetic and molecular abnormalities frequently described in sporadic cases of gastric carcinoma. Immortalizing telomerase activity is commonly noted in advanced gastric cancers, but not in surrounding normal gastric mucosa,⁸⁰ and is associated with a poor prognosis.⁸¹ Inactivation of the p53 gene and abnormal expression has been detected in more than 60% of gastric cancers.⁸² In diffuse-type tumors, E-cadherin expression is reduced in as many as 92% of tumors, compared to adjacent normal tissue.⁸³ Reduced expression of alpha-catenin, which forms intracytoplasmic complexes with the cadherins, is noted in 56% of tumors.⁸⁴ Overexpression of the MET gene that encodes a tyrosine kinase receptor for hepatocyte growth factor (HGF) is seen in approximately half of gastric cancers and tends to be associated with poor prognosis.⁸⁵⁻⁸⁷ Loss of trefoil peptide, the isomerization of which relates to repair of gut mucosa,⁸⁸ occurs in approximately half of gastric carcinomas, especially the intestinal type.⁸⁹⁻⁹² Proliferation of gastric cancer cell lines is decreased by this peptide.⁹³ Expression tends to be decreased in intestinal metaplasia.⁹⁴ This family of peptides appears to play a key role in the multistep progression to gastric cancer.⁹⁵ Epidermal growth factor (EGF) is detected in more than 50% of gastric cancers and epidermal growth factor receptor in approximately a third, and these have been associated with invasiveness and poor prognosis.⁹⁶⁻⁹⁹ Subtypes c-erb-B1 and -B2 (HER-2/neu) have also been detected¹⁰⁰ in up to a third of cases, and the latter has similarly been associated with poor prognosis.¹⁰⁰⁻¹⁰² Similarly, fibroblast growth factor is expressed in 54% to 70% of gastric cancers.^{103,104} Cyclin D is another protein variably overexpressed in gastric cancer, with incidence of overexpression approximately 20% to 30% in sporadic cases,¹⁰⁵⁻¹⁰⁸ and possibly more in familial tumors.¹⁰⁹ COX-2 is not normally expressed in gastric mucosa but is in tumors,^{110,111} precancerous lesions,¹¹² and inflammatory states (especially those induced by *H. pylori*).^{113,114} In tumors, its presence seems to correlate with angiogenesis and invasiveness, and it tends to inhibit apoptosis.¹¹⁵⁻¹¹⁷ For these reasons, and observational evidence of possible chemoprevention by aspirin,¹¹⁸⁻¹²¹ COX-2 inhibitors have been proposed as chemopreventive agents in gastric cancer.¹²²

Differences among molecular and genetic patterns for gastrointestinal cancers can also provide clues to etiology and therapy. Ras proto-oncogene mutations, which are frequent in colon cancer, are infrequent in gastric cancer.¹²³

Paracrine-like interactions between gastric cancer and fibroblasts have also been reported, particularly those involv-

TABLE 41.2. Frequent genetic and molecular abnormalities in sporadic gastric cancer.

Telomerase expression	85% of advanced tumors, poor prognosis
E-cadherin	In 92%, downregulation or mutation
p53 mutations	More than 60% of tumors
Trefoil peptide, TFF-1 (sP2)	Loss in 50% of gastric tumors, and decrease in intestinal metaplasia
MET, <i>c-met</i>	Overexpression in approximately 50%, a marker for poor prognosis
Epidermal growth factor (EGF)	Expression in more than 50% of advanced cancers
Fibroblast growth factor	70% expression, especially undifferentiated tumors
Cyclooxygenase 2 (COX-2)	Expressed frequently in tumors and precancerous lesions, but not in normal mucosa

ing transforming growth factor-beta (TGF- β) and hepatocyte growth factor (HGF),^{80,124} as well as other factors.¹²⁵ Such tissue interactions appear to impact on the proliferation of neoplastic and preneoplastic cells.

Diagnosis

Data from a registry-based American College of Surgeons Patient Care Evaluation Study nicely documents the presenting symptoms of patients with gastric cancer: weight loss in 62%, abdominal or epigastric pain in 52%, nausea in 34%, anorexia or early satiety in 32%, frank dysphagia in 26%, and melena in 18%.¹²⁶ Specific signs of gastric cancer are generally associated with more-advanced disease; these include palpable epigastric mass, ascites, left supraclavicular adenopathy, and Blummer's shelf palpable on rectal examination.

In low-incidence countries, fecal occult blood testing, when positive, triggers endoscopic investigation of both upper and lower gastrointestinal (GI) tract; this can lead to a diagnosis of early disease. Patients in defined higher-risk groups (e.g., positive family history or previously documented intestinal metaplasia) are increasingly being screened by surveillance endoscopy, and this, too, leads to diagnosis of more-localized disease. Overall in the United States and most low-incidence regions, stage IB or less (see following for staging) disease is detected in fewer than 23% of cases.¹²⁷

In high-incidence countries, such as Japan, mass screening with upper GI contrast studies and endoscopy have proven successful in shifting stage distribution to lower stages, with measurable improvement in overall survival rates (level of evidence, II-1).¹²⁸⁻¹³³ Pepsinogen I/II ratio of less than 2.0 (a marker of loss of oxyntic mucosa and the extent of intestinal metaplasia) has also been used as a mass screening tool.¹³⁴ In Japan, where mass screening has been established as national policy, the percentage of early gastric cancer cases among screening program participants is a staggering 74%.¹³⁵ Unfortunately, such mass screening is far less feasible in the poorer, less-developed nations of the world where gastric cancer tends to occur more frequently.¹³⁶

Extent-of-Disease Evaluation

Most patients undergo upper endoscopy as part of their initial evaluation. Key information gleaned from this examination includes tumor location and extent of mucosal involvement, distance from the esophagogastric junction, and Borrmann type.

Endoscopic ultrasound examination (EUS), using a 7.5- to 12-MHz transducer at the end of an endoscope, offers a reliable means of preoperatively assessing the depth of tumor penetration of the wall and a fairly reliable means of assessing for gross lymph node enlargement.¹³⁷⁻¹³⁹ Concordance of EUS and pathologic T stage in most series is 85% or better.^{137,140} Endoscopic ultrasound examination appears more accurate than even helical computed tomography.^{137,141}

CT scanning of the abdomen and chest should be performed in most cases. It is very helpful in detecting distant metastatic disease, extraregional adenopathy, and signs of locally-advanced disease unlikely to be removed to negative margins with up-front surgery. Helical CT, particularly if enhanced by the triphasic water-filling scanning technique, appears to be more sensitive than conventional CT.¹⁴²

Positron emission tomography (PET) with [¹⁸F]fluorodeoxyglucose (FDG) and PET-CT fusion scanning have enhanced detection of distant metastases in a variety of cancers. Unfortunately, gastric adenocarcinoma is not as suited for PET scanning as other tumors.¹⁴³ Primary tumor uptake is seen in only approximately 75% of cases, and the technique is less sensitive than CT for detecting nodal disease.¹⁴⁴ Neither mucus-containing tumors nor diffuse-type scirrhous tumors image well.¹⁴⁵ Furthermore, different regions of the normal stomach have different uptake of FDG,¹⁴⁶ thus complicating image interpretation. PET does appear to be somewhat helpful in detecting certain distant organ metastases, however.^{147,148}

Laparoscopy and minilaparotomy represent invasive procedures, but can accurately detect serosal spread and small peritoneal implants, as well as extraregional nodal disease and small hepatic metastases.¹⁴⁹⁻¹⁵¹ In a recent large series, laparoscopy outperformed EUS and CT in detecting signs of unresectability and/or extraregional metastases.¹⁵² It consistently outperforms CT.¹⁵³ In a recent series, laparoscopy proved more accurate than peritoneal fluid cytology in detecting peritoneal implants.¹⁵⁴ Lack of a prospective randomized trial showing resultant outcome differences makes inclusion of laparoscopy in pretreatment staging a level II-1 recommendation, however.¹⁵⁵

Staging and Prognosis

Since 1987, the American Joint Committee on Cancer (AJCC) and the Union Internationale Contra le Cancer (UICC) systems for the staging of cancer have been identical.¹⁵⁶ Fifth and sixth edition UICC/AJCC TNM staging for adenocarcinoma of the stomach is summarized in Table 41.3.¹⁵⁷ This TNM staging system differs from previous versions with respect to nodal classification. Formerly, nodal classification was based on anatomic location of lymph nodes. In the current fifth–sixth edition system, nodal staging is based on the number of pathologically involved nodes, thus (at least partially) addressing the thorny issue of stage migration related to extent of lymphadenectomy.

The staging of tumor depth, or T staging, for this site has not changed since 1988. The reader should be aware that T staging for this site differs from that of colorectal cancer. Invasion of the lamina propria or submucosa, but not the muscularis propria of the gastric wall, is deemed T1 disease. Invasion of the muscularis propria or a breach of the muscularis propria without a serosal breach is deemed T2 disease. A tumor may extend into the lesser omentum or the greater omentum adjoining the stomach and, provided the serosa (i.e., visceral peritoneum) is not breached, the tumor is deemed T2. A T3 tumor breaches the serosa, thus placing the patient at increased risk of peritoneal dissemination. Microscopic breach of the serosa can be difficult for the pathologist to detect, but prognostically, presence or absence of such penetration has great impact (e.g., one recent study from Hong Kong reports 5-year survival of 64% versus 10% based on this feature alone).¹⁵⁸ A T4 tumor invades adjacent structures such as spleen, transverse colon, liver, diaphragm, pancreas, abdominal wall, adrenal gland, kidney, small intestine, or retroperitoneum. Intramural extension to the duodenum or the esophagus is not considered invasion of an adjacent structure, and a tumor exhibiting such intramural extension is

TABLE 41.3. UICC/AJCC Staging for Gastric Adenocarcinoma, 6th ed.

<i>Primary tumor (T)</i>	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ: intraepithelial tumor without invasion of the lamina propria
T1	Tumor invades lamina propria or submucosa
T2	Invades muscularis propria or subserosa ^a
T2a	Tumor invades muscularis propria
T2b	Tumor invades subserosa
T3	Tumor penetrates serosa (visceral peritoneum) without invasion of adjacent structures ^{b,c}
T4	Tumor invades adjacent structures ^{b,c}
<i>Regional lymph nodes (N)</i>	
NX	Regional lymph nodes cannot be assessed
N0	No regional node metastasis ^d
N1	Metastasis in 1 to 6 regional lymph nodes
N2	Metastasis in 7 to 15 regional lymph nodes
N3	Metastasis in more than 15 regional lymph nodes
<i>Distant metastasis (M)</i>	
Mx	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

^a A tumor may penetrate the muscularis propria with extension into the gastroduodenal or gastrophrenic ligaments, or into the greater or lesser omentum, without perforation of the visceral peritoneum covering these structures. In this case, the tumor is classified T2. If there is perforation of the visceral peritoneum covering the gastric ligaments or the omentum, the tumor should be classified T3.

^b The adjacent structures of the stomach include the spleen, transverse colon, liver, diaphragm, pancreas, abdominal wall, adrenal gland, kidney, small intestine, and retroperitoneum.

^c Intramural extension to the duodenum or esophagus is classified by the depth of the greatest invasion in any of these sites, including the stomach.

^d A designation of pN0 should be used if all examined lymph nodes are negative, regardless of the total number removed and examined.

Stage grouping

0	TisN0M0

staged based on the depth of greatest invasion, as described above.¹⁵⁷

Nodal staging in the fifth and sixth edition UICC/AJCC system is by number of involved nodes. Absence of nodal metastasis is considered N0 disease. Nodal metastasis in 1 to 6 nodes is considered N1 disease and metastasis in 7 to 15

nodes is considered N2 disease. Metastasis to more than 15 lymph nodes is considered N3 disease, and most regard this extent of nodal disease as incompatible with survival following surgery treatment alone; hence, any N3 case is classified as stage IV.

Nodal data for prognostic estimates in large databases encompass hematoxylin and eosin (H&E) staining of nodes. Methods of nodal analysis such as immunohistochemistry or polymerase chain reaction analysis enhance sensitivity to a degree far beyond H&E analysis. Prognostic implications for nodes positive only by such methods are likely different, and to a degree that remains controversial.

Distant metastasis is scored as M1 disease and all such cases are deemed stage IV. Common sites of M1 disease include the peritoneal cavity, extraregional lymph nodes (e.g., paraaortic, retropancreatic, portal, retroperitoneal, and mesenteric lymph nodes), liver, ovaries, and, less commonly, lung and bone.¹⁵⁷

The TNM staging matrix for stomach cancer is summarized in Table 41.3. If one creates a 2 × 2 table with T stages representing rows and N stages representing columns, stage categories generally map to the diagonals (i.e., if the sum of T and N is 1, stage IA; if the sum is 2, then stage IB; if the sum is 3, then stage II; if the sum is 4, then stage IIIA). Stage IIIB is reserved for stage T3N2M0 tumors. All cases with N3 disease, and all cases with a sum of T and N greater than 5, are considered stage IV.

Five-year and 10-year relative survival rates for U.S. cases treated by gastrectomy and pathologically staged according to the fifth–sixth edition UICC/AJCC system are depicted in Table 41.4.¹²⁷ Comparison of these rates suggests that 10-year relative survival (versus 5-year relative survival) should probably be considered as the preferred outcome standard for this cancer; in modern series, survival curves tend to plateau not at 5 years, but rather between 7 and 8 years.¹²⁷

Clinicians in Japan and elsewhere often use an alternate staging system derived from a set of “General Rules for Gastric Cancer Study,” first published in 1963 and revised many times since.¹⁵⁹ A complete version of the 12th edition of this staging system, usually referred to as the “General Rules,” has been published in English, complete with color tables and diagrams.^{159,160} The T stages in this system are similar to those in the UICC/AJCC system, but it is otherwise different. Nodal staging differs considerably, with node-level definitions ranging from (regional) N1 and N2 nodal levels to (generally considered extraregional) N3 and N4 levels. The specific definitions for such levels vary according to location of tumor within the stomach (e.g., proximal third, middle third, distal third). The system includes macroscopic

TABLE 41.4. TNM staging and relative survival for U.S. cases treated by gastrectomy, 1985–1996 (n = 50, 169).

<i>6th edition UICC/AJCC stage</i>	<i>Five-year relative survival</i>	<i>Ten-year relative survival</i>
IA	78%	65%

II	34%	26%
IIIA	20%	14%
IIIB	8%	3%
IV	7%	5%

Source: Data from Hundahl et al.¹²⁷

description of the tumor (e.g., early gastric carcinoma type or, if more advanced, Borrmann type), but such description does not directly impact on final stage assignment. Peritoneal metastases are described separately (e.g., P0–P3), as are liver metastases (e.g., H0–H3). Other sites are described conventionally (i.e., M0, M1). In the overall “General Rules” staging matrix, limited peritoneal or hepatic disease is lumped in stage IVA, and other distant metastatic disease is classified as stage IVB. In this Japanese system, nodal disease that one might term extraregional in the UICC/AJCC classification (e.g., General Rules N3 disease), is incorporated into stage IIIA or IIIB if the depth of invasion is T1 or T2. Fortunately, it is fairly easy to translate from the General Rules staging to UICC/AJCC staging, provided accurate node counts are also available.¹⁵⁹

The Japanese General Rules system is of interest primarily because the extent of surgical lymphadenectomy in stomach cancer has been historically defined according to this system’s lymph node classification. Before the mid-1990s, the Japanese described as an “R-level” the extent of lymphadenectomy according to the highest echelon of lymph node stations completely dissected by the surgeon. To avoid confusion with the UICC R-factor, which described completeness of resection, extent of lymphadenectomy was described as a “D-factor” after the 12th edition of the General Rules.^{159,160} In reviewing earlier literature in gastric cancer, one should be aware of the dual use of “R” terminology. Also, one should remember that the D-level description for level of lymphadenectomy is based on the Japanese nodal classification system (e.g., a lymphadenectomy is classified as D4 if all Japanese General Rules N1–N4 nodes are surgically removed, D3 if all N1–N3 but not all N4 nodes are cleared, etc.).^{159,160}

In the current AJCC/UICC staging system, the choice of numerical thresholds for nodal categories represents a point of ongoing controversy. A number of investigators have observed progressive decrease in survival with increasing number of involved nodes,^{161–168} with an apparent dropoff in survival when more than 3 nodes are involved.^{162–167,169} Another dropoff when more than 6 nodes are involved has been reported.^{163,165,167,168,170,171} Involvement beyond 15 or 16 nodes has been observed to be largely incompatible with long-term survival.^{161,169,171} UICC/AJCC cutoffs are based on these observations, but it must be recognized that differences in the pathologic analysis of surgical specimens and differences in the extent of surgical lymphadenectomy can alter thresholds. A National Cancer Data Base (NCDB) report of 50,169 cases, all treated by gastrectomy, from 1985 through 1995, has documented that only 18% of U.S. gastric cancer cases have more than 15 nodes analyzed by the pathologist,¹²⁷ as recommended by the AJCC for accurate nodal staging.¹⁵⁷ The study further documented that stage migration related to nodal analysis persists in the United States despite the move to the fifth edition AJCC staging system based on number of nodes positive. Inadequate nodal analysis generated observed survival differences within assigned stage levels of up to 20%, and this was clearly related to the number of nodes analyzed. Nodal analysis beyond 15 nodes failed to generate any measurable enhancement in stage-stratified survival rates. Overall, 5-year relative survival was 28% and 10-year relative survival was 20%. Of the 10-year survivors in this series, 67% were node negative and 98% had 8 or fewer nodes involved.¹²⁷ Despite documented variation in nodal sampling and analysis, how-

ever, assigning nodal stage categories based on the number of involved lymph nodes does appear to generate better prognostic estimates compared to previous versions of the UICC/AJCC system^{172–174} and the Japanese General Rules.¹⁷³

Recently, Kattan and colleagues at Memorial Sloan-Kettering Cancer Center in the United States have published a prognostic normogram based on multivariate analysis of 1,039 completely resected cases that somewhat corrects for inadequate nodal analysis in gastric cancer cases. Higher relapse risk is assigned when number of nodes analyzed is suboptimal.¹⁷⁵ This potentially useful prognostic tool awaits validation in a separate cohort.

Residual disease after surgical treatment is not included in the UICC/AJCC TNM stage grouping matrix. It nonetheless represents a powerful, significant, independent prognostic factor.¹⁷⁶ The UICC and AJCC code residual disease as R0 for none, R1 for microscopic residual, and R2 for macroscopic residual tumor.¹⁵⁷ The completeness of resection R-factor should be specifically assigned and recorded for all patients undergoing surgical treatment.

Surgical Treatment

Historical Overview

In the United States, increasingly radical surgical approaches for gastric cancer during the 1940s and 1950s^{177–180} fell into disfavor in the late 1960s and 1970s with recognition of the sometimes considerable mortality such procedures entail, at least when performed on U.S. or European patients, given the level of patient selection and the level of postoperative care possible in that era.¹⁸¹

Encouraged by generally lower surgical mortality rates and favorable 5-year survival rates, Japanese surgeons, led principally by Kajitani and colleagues, adopted a related, but distinct, approach: negative-margin gastrectomy (with initial gross margins guided by the Borrmann type of the tumor: 2 cm for exophytic nodular tumors and 5+ cm for ulcerated infiltrating tumors or linitis plastica) combined with aggressive removal of regional/extraregional lymph nodes, omentum, and en bloc removal of the peritoneum lining of the floor of the omental bursa along with the pancreatic capsule and associated fatty nodal tissue (i.e., omentobursectomy). Also, depending on tumor location, resection of contiguous organs such as tail of pancreas and spleen were advocated in an effort to better clear lymph node stations along the splenic artery and the splenic hilum.^{182–185} Reports from large cancer hospitals in Japan emphasized increasingly favorable stage-stratified results with such techniques, multiplied by screening-driven trends to earlier-stage diagnosis and improvement in overall survival.^{186–189}

Genuinely increased overall survival as a result of early diagnosis in Japan has been generally accepted as valid.^{190–193} However, claims by Japanese surgeons that more-radical surgical treatment was simultaneously generating better stage-for-stage results^{189,194–198} failed to uniformly win international acceptance, given the previous observation of high perioperative mortality accompanying U.S.-style radical surgery.¹⁸¹ By the late 1980s, however, remarkably low 30-day postoperative mortality rates reported from major Japanese institutions (e.g., 0.6% for expert institutions such as the National Cancer

Center Hospital in Tokyo)¹⁹⁴ stimulated renewed interest in Japanese surgical methods. The much higher proportion of low-stage (early gastric cancer) patients in Japanese series, combined with marked differences between the Japanese staging system (see earlier) and the UICC/AJCC staging system, confounded direct international comparison of survival rates. The UICC and AJCC successfully standardized staging worldwide in 1987,^{199,200} thus facilitating stage-stratified comparisons between Japanese and non-Japanese gastric cancer cohorts. Such comparisons revealed substantial stage-stratified survival differences,^{126,201} prompting some to question whether gastric cancer in Japan was a “different disease” from that seen in Western industrial countries.²⁰² Several retrospective analyses from Japan and elsewhere suggested that Japanese-style surgical treatment generated higher stage-stratified survival.^{203–207} With seemingly uniform UICC/AJCC staging, large apparent differences in stage-stratified survival rates were noted, with 5-year survival rates for each stage routinely much higher in the more radically treated Japanese cohorts.^{126,208} Such observations set the stage for prospective, randomized clinical trials addressing the following two surgical questions: (1) What is the optimal extent of lymphadenectomy (i.e., Japanese D1 versus Japanese D2) in the treatment of gastric cancer? and (2) Is routine total gastrectomy with or without extended node dissection more effective than simple subtotal gastrectomy? Results of these trials are summarized next and in Table 41.5.

Prospective, Randomized Trials of Surgical Treatment

The Cape Town South Africa Trial (1982–1986)^{209,210} of D1 Versus D2 Lymphadenectomy (termed Japanese R1 versus

R2 at that time) was conducted between January 1982 and November 1986 by Dent and colleagues. Inclusion criteria included T1–T3, N0–N1 disease, no distant metastases, absence of significant comorbidity, and age less than 75 years. Patients from “remote areas” were excluded. For accurate staging, biopsies of celiac, common hepatic, hepatic nodes, and “any abnormal nodes” were taken for all patients. D2 (aka R2 dissection in the nomenclature of the time) was performed according to the Japanese methods described by Kajitani and Nakajima (i.e., removal of omentum, superior leaf of peritoneum on the transverse mesocolon, removal of the capsule of the pancreas, aka omentobursectomy, and celiac-based lymph node dissection).^{182,185} For the gastric resection itself, gross proximal clearance of 5 cm was required in both arms, and reconstructive techniques were specified. Over the period of study, 608 cases were reportedly evaluated; 403 were deemed surgical candidates, but only 43 (7% overall and 11% at laparotomy) were deemed to meet all eligibility criteria. Following treatment and discharge, patients were followed by examination at 3-month intervals. No attempt was made to screen for recurrence.^{209,210} No survival differences were noted. In-hospital mortality was zero for both groups. The trial did document increased operative time (*P* less than 0.005), increased blood transfusions (*P* less than 0.005), and longer hospital stay (*P* less than 0.05) for the D2 group. This single-institution trial was halted when single-institution accrual to adequate statistical power for the question was deemed unlikely.^{209,210}

The French Subtotal Versus Total Gastrectomy Trial,²¹¹ by the French Association for Surgical Research, was conducted between 1980 and 1985 to address the potential value of routine total gastrectomy versus the higher mortality and morbidity associated with this procedure, as documented by

McNeer and others.^{180,212} Eligibility criteria included presence of an adenocarcinoma located in the distal half of the stomach, good organ function, and no evidence of nodal involvement higher than the gastroesophageal junction or in the splenopancreatic region. Cases of superficial carcinoma (in situ or early T1) were to be excluded, as were cases of obvious linitis plastica type extensive infiltration within the gastric wall. Extensive lymph node dissection was not mandated, but proximal ligation/resection of the left gastric artery was. A Billroth II gastrojejunostomy reconstruction was used for all subtotal gastrectomy cases, reconstruction for all total gastrectomy cases consisted of Roux-en-Y esophagojejunostomy, and 169 patients were randomized. Somewhat paradoxically, postoperative mortality was observed to be lower in the total gastrectomy group (1.3% versus 3.2%). Five-year survival rate for both groups was identical at 48%.²¹¹

The Italian Subtotal Versus Total Gastrectomy Trial^{213,214} was conducted from April 1982 through December 1993. Six hundred eighteen patients with localized gastric adenocarcinoma of the antrum were randomized to subtotal gastrectomy versus total gastrectomy. A D2 lymphadenectomy and omentobursectomy was recommended for all patients but not mandated. Inclusion criteria included histologic confirmation of adenocarcinoma, age less than 75, absence of serious comorbid conditions, and no history of previous malignancy, gastric surgery, or chemotherapy. Additionally, during laparotomy, all patients were required to have a tumor-free proximal margin of 6 cm and absence of any extraregional nodes, hepatic metastases, peritoneal metastases, or unresectable infiltration of contiguous organs. Over this 1982–1993 period, 1,372 patients from 31 Italian institutions were evaluated and 648 randomized; after exclusions, 311 were left in the subtotal gastrectomy group and 296 in the total gastrectomy group.^{213,214} With median 72-month follow-up, 5-year Kaplan–Meier survival was 65.3% for the subtotal gastrectomy group and 62.4% for the total gastrectomy group ($P = \text{n.s.}$).^{213,214}

The Hong Kong Trial of D1 Subtotal Versus D3 Total Gastrectomy²¹⁵ was conducted between October 1987 and December 1991 by Robertson and colleagues at the Prince of Wales Hospital in Hong Kong. The trial was open to patients undergoing laparotomy for grossly localized antral tumors that could be cleared to a 6-cm proximal margin with subtotal gastrectomy. Additional entry criteria included negative distal margin, absence of liver metastases, absence of peritoneal metastases, age less than 75 years, and absence of serious comorbid conditions. Neither intraoperative cytologic nor histologic analyses were performed. In the D3 group, distal pancreatectomy and splenectomy and D3 lymph node dissection were routinely performed, but without omentobursectomy. The R1 subtotal group underwent simple distal gastrectomy with a 6-cm proximal margin, high ligation of the right and left gastric arteries, and simple omentectomy, but no other node dissection. Over the study period, 55 cases were randomized, 25 in the D1 subtotal group and 30 in the D3 total group.²¹⁵ In this trial, survival was actually better for the more simply treated D1 subtotal group (median survival, 1511 versus 922 days; P less than 0.05). The D3 total group had longer operative time (260 versus 140 minutes; P less than 0.05), more transfusions (P less than 0.05), and much longer hospital stay (16 versus 8 days; P less than 0.05). No patient in the D1 subtotal group died postoperatively in hospital, in contrast to 1 patient in the D3 total group ($P = \text{n.s.}$).²¹⁵

The Medical Research Council (MRC) Trial of Modified “D1” Versus Modified “D2” Lymphadenectomy^{216–218} was conducted in 1986 through 1995, by Cushieri, Fielding, Craven, Joypaul, and colleagues of the Surgical Co-operative Group. In this trial, a D1 procedure was defined in a manner at variance with the definition used by the JRS GC. For this trial, a D1 lymph node dissection was one in which only those lymph nodes within 3 cm of the tumor were removed (consistent with pre-1997 TNM definitions of N1 nodes). The D2 procedure was defined as one in which TNM N2 nodes (i.e., “celiac, hepatoduodenal, retroduodenal, splenic, and retropancreatic nodes, depending on location of the tumor,” as well as perigastric nodes more than 3 cm from the tumor) were removed and the omental bursa resected (omentobursectomy). Distal pancreaticosplenectomy was performed almost exclusively in the D2 group, and splenectomy in both groups, but more frequently in the D2 group. Eligibility was assessed at staging laparotomy. Prelaparotomy exclusions included age less than 20 and those with serious comorbid disease. All patients were assessed, at laparotomy, for the presence of peritoneal implants, liver metastases, and extraregional/periaortic adenopathy, particularly in the area of the left renal vein. Those with disease in these sites were excluded. Intraoperative peritoneal cytology was not used. Eligible cases were deemed to have TNM stage I–III disease with negative margins of resection and a proximal margin of at least 2.5 cm free of gross disease. Of 737 cases registered, 337 were deemed ineligible at staging laparotomy because of advanced disease, leaving 400 cases for intraoperative randomization.^{216–218} With median follow-up of 6.5 years, 5-year overall survival for the D1 group was 35% versus 33% for the D2 group ($P = \text{n.s.}$). Recurrence-free survival and disease-specific survival did not differ significantly. Unfortunately, splenic resection, performed more frequently in the D2 group, and pancreatic resection, performed almost exclusively in the D2 group, seriously impacted survival and proved to be independent predictors of poor survival. Complications and mortality were higher in the D2 group, and pancreaticosplenectomy appeared to be a powerful influence. The adverse impact of pancreaticosplenectomy, particularly pancreatectomy, somewhat confounded this trial with respect to the lymphadenectomy question.^{216–218}

The Dutch Trial of D1 Versus D2 Lymphadenectomy^{219,220} was conducted between August 1989 and July 1993 by surgeons participating in the Dutch Gastric Cancer Group. Eligibility criteria included age less than 85 years, adequate physical condition with no serious comorbid diseases, no previous cancer, no previous gastric surgery, and histologically confirmed gastric adenocarcinoma without evidence of distant metastases. Patients in both groups underwent distal or total gastrectomy according to the location of the tumor, with subtotal gastrectomy allowed if a proximal tumor-free margin of 5 cm could be achieved. At the onset of the trial, surgeons from 80 centers and 8 expert consulting surgeons were extensively instructed concerning Japanese-type surgical treatment according to Japan Research Society for Gastric Cancer (JRS GC) definitions and guidelines.^{160,182,221} Patients were randomized preoperatively to arrange for the intraoperative presence of an expert consultant surgeon for all D2 cases. A Japanese expert surgeon attended every case during the first 4 months of the trial. The D1 procedure involved removal of all JRS GC-defined N1 nodes, generally the

perigastric nodes at stations 1–6 along the greater and lesser curvatures of the stomach, along with removal of the lesser and greater omentum. The D2 procedure involved omentobursectomy (i.e., removal of greater and lesser omentum, the superior leaf of the transverse mesocolon and the capsule of the pancreas), frequent distal pancreatectomy and splenectomy (depending on tumor location), and removal of all JRSGC-defined N2 nodes at stations 7–12 (i.e., left gastric, celiac, common hepatic, proper hepatic, and splenic arteries and splenic hilar nodes). Reconstruction following completion of the D2 node dissection was left to the local institutional surgeon, as was the postoperative care of the patient.^{219,220} Of the 1,078 cases randomized preoperatively, 82 (8%) were excluded for various reasons, most commonly, unavailability of a consultant reference surgeon (35 cases), poor physical condition, or lack of histologic confirmation of the diagnosis. Of the remaining 996 patients randomized and entered into the study, 285 had evidence of incurable/extraregional disease and were excluded; 711 deemed potentially curable underwent the randomly assigned treatment (i.e., D1 or D2 resection) with curative intent. The 380 cases in the D1 group and the 331 cases in the D2 group were well balanced with respect to age, gender, tumor location, and tumor depth. Eighty-nine percent of the cases in each group underwent apparent, pathologically confirmed, negative-margin resection. A slightly higher proportion of cases in the D2 group underwent total gastrectomy (38% versus 30% in the D1 group).^{219,220}

Among randomized cases, morbidity (25% versus 43%; P less than 0.001) and in-hospital mortality (4% versus 10%; $P = 0.004$) were higher for the D2 group. With a median follow-up of 72 months, 5-year survival was 45% for the D1 group and 47% for the D2 group ($P = \text{n.s.}$). Pancreatic and splenic resection, performed mostly in the D2 group (and mandated for particular tumor subsites) were associated with significantly higher morbidity and mortality in this study. Restricting the analysis to patients who did not undergo pancreatic or splenic resection (a post hoc, selected analysis), survival was higher for the D2 group (59% for the D1 group versus 71% for the D2 group; $P = 0.02$).²²² Overall, however, for those who indeed had a negative-margin resection deemed potentially curative, risk of relapse at 5 years was 43% for the D1 group versus 37% for the D2 group (difference between relapse rates was not significant). An 11-year follow-on report for this trial indicates that of the 89 cases with pathologic N2 disease, there were nine 10-year survivors, and 8 of the 9 were in the D2 group ($P = 0.01$ for this post hoc analysis of the N2 subgroup).²²² Overall survival at the 11-year mark is 31% versus 35% for D1 and D2, respectively ($P = 0.53$). Post hoc subset analysis notwithstanding, overall, this trial fails to support routine D2 lymphadenectomy.^{219,220}

At the time, both the MRC trial and the Dutch Trial were initiated, pancreaticosplenectomy was still deemed a standard part of a Japanese-type operation for cancers involving the cardia. By the mid-1990s, Japanese recommendations with respect to pancreaticosplenectomy had shifted^{223–225}; however, both trials were already well under way. Perhaps in response to MRC and Dutch Trial findings, pancreas-preserving D2 (or D2+) operations are now favored by the Japanese and others, unless resection of these organs is required to achieve negative margins.^{223–225}

A multicenter Japanese Trial of D2 Versus D4 Lymphadenectomy,²²⁶ initiated by Sasako, Sano, and colleagues,

dwells on the potential value of paraaortic lymph node dissection for deep T2 (i.e., serosal invasion suspected) and T3–T4 proximal tumors. In both Japan and Italy, microscopic disease in such nodes is not infrequent, and resection of such diseased nodes can generate approximately 15% 5-year survival.^{227–231} This trial has now completed accrual of 523 eligible cases. Thirty-day operative mortality for both D2 and D4 groups in this trial is 0.8%.²²⁶ The trial remains immature with respect to survival.²²⁶

Summarizing results from all these surgical trials, neither routine D2 (or greater) lymphadenectomy with pancreatic-splenic resection nor routine total gastrectomy can be routinely recommended (level of evidence, I). Overall, the somewhat arbitrary D-level system for guiding lymphadenectomy has not proven helpful in increasing survival. However, the potential value of pancreas/spleen-preserving lymphadenectomy, particularly if performed in low-mortality centers (e.g., those in Japan and certain other expert centers) remains an open question.

In-Hospital Mortality Rates Associated with Gastrectomy for Cancer

In both the MRC trial (6.5% versus 13%, $P = 0.04$)²¹⁷ and the Dutch Trial (4% versus 10%, $P = 0.004$).^{219,232} in-hospital mortality was significantly associated with pancreatic-splenic resection,^{217,232} which, in turn, was far more frequent in the D2 group (mandated component of D2 for most nonantral tumors). Viewed critically, in-hospital mortality was also very high for the D1 groups. In the aforementioned Japanese multicenter D2 versus D4 trial, surgical mortality was only 0.8% for both groups.²²⁶ Certainly, comorbid cardiovascular disease probably differs among international patient populations, but other factors such as surgical experience, technique, and variation in morbidity management can also play a role.²³³ In U.S. studies, surgeon volume and hospital volume persistently impact on in-hospital mortality.^{234–236} The mechanisms for the volume–mortality relationship have yet to be fully elucidated. Specialists, well-equipped and well-staffed operating rooms, and specialized services, including sophisticated ICU care, tend to be more available in larger hospitals.^{237,238} Additionally, when surgeons have open access to various hospitals, high-volume surgeons might preferentially prefer to practice in such environments.^{237,238} For a major procedure such as gastrectomy for cancer, there is evidence of both a learning curve²³⁹ and value to volume. Referral to specialist centers has been proposed.^{240,241}

Maruyama Index of Unresected Disease and Computer-Guided Lymphadenectomy

In the late 1980s, Keiichi Maruyama and colleagues at the National Cancer Center Hospital in Tokyo created a computer program (known as the Maruyama Program) that searched a meticulously-maintained 3,843-patient database of gastric cancer cases treated by extensive lymphadenectomy, matching cases with similar characteristics to a given case. With seven demographic and clinical inputs (all identifiable preoperatively or intraoperatively), the program predicts the statistical likelihood of nodal disease for each of 16 (JRSGC-defined) nodal stations around the stomach (note that current JRSGC General Rules identify 33 nodal stations, substations,

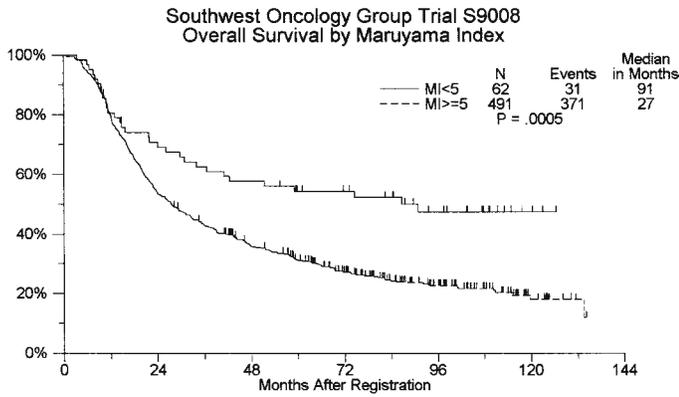

FIGURE 41.6. Impact of a surgical factor, Maruyama Index of Unresected Disease (MI), on overall survival for cases enrolled in SWOG 9008/INT 0116, a large U.S. adjuvant trial. (Updated data courtesy of Southwest Oncology Group.²⁴⁶)

and optional sites). Maruyama Program predictions have been assessed in Japanese, German, and Italian populations and found to be highly accurate.²⁴²⁻²⁴⁴ The tool is designed to be used by surgeons preoperatively or intraoperatively as a convenient means of rationally planning the optimal extent of lymphadenectomy for a given patient. Since the late 1980s, the program has been used in exactly this way by surgeons at the National Cancer Institute Hospital in Tokyo and by many gastric cancer surgeons around the world. In an effort to expand use of this computerized tool, a CD-ROM with expanded case volume has been prepared.²⁴⁵

In a prospectively planned surgical analysis of a large multicenter U.S. trial of adjuvant postoperative chemoradiation in gastric cancer (SWOG 9008/Intergroup 0116; see following), the extent of surgical treatment was specifically assessed and prospectively coded through both detailed reporting forms and review of records (e.g., operative reports). The prospectively planned surgical analysis of survival in Intergroup 0116 made use of a novel means of quantifying the ade-

quacy of lymphadenectomy relative to likely extent of nodal disease: the “Maruyama Index of Unresected Disease” (MI). The Maruyama Index of Unresected Disease was defined (by the author, S.H.) as the sum of Maruyama Program predictions for those Japanese-defined regional node stations (stations 1–12) left in situ by the surgeon.²⁴⁶ Based on the Intergroup trial’s entry criteria, and the definition of MI, every case registered to INT-0116 could have had an MI of 0; this variable was under the surgeon’s control. Before any survival analysis in this trial, it was speculated that patients with MI less than 5 would have measurably superior survival. As shown in Figure 41.6, this indeed proved to be the case, with median overall survival for the MI less than 5 subgroup 91 months versus 27 months ($P = 0.005$). By multivariate analysis, adjusting for treatment, T stage, and number of nodes positive, MI proved an independent predictor of survival ($P = 0.0049$). Data for disease-free survival are similar.^{246,247} The overall median Maruyama Index of Unresected Disease in this chemoradiation trial was 70 (range, 0–429), suggesting undertreatment. An effect for “dose of surgery,” as measured by MI, was also evident: median survival was 20 months for the highest MI quartile and 46 months for the lowest MI quartile (treatment-adjusted $P = 0.002$).²⁴⁶ In summary, by univariate analysis and by multivariate analysis, MI proved to be a strong and significant predictor of prognosis.^{246,248}

To further assess of the utility of MI as a prognostic tool, the Dutch Trial has recently been reanalyzed. Blinded to survival, and eliminating cases with incomplete information, 648 of the 711 patients treated with curative intent had MI assigned. Median MI was 26 and varied according to UICC stage, nodal stratum, T stage, D level, and tumor involvement of overlapping sites, in that order. In contrast to D level, MI less than 5 proved an independent predictor of both overall [$P = 0.016$, hazard ratio (HR) = 1.45, 95% confidence interval (CI) = 1.07–1.95] and relapse risk ($P = 0.010$, HR = 1.72, 95% CI = 1.14–2.60).²⁴⁹ As shown in Figures 41.7 and 41.8, a dose–response effect was also evident.²⁴⁹ This blinded

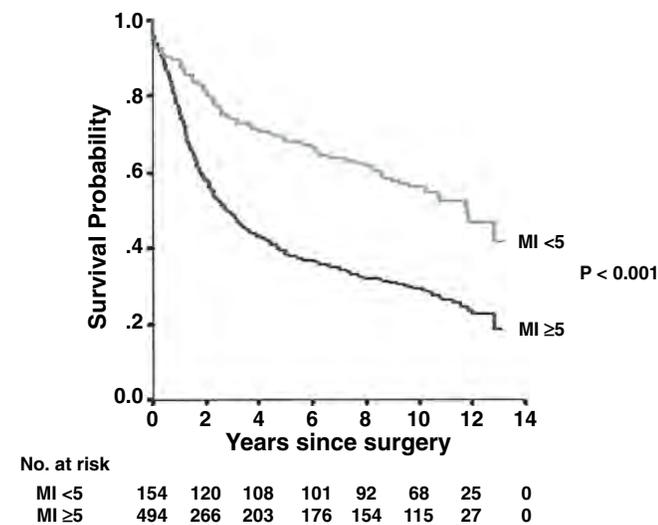

FIGURE 41.7. Reanalysis of the Dutch D1–D2 Trial. Maruyama Index of Unresected Disease (MI) is a major independent prognostic factor. Low MI is associated with superior survival. (From Peeters et al.,²⁴⁹ by permission of *World Journal of Surgery*.)

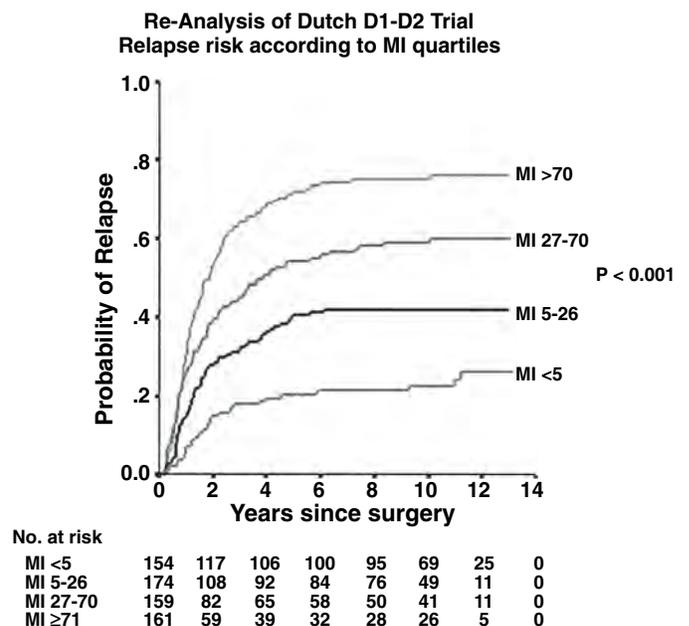

FIGURE 41.8. Dose–response effect for MI with respect to relapse in the Dutch D1–D2 Trial (data for survival similar, not shown). (From Peeters et al.,²⁴⁹ by permission of *World Journal of Surgery*.)

reanalysis further supports the utility of the Maruyama computer program in customizing the extent of lymphadenectomy in individual gastric cancer cases according to the predicted extent of nodal disease. "Low Maruyama Index" surgery, which can easily be accomplished by using the Maruyama Program to prospectively plan lymphadenectomy for a given patient, appears to enhance survival (level II-1 evidence). This conclusion has yet to be validated in a prospective, randomized trial.

Endoscopic Mucosal Resection of Selected T1 Cancers

In countries such as Japan, where the incidence of early gastric cancer (i.e., T1 tumor) is high, endoscopic mucosal resection (EMR) has emerged as a reasonable option for selected cases.²⁵⁰⁻²⁵⁵ In the traditional technique of endoscopic mucosal resection, submucosal injection of saline floats the small area of tumor-bearing mucosa off the underlying muscularis propria and the lesion is resected with a special cautery snare with hooks to preserve specimen orientation for margin analysis. The procedure can be technically challenging, but innovations such as use of incision endo-forceps,²⁵⁶ aspiration mucosectomy,²⁵⁷ use of a stabilizing distal magnetic anchor,²⁵⁸ or use of the double endoscope resection technique²⁵⁹ can facilitate its proper execution. Percutaneous traction assist techniques using small percutaneous ports and instrumentation can also facilitate the procedure,²⁶⁰ but percutaneous violation of the gastric lumen in such cases can risk unnecessary intraabdominal or port site tumor implantation. For this reason, laparoscopic resection for superficial T1 tumors suitable for EMR has been viewed with caution.²⁵⁵

Selection of cases suitable for EMR hinges on the absence of disease in the regional lymphatics. A combined series of 5,265 surgically treated T1 cases from the National Cancer Center Hospital and the Cancer Institute Hospital in Tokyo offers unsurpassed level II guidance.²⁶¹ For *intramucosal tumors*, none of 1,230 well-differentiated cancers of less than 30mm diameter, regardless of ulceration findings, were associated with metastases (95% CI, 0%–0.3%). Regardless of tumor size, none of 929 cancers without ulceration were associated with nodal metastases (95% CI, 0%–0.4%). For *submucosal cancers*, there was a significant correlation between tumor size larger than 30mm and lymphatic-vascular involvement with an increased risk of nodal involvement. None of the 145 well-differentiated adenocarcinomas of less than 30mm diameter without lymphatic or venous permeation were associated with nodal involvement, provided that the lesion had invaded less than 500µm into the submucosa (95% CI, 0%–2.5%).²⁶¹

In an 11-year, 445 case series by Ono and colleagues from the National Cancer Center Hospital in Tokyo, there were no gastric cancer related deaths during a median follow up period of 38 months (3–120 months).²⁵⁰ Although bleeding and perforation occurred in 5%, there were no treatment-related deaths.²⁵⁰ For selected superficial T1 cancers, endoscopic mucosal resection performed by experienced personnel can generate superb results and can certainly be recommended, especially because local recurrences can be addressed with salvage gastrectomy (level II-2 evidence).

Adjuvant Treatments

Radiation and Chemoradiation

For locally advanced tumors deemed unresectable to negative margins, radiation and concomitant chemoradiation appear to make long-term disease-free survival possible for a small, but significant, subset of patients.²⁶² In a Mayo Clinic series published in 1969, Moertel and colleagues documented rare long-term survivals with regional chemoradiation.²⁶³ In a follow-up prospective, randomized trial of radiation alone ($n = 23$) versus concomitant bolus 5-fluorouracil (5-FU) plus radiation ($n = 25$), mean survival was 13 months versus 6 months, favoring combined therapy (P less than 0.05) and 5-year survival was 12% versus 0%.²⁶⁴ In a follow-up study, the Gastrointestinal Tumor Study Group randomized 90 eligible cases to receive either combination chemotherapy alone or concomitant chemoradiation with further, follow-on chemotherapy. Early nutritional and myelosuppressive complications rendered initial survival of the chemoradiation arm inferior, but with minimum 5-year follow-up, survival was significantly higher for the chemoradiation arm, with 16% alive disease free compared to 7% among those treated with chemotherapy alone (P less than 0.05).²⁶⁵

For cases treated surgically, historical pattern-of-failure data from clinical, operative second look, and autopsy sources document that approximately 60% of node-positive and/or transserosal cancers (T3 or more) recur in regional nodes, tumor bed, or anastomosis, with 20% of tumors recurring only locoregionally (Table 41.6).^{262,266-270} Such data compellingly invited application of locoregional radiation or chemoradiation as an adjuvant to surgical treatment. Figure 41.9 depicts a early proposal by Gunderson and Sosin for a radiation treatment field encompassing frequent locoregional areas of failure, based on Wangenstein's University of Minnesota reoperative series.²⁷¹

Between 1991 and 1998, the Southwest Oncology Group and the Gastric Intergroup conducted SWOG 9008/INT 0116, a two-armed prospective randomized trial of postoperative adjuvant chemoradiation versus surgery alone in patients with completely resected adenocarcinoma of the stomach and esophagogastric junction. Eligibility criteria for this trial specified complete negative-margin resection, registration 20–41 days postoperatively, adequate organ function, good performance status (i.e., Zubrod 1 or 2), postoperative caloric intake of more than 1,500 kcal per day, and fourth edition TNM stage IB or higher, distant-metastasis-negative, disease.²⁷² Of 603 cases accrued to the study, 46 (8%) were ineligible, leaving

(From Gunderson and Sosin,²⁶⁷ by permission of *International Journal of Radiation Oncology Biology Physics*.)

556 cases; 20% of eligible cases registered had disease of the cardia/gastroesophageal junction, and advanced-stage cases were overrepresented. Eighty-five percent of cases were node positive. Using AJCC/UICC fifth edition criteria, fully 69% of the cases had AJCC IIIA or IIIB disease (46% and 23%, respectively) and only 8% had stage IB disease.²⁷² Of the cases in this trial, 54% underwent D0 (i.e., less than D1 lymphadenectomy), a source of subsequent criticism. The treatment consisted of one cycle of 5-FU (425 mg/m²) and leucovorin (LV, 20 mg/m²) in a daily × 5 regimen followed by 4,500 cGy (180 cGy/day, M–F) given with 5-FU/LV (400 mg/m² and 20 mg/m²) on days 1 through 4 and on the last 3 days of radiation. On completion of the radiation, two additional cycles of daily × 5% FU/LV were given at the original dose levels at monthly intervals.²⁷² Results for this trial were recently updated with more than 6 years of median follow-up (Figure 41.10).²⁷³ Overall survival was 35 months median for chemoradiation versus 26 months for surgery alone [$P = 0.006$;

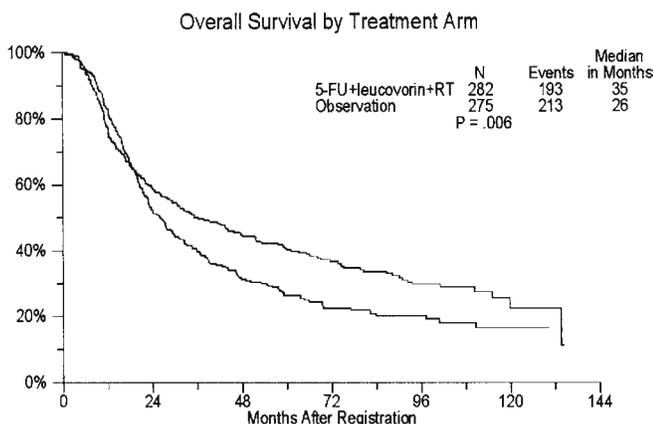

FIGURE 41.10. Updated survival with more than 6 years median follow-up for INT-0116, a trial of postoperative adjuvant chemoradiation (upper curve) versus postoperative observation (see text). (Updated data courtesy of Southwest Oncology Group.^{272,273})

hazard ratio, 1.31 (1.08–1.61)]. Disease-free survival was also significantly different at 30 months median for chemoradiation and 19 months for surgery alone [P less than 0.001; hazard ratio, 1.52 (1.75–1.85)].²⁷³

Exploratory subgroup analyses for INT-0116 were recently performed for six variables: gender, T stage, N stage, gastric subsite, D level of dissection, and diffuse versus intestinal histology. Positive treatment effects were seen in all subsets. A possible treatment interaction was seen, with diffuse-type histology cases doing poorly with therapy, but after adjusting for multiple testing, this result was not significant.²⁷³

The likely burden of unresected locoregional disease in this trial is problematic.²⁷⁴ Less than D1 lymphadenectomy, considered suboptimal in the opinion of most experts, was performed in 54% of the cases.^{246,272} As noted in the previous section, cases with Maruyama Index of Unresected Disease (MI) less than 5 enjoyed significantly greater survival (median overall survival for the MI less than 5 subgroup, 91 months versus 27 months; $P = 0.005$), and this was an independent predictor of survival.²⁴⁶ By D level, median survival was 27 months for D0 lymphadenectomy and 48 months for D2 lymphadenectomy, but only 10% of cases registered to this trial underwent D2, and this difference was not significant.²⁴⁶ Surgical undertreatment may have played a role in making this a positive trial.²⁷⁴

On the basis of INT 0116, adjuvant chemoradiation has been recommended in the United States for all patients with stage IB or greater, M0 disease (i.e., locoregional disease), *provided* they meet criteria for adequate caloric intake (more than 1,500 cal/day), good organ function, and good performance status.²⁷² Do all patient subgroups really benefit? The power to detect differing treatment effect in various subgroups in this trial (especially the stage IB subset) is low. Statistical tests of treatment interaction with pathology and surgical variables have been negative, however.²⁷² A cautionary note concerning the lower-risk, stage IB subgroup (i.e., patients with T2N0 or T1N1 disease) has been voiced.²⁷⁴

On the basis of this study, a new U.S. Intergroup trial, examining postoperative etoposide, cisplatin, and 5-FU (ECF) chemotherapy before and after radiation with continuous infusion 5-FU versus adjuvant treatment according to the INT-0116 protocol, is now under way, as well as other, similar trials in Europe.

Early Postoperative Intraperitoneal Chemotherapy

Japanese investigators have advocated intraperitoneal and intralymphatic installation of mitomycin C bound to micro-carbon particles for some time.²⁷⁵ This treatment has been tested in an Austrian prospective randomized trial with negative results.²⁷⁶ Another Austrian prospective randomized trial of perioperative cisplatin has also been reported as negative.²⁷⁷ A Japanese trial of intraperitoneal OK-432 in addition to systemic therapy has also been negative.²⁷⁸ Phase II investigations of intraperitoneal therapy have also been conducted in the United States and elsewhere,^{279,280} with some investigators enthusiastic²⁸¹ and some advising caution because of the associated morbidity.²⁸²

One positive prospective randomized clinical trial of perioperative intraperitoneal has been reported.²⁸³ Between 1990 and 1995, 248 Korean patients with biopsy-proven gastric

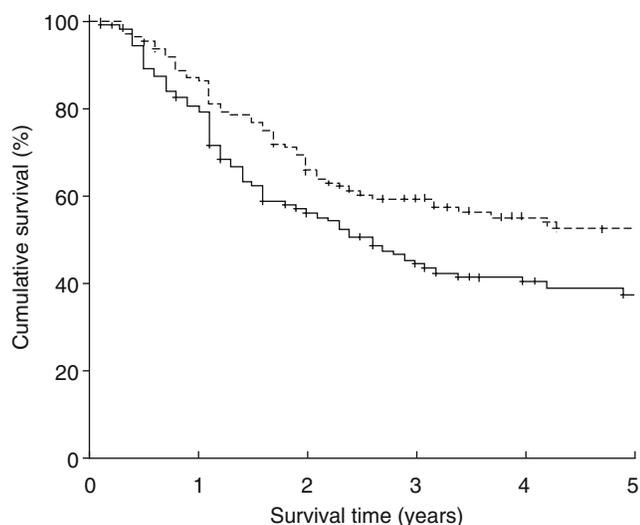

FIGURE 41.11. Kaplan–Meier overall survival for group treated with early postoperative intraperitoneal chemotherapy (mitomycin C on postoperative day 1 and 5-fluorouracil [5-FU] daily on postoperative days 2–5; *upper curve*) versus controls receiving surgery alone (*lower curve*). With mean follow-up of 36 months, survival difference is significant ($P = 0.0278$). (From Yu et al.,²⁸³ by permission of *World Journal of Surgery*.)

cancer without intraoperatively detected distant organ metastases were randomized intraoperatively following complete resection and minimum D2 lymphadenectomy to receive postoperative intraperitoneal mitomycin C and 5-FU versus surgery alone (Figure 41.11). Stage I cases and those more than 70 years of age were excluded. Postoperative adjuvant treatment, delivered intraperitoneally through a Tenckhoff catheter, consisted of 10mg/m² mitomycin C delivered at body temperature in 1L dialysis solution on the first postoperative day, followed by 700mg/m² 5-FU plus 50mEq sodium bicarbonate in 1L dialysis solution daily on days 2 through 5. No further antitumor treatment was administered during the disease-free interval. In-hospital mortality was 6.4% in the treated group versus 1.6% in the surgery-only group ($P = n.s.$). Among morbidities, intraabdominal bleeding (10% versus 1%; $P = 0.002$) and intraabdominal abscess/peritonitis (14% versus 4%; $P = 0.008$) were more frequent among treated cases. Follow-up consisted of regular physical examinations, but CT scans, paracentesis, etc., were initiated only at the discretion of the surgeon to confirm clinical findings. The initial report of this trial in 1998 reported a significant positive effect on survival only for stage III cases.²⁸⁴ A subsequent follow-up in 2001 reported significantly improved overall survival for the treatment group (54% versus 38%; $P = 0.0278$).²⁸³ Subset analysis revealed the benefit was enjoyed predominantly by those with fifth–sixth edition UICC TNM stage III (57% versus 23%; $P = 0.0024$) and stage IV (28% versus 5%; $P = 0.0098$) disease.²⁸³ Further subset analysis showed benefit for those with involved lymph nodes (46% versus 22%; $P = 0.0027$) and those with serosal invasion (52% versus 25%; $P = 0.0004$).²⁸³ Although this trial has yet to be duplicated, and there are some methodological criticisms, it has encouraged continued investigation of both perioperative intraperitoneal therapy and methods to decrease the associated morbidity. In the view of advocates, this trial constitutes level I evidence in favor of such intraperitoneal therapy.²⁸¹

Chemotherapy Without Radiation

A succession of meta-analyses concerning the value (or non-value) of systemic chemotherapy for gastric cancer have been conducted over the past decade. In 1993, Hermans et al. published a meta-analysis of 11 randomized trials of adjuvant chemotherapy, mostly involving treatment with 5-FU-based regimens, conducted over the previous decade. The odds ratio of 0.88 among treated patients was not significant.²⁸⁵ A year later, in response to a journal letter,²⁸⁶ two additional trials were added, and the addition of 318 cases from the two erroneously omitted trials lowered the odds ratio to 0.82; this was of borderline significance (CI, 0.68–0.98).²⁸⁷ In 1999, Earle and Maroun published a 13-trial meta-analysis of non-Asian trials published between 1980 and 1996, with a similar odds ratio for death in the treated group of 0.80 (95% CI, 0.66–0.97).²⁸⁸ In 2000, Mari et al. published a 20-article, 3,658 patient meta-analysis with an odds ratio for the treated group of 0.82; with the additional trials and patients, this was significant (95% CI, 0.75–0.89; P less than 0.001).²⁸⁹ Nonetheless, even including subgroup analyses, only a few trials showed significant results favoring chemotherapy,^{290–295} and the authors still considered adjuvant chemotherapy as investigational.²⁸⁹ In 2002, Panzini et al., from Italy, restricted meta-analysis to those trials where all patients were treated with “radical” surgical techniques. Of the 17 papers eligible for inclusion, 3,118 patients were available for analysis. Odds ratio for death among the treated cases was 0.72 (95% CI, 0.62–0.84),²⁹⁶ and on the basis of this, a large confirmatory randomized controlled trial of cisplatin-based chemotherapy was recommended.²⁹⁶ In 2001, a less-selective, but more-comprehensive, meta-analysis was conducted by the Swedish Council of Technology Assessment in Health Care (SBU),²⁹⁷ based on 153 scientific papers, 18 reviews, 60 randomized studies, and 57 prospective studies encompassing 12,367 patients. The authors’ meta-analysis of 21 randomized adjuvant studies revealed a statistically significant survival benefit with odds ratio 0.84 (95% CI, 0.74–0.96); however, analyzing Western world and Asian studies separately, a statistically significant difference was noticed: Western world studies showed an odds ratio of 0.96 (95% CI, 0.83–1.12) and the Asian studies an odds ratio of 0.58 (95% CI, 0.44–0.76).²⁹⁷ The authors concluded that adjuvant chemotherapy could not be recommended in Western patients, but that benefit in Japanese series was evident.²⁹⁷ Overall, the benefit of adjuvant therapy in all these meta-analyses equates to an odds ratio of approximately 0.80 at best. The extent of surgical resection for patients entered into these adjuvant studies, and the consequent burden of residual locoregional microscopic disease, may, as Panzini et al. suggest, be the key confounding variable.²⁹⁶ Nakajima et al., in a meta-analysis of 10 Japanese trials conducted at the Cancer Institute Hospital in Tokyo on radically treated surgical cases from 1959 to 1982 ($n = 1,177$ cases), noted a much better odds ratio of 0.63 favoring the treatment groups (P less than 0.01).²⁹⁸

As depicted in Table 41.7, most trials of adjuvant systemic chemotherapy versus surgery alone have been negative.^{291,294,295,299–311} For the positive trials, unusually low control group survival,²⁹⁵ or findings at odds with other trials,²⁹⁴ undermine general applicability.

Following the aforementioned INT-0116 adjuvant chemoradiation trial, for patients with disease resectable to

negative margins, clinical trials involving arms with only surgery or only postoperative adjuvant chemotherapy have become less feasible in the United States.^{272,273}

To date, no neoadjuvant preoperative chemotherapy regimen has been shown superior to postoperative therapy or surgery alone in a Phase III prospective randomized trial, despite promising Phase II results.³¹² Further, a recently reported trial of neoadjuvant FAMTX versus surgery alone showed median survival of 18 months for the treated group versus 30 months for the surgery-alone group ($P = 0.17$). On the basis of this result, the risk that neoadjuvant treatment with insufficiently effective chemotherapy might jeopardize survival must be considered.³¹¹

Advanced and Metastatic Disease

A variety of combination chemotherapy regimens have been used in the palliative management of patients with gastric cancer.³¹³⁻³¹⁹ Although the EAP type regimens pioneered by

Preusser, Wilke, and colleagues³¹⁷ led to a new era in combination chemotherapy, in which expectations of response rates in excess of 30%, and some complete tumor regressions, were possible, the EAP regimen is now utilized only rarely because of its significant toxicity.³²⁰ There are now other regimens that are widely used. The major regimens of current interest include methotrexate-directed 5-FU combinations,³²¹ infusional 5-FU regimens,^{37,314,322} and combinations containing taxanes³¹⁶ and irinotecan-based regimens.^{315,323}

Over the past decade, there has been interest in the use of prolonged infusion of 5-FU as a part of the combination chemotherapy treatment for stomach cancer. Crookes and colleagues³¹⁴ used continuous infusion 5-FU as a major component of a neoadjuvant program described below. Webb and colleagues reported important results with a combination regimen designated ECF (epirubicin, cisplatin, and 5-FU).³²² Of note, ECF uses protracted infusion of 5-FU at a daily rate of 200mg/m² with intermittent epirubicin and cisplatin. Epirubicin is an anthracycline analogue available in Western Europe for several years and now commercially available in

the United States (although its approval indication is for breast cancer, not gastrointestinal cancer, in the United States). ECF was tested in a major Phase III randomized trial reported in 1997.³²² This study compared ECF with FAMTX in patients with gastroesophageal adenocarcinoma. In this study, 274 patients with adenocarcinoma or undifferentiated cancer were randomized between FAMTX and ECF. The FAMTX regimen caused significant hematologic toxicity and was inferior in regard to response rate and survival when compared to ECF. The overall response rate for ECF was 45% versus 21% for FAMTX ($P = 0.002$). The median survival for ECF was 8.9 versus 5.7 months ($P = 0.0009$). At 1 year, 36% of ECF and 21% of FAMTX patients were alive. Webb and colleagues also assessed global quality of life scores in their study. The global quality of life was superior for ECF at 24 weeks. This advantage in quality of life, however, did not persist as patients were followed further on the study.³²² Of interest, Ross and colleagues performed a Phase III study of ECF versus a very similar regimen, MCF, that substituted mitomycin C (7 mg/m² every 6 weeks) for epirubicin and uses somewhat different doses of 5-FU (300 mg/m²/day × 24 weeks) and cisplatin (50 mg/m² every 3 weeks).³²⁴ The overall rates of survival were no different between the ECF and MCF regimens. This trial supports the use of MCF if either epirubicin is not available or a clinician would prefer not to use an anthracycline.³²⁰

Other, more-recent, regimens include the combination of docetaxel-cisplatin³¹⁶ and the regimen of irinotecan-cisplatin.³¹⁵ The irinotecan and cisplatin combination has been evaluated and shown to have good activity in gastroesophageal cancers. The response rate for adenocarcinoma with the regimen was 12 of 23 (57%), with excellent palliation of tumor-related symptoms.³¹⁵ Another regimen of interest recently is the combination of docetaxel and cisplatin.³¹⁶ In a European study of 85 patients with advanced gastric cancer, the overall response rate was 36%, and 7 of 85 (8%) had complete responses. The median survival in this study was 10 months, and grade IV toxicity was seen in only 4% of cases.³¹⁶

Data on therapy of advanced gastric cancer allow one to draw some conclusions in regard to the standard recommendations for patients with metastatic stomach cancer. It is reasonable to assume that several approaches can be considered appropriate chemotherapeutic management for patients with advanced gastric cancer. FAMTX is well tolerated and can certainly result in some complete responses in patients with gastric cancer, but it is no longer considered a front-line regimen for advanced gastric cancer (level I evidence). More promising approaches entail the use of continuous infusions of fluorinated pyrimidines, such as 5-FU. The ECF regimen, along with similar regimens using alternate anthracyclines, continue to be investigated. Finally, taxane- and irinotecan-based regimens are also of interest and appropriate for use in patients with advanced gastric cancer (level IIc data). However, it is important to stress that none of these regimens results in long-term control of metastatic adenocarcinoma of the stomach.

For a subset of cases with advanced locoregional disease followed by major response to chemotherapy, eventual R0 surgical resection is sometimes possible, and occasional long-term disease-free survival can result.³²⁵⁻³²⁷ It should also be noted that surgical resection of isolated hepatic metastases,

before or after chemotherapy, can also result in occasional long-term disease-free survival.³²⁸ In general, however, although some chemotherapy regimens produce major partial responses and complete response rates as high as 15%, such responses are usually not durable.

Colon, Rectal, and Anal Cancer Management

John M. Skibber and Cathy Eng

Treatment of Precancerous Conditions

Neoplastic Polyps (Adenomas)

Adenomas are the most common neoplasms in the large bowel. They are classified into three types—tubular, tubulovillous, and villous—according to the histologic appearance. Tubular adenomas account for 75% of polyps found, tubulovillous adenomas account for 25%, and villous adenomas account for 10%.¹ The malignancy rate of tubular adenomas is about 5%, but it rises to about 40% in villous adenomas. The entire colon should be examined if a histologically proven adenoma has been removed from the colon or is found on endoscopic biopsy.^{2,3} Endoscopic removal of polyps should be performed to confirm the diagnosis of a benign or malignant polyp.⁴ Polyps with a stalk can be removed by endoscopic snare polypectomy. Judgment must be used to assess the practicality of attempting endoscopic removal of sessile polyps, especially in the relatively thin-walled abdominal colon.⁵

Further management and timing of surveillance depends on the characteristics of the adenomas removed initially, as well as on their number and the clinical risk status of the patient. Follow-up of small adenomas containing in situ carcinoma or severe dysplasia that have been completely removed is the same as that for benign adenomas: routine follow-up colonoscopy at 3-year intervals once the colon is cleared.⁶ Patients having multiple adenomas are at higher risk for oversight of synchronous adenomas, and therefore these patients should be examined at 1 year. Small polyps (less than 1 cm) carry a low likelihood of malignancy and are adequately treated with excisional biopsy.⁷

Villous adenomas (i.e., more than 2 cm in diameter) have a malignant potential that is significantly greater than that for other adenomatous polyps. Villous adenomas require complete excision for adequate histologic examination. Large sessile polyps with villous features have a significant rate of local recurrence.⁸ Even if endoscopic excision of a large sessile polyp is done, the patients should be reexamined 3 months later to evaluate the completeness of resection.⁹ Ultimately, surgery can be required, as these polyps are highly likely to harbor invasive cancer. For rectal polyps, local excision techniques may be an acceptable form of excisional biopsy. Submucosal techniques of transanal excision are appropriate in the excision of rectal villous adenomas.¹⁰

Management of Malignant Polyps

A malignant polyp is one where cancer cells have extended into the submucosal layer. Theoretically, this results from the cancer cells gaining access to lymphatics and blood vessels in this layer and thereby having the potential for regional and systemic spread.^{11,12} In a pedunculated malignant polyp, there is an opportunity for complete excision because of the stalk. Sessile tumors often cannot be endoscopically completely excised in a manner that allows for an accurate examination of the margin and the completeness of excision.¹³

Essentially, the risk of local recurrence of a malignant polyp or undetected regional lymph node spread must be weighed against the patient's operative risk.¹⁴ The risk of local recurrence is related to the completeness of excision and resection margin. The definition of an adequate resection margin varies from 3 to 1 mm or simply the absence of malignant cells at the cut edge.¹⁵⁻¹⁷ In one study, simply the assessment of the adequacy of the resection by the endoscopist was an adequate criteria for a low risk of recurrence.¹⁸ Piecemeal excision or improper retrieval or processing of the polyp makes assessment of the margin indeterminate.

The risk of regional lymphatic spread appears to be increased in cases in which the malignant component has poor differentiation or lymphatic/vascular invasion. Poor differentiation appears to be a factor correlated with lymph node metastases in endoscopically removed polyps.¹⁸ Vascular and lymphatic or perineural invasion increases the risk of lymphatic metastases.¹⁹⁻²²

Haggitt et al.²³ (1985) have described various levels of invasion of carcinoma into pedunculated polyps (Table 42.1). They noted that, in a pedunculated polyp, an invasive component in the head of the polyp may be a substantial distance from the submucosa and therefore may be resected endoscopically with a significant margin. In a sessile polyp, the invasive component has early access to the submucosa and therefore has an earlier opportunity for dissemination. Sessile polyps have a higher incidence of lymph node metastasis than pedunculated polyps with invasive cancer.²⁴ When the invasive cancer is limited to the head of a pedunculated polyp, lymph node metastasis rates appear to be approximately 3%, in contrast to 10% to 25% for sessile polyps (Table 42.2).

The operative mortality for elective colon resection scores from 0.2% to 2%.^{25,26} For low-risk malignant polyps, the incidence of residual disease appears to be less than this.^{25,27,28} The criteria of incomplete excision or poor histologic appearances

TABLE 42.1. AJCC/UICC TNM staging of colon and rectal cancer.

Primary tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ: intraepithelial or invasion of lamina propria ^a
T1	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades through muscularis propria into subserosa, or into nonperitonealized pericolic or perirectal tissues
T4	Tumor directly invades other organs or structures, and/or perforates visceral peritoneum ^{b,c}
Regional lymph nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in 1 to 3 regional lymph nodes
N2	Metastasis in 4 or more regional lymph nodes
Distant metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

^aThis includes cancer cells confined within the glandular basement membrane (intraepithelial) or lamina propria (intramucosal) with no extension through the muscularis mucosae into the submucosa.
