Foreword

Compared to more traditional subspecialties, oncology is a young, vibrant, and progressive branch of medicine that has relatively few ties to a dogmatic past. Perhaps for this reason many innovations in oncology have occurred as a consequence of rapid cultural changes within the specialty, and continued change remains an accepted and integral part of our field. While most other practitioners of medicine learned a “standard of practice” and some dedicate their practice to clinical and/or basic research, research has been an integral and inseparable part of oncology since its inception. Consequently, virtually all oncologists consider clinical trials and experimental therapeutics as bread and butter and as necessary components of an ongoing progress. The broad acceptance of the necessity of prospective clinical trials and the continued testing of new drugs, strategies, and concepts highlights the need for differentiating hypothesis from fact, experience from experimental results, and opinion from fact. Such separation is the basis of evidence-based medicine, and oncology is one of the specialties with perhaps the richest tradition of practicing it. Considering that medicine has relied almost exclusively on clinical observation, anecdotal series, and uncontrolled personal experience for the past many centuries, such rapid adoption of evidence-based medicine is somewhat surprising and attests to the scientific orientation of our discipline.

For the past three decades several excellent textbooks on oncology were developed. The leading examples are multiauthored volumes that summarize the results of clinical trials placed in clinical context by experts on the field. These are encyclopedic textbooks in the best tradition of medicine, and several have progressed through multiple editions. In that context, what will the current textbook contribute to the field and how is it different from other volumes in the crowded field of oncology? Multiple answers to this question emerge from a careful review of this textbook. First, this book reflects a mature field of oncology; in addition to descriptions of natural history, clinical course, and the value of commonly used therapeutic strategies, much emphasis is placed on the cost, in terms of unwanted effects or toxicities associated with treatments. In addition to detailed presentations of acute side effects and their management, there is careful presentation of long-term effects, most of which are irreversible and some, potentially lethal. Only such careful assessment and tabulation of quantifiable therapeutic effects placed on the balance along with acute and long-term toxicities can provide a true picture of the therapeutic ratio of an intervention, which can then be translated in the context of each patient’s clinical situation, risk of progression, recurrence, or death. Second, the book presents a systematic approach to issues of survivorship. Physicians with a major interest in survivorship describe some of these, while survivors themselves describe others, providing a poignant perspective not found in books entirely authored by medical specialists. This aspect is the logical consequence of the increasing integration of users in breast cancer research and allocation of resources. Patient perspectives have contributed in a major way to identification of research fund over the past decade, and their participation in the activities of multiple research groups have contributed to identification of important questions to be addressed and the prioritization of research activities in cancer centers, SPOREs, and other multi-investigator activities. Such contributions are irreplaceable and of great importance to reaching the ultimate goals of cancer research: improvements in quality and duration of life.

The third, and perhaps most important contribution of this volume, is the emphasis on determining the quality of evidence in the integration of research results into guidelines or recommendations for patient care or design of subsequent research. The first chapter is dedicated to the definitions of research quality, systematic approaches to quantify levels of evidence, and providing examples of such systematic approach to grading quality of cancer investigation. It is no accident that the editor in chief of the *Journal of the National Cancer Institute*, dedicated for many years to the assessment of the quality of research publications is the senior author of this chapter. In

earlier decades, assessment of the quality of research was an intuitive process, and most seasoned oncologists based their enthusiasm for specific reports or research results on their subjective assessment of the research in question. Such subjective assessments were based, in part, on the name recognition of the reporting investigator(s), the reputation of the center or group behind the research, the sample size, and often the biases of those engaged in the assessment. The systematic approach to assigning specific levels of evidence to research reports goes a long way toward removing subjectivity from these assessments, focusing more on the methodology and the inherent strengths and weaknesses of any particular research approach than on the concordance of the results with preconceived biases or favored hypothesis. Identifying reports with the highest levels of evidence often clarifies seemingly confusing collections of data and often points out the glaring weaknesses or deficiencies of specific fields of interest. Sometimes it becomes apparent that despite decades of accepted treatment approaches, no evidence exists on which to base such approaches. It is apparent from such application of evidence-based scrutiny that modern medicine is still a hybrid field, where evidence-based approaches coexist and often mingle with old observations, qualitative personal experiences, opinions, and anecdotes. It is amply clear that the generation of high-quality evidence requires time and resources, including the willing participation of users, in this case, research subjects and patients. It is also clear that in many situations, physicians will have to continue using clinical judgment, extrapolate from related evidence and utilize common sense in the day-to-day management of clinical problems, because only a relatively small proportion of oncological treatments have been subjected to strict, controlled, prospective clinical trials, and not every question will be the subject of high-quality clinical trials in the future. Limitations in time and resources and the ongoing supply of high-priority biological questions will always displace questions of lower priority.

Let us examine then other features of this remarkable book. The first few chapters review the basic approaches to treat cancer. Surgery, radiotherapy, and chemotherapy are carefully presented, with a clear description of mechanisms of action and in the context of modern biological understanding of the malignant process. The chapter about radiation therapy is an example of the enormous progress made in our understanding of this highly technological branch of cancer treatment and the major progress that has occurred in this specialty over the past few years. Targeted therapy is the latest addition to our armamentarium, but it is one of the most exciting aspects of systemic treatments because it is based on clear understanding of the molecular underpinnings of the biological advantage of certain malignant cells over their normal components, biological characteristics that drive the proliferation, invasion, metastasis, and survival of such cells. The recent success of specific forms of targeted therapies (imatinib, trastuzumab, bevacizumab, and the endocrine agents) emphasize the enormous potential of this approach in the development of more specific treatments with fewer expected consequences on nonmalignant tissue. This chapter also highlights the many challenges encountered in the development of targeted agents, such as the need to validate molecular targets, to demonstrate *in vivo* that the agent accomplishes its desired effect on the target and, in consequence, can be expected to produce a specific clinical effect. These challenges have proved to be major obstacles in the case of certain targets, yielding easily in the case of others.

Tumor markers are an inherently attractive concept. Would it not be desirable to have a marker of disease extent, activity or malignant potential that one can identify and quantify in a minimally invasive or noninvasive manner? Would it not be helpful to rely on such markers to determine the efficacy of therapy early in a therapeutic intervention? The author of Chapter 7 is a recognized expert in this field and has contributed to our conceptual systematization of the tumor marker field with the development of clear criteria for validating markers and guidelines for their utilization, as well as recommendations to avoid obvious pitfalls in this area.

Much of the high-level evidence we have today was derived from prospective clinical trials. The chapter describing these master tools is authored by enormously experienced clinical trials who have contributed both conceptually and practically to the definition, implementation and analysis of randomized clinical trials. This chapter provides an excellent roadmap for current and future investigators.

The ethics of human experimentation are a critical subject for all investigators and patients. Decades of controversy have refined our approach to randomized trials,

no treatment or placebo controls, and defined optimal approaches for analysis and release of trial results. High-quality evidence can only be generated in the context of a highly ethical trial design. Screening and early diagnosis present particular challenges, largely because they relate to asymptomatic subjects, most of whom will not need nor benefit from these interventions. Therefore, these approaches benefit a few, while exposing many to potential risks. Trial design, ethics, and economics meet and often collide in this field.

As increasing emphasis has been placed on patient autonomy and as the population at large has gained increasing access to medical information, issues related to alternative and complementary therapies have also become prominent. This field includes IT, where assessment of levels of evidence can provide enormous benefits to our patients and also to healthcare providers, who often have only a passing knowledge of such popular, but often untested approaches, to the treatment of cancer or its symptoms. The lead author is clearly one of the most knowledgeable experts on this field and provides a broad overview of the issues.

Outstanding contributions cover the potential etiologies of cancer, as well as the basic biological principles of malignant transformation, invasion, and metastases. The role of the immune system is receiving increasing attention, as greater effort is being expended on the development of vaccines and other immunological approaches to cancer control.

One of the outstanding examples of the application of evidence-based medicine is Chapter 23. The authors describe the complexity of research that brings together epidemiology, basic sciences, and chemoprevention trials, in a field where isolated causes of cancer are seldom identified and where control of all variables is an unrealistic expectation. These issues are highlighted in examples of dietary intervention or the use of specific components of the human diet, such as vitamins, minerals, and other micronutrients.

The identification of genes involved in cancer predisposition has dramatically changed our approach to familial cancer syndromes. Our ability to precisely identify subjects at risk for certain malignant tumors has also placed in evidence complex social, psychological, financial, and ethical issues that need to be addressed with subjects potentially eligible for genetic screening or preventive interventions. Such advances have also uncovered potential leads for identifying other genes that influence the development of more common, apparently sporadic cancers in the population, and eventually point to future therapeutic strategies.

The chapters dedicated to specific malignant tumors bring together updated information about epidemiology, carcinogenesis, natural history, diagnostic procedures, and therapeutic interventions. The book highlights, in general, that optimal care requires close interdisciplinary collaboration, both in the diagnostic process and therapeutic strategies. There is much emphasis on the results of randomized trials, as the major theme of the book would indicate. It is painfully clear, however, that for common adult malignancies there is much evidence generated from prospective randomized trials that allows the development of evidence-based treatment guidelines; however, this is often not the case for less common tumors, especially those most resistant to systemic treatments. For these, treatment strategies are often based on observational or single-arm prospective trials. The recent identification of molecular targets for some of these tumors (renal cell or pancreatic cancers) has led to renewed interest and some notable successes in recent clinical trials.

Chapter 63 is an excellent example of how the editors envision the presentation of systematic knowledge about a specific disease condition. The authors synthesized an enormous body of information derived from clinical trials of patients with acute leukemia or myelodysplastic syndromes. The highest quality evidence, based on multiple phase III trials, is presented first, followed in descending order of quality by other types of evidence.

The stepwise development of therapeutic interventions, comparing the best "standard" to an investigational approach, is a logical candidate for evaluation in prospective randomized trials. Patient selection can be predetermined, and, in general, treatments can be compared on relatively homogeneous groups of patients. That is clearly not the case for complications of malignancy or treatment; such events occur at different times of the clinical course of the disease, and of course, patients cannot be selected a priori. Rather, the development of the complication selects the patients and treatments must be adjusted to the patients' circumstances.

For these reasons it is all the more satisfying to review Chapter 71 about acute CNS complications. Such complications are almost always dramatic and require prompt intervention. It is, therefore, all the more admirable to find level I evidence and Grade A recommendations for the management of an oncological emergency. The secondary message of these results is that appropriate controlled trials can be ethically developed in almost every circumstance in the oncological patient, and high level evidence can be generated for optimal management of subsequent patients.

Another excellent chapter, Chapter 76, summarizes current knowledge and therapeutic approaches to infectious complications of malignant disease and their treatments. While not presented with detailed assessment of levels of evidence, this chapter highlights current approaches to common and uncommon infections, the appropriate use of antibiotics and hematopoietic growth factors, and introduces methods to prevent or reduce the risk of infectious complications. It is gratifying how, from the number one cause of treatment-related mortality a few decades ago, infectious complications have become a much more manageable, and in fact, almost completely preventable complications of cancer treatment, especially in patients with solid tumors.

Chapter 83 focuses on a difficult field of research, the assessment, management, and prevention of nausea and emesis. While a common side effect of cancer treatment, especially chemotherapy and radiotherapy, nausea and emesis are difficult research subjects because of the major subjective component, interindividual variability, and the lack of external, validated, hard endpoints, short of counting the numbers of emetic episodes. Despite these obstacles, multiple prospective randomized have been conducted, comparing antiemetics with placebo or no treatment, or two antiemetics, or single antiemetics with combination therapy. The tables not only describe the results of such research, but list them in the order of higher to lower level of evidence. Such ranking facilitate the assessment of relative value of information derived from different clinical trials and also identifies opportunities to conduct additional research to clarify or complement existing evidence.

Other fields of research, especially those in the psychosocial and behavioral disciplines, have made less progress in the implementation of levels of evidence to research results. This observation is largely based on the predominantly “soft” endpoints utilized in many of these disciplines—endpoints that lend themselves less to easy quantification. As validated instruments are developed and employed in prospective research, this is also likely to change, and we can expect an increasing emphasis on evidence-based recommendations and guidelines in these fields too.

Much progress has been made since the War on Cancer was declared in 1971. Some of it was the result of the outstanding laboratory based research conducted with the support of the National Institutes of Health, National Cancer Institute, American Cancer Society, and multiple foundations, and resulted in marked improvement in our understanding of the basic biological underpinnings of malignant disease and the processes that give it its life-threatening characteristics. Some progress was derived from the technological progress in developing new diagnostic methods, refining our ability for early diagnosis, staging, and focusing of therapeutic interventions. Some progress was the result of successful drug development resulting in more effective therapeutic interventions that reduced markedly the probability of recurrence and mortality for patients diagnosed with several common human solid tumors and hematological malignancies. However, progress has been costly in financial terms, infrastructure building, and human resources. With more than 1800 new oncological drugs in the pipeline, and almost half of them at some stage of clinical development, resources are becoming even scarcer and more precious. It behooves us, as a community, to find or develop more effective and more cost-effective methods to assess the efficacy of drugs and procedures, to identify patients more and less likely to benefit from a specific intervention, and to minimize waste in the utilization of the multiple diagnostic and therapeutic approaches we have available to us today. Such urgent need for cost-effective approaches is even more dramatically highlighted by the plight of the majority of countries with limited resources around the globe. Squandering precious resources in poorly designed healthcare strategies limits access to life saving procedures. Our best hope is the increasingly stringent application of high-level evidence to decision making at the level of public health officials but also at the level of each individual physician. To enhance our probability of success, we need to speak in the language of evidence, think of levels of evi-

dence in the design of research projects and clinical trials, and increasingly limit our recommendations to those interventions supported by the highest levels of evidence. Anything less will limit access to high-quality care and dilute our efforts to serve our patients. We hope that this textbook and subsequent editions of it will lead the way towards the implementation of evidence-based oncology and set the tone for future textbooks in other medical fields.

Preface

A new textbook in oncology?! What is different about this book compared to other established texts that have already been published? Why do we need a new book? For anyone in the market for a textbook, the main reason is to keep pace with the knowledge base that is growing ever so rapidly in oncology, a field that is evolving faster than all other medical fields. This book does not attempt to be an encyclopedic summary of that information. Rather, this textbook strives to organize that knowledge into a unified approach that categorizes and summarizes the evidence that is currently available. We realize that clinicians are too busy to keep up with the literature that is published in the many available journals. Therefore, a key feature of this book is the evidence-based tables that collate the best available evidence from the literature, enabling the reader to make decisions on the basis of data. We have chosen current experts to create evidence-based chapters on topics that span the field from basic and translational science to prevention to clinical practice, and ultimately to survivorship, totaling 113 chapters written by more than 250 contributors. The tone of this book is established in the first chapter, "Evidence-Based Approach to Oncology," which reviews the history of evidence-based medicine and describes the different levels of evidence. This book will be informative to residents, fellows, practicing clinicians, and allied health professionals.

This book has several unique features. Section One, "Principles of Oncology," contains several chapters that discuss areas that have only recently matured. The topics include the biologic principles of hematopoietic stem cell therapies; informatics infrastructure; economics of cancer care; and, patient decision making. The section on "Translational Basic Science," includes chapters that review the basic concepts of cancer biology; these are written from the perspective of clinical translational science and how it is relevant to the physician. The chapter entitled "Technologies in Molecular Biology: Diagnostic Applications" is both timely and concise, while exploring the application of genomics to daily clinical practice. In the section on "Cancer Prevention and Control," the chapter, "Behavioral Modification" is unique in the literature. Similarly, the section on "Cancer Imaging" has a chapter on the "Imaging of Gastrointestinal Stromal Tumor," which is not found in current oncology textbooks. The chapter on PET imaging investigates the promise of that modality. In the "Practice of Oncology" section, several chapters discuss the care of subpopulations of patients who pose different challenges to the clinician: immunosuppressed patients; elderly patients; patients with organ dysfunction; and pregnant women. Foremost, an entire section of 13 chapters is devoted to "Cancer Survivorship." These innovative chapters represent a broad and in-depth review of the long-term consequences of cancer treatment with respect to specific malignancies. A chapter on "Cancer Advocacy" from the perspectives of cancer survivors is in this section.

Most of the chapters fall into sections on Solid Tumors, Hematologic Malignancies, and the Practice of Oncology. These sections cover site-specific malignancies, treatment toxicities, oncologic emergencies, and supportive care. They focus on the latest multimodality approach to the patient, with an emphasis on the best-available evidence from the literature. Where available, we have asked authors to include Level 1 clinical, treatment, and management data for each site-specific chapter. In those instances where Level 1 evidence may not be available, the best clinical practices based on published clinical experience are summarized. As opposed to review articles or standard textbook chapters, the evidence-based chapters presented in this book strive to present the reader with a thorough search of the evidence, judgment of the scientific quality of the evidence, and lastly a bias-free conclusion of the evidence.

This new book offers readers a user-friendly approach to the vast amount of information in the oncology literature. It is our intention that this book will become a useful tool for the improvement of readers' clinical practices. The Editorial Board

would like to acknowledge the outstanding effort of the Springer staff for pulling this project together. In particular, we would like to thank Laura Gillan who initiated this book project, and Paula Callaghan who brought it to its completion.

Contents

Foreword by Gabriel N. Hortobagyi	vii
Preface	xiii

Section One Principles of Oncology

1 Evidence-Based Approach to Oncology	3
<i>Emily DeVoto and Barnett S. Kramer</i>	
2 Principles of Chemotherapy	14
<i>Grace K. Dy and Alex A. Adjei</i>	
3 Principles of Radiation Oncology	41
<i>Timothy J. Kinsella, Jason Sohn, and Barry Wessels</i>	
4 Principles of Surgical Therapy in Oncology	58
<i>Michael S. Sabel, Kathleen M. Diehl, and Alfred E. Chang</i>	
5 Principles of Targeted and Biological Therapies	73
<i>Stephen R.D. Johnston, Sue Chua, and Charles Swanton</i>	
6 Biologic Principles of Hematopoietic Stem Cell Transplantation	91
<i>Robert J. Soiffer</i>	
7 Evaluation of Tumor Markers: An Evidence-Based Guide for Determination of Clinical Utility	106
<i>Daniel F. Hayes</i>	
8 Design and Analysis of Oncology Clinical Trials	112
<i>James J. Dignam, Theodore G. Karrison, and John Bryant</i>	
9 Ethics of Clinical Oncology Research	127
<i>Manish Agrawal, Lindsay A. Hampson, and Ezekiel J. Emanuel</i>	
10 Informatics Infrastructure for Evidence-Based Cancer Medicine	143
<i>Jeffrey P. Bond and Scott D. Luria</i>	
11 Economics of Cancer Care	151
<i>James Katcheressian and Thomas J. Smith</i>	
12 Principles of Screening for Cancer	161
<i>Russell Harris and Linda S. Kinsinger</i>	
13 Patient Decision Making	177
<i>Peter A. Ubel</i>	
14 Establishing an Interdisciplinary Oncology Team	184
<i>Nathan Levitan, Meri Armour, and Afshin Dowlati</i>	

- 15 Principles of Complementary and Alternative Medicine
for Cancer 194
Andrew J. Vickers and Barrie Cassileth

Section Two Translational Basic Science

- 16 Fundamental Aspects of the Cell Cycle and
Signal Transduction 207
Jeffrey R. Skaar and James A. DeCaprio
- 17 Viral Carcinogenesis 214
Michele Carbone and Giuseppe Barbanti-Brodano
- 18 Environmental Carcinogenesis 233
*T. Sabo-Attwood, M. Ramos-Nino, and
Brooke T. Mossman*
- 19 Cancer Metastasis 244
Kevin McDonnell and Anton Wellstein
- 20 Tumor Immunology and Immunotherapy 254
Jeffrey Weber, Sophie Dessureault, and Scott Antonia
- 21 Technologies in Molecular Biology:
Diagnostic Applications 269
Timothy J. Triche

Section Three Cancer Prevention and Control

- 22 Cancer Epidemiology 287
Melissa L. Bondy and Shine Chang
- 23 Evidence-Based Cancer Prevention Research:
A Multidisciplinary Perspective on Cancer
Prevention Trials 301
*Stephen D. Hursting, Michele R. Forman, Asad Umar,
Nomeli P. Nunez, and J. Carl Barrett*
- 24 Screening 317
*Stephen H. Taplin, Sarah Dash, Paula Zeller,
and Jane Zapka*
- 25 Genetic Screening and Counseling for
High-Risk Populations 341
Mary B. Daly
- 26 Behavior Modification 358
Christopher N. Sciamanna

Section Four Cancer Imaging

- 27 Central Nervous System Imaging 369
Dima A. Hammoud and Martin G. Pomper

28	Breast Imaging	381
	<i>Wendie A. Berg</i>	
29	Imaging of Thoracic Malignancies	392
	<i>Caroline Chiles and Suzanne L. Aquino</i>	
30	Imaging of Gastrointestinal Stromal Tumor	413
	<i>Ihab R. Kamel and Elliot K. Fishman</i>	
31	Genitourinary Imaging	425
	<i>Satomi Kawamoto, Harpreet K. Pannu, David A. Bluemke, and Elliot K. Fishman</i>	
32	Musculoskeletal Imaging	442
	<i>Leanne L. Seeger and Kambiz Motamedi</i>	
33	Positron Emission Tomography and Cancer	449
	<i>Daniel N. Chatzifotiadis, Julia W. Buchanan, and Richard L. Wahl</i>	

Section Five Solid Tumors

34	Central Nervous System Tumors	487
	<i>Ravi D. Rao, Paul D. Brown, Caterina Giannini, Cormac O. Maher, Fredric B. Meyer, Evanthia Galanis, Brad J. Erickson, and Jan C. Buckner</i>	
35	Eye, Orbit, and Adnexal Structures	506
	<i>Daniel M. Albert, Marni Feldmann, Heather Potter, and Amit Kumar</i>	
36	Head and Neck Cancer	528
	<i>Ezra E.W. Cohen, Kerstin M. Stenson, Michael Milano, and Everett E. Vokes</i>	
37	Lung Cancer	545
	<i>Hak Choy, Harvey I. Pass, Rafael Rosell, and Anne Traynor</i>	
38	Therapy for Malignant Pleural Mesothelioma	622
	<i>Harvey I. Pass, Nicholas Vogelzang, Steven Hahn, and Michele Carbone</i>	
39	Mediastinum	645
	<i>Alexander S. Krupnick and Joseph B. Shrager</i>	
40	Esophageal Cancer	664
	<i>John D. Urschel</i>	
41	Stomach	680
	<i>Scott A. Hundahl, John S. Macdonald, and Stephen R. Smalley</i>	
42	Colon, Rectal, and Anal Cancer Management	704
	<i>John M. Skibber and Cathy Eng</i>	

43	Adenocarcinoma and Other Small Intestinal Malignancies . . .	733
	<i>John H. Donohue</i>	
44	Cancer of the Liver and Bile Ducts	745
	<i>Michael L. Kendrick, Annette Grambihler, Gregory J. Gores, Steven Alberts, and David M. Nagorney</i>	
45	An Evidence-Based Approach to the Management of Pancreatic Cancer	764
	<i>Dan Laheru</i>	
46	Renal Cell Cancer	782
	<i>Joseph I. Clark, Craig Hofmeister, Vicki Keedy, and Jeffrey A. Sosman</i>	
47	Ureter, Bladder, Penis, and Urethra	806
	<i>Cheryl T. Lee, Brent Hollenbeck, and David P. Wood, Jr.</i>	
48	Prostate Cancer	826
	<i>Richard Whittington and David J. Vaughn</i>	
49	Testis Cancer	844
	<i>Timothy Gilligan and Phillip W. Kantoff</i>	
50	Cervix, Vulva, and Vagina	874
	<i>Julian C. Schink</i>	
51	Gestational Trophoblastic Neoplasia	892
	<i>John R. Lurain</i>	
52	Ovarian Cancer	903
	<i>Yukio Sonoda and David Spriggs</i>	
53	Uterine Malignancies	928
	<i>Gini F. Fleming, Anthony C. Montag, Arno J. Mundt, and S.D. Yamada</i>	
54	Evidence-Based Management of Breast Cancer	951
	<i>Lisa A. Newman and Daniel F. Hayes</i>

Contributors

Alex A. Adjei, MD, PhD

Professor, Department of Oncology, Mayo Clinic Foundation, Rochester, MN, USA.

Manish Agrawal, MD

Staff Scientist, Department of Clinical Bioethics, Warren G. Magnuson Clinical Center and Medical Oncology Research Unit, National Cancer Institute, National Institutes of Health, Bethesda, MD, USA.

Daniel M. Albert, MD, MS

Chair Emeritus, F.A. David Professor, and Lorenz E. Zimmerman Professor, Department of Ophthalmology and Visual Sciences, University of Wisconsin-Madison, Madison, WI, USA.

Mark R. Albertini, MD

Associate Professor, Department of Medicine, University of Wisconsin-Madison; Chief of Oncology, William S. Middleton Memorial Veterans Hospital, Madison, WI, USA.

Steven Alberts, MD, MPH

Associate Professor, Department of Oncology, Mayo Clinic College of Medicine, Rochester, MN, USA.

Sarah W. Alexander, MD

Assistant Professor, Department of Pediatrics, Case Western University, Division of Pediatric Hematology and Oncology, Rainbow Babies and Children's Hospital, Cleveland, OH, USA.

Asim Amin, MD, PhD

Immunotherapy Co-Director, Blumenthal Cancer Center, Carolinas Medical Center, Charlotte, NC, USA.

Scott Antonia, MD, PhD

Medical Director, Cellular Therapies Core, Department of Interdisciplinary Oncology, H. Lee Moffitt Cancer Center & Research Institute, University of South Florida, Tampa, FL, USA.

Suzanne L. Aquino, MD

Assistant Professor, Department of Radiology, Harvard Medical School/Massachusetts General Hospital, Boston, MA, USA.

Meri Armour, RN, MSN

Senior Vice President, Ireland Cancer Center/University Hospitals of Cleveland, Cleveland, OH, USA.

David A. August, MD

Associate Professor, Department of Surgery; Chief, Division of Surgical Oncology, UMDNJ/Robert Wood Johnson Medical School and the Cancer Institute of New Jersey, New Brunswick, NJ, USA.

Noreen M. Aziz, MD, PhD, MPH

Senior Program Director, Office of Cancer Survivorship, Division of Cancer Control and Population Sciences, National Cancer Institute, Rockville, MD, USA.

Giuseppe Barbanti-Brodano, MD

Professor, Department of Experimental and Diagnostic Medicine, Section of Microbiology, University of Ferrara, Ferrara, Italy.

J. Carl Barrett, PhD

Director, Center for Cancer Research, National Cancer Institute, Bethesda, MD, USA.

Karen Basen-Engquist, PhD, MPH

Associate Professor, Department of Behavioral Science, The University of Texas at M. D. Anderson Cancer Center, Houston, TX, USA.

Wendie A. Berg, MD, PhD

Breast Imaging Consultant, Study Chair, American College of Radiology Imaging Network, Lutherville, MD, USA.

Smita Bhatia, MD, MPH

Director, Epidemiology and Outcomes Research, Department of Pediatric Oncology, City of Hope Cancer Center, Duarte, CA, USA.

Rina M. Bloch, MD

Assistant Professor, Department of Rehabilitation Medicine, Tufts-New England Medical Center, Boston, MA, USA.

David A. Bluemke, MD, PhD

Associate Professor, The Russell H. Morgan Department of Radiology and Radiological Science, The Johns Hopkins Hospital, Baltimore, MD, USA.

Diane C. Bodurka, MD

Associate Professor, Department of Gynecological Oncology, The University of Texas at M. D. Anderson Cancer Center, Houston, TX, USA.

Michael Boeckh, MD

Assistant Member, Program in Infectious Diseases, Fred Hutchinson Cancer Research Center; Assistant Professor of Medicine, University of Washington School of Medicine, Seattle, WA, USA.

Jeffrey P. Bond, PhD

Research Associate Professor, Department of Microbiology and Molecular Genetics, University of Vermont, Burlington, VT, USA.

Melissa L. Bondy, PhD

Professor, Department of Epidemiology, The University of Texas M. D. Anderson Cancer Center, Houston, TX, USA.

Louise J. Bordeleau, MD, FRCP(C), MSc

Attending, Department of Medical Oncology, Mount Sinai Hospital, Toronto, Ontario, Canada.

Kristin Bradley, MD

Assistant Professor of Human Oncology, University of Wisconsin, Madison, WI, USA.

Paul D. Brown, MD

Assistant Professor, Division of Radiation Oncology, Department of Oncology, Mayo Clinic College of Medicine, Rochester, MN, USA.

John Bryant, PhD

Professor, Associate Director, Departments of Biostatistics, National Surgical Adjuvant Breast and Bowel Project Biostatistical Center, Pittsburgh, PA, USA.

Julia W. Buchanan, BS

Associate in Research, Russell H. Morgan Department of Radiology and Radiological Science, Division of Nuclear Medicine, The Johns Hopkins University School of Medicine, Baltimore, MD, USA.

Jan C. Buckner, MD

Chair, Division of Medical Oncology, Professor of Oncology, Mayo Clinic College of Medicine, Rochester, MN, USA.

Susan V. Bukata, MD

Assistant Professor, Department of Orthopedics, University of Rochester Medical Center/Strong Memorial Hospital, Rochester, NY, USA.

Alan K. Burnett, MD, FRCPath, FRCP(Glasgow), FRCP(Edinburgh), FRCP(London), FMSci

Professor, Department of Haematology, University of Wales College of Medicine, Cardiff, Wales, UK.

John C. Byrd, MD

Associate Professor, Department of Internal Medicine, Division of Hematology and Oncology, The Ohio State University, The Arthur James Comprehensive Cancer Center, Columbus, OH, USA.

Michele Carbone, MD, PhD

Associate Professor, Department of Pathology, Cardinal Bernardin Cancer Center, Loyola University Chicago, Maywood, IL, USA.

Daniel B. Carr, MD, DABPM, FFPANZCA(Hon)

Saltonstall Professor of Pain Research, Department of Anesthesia; Medical Director, Pain Management Program, Tufts-New England Medical Center, Boston, MA, USA.

Shamus R. Carr, MD

Surgical Resident, Department of Surgery, Thomas Jefferson University, Philadelphia, PA, USA.

Jacqueline Casillas, MD, MSHS

Assistant Professor, Department of Pediatrics, Division of Hematology/Oncology, David Geffen School of Medicine at UCLA, Los Angeles, CA, USA.

Barrie Cassileth, PhD

Chief, Integrative Medicine Service; Laurance S. Rockefeller Chair in Integrative Medicine, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY, USA.

Mark S. Chambers, DMD

Associate Professor, Head & Neck Surgery; Deputy Chief, Section of Oncologic Dentistry and Prosthodontics, M. D. Anderson Cancer Center, Houston, TX, USA.

Alfred E. Chang, MD

Hugh Cabot Professor of Surgery; Chief, Division of Surgery Oncology; Department of Surgery, University of Michigan, Ann Arbor, MI, USA.

Shine Chang, PhD

Associate Director, Office of Preventive Oncology, National Cancer Institute, National Institutes of Health, Bethesda, MD, USA.

Daniel N. Chatzifotiadis, MD

Post Doctoral Research Fellow, Department of Radiology, Division of Nuclear Medicine, The Johns Hopkins Medical Institute, Baltimore, MD, USA.

Caroline Chiles, MD

Professor, Department of Radiology, Wake Forest University School of Medicine, Winston-Salem, NC, USA.

Hak Choy, MD

Nancy B. and Jake L. Hamon Distinguished Chair in Therapeutic Oncology Research, Professor and Chairman, Department of Radiation Oncology, Moncrief Radiation Oncology Center, University of Texas, Southwestern Medical Branch, Dallas, TX, USA.

Sue Chua, MBBS, FRACP

Senior Clinical Research Fellow, Breast Unit, Department of Medicine, Royal Marsden Hospital, Chelsea, London, UK.

Joseph I. Clark, MD

Associate Professor, Department of Medicine, Loyola University Chicago, Maywood, IL, USA.

Ezra E.W. Cohen, MD

Assistant Professor, Section of Hematology/Oncology, Department of Medicine, University of Chicago, Chicago, IL, USA.

Anne Coscarelli, PhD

Research Psychologist, Department of Public Health; Director, Ted Mann Family Resource Center, UCLA/David Geffen School of Medicine, Los Angeles, CA, USA.

Christopher J. Crnich, MD, MS

Research Fellow, Section of Infectious Diseases, Department of Medicine, University of Wisconsin, Madison, WI, USA.

Alvin A. Dahl, MD, PhD

Professor, Department of Clinical Cancer Research, National Hospital-Radium Hospital, Oslo, Norway.

Mary B. Daly, MD, PhD

Director, Cancer Prevention and Control Program, Department of Population Science, Fox Chase Cancer Center, Philadelphia, PA, USA.

Suzanne C. Danhauer, PhD

Assistant Professor and Associate Director, Psychosocial Oncology & Cancer Patient Support Programs, Department of Internal Medicine, Wake Forest University Baptist Medical Center, Winston-Salem, NC, USA.

Sarah Dash, MPH

Cancer Research Training Fellow, Applied Research Program, Division of Cancer Control and Population Sciences, National Cancer Institute, Bethesda, MD, USA.

Daniel J. De Angelo, MD, PhD

Assistant Professor, Department of Medicine, Harvard Medical School; Adult Leukemia Program, Dana-Farber Cancer Institute, Brigham and Women's Hospital, Boston, MA, USA.

James A. DeCaprio, MD

Associate Professor, Department of Medical Oncology, Dana-Farber Cancer Institute, Boston, MA, USA.

Joachim Deeg, MD

Member, Clinical Research Division, Fred Hutchinson Cancer Research Center; Professor of Medicine, University of Washington School of Medicine, Seattle, WA, USA.

George D. Demetri, MD

Clinical Director, Sarcoma Program, Dana-Farber Cancer Institute; Associate Professor, Department of Medicine, Harvard Medical School, Boston, MA, USA.

Sophie Dessureault, MD, PhD

Staff, Department of Interdisciplinary Oncology, H. Lee Moffitt Cancer Center & Research Institute, University of South Florida, Tampa, FL, USA.

Emily DeVoto, PhD, MSPH

Health Science Policy Analyst, Office of Medical Applications of Research, National Institutes of Health, Bethesda, MD, USA.

Kathleen M. Diehl, MD

Assistant Professor, Division of Surgical Oncology, Department of Surgery, University of Michigan, Ann Arbor, MI, USA.

James J. Dignam, PhD

Assistant Professor, Department of Health Studies, University of Chicago and University of Chicago Cancer Research Center, Chicago, IL, USA.

Gerard M. Doherty, MD

Norman W. Thompson Professor; Section Head, General Surgery; Chief, Division of Endocrine Surgery; Director, Department of Surgery, University of Michigan Health System, Ann Arbor, MI, USA.

Jessica S. Donington, MD

Assistant Professor, Department of Cardiothoracic Surgery, Stanford University School of Medicine, Stanford, CA, USA.

John H. Donohue, MD

Consultant in Surgery, Department of General Surgery, Mayo Clinic; Professor of Surgery, Mayo Graduate School of Medicine, Rochester, MN, USA.

Kristine A. Donovan, PhD, MBA

Assistant Professor, Department of Interdisciplinary Oncology, H. Lee Moffitt Cancer Center and Research Institute at the University of South Florida, Tampa, FL, USA.

Afshin Dowlati, MD

Assistant Professor, Department of Medicine, Case Western Reserve University, University Hospitals of Cleveland, Cleveland, OH, USA.

Faith M. Durden, MD

Assistant Professor, Department of Dermatology, Case Western Reserve University, University Hospitals of Cleveland, Cleveland, OH, USA.

Grace K. Dy, MD

Fellow, Department of Oncology, Mayo Clinic College of Medicine, Rochester, MN, USA.

Douglas B. Einstein, MD, PhD

Assistant Professor, Department of Radiation Oncology, Case Western Reserve University, Cleveland, OH, USA.

Ezekiel J. Emanuel, MD, PhD

Chair, Department of Clinical Bioethics, Warren G. Magnuson Clinical Center, National Institutes of Health, Bethesda, MD, USA.

Cathy Eng, MD

Assistant Professor, Department of Gastrointestinal Medical Oncology, The University of Texas M. D. Anderson Cancer Center, Houston, TX, USA.

Brad J. Erickson, MD

Associate Professor, Department of Radiology, Mayo Clinic Foundation, Rochester, MN, USA.

Scott E. Evans, MD

Instructor, Department of Pulmonary and Critical Care Medicine, Mayo Clinic College of Medicine, Mayo Clinic Foundation, Rochester, MN, USA.

Marni Feldmann, MD

Resident, Department of Ophthalmology and Visual Sciences, University of Wisconsin, Madison, WI, USA.

Elliot K. Fishman, MD

Professor, The Russell H. Morgan Department of Radiology and Radiological Science, The Johns Hopkins University School of Medicine, Baltimore, MD, USA.

Gini F. Fleming, MD

Associate Professor, Department of Medicine, University of Chicago, Chicago, IL, USA.

Michele R. Forman, PhD

Senior Investigator, Center for Cancer Research, National Cancer Institute, Bethesda, MD, USA

Sophie D. Fosså, PhD

Professor, Department of Long-term Studies, National Hospital-Radium Hospital, University of Oslo, Oslo, Norway.

Joseph S. Friedberg, MD

Chief, Division of Thoracic Surgery, Department of Surgery, Thomas Jefferson University, Philadelphia, PA, USA.

Shirish M. Gadgeel, MD

Assistant Professor, Department of Internal Medicine, Division of Hematology & Oncology, Karmanos Cancer Institute/Wayne State University, Detroit, MI, USA.

Evanthia Galanis, MD

Associate Professor, Division of Medical Oncology, Mayo Clinic College of Medicine, Rochester, MN, USA.

Patricia A. Ganz, MD

American Cancer Society Clinical Research Professor; Director, Division of Cancer Prevention and Control Research, Jonsson Comprehensive Cancer Center at UCLA, Professor, Schools of Public Health and Medicine, University of California, Los Angeles, Los Angeles, CA, USA.

Adam S. Garden, MD

Professor, Department of Radiation Oncology, The University of Texas M. D. Anderson Cancer Center, Houston, TX, USA.

Patrick J. Getty, MD

Assistant Professor, Department of Orthopaedic Surgery, Case Western Reserve University/University Hospitals of Cleveland, Cleveland, OH, USA.

Maged I. Gharib, MSc, MD, MRCP, MRCPATH

Attending, Department of Haematology, Royal Manchester Children's Hospital, Manchester, UK.

Caterina Giannini, MD

Consultant, Department of Anatomic Pathology, Mayo Clinic Foundation, Rochester, MN, USA.

Paula Gill, MD

Fellow, Department of Oncology, Mayo Clinic Foundation, Rochester, MN, USA.

Montgomery Gillard, MD

Lecturer, Department of Dermatology, University of Michigan, Ann Arbor, MI, USA.

Timothy Gilligan, MD

Instructor in Medicine, Department of Medical Oncology, Harvard Medical School, Dana-Farber Cancer Institute, Boston, MA, USA.

Pamela J. Goodwin, MD, MSc, FBPC

Professor, Department of Medicine, University of Toronto; Senior Scientist, Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, Ontario, Canada.

Gregory J. Gores, MD

Professor, Department of Medicine, Mayo Clinic College of Medicine, Rochester, MN, USA.

Leonidas C. Goudas, MD, PhD

Assistant Professor, Department of Anesthesiology, Tufts-New England Medical Center, Boston, MA, USA.

Annette Grambihler, MD

Staff, First Department of Internal Medicine, University of Mainz, Mainz, Germany.

Frederic W. Grannis, Jr., MD

Assistant Professor, Department of Thoracic Surgery, City of Hope National Medical Center, Duarte, CA, USA.

F. Anthony Greco, MD

Medical Director, Sarah Cannon Cancer Center, Nashville, TN, USA.

Axel Grothey, MD

Mayo Foundation Scholar, Division of Medical Oncology, Mayo Clinic Foundation, Rochester, MN, USA.

Steven Hahn, MD

Attending, Department of Surgery, Hospital of the University of Pennsylvania, Philadelphia, PA, USA.

John D. Hainsworth, MD

Director of Clinical Research, Sarah Cannon Cancer Center, Nashville, TN, USA.

Dima A. Hammoud, MD

Assistant Professor, Department of Diagnostic Radiology, Division of Neuroradiology, The Johns Hopkins University, Baltimore, MD, USA.

Lindsay A. Hampson, BS

Fellow, Department of Clinical Bioethics, Warren G. Magnuson Clinical Center, National Institutes of Health, Bethesda, MD, USA.

Paul M. Harari, MD

Associate Professor, Department of Human Oncology, University of Wisconsin Comprehensive Cancer Center, Madison, WI, USA.

Russell Harris, MD, MPH

Professor, Department of Medicine, University of North Carolina, Chapel Hill, NC, USA.

Lawrence E. Harrison, MD

Associate Professor, Chief, Division of Surgical Oncology, UMDNJ-New Jersey Medical School, Newark, NJ, USA.

Daniel F. Hayes, MD

Clinical Director, Breast Oncology Program, University of Michigan Comprehensive Cancer Center, Ann Arbor, MI, USA.

Craig Hofmeister, MD

Fellow, Division of Hematology-Oncology, Loyola University Chicago, Cardinal Bernadin Cancer Center, Maywood, IL, USA.

Brent Hollenbeck, MD

Lecturer, Department of Urology, University of Michigan, Ann Arbor, MI, USA.

Steven M. Horwitz, MD

Clinical Assistant Physician, Lymphoma Services, Department of Hematology, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY, USA.

Thomas Huff, MD

Staff, Department of Orthopaedic Surgery, Case Western Reserve University, Cleveland, OH, USA.

Scott A. Hundahl, MD, FACS, FSSO, FAHNS

Professor, Department of Clinical Surgery, U.C. Davis; Chief of Surgery, VA Northern California Health Care System, Sacramento VA at Mather, Mather, CA, USA.

Stephen D. Hursting, PhD, MPH

Deputy Director, Office of Preventive Oncology, National Cancer Institute, Bethesda, MD, USA.

Jimmy Hwang, MD

Attending, Lombardi Comprehensive Cancer Center, Georgetown University Medical Center, Washington, DC, USA.

Paul B. Jacobsen, PhD

Professor and Program Leader, Health Outcomes and Behavioral Program, Department of Psychosocial and Palliative Care Program, H. Lee Moffitt Cancer Center and Research Institute, Tampa, FL, USA.

Timothy M. Johnson, MD

Professor, Departments of Dermatology, Otolaryngology, and Surgery, University of Michigan Medical School, University of Michigan, Ann Arbor, MI, USA.

Stephen R.D. Johnston, MA, PhD, FRCP

Consultant Medical Oncologist, Department of Medicine—Breast Unit, Royal Marsden Hospital, London, UK.

Stein Kaasa, MD, PhD

Professor, Department of Cancer Research and Molecular Medicine, Faculty of Medicine, The Norwegian University of Science and Technology and the Palliative Care Unit, St. Olavs Hospital, Trondheim, Norway.

Ihab R. Kamel, MD, PhD

Assistant Professor, The Russell H. Morgan Department of Radiology and Radiological Sciences, The Johns Hopkins Hospital, Baltimore, MD, USA.

Phillip W. Kantoff, MD, PhD

Professor, Department of Medicine; Chief, Division of Solid Tumor Oncology; Director, Lank Center for Genitourinary Oncology, Harvard Medical School, Dana-Farber Cancer Institute, Boston, MA, USA.

Theodore G. Karrison, PhD

Research Associate, Associate Professor, Department of Health Studies, University of Chicago and University of Chicago Cancer Research Center, Chicago, IL, USA.

Satomi Kawamoto, MD

Assistant Professor, The Russell H. Morgan Department of Radiology and Radiological Science, The Johns Hopkins Hospital, Baltimore, MD, USA.

Thomas Kearney, MD, FACS

Associate Professor, Department of Surgery, UMDNJ/Robert Wood Johnson Medical School; The Cancer Institute of New Jersey, New Brunswick, NJ, USA.

Vicki Keedy, MD

Fellow, Division of Hematology/Oncology, Vanderbilt University Medical Center, Nashville, TN, USA.

Michael L. Kendrick, MD

Assistant Professor, Department of Surgery, Mayo Clinic College of Medicine, Rochester, MN, USA.

Michael S. Kent, MD

Staff, Department of Cardiothoracic Surgery, Weill-Cornell Medical Center, New York, NY, USA.

James Khatcheressian, MD

Assistant Professor, Department of Internal Medicine, Division of Hematology/Oncology, Virginia Commonwealth University Health System, Richmond, VA, USA.

Timothy J. Kinsella, MD

Vincent K. Smith Professor and Chairman, Department of Radiation Oncology, University Hospitals of Cleveland, Case Western Reserve University, Cleveland, OH, USA.

Linda S. Kinsinger, MD, MPH

Assistant Director, VA National Center for Health Promotion and Disease Prevention, Durham, NC, USA.

Clifford Y. Ko, MD

Associate Professor, Department of Surgery, UCLA School of Medicine/West Los Angeles VA Medical Center, Los Angeles, CA, USA.

Jonathan E. Kolitz, MD

Director, Leukemia Service, Department of Medicine, North Shore University Hospital, New York University School of Medicine, Manhasset, NY, USA.

Barnett S. Kramer, MD, MPH

Associate Director for Disease Prevention, Office of Disease Prevention, National Institutes of Health, Bethesda, MD, USA.

Alexander S. Krupnick, MD

Fellow, Department of Surgery, Division of Cardiothoracic Surgery, Washington University, St Louis, MO, USA.

Tracey L. Krupski, MD

Resident, Department of Urology, David Geffen School of Medicine, University of California, Los Angeles, CA, USA.

Amit Kumar, MD

Resident, Department of Ophthalmology and Visual Sciences, University of Wisconsin, Madison, WI, USA.

Dan Laheru, MD

Assistant Professor, Department of Medical Oncology, The Sidney Kimmel Comprehensive Cancer Center at The Johns Hopkins, Baltimore, MD, USA.

Wendy Landier, RN, MSN, CPNP

Pediatric Nurse Practitioner, Division of Pediatrics, City of Hope Comprehensive Cancer Center, Duarte, CA, USA.

Joseph Lau, MD

Professor, Department of Medicine, Institute for Clinical Research and Health Policy Studies, Tufts-New England Medical Center, Boston, MA, USA.

Donald P. Lawrence, MD

Assistant Professor, Division of Hematology-Oncology, Tufts-New England Medical Center, Boston, MA, USA.

Cheryl T. Lee, MD

Assistant Professor, Department of Urology, The University of Michigan, Ann Arbor, MI, USA.

Julie Lemieux, MD

Attending, Department of Medicine, Mount Sinai Hospital, Toronto, Ontario, Canada.

Nathan Levitan, MD, MBA

Professor, Department of Medicine, Ireland Cancer Center/University Hospitals of Cleveland, Cleveland, OH, USA.

Andrew H. Limper, MD

Professor of Medicine, Biochemistry, and Molecular Biology, Department of Pulmonary & Critical Care Medicine, Mayo Clinic College of Medicine, Rochester, MN, USA.

Thomas S. Lin, MD, PhD

Assistant Professor, Department of Internal Medicine, Division of Hematology and Oncology, The Ohio State University, Columbus, OH, USA.

Andrew J. Lipman, MD

Clinical and Research Fellow, Division of Hematology-Oncology, Tufts-New England Medical Center, Boston, MA, USA.

Mark S. Litwin, MD, MPH

Professor, Department of Urology and Health Services, David Geffen School of Medicine, School of Public Health, Jonsson Comprehensive Cancer Center, University of California, Los Angeles, CA, USA.

Jon Håvard Loge, MD, PhD

Professor, Department of Behavioural Sciences in Medicine, University of Oslo and the Centre for Palliative Medicine, Ullevål University Hospital, Oslo, Norway.

B. Jack Longley, MD

Professor, Department of Dermatology, University of Wisconsin-Hospital and Clinics, Madison, WI, USA.

Charles Loprinzi MD

Professor, Division of Medical Oncology, Mayo Clinic Foundation, Rochester, MN, USA.

John R. Lurain, MD

John & Ruth Brewer Professor of Gynecology and Cancer Research, Department of Obstetrics and Gynecology; Director, John I. Brewer Trophoblastic Disease Center; Northwestern University Feinberg School of Medicine, Chicago, IL, USA.

Scott D. Luria, MD

Associate Professor, Department of Medicine, University of Vermont, Burlington, VT, USA.

John S. Macdonald, MD

Professor, Department of Medicine, New York Medical College; Medical Director, St. Vincent's Comprehensive Cancer Center, New York, NY, USA.

Cormac O. Maher, MD

Chief Resident Associate, Department of Neurosurgery, Mayo Clinic College of Medicine, Rochester, MN, USA.

Dennis G. Maki, MD

Chief, Section of Infectious Diseases, Department of Medicine, University of Wisconsin Medical School, Madison, WI, USA.

Karim S. Malek, MD

Assistant Professor, Department of Medicine, Section of Hematology and Oncology, Boston University School of Medicine, Boston, MA, USA.

Shakun Malik, MD

Chief, Center for Thoracic Medical Oncology, Director, Multidisciplinary Thoracic Oncology, Associate Professor, Division of Hematology/Oncology, Department of Medicine and Lombardi Cancer Center, Georgetown University Hospital, Washington, DC, USA.

Paul F. Mansfield, MD, FACS

Professor, Department of Surgical Oncology, The University of Texas M. D. Anderson Cancer Center, Houston, TX, USA.

John L. Marshall, MD

Associate Professor, Lombardi Cancer Center, Georgetown University, Washington, DC, USA.

Paul Martin, MD

Member, Clinical Research Division, Fred Hutchinson Cancer Research Center; Professor, Department of Medicine, University of Washington School of Medicine, Seattle, WA, USA.

Matthew J. Matasar, MD

Instructor, Department of Medicine, Columbia University Medical Center, New York, NY, USA.

Kevin McDonnell, MD, PhD

Fellow, Lombardi Cancer Center, Georgetown University, Washington, DC, USA.

Kevin P. McMullen, MD

Assistant Professor, Department of Radiation Oncology, Wake Forest University School of Medicine, Winston-Salem, NC, USA.

Richard P. McQuellon, PhD

Associate Professor and Director, Psychosocial Oncology & Cancer Patient Support Programs, Wake Forest University Health Sciences, Winston-Salem, NC, USA.

Fredric B. Meyer, MD

Professor, Department of Neurosurgery, Mayo Clinic College of Medicine, Rochester, MN, USA.

Laura C. Michaelis, MD

Fellow, Department of Medicine, Section of Hematology/Oncology, University of Chicago, Chicago, IL, USA.

Michael Milano, MD

Chief Resident, Department of Radiation and Cellular Oncology, University of Chicago, Chicago, IL, USA.

Paradi Mirmirani, MD

Assistant Professor, Department of Dermatology, Case Western Reserve University, University Hospitals of Cleveland, Cleveland, OH, USA.

Anthony C. Montag, MD

Associate Professor, Department of Pathology, University of Chicago Hospital, Chicago, IL, USA.

Craig H. Moskowitz, MD

Associate Professor, Department of Medicine, Lymphoma Service, Memorial Sloan-Kettering Cancer Center, New York, NY, USA.

Brooke T. Mossman

Professor, Department of Pathology, College of Medicine, University of Vermont, Burlington, VT, USA.

Kambiz Motamedi, MD

Assistant Professor, Department of Radiology, David Geffen School of Medicine at UCLA, Los Angeles, CA, USA.

Arno J. Mundt, MD

Associate Professor, Department of Radiation and Cellular Oncology, University of Chicago, Chicago, IL, USA.

David M. Nagorney, MD

Professor, Department of Surgery, Mayo Clinic College of Medicine, Rochester, MN, USA.

Alfred I. Neugut, MD, PhD

Professor, Department of Epidemiology, Mailman School of Public Health; Department of Medicine, Herbert Irving Comprehensive Cancer Center, College of Physicians and Surgeons, Columbia University Medical Center, New York, NY, USA.

Lisa A. Newman, MD, MPH

Associate Professor, Division of Surgical Oncology; Director, Breast Care Center, University of Michigan, Ann Arbor, MI, USA.

Jeffrey L. Nielsen, MD

Chief Resident, Department of Radiology, University Hospitals of Cleveland, Case Western Reserve University School of Medicine, Cleveland, OH, USA.

Jeffrey A. Norton, MD

Professor, Department of Surgery, Division of General Surgery, Stanford University Medical Center, Stanford, CA, USA.

Nomeli P. Nunez, PhD, MPH

Cancer Prevention Fellow, Center for Cancer Research, National Cancer Institute, Bethesda, MD, USA.

Olatoyosi M. Odenike, MD

Assistant Professor, Section of Hematology/Oncology, Department of Medicine, University of Chicago, Chicago, IL, USA.

Beth A. Overmoyer, MD, FACP

Assistant Professor, Department of Medicine, Case Western Reserve University, Cleveland, OH, USA.

Harpreet K. Pannu, MD

Consultant, The Russell H. Morgan Department of Radiology and Radiological Science, The Johns Hopkins Hospital, Baltimore, MD, USA.

Harvey I. Pass, MD

Professor and Chief of Thoracic Surgery, Department of Cardiothoracic Surgery; Head, Thoracic Oncology, New York University School of Medicine and Comprehensive Cancer Center, New York, NY, USA.

Martin G. Pomper, MD, PhD

Associate Professor, Department of Diagnostic Radiology, Division of Neuroradiology, The Johns Hopkins University, Baltimore, MD, USA.

Jeffrey L. Port, MD

Assistant Professor, Department of Cardiothoracic Surgery, Weill-Cornell Medical Center/New York Presbyterian Hospital, New York, NY, USA.

Heather Potter, MD

Resident, Department of Ophthalmology and Visual Sciences, University of Wisconsin, Madison, WI, USA.

Andrew Putnam, MD

Assistant Professor, Departments of Medicine and Oncology, Georgetown University, Washington, DC, USA.

M. Ramos-Nino, PhD

Research Assistant Professor, Department of Pathology, College of Medicine, University of Vermont, Burlington, VT, USA.

Ravi D. Rao, MBBS

Senior Associate Consultant, Division of Medical Oncology, Mayo Clinic College of Medicine, Rochester, MN, USA.

Douglas Reintgen, MD

Director, Department of Surgery, Lakeland Regional Cancer Center, Lakeland, FL, USA.

Mark R. Robbin, MD

Chief, Musculoskeletal and Emergency Radiology; Assistant Professor of Radiology, Department of Radiology, University Hospitals of Cleveland, Case Western Reserve University, Cleveland, OH, USA.

H. Ian Robins, MD, PhD

Professor, Department of Medicine, Human Oncology, and Neurology, University of Wisconsin, Madison, WI, USA.

Rafael Rosell, MD

Chief, Medical Oncology Service, Associate Professor, University of Barcelona; Scientific Director of Oncology Research, Catalan Institute of Oncology, Hospital Germans Trias i Pujol, Barcelona, Spain.

Randy N. Rosier, MD, PhD

Professor and Chairman, Department of Orthopaedics, The University of Rochester Medical Center/Strong Memorial Hospital, Rochester, NY, USA.

Julia H. Rowland, PhD

Director, Office of Cancer Survivorship, Division of Cancer Control and Population Sciences, National Cancer Institute, Bethesda, MD, USA.

Michael S. Sabel, MD

Assistant Professor, Division of Surgical Oncology, Department of Surgery, University of Michigan, Ann Arbor, MI, USA.

T. Sabo-Attwood, PhD

Fellow, Department of Pathology, College of Medicine, University of Vermont, Burlington, VT, USA.

Nasia Safdar, MD, MS

Clinical Instructor, Section of Infectious Diseases, Department of Medicine, University of Wisconsin Medical School, Madison, WI, USA.

Linda Sarna, RN, DNSc, FAAN

Professor, School of Nursing, University of California, Los Angeles, Los Angeles, CA, USA.

David T. Scadden, MD

Professor, Department of Medicine, Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA.

Julian C. Schink, MD

Chief, Division of Gynecologic Oncology; Professor of Obstetrics and Gynecology, Northwestern University Medical School, Chicago, IL, USA.

Robert L. Schlossman

Dana-Farber Cancer Institute, Boston, MA, USA.

Leslie R. Schover, PhD

Professor, Department of Behavioral Science, University of Texas M. D. Anderson Cancer Center, Houston, TX, USA.

Professor, Departments of Pediatrics, Anesthesiology, Psychiatry and Biobehavioral Sciences; Director, Pediatric Pain Program, David Geffen School of Medicine at UCLA; Associate Director, Patients and Survivors Program, Division of Cancer Prevention and Control Research; UCLA Jonsson Comprehensive Cancer Center, Los Angeles, CA, USA.

SECTION ONE

*Principles of
Oncology*

Evidence-Based Approach to Oncology

Emily DeVoto and Barnett S. Kramer*

In the early years of the 21st century, clinicians and medical researchers often use the term *evidence-based medicine*. Cancer prevention, screening, diagnosis, and therapy, we hear, must be based on the best evidence to provide the best care. But is this approach new? And if it is, what have we been doing until now? In this chapter, we hope to provide perspectives on this question, by examining what evidence-based medicine (EBM)—oncology, in particular—is and is not, and by looking at the history of clinical inquiry, up to and including current research. We also hope to provide readers with a theoretical framework that will be useful in placing the results of new research into the context of existing knowledge, with the ultimate goal of improving clinical practice.

The principles of EBM were delineated by a working group in Canada (led by Gordon Guyatt of McMaster University) and published in *JAMA* in 1992.¹ According to Sackett and colleagues, some of the earliest promoters of the principles of the concept, EBM is “the integration of best research evidence with clinical expertise and patient values.”² Thus, EBM is *not* cookbook practice performed by technicians without regard to experience, training, or independent clinical judgment. The practice of EBM has occurred with the recognition that up-to-date, scientifically valid medical information is needed on a regular basis; that traditional sources of information (such as textbooks, expert opinion, and the flood of new research) are either unreliable or overwhelming; and that patient and other demands limit clinicians’ time available for keeping skills current and for identifying the most relevant information. In response, medicine has developed strategies and information systems for tracking down useful information quickly and mechanisms for stringent, systematic review and evaluation of clinical research.² The purpose of textbooks such as this, and other forums for EBM, is to empower practicing clinicians with the skills to evaluate the literature, to identify relevant clinical guidelines and recommendations, and to understand the study design factors that affect the quality of medical evidence, in support of sound clinical decision making.

Sackett and colleagues propose the following five steps for clinicians in making evidence-based decisions: “(1) Converting the need for information into an answerable question; (2)

Tracking down the best evidence to answer the question; (3) Critically evaluating that evidence; (4) Integrating the critical evaluation with clinical expertise and knowledge of the patient; (5) Evaluating our effectiveness and efficiency in steps 1 to 4 and seeking ways to improve both for next time.”²

Later in this chapter, we elaborate on these steps to provide a practical framework for clinical decision making. First, however, we attempt to place the development of the concept of medical evidence in a historical context, focusing on aspects of research that point to quality of evidence.

The History of *Evidence* in Medicine

Francois Joseph Victor Broussais (1772–1838) was a professor of General Pathology at Paris and one of the leading physicians in France. His central theoretical model of disease physiology was that vital processes depended on external stimuli, especially heat; these stimuli produced chemical changes, which modified normal tissue function. He conceived that if the stimuli are in balance, one is healthy, but if they are too weak or too strong, disease results. All disease is local, he held, but is transmitted to other organs by sympathy or via the gastrointestinal mucosa; he believed gastroenteritis was the basis of all pathology (Table 1.1).

P.C.A. Louis (1787–1872), a French contemporary of Broussais, agreed with Broussais that objective observation is central to medicine, but in their methods of observation and the conclusions they drew, their views diverged greatly, and this is why Louis has the more-lasting legacy in the annals of medicine. Louis devoted himself to the observation of inflammatory diseases such as typhoid fever and pneumonia. Until his time, bloodletting (using leeches) was the unchallenged treatment for inflammatory disease. Louis and a few contemporaries were the first to question explicitly whether full-force application of leeches was appropriate under all circumstances, and Louis was the first to test the hypothesis. To address this question, Louis examined the medical records of 79 pneumonia patients in his practice and analyzed their disease duration and mortality experience with respect to the time of their first bleeding relative to the course of the disease. He also took into account the number of bleedings and the subjects’ ages. Of note, he started the investigation with a belief that bloodletting was effective. The finding of the study, that the beneficial effect of bloodletting was “much less than has been commonly believed,” probably contributed to the demise of bloodletting as a widespread practice.³

*The opinions expressed in this manuscript are those of the authors and do not represent official opinions or positions of the National Institutes of Health, the Department of Health and Human Services, or the federal government.

TABLE 1.1. Historical landmarks in the development of evidence-based medicine.

1828	<ul style="list-style-type: none"> • First application of mathematical analysis to test a hypothesis • Introduction of concept of confounding (i.e., patients' response may vary for reasons other than treatment) 	P.C.A. Louis: observations of the effect of timing of bloodletting on pneumonia outcomes
1853–1856	<ul style="list-style-type: none"> • First systematic use of statistics in medicine • Development of systematic data collection • Calculation of rates of morbidity and mortality, based on hospital intake and discharge data 	Florence Nightingale presented data on mortality in field hospitals during Crimean War, leading to fundamental changes in patient hygiene
1920s–1930s	<ul style="list-style-type: none"> • Development of statistical methods: accounting for the role of chance in scientific studies • Development of experimental study design 	Ronald Fisher, as described in his book <i>Design of Experiments</i> (1935)
1948	<ul style="list-style-type: none"> • First randomized clinical trial (RCT) 	Sir Austin Bradford Hill assessed the use of streptomycin in treating tuberculosis
1970s	<ul style="list-style-type: none"> • U.S. 6th Circuit Court of Appeals grants RCTs status as a standard of evidence in the regulatory authority of the Food and Drug Administration 	
1992	<ul style="list-style-type: none"> • Principles of evidence-based medicine delineated and published 	Working group led by Gordon Guyatt, McMaster University

Louis was well ahead of his time in his use of standardized data collection and in his framing of research questions, but perhaps more importantly to the history of evidence-based medicine, Louis clearly recognized the limitations of his work. He wrote of the possibility that alternative, unmeasured factors (besides bloodletting) could explain his findings. He understood that his patients may have differed for reasons unrelated to treatment and that these differences might have had a more important influence on their outcomes than the treatment itself.³ That is, Louis questioned the cause-and-effect relationship between bloodletting and increased survival, whether or not he articulated it as such.

The first historic example of the use of comparison control groups in clinical investigation comes from the well-known story of James Lind, an 18th-century British physician (1716–1794) who addressed the issue of scurvy in the British Navy. The value of fresh fruit in treating and preventing scurvy had been suggested by an earlier scholar, but Lind was the first to apply an experimental design to the investigation of this hypothesis. In 1747, he selected 12 patients/seamen on board a navy vessel, as he said, “as similar as I could have them,” and then assigned 2 each to various treatments, one of which was to eat two oranges and one lemon per day (others were given cider or seawater). He found, of course, that the 2 who received the citrus fruits recovered the best, with those taking cider recovering next best. Although not a randomized design (he stated that “two of the worst” received the course of seawater), Lind at least attempted to start with a homogeneous group, reflecting his intent to reduce the

effect of confounding. Although there was no formally declared untreated group, and each treatment group was quite small, the systematic, prospective construction of comparison groups was new to medical science.⁴

Florence Nightingale (1820–1910) collected data on the mortality experience of soldiers injured in the Crimean War (1853–1856). Her presentation of statistics on the vast improvement in patient outcomes following the introduction of hygienic practices into the field hospital led to widespread reforms in military medicine. Nightingale found, based on careful record keeping and comparisons to civilian populations, that infection among soldiers led to a doubling of expected mortality; this required development of new statistical methods. From this experience, Nightingale collaborated with other scientists to develop a systematic method for collecting data on disease and mortality in hospitals. The key data elements collected in this system were the counting of all patients entering and leaving the hospital, and the mean duration of stay, thus providing denominators for the reporting of true rates of morbidity and mortality.⁵

After scientists of the 19th century (such as Nightingale) developed their work in vital statistics, the growth of statistical theory, including ideas about randomization, flowered in the first half of the 20th century.⁶ Ronald Fisher, an agricultural scientist, pioneered the theory and use of randomization in experiments. Fisher asserted that a “properly designed” experiment is one about which one can say that “Chance would so rarely cause such a large difference in outcome that I shall attribute the observed difference to the treatments,”

and that the only two possible explanations are chance and the treatments, that is, not bias or confounding. Another key feature of the randomized design is to vary the essential conditions only one at a time. In summary, the two main principles of the experimental method are numerical balance (equal numbers of subjects in the test and control group) and randomization of all the factors that are not being tested.⁷

In the area of observational medical science, or epidemiology, Austin Bradford-Hill developed a set of criteria to evaluate cause-and-effect relationships in disease. Around the same time, Bradford-Hill launched the first randomized clinical trial, investigating the efficacy of streptomycin in treating tuberculosis, which introduced the only clinical study design able to assess the question of cause and effect directly (more on this design follows). The introduction of the randomized trial to clinical cancer research followed a few years thereafter.

The design of clinical trials evolved in the 1950s and 1960s through the many trials that were initiated as a result of demand from the pharmaceutical industry, which wished to introduce to the market new drugs that met the standards of rigorous clinical testing. Despite struggles by research clinicians against rigorous randomized clinical trial designs (typically in the interest of providing all patients the opportunity of palliation or preventing disease progression), some important trials proceeded. In the 1970s, the U.S. 6th Circuit Court of Appeals granted randomized trials status as a standard of evidence toward the U.S. Food and Drug Administration's regulatory authority over the pharmaceutical industry.⁸ Trials of chemotherapeutic agents and analgesics often gave disappointing results; however, a landmark randomized trial showing segmental mastectomy with axillary node dissection for breast cancer to be as effective as total mastectomy in demonstrating long-term survival was published by Bernard Fisher and colleagues in the National Surgical Adjuvant Breast and Bowel Program⁹ and produced a demonstrable breakthrough in breast cancer care. At the same time, the results overturned centuries-old assumptions about the biology of breast cancer and how it spreads.

Evidence-Based Medicine as a Tool for Clinical Decision Making

Dr. A, a first-year oncology resident, sees patient X, a 47-year-old woman referred to the service with a 2-cm ductal carcinoma in situ found on a screening mammogram. How does Dr. A approach the management of patient X?

The classic approach Dr. A. might take is to consult someone who has treated similar patients before. She can also call on her knowledge from coursework. Finally, she can consult the literature, which might well be a daunting task in itself. The primary literature consists of scores of thousands of original research articles; the secondary literature consists of thousands of review articles.

Asking Answerable Clinical Questions

The first stage of evidence-based decision making is to look closely at the information available. When a clinical scenario is written down, the practitioner can scan it with regard to a

set of central clinical issues to identify gaps in knowledge that need to be filled with additional clinical information, or by turning to the literature, or both. These issues are (1) clinical findings, (2) etiology, (3) clinical manifestations of disease, (4) differential diagnosis, (5) diagnostic tests, (6) prognosis, (7) therapy, (8) prevention, (9) patient experience and meaning, and (10) practitioner self-improvement.² Then, the questions can be formulated, and the questions should comprise four components: description of the patient or target disorder of interest, intervention, comparison intervention (relevant for therapy questions), and outcome.¹⁰ Using the previous example, the clinician might ask, "For a 47-year-old woman with ductal carcinoma in situ, what is the likelihood that lumpectomy followed by radiation, compared to lumpectomy alone, will prevent recurrence?"

Research Design and Quality of Evidence

Central to the idea of evidence-based medicine is the idea that there is a hierarchy of quality of evidence that is related to the design and conduct of the study or studies from which it arose. It should be kept in mind as well that different study designs on the same topic often answer rather different questions from one another. The hierarchy of study designs is illustrated in the pyramid in Figure 1.1, which also reflects the relative numbers of studies in each category.

As described previously, P.C.A. Louis' writings were centuries ahead of his time in terms of suggesting the possibility of alternative explanations for his findings, or the concept of confounding, defined as a factor that tends to co-occur with the predictive (presumed causal) factor under study and that also tends to co-occur with the outcome. Louis, for example, found that bloodletting later in the disease process was associated with longer survival. To our knowledge, Louis did not make note of his patients' diet. It is possible that those who consumed more calories would have on the one hand received the bloodletting intervention later in their disease course, because they looked healthier to begin with, and on the other

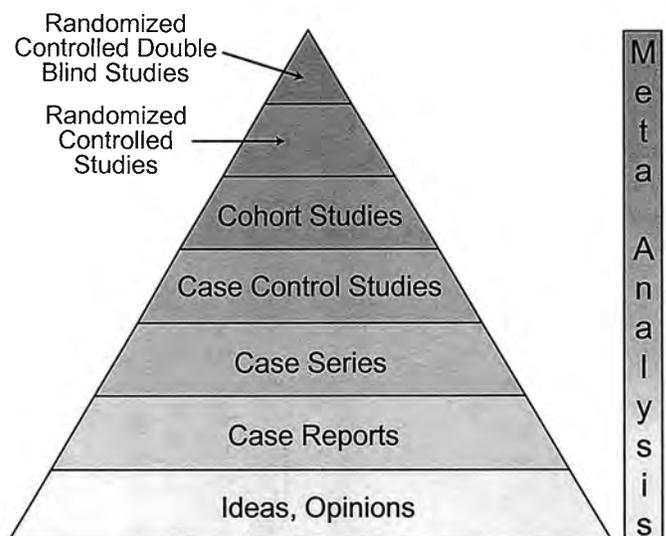

FIGURE 1.1. The pyramid of evidence represents levels of evidence as well as the relative numbers of studies at each level.

hand would have survived their disease better because in fact they *were* healthier. Diet would thus have been a *confounder* of the apparent association between timing of bloodletting and improved survival.

Unmeasured confounding is a central reason for distortion of study results, although it arises in different ways, which we discuss as they appear throughout this chapter. One of those is selection bias: in the case of Louis' work, patients may have been selected for late treatment as opposed to the early-treatment group for reasons other than random chance, thus leaving open the likelihood that factors (that is, the confounders) other than the treatment influenced the outcome.

Randomized Clinical Trials

Random allocation to a treatment or control group is the basis of all experimental design, and it is the only way to isolate the effect of a single factor under study on a given outcome and thus avoid the distorting effects of confounding. Even though potential confounding variables still exist among study subjects, randomization is designed to distribute them evenly between the test and control groups, thus removing their effects. The power of the randomized design is that it should provide equal balance not only of known confounding factors but also of unknown potential confounders. We discuss a few refinements to the randomized study design in the remainder of this chapter, but an entire chapter of this book is dedicated to randomized trials in cancer as well (see Chapter 8).

Another central (and related) tenet of scientific inquiry is the idea of a comparison or control group. In clinical research, in the absence of a control group similar in every way to the test group receiving an investigational intervention, it is impossible to discern how many subjects benefited from treatment as opposed to improving on their own.

An important factor to consider when evaluating oncology research, particularly studies of cancer therapy, is the choice of endpoints. Endpoints include health outcomes (total mortality, cause-specific mortality, quality of life) or indirect surrogates for any of these. Examples of surrogate endpoints are disease-free survival, progression-free survival, or tumor response rate. Studies of surrogate endpoints represent weaker, more indirect, evidence; however, a clinician may weigh studies differently depending on patient values.

The bulk of our understanding of risk factors and preventive factors for cancer comes from observational studies (that is, those described here). Recent research has moved toward testing hypotheses generated by observational studies in the context of clinical trials, sometimes with unexpected results, such as a study of prevention of cancer by beta-carotene in smokers that found that beta-carotene increased lung cancer incidence compared with placebo.¹¹ This finding stood in contrast to results from nonrandomized observational studies, which had suggested a benefit.

Cohort Studies in Oncology

A cohort study identifies a group of subjects on the basis of their naturally occurring exposure to an agent or agents of interest and follows them in time to observe their experience (incidence) of disease. Data can be collected from the present

into the future (prospective cohort study) or use historic data, such as records of occupational exposure, to look from the present into the past (retrospective cohort study). For cancer, the cohort study design tends to be inefficient, because cancer is considered to be a relatively rarely occurring outcome requiring the following over time of rather large initial populations to observe statistically meaningful results. Most prospective cohorts that study cancer were constructed to study other diseases, such as heart disease (for example, the Framingham Heart Study), or a range of diseases (for example, the Nurses Health Study). The benefit of a prospective cohort design is that exposures are evaluated in individuals before their diagnosis of disease; thus, the disease cannot distort the measurement of exposure as in cross-sectional or retrospective study designs. Often cohort studies collect baseline exposure information in great detail that is highly useful (although imperfect) in controlling for confounding.

A drawback of prospective cohort studies is the attrition of participation over time, or *loss to follow-up*. Cohort studies often involve the repeated filling out of lengthy, detailed questionnaires on diet and other lifestyle factors, clinical examinations, and/or telephone interviews. Subjects remaining in such studies tend to be healthy relative to those who drop out, or the most motivated by health concerns, and may differ from those who drop out in other respects that are difficult to measure, which can result in confounding. Other reasons for attrition are illness, changing residence, and other changes in life circumstances that may be associated with unmeasured characteristics which differ between those who remain in a cohort study and those lost to follow-up and that are associated with disease risk. Such differences can distort the results or make study results less representative of the original target population.

In addition, cohort studies can be extremely expensive. Designing and implementing a cohort study that provides adequate richness of data and study outcomes and avoids issues of loss to follow-up is resource intensive, as are maintenance and analysis of the data, keeping track of the details of protocols, and many other administrative tasks.

Nested Case-Control Studies

A nested case-control study selects, from subjects in a cohort study, subjects who have the disease of interest (called *case subjects*) and a sample of subjects who are disease free at the time of sampling as controls. Similar to a conventional case-control study, this study design is efficient for studying rare diseases. It is a useful design if it is too expensive to measure a risk factor for every subject within a cohort study. It also shares with cohort studies the advantage of having subjects selected at baseline from the same population, so that case and control subjects chosen later are likely to be more comparable than those in a conventional case-control study.

It is possible, if the exposure of interest is not measured before subjects in the nested case-control study are selected, that such measurement will be essentially retrospective, for example, if a detailed dietary frequency questionnaire is administered, which results in the same limitations as a conventional case-control study. However, this design is useful for studying biologic markers of exposure that are measurable in blood or other tissue samples and that remain stable in

storage, especially freezing. Often blood samples are taken from all subjects of a cohort at baseline and frozen for later analysis. As an example, the Kaiser Permanente Health Maintenance Organization collected and froze serum samples for all subjects on enrollment. Their record-keeping system provided longitudinal data on patients, including data on disease incidence. Researchers who wished to investigate the association between exposure to the pesticide DDT (dichlorodiphenyltrichloroethane) first selected, from the Kaiser cohort, breast cancer case subjects and a sample of control subjects who were disease free when the case was diagnosed. They then retrieved frozen serum samples that, for the case subjects, were taken at least several years before diagnosis with breast cancer, and measured the concentration of DDT in the samples to compare the concentrations in case and control subjects.¹²

Case-Control Studies

Many life-threatening diseases studied by epidemiologists are relatively rare. Consider, for example, the likelihood of being diagnosed with breast cancer in a given year, compared with that of coming down with a cold. If you only had the resources to study 500 women aged 50, with average risk factors, over a 5-year period, only 5 or 10 of them would be expected to be diagnosed with breast cancer during that time, whereas a large majority of them are likely to come down with a cold at least once in 5 years. The number of breast cancer cases is simply not adequate to allow valid comparisons among different hypothesized risk factors between women who are diagnosed with breast cancer and those who are not. On the other hand, if you set out to identify 250 women newly diagnosed with breast cancer (case subjects) in a given population, and simultaneously identified a suitable comparison group of 250 women (control subjects), you could substantially improve the statistical power (also called *efficiency*) of the study.

A study in which subjects are identified on the basis of their disease status has what is known as a *case-control* design. Once you identify the subjects, you can then interview them about hypothesized disease risk factors such as diet, pharmaceuticals, sun exposure, pregnancy history, and so on. This is the *bread-and-butter* design of the bulk of cancer epidemiology. However, it is particularly prone to sources of bias and confounding that randomized controlled trials and cohort studies are not.

The most important downside of case-control studies is potential bias from errors in recalling and reporting risk factors. For example, many people tend to underestimate or underreport their alcohol consumption. If people with and without a disease under study underestimate their consumption to a similar degree, then a true association between alcohol consumption and the disease would be more difficult to observe. In contrast, if someone diagnosed with a disease believes that his or her past alcohol consumption may have played a role in the disease, that consumption could either be further underreported or overreported relative to the true exposure. In any case, it is quite possible that the recall is different from that of someone without the disease. Just as it is difficult to predict which way someone is likely to misreport exposure, it is by extension difficult to predict the effect

of such misreporting on estimates of disease association or risk.

Another drawback of case-control studies is the fact that exposures reported to occur at a given point in time might not represent the exposures that actually cause the disease. This consideration is important in diseases such as cancer that have a long latency period, that is, the time between a causal exposure and the diagnosis of disease. Conceivably, cancer itself could alter dietary or lifestyle patterns in the period before diagnosis, thus reversing the cause-and-effect sequence. In addition, if a marker of a hypothesized disease risk factor is measured in a body tissue, such as the concentration of a pesticide in blood, it is possible that the measurement could be affected by the disease, resulting in a spurious association or masking a true association.

Selection of an appropriate control group is particularly important, but also particularly difficult, for case-control studies. Bias, used here to mean systematic error in an estimate, can arise if case subjects and control subjects arise from populations with different underlying baseline characteristics. The more the case and control populations differ from one another, the more difficult it is to ensure that observed differences in risk factors are not due to extraneous, unmeasured factors, or *confounders*, that are associated with the factors under study and with the disease. For example, a study might find that people with lung cancer are more likely to drink alcohol than a group of control subjects similar in age. Rather than assuming that this finding indicates that alcohol is a risk factor for lung cancer, it is prudent to consider whether alcohol consumption is related to smoking, an established cause of lung cancer.

In summary, case-control studies are often more convenient to assemble than the preceding study designs when a rare disease or outcome is being studied, and they are less expensive than cohort (follow-up) or experimental studies. However, because exposure is assessed retrospectively, errors in recall are often a problem. In addition, it is sometimes difficult to generalize the results or to avoid bias from confounding because of the ways in which patient and control groups are selected. For these reasons, case-control studies tend to provide a lower level of evidence than cohort studies or experimental studies.

Cross-Sectional Studies

A cross-sectional study estimates the *prevalence* of disease (the number of cases of a disease) and possible disease risk factors in a given population at one point in time. Such studies are most usefully conducted by random sampling, which helps ensure that their results are representative of the larger population of interest. A special case of the cross-sectional design, which is, technically, a survey follow-up study because it is repeated on a regular basis, can be found in the Behavioral Risk Factor Surveillance System (<http://www.cdc.gov/brfss/>), an annual national survey that selects a representative sample of U.S. residents and interviews them about such behavioral factors as exercise, human immunodeficiency virus (HIV) awareness, drug use, and smoking. Statistics describing the prevalence of these factors can then be compared from year to year, and a new set of subjects is sampled each year.

Similar to cohort studies, subjects in cross-sectional studies are not selected for study on the basis of their disease status. Similar to case-control studies, however, measurement of risk factors is either nondirectional or retrospective, and the presence of risk factors cannot be shown to precede disease; that is, the temporality requirement for declaration of cause and effect is lost. Therefore, although cross-sectional studies are sometimes used to evaluate associations between risk factors and disease and to generate hypotheses, their ability to support evidence of causation is more limited than that of other observational studies.

Ecologic Studies

In studies of ecologic design, the number of people with an exposure is known, as is the number of people with a disease or outcome (mortality, for example), but the number of people with both the exposure and the disease is not known. In general, relevant information on individuals in the population is unknown. A study that is at least partly ecologic in design may be the only feasible option in the case of an environmental exposure experienced by an entire population. A well-known example of an ecologic study stemmed from the observation that the number of deaths in London increased sharply relative to average death rates during a period of particularly heavy smog and was closely proportional to the ambient temperature during that period.

Generally, however, the level of evidence provided by ecologic studies is considered quite weak, primarily because of the studies' inability to correct for other variables, that is, confounders, at the individual or aggregate level that could explain the observed associations. Indeed, such confounding remains a possibility in the London smog example, in which the agent that caused the excess deaths cannot be known with certainty. A commonly encountered example of ecologic data is the observation that rates of certain kinds of cancer, especially breast cancer, are high in countries with high consumption of dietary fat and that cancer rates are low in those countries reporting low dietary fat consumption. Such observations are useful in generating hypotheses for further study; however, as in the example of dietary fat and breast cancer, epidemiologic studies based on individual-level data with the ability to adjust for confounding factors often show little or no association between dietary fat and breast cancer.

Case Series and Case Reports

Reports of individual cases and case series represent the earliest known method of accumulating medical knowledge on most diseases. Although their importance is lower today given the availability of controlled studies, particularly clinical trials, they remain a popular mode of publication by clinicians of their investigations and observations. As evidence, however, case series and reports pose a number of problems and should be interpreted with substantial caution.

Many case series are collected retrospectively from medical records, and recording of information may be selective and subject to incompleteness or other forms of error compared to information collected according to a predefined plan. Selection bias can occur when the series is not representative of the general population, in particular when subjects with similar prognosis are selectively lost to follow-up.

Case series based on medical records are also likely to lack adequate (if any) information on confounders. Finally, the decision as to which data to report may be selective, particularly if eligibility criteria are not established in advance. For example, striking results may lead to report of a case or a series of cases, distorting the sense of what would be expected in general. Unfortunately, for some exceedingly rare diseases, clinical knowledge rests on case series and case reports for lack of sufficient numbers to support more robust study designs (J. Lau, unpublished observation).

Preclinical Studies

Laboratory studies using immortalized cell lines, whole tumors, or some other system below the level of the organism are important in basic oncology, but their purpose is to isolate small subsets of the complex tumor biology machinery to elucidate mechanisms (Table 1.2). Rarely should they be taken in isolation as evidence for or against a given treatment strategy. They do represent a level of control that may never be attainable or ethical in whole humans; on the other hand, it is their very lack of organismal context that makes them unreliable to extrapolate to humans. Despite a tendency of some researchers and the media to tout breakthroughs in biomedical research on the basis of laboratory studies, they should be seen by practicing clinicians for their intent: mechanistic, preliminary, and hypothesis generating in relation to medical practice.

The toxic or beneficial effects of drugs, environmental agents, and foods are typically evaluated using laboratory rodents or other small mammals, according to stringent experimental and statistical analytic protocols. These protocols allow statistically efficient estimates of beneficial, safe, or toxic doses of chemicals in genetically homogeneous animals. Laboratory animals may also be used for mechanistic studies, for example, using gene *knockout* models. It is important to be able to test chemicals with uncertain safety on nonhumans. However, because mice and rats are not humans, assumptions must be made regarding the extrapolation of results to humans and again should not be used by the clinician in isolation for clinical decision making.

Expert Opinion

Until modern times, 'facts' were deduced by arguments from premises approved by tradition and authority, without appeal to experimental validation. Even when observation ran counter to 'facts,' it was still believed that in some mysterious way authority must still be correct, particularly at a time in history when the fabric of society was such as to frown upon the challenge of authority. The modern therapeutic trial offers an alternative by relying upon impartial observance without regard for authoritarianism. Such an approach provides the foundation of scientific medicine."

—Bernard Fisher¹³

In other words, the evidence of expert opinion is only as strong as the empiric evidence from which it is derived. As Albert Einstein pointed out: "Propositions arrived at purely by logical means are completely empty as regards reality. Because Galileo saw this, and particularly because he drummed it into the scientific world, he is the father of modern physics—indeed of modern science altogether." (From *Ideas and Opinions*, Modern Library, 1994)

The Role of Meta-Analyses and Literature Reviews

For many clinical questions, the practitioner will find that much of the work of reviewing and evaluating research has already been done, or at least addressed, and that summaries of literature exist. The end of this chapter offers a number of readily available sources of comprehensive literature reviews, along with other convenient sources of evidence-based medical knowledge. By way of definition, an overview or review of literature may be any type of summary, whereas the term *meta-analysis* describes a quantitative summary of results from different studies. Because a meta-analysis attempts to combine results from a number of studies into a summary statistic, it is important to be sure that the studies have a common outcome measure. Also, the underlying assumption is made that the studies are drawn from the same pool or universe of studies and can therefore be legitimately combined. Statistical tests for homogeneity are therefore often used to test this assumption. Also, the validity of a meta-analysis depends upon the assumption that there has not been substantial selective reporting of studies depending on their result (e.g., greater likelihood to report small positive studies than small negative studies). Funnel plots are used to assess this possibility graphically. In a funnel plot, the outcome variable for each study is graphed versus its variance.

Literature reviews may be systematic or rely on the recall of the author. In a systematic review, a complete computer search is made of the relevant literature using specific search terms and prospective rules for inclusion or exclusion of studies found in the systematic search.

To begin evaluating a review, the practitioner should ask two questions: does it ask a carefully focused clinical question, and is the method for including studies reasonable and appropriate? The latter question can be expanded as follows: are methodological standards articulated (for example, those laid out in this chapter), and do the studies chosen address the research question articulated by the reviewer? Stating inclusion criteria up front helps avoid any biases toward preconceived conclusions a reviewer might hold. Aspects of oncology studies to keep in mind when reviewing a review are outcomes (as described previously) and latency periods. Review writers should demonstrate that they exhaustively searched appropriate bibliographic databases (such as Medline), but also that they contacted experts in the area who might be aware not only of published studies not yet appearing in Medline, but of unpublished studies; this is important because studies with negative findings are less likely to reach publication.

Practitioners reading reviews should consider whether results of reasonably comparable studies are similar. Meta-analyses study formally and quantitatively whether results of similar studies differ more than would be expected by chance alone. If so, it is likely that study designs differ enough to account for observed differences in results.

A review should not simply compare the number of positive and negative studies of a given question to obtain an answer, as this fails to give different weight to large and small studies, large studies being more likely to show a positive result because of increased statistical power or efficiency. In addition, such a comparison ignores effects other than the

primary outcome of interest, and says nothing about the magnitude of an effect, its clinical importance, or the relatively quality of individual studies.

Ranking the Evidence: The Role of Study Design and Study Quality

Looking at evidence in the field of oncology is similar to analogous processes in other fields of medicine. An example evidence rating system for research on cancer screening and prevention is used by the Physician's Data Query (PDQ) of the U.S. National Cancer Institute and can be found at <http://cancer.gov>. It rates evidence based on five domains of quality:

- Study design (evidence from the best studies available, ranked in descending order of strength)
- Internal validity ("quality" of execution within the study design)
- Consistency (coherence)/volume of the evidence
- Direction and magnitude of effects for health outcomes (both absolute and relative risks; as quantitative as possible; may vary for different populations)
- External validity/generalizability to other populations

When evaluating therapy studies, the strength of study endpoints (described under Randomized Clinical Trials) should be combined with the strength of the study design in ranking results (Table 1.3).

Illustration: Postmenopausal Hormone Therapy

Recently, the administration of hormones to postmenopausal women was brought into the spotlight. For decades, doctors had prescribed various combinations of estrogen and progesterone not only to relieve menopausal symptoms but also to reduce women's risk of osteoporosis, heart disease, and Alzheimer's disease. Consistent evidence for the beneficial effect of these hormones for prevention of several chronic diseases came from a large number of prospective cohort studies (as well as observational studies of other designs) comprising hundreds of thousands of women. In 2002, the practice of prescribing hormones returned abruptly to attention when results from the Women's Health Initiative, a large randomized controlled trial, showed that the drug PremPro (combined estrogen plus progestin) not only did not appear to protect women from heart disease and Alzheimer's disease but actually produced a modest increase in cardiovascular outcomes and cognitive disorders as well as breast cancer.¹⁴ How is it possible that such a large, apparently authoritative body of evidence could give an answer at odds with that of a randomized trial, and the landscape of hormone therapy change so rapidly? In an observational cohort study, women are free to take postmenopausal hormones or not. Women who do choose hormone therapy tend to be more healthy and health conscious: they are more likely to see a physician on a regular basis, eat a healthful diet, and exercise. All these variables could affect the development and incidence of disease. Although an observational study can take such differences into account, there may remain other, unmeasured factors (confounding), or there may be systematic imprecision (bias) in the measurement of known factors, both of which

TABLE 1.2. Summary of study designs.

<i>Study design</i>	<i>Description</i>	+	-
Systematic reviews and meta-analyses	Summarize findings from a number of studies addressing a given clinical question; meta-analyses quantitatively estimate effects based on combining data from different studies.	Meta-analyses have greater statistical power than single studies to address questions. Convenient way to summarize findings from a range of studies.	Must meet assumption that studies can legitimately be combined (based on population, study design, etc.). Literature searches must be performed systematically and studies included without bias.
Randomized clinical trial	Subjects randomly assigned to an intervention or control group. Randomization ensures that the intervention is the only factor to vary between the comparison groups.	Represents true experiment. Randomization removes effects of confounding and bias. Considered gold standard among clinical studies. The most efficient method to test definitively for causal relationships between an intervention and health outcomes.	Expensive: requires extensive study infrastructure and training of staff. May be unethical or impracticable for some hypotheses.
Prospective cohort study (includes nested case-control study)	Exposures of subjects assessed at beginning of study; disease or other outcomes evaluated over time.	More efficient for common diseases. Allows assumption that exposure precedes disease. Allows consideration of a wide range of confounders.	Often expensive: requires large study infrastructure. Time consuming (subjects often followed for years). Subject to confounding (measured or unmeasured). Attrition of study population can affect generalizability.
Retrospective cohort study	Exposures of subjects assessed retrospectively, e.g., occupational exposures via historic job records.	Useful for assessing past exposures of large numbers of subjects over time.	Assumption that exposure precedes disease may be less strong than in prospective design. Confounders may have to be assessed at the present, and proxies for nonliving subjects may introduce bias.
Case-control study	Prior exposure and disease assessed at a point in time. Subjects selected on the basis of disease status (with or without); past exposures evaluated retrospectively.	More efficient for relatively rare diseases such as cancer. May allow consideration of a wide range of confounders.	Disease itself may affect evaluation of exposure (changes to biochemical measurement, selective recall). Subject to various types of error in evaluation of past exposure. Subject to confounding (measured or unmeasured). Exposure does not necessarily precede disease.

can distort estimates of risk and benefit. Such unmeasured confounding is believed to have resulted from the crucial bias (selection bias) that rather impressively provided such consistency of results among observational studies of combined hormone therapy. The Women's Health Initiative, in contrast, was able to eliminate whatever confounders were at play by virtue of its randomized placebo-controlled design.

Applying Research Evidence to the Individual

After identifying relevant studies, the clinician must think about their applicability to the individual patient, because even the best studies report estimates of effect in terms of an average. Study participants and real-world patients are likely to differ by degree, rather than grossly, in their response to treatment.¹⁵ Individualizing treatment decisions involves estimation of the balance of risks and benefits, combined with a consideration of patient values. The number needed to treat (NNT) is the number of patients that need to be treated to prevent one additional adverse event, and it is the inverse

of the absolute risk reduction, as described by McAlister et al.,¹⁶ who provide a detailed guide to individualizing evidence from research. The number needed to harm (NNH), in contrast, is the number of patients treated who would be expected to experience one adverse event. NNT and NNH illustrate the balance between benefits and risks of a given intervention; in oncology, this is particularly relevant with regard to screening, which may result in harms from follow-up of false positives, and treatment, which often produces dose-dependent toxicity.

Clinicians should also consider the following levels of decision making when thinking about applying evidence to a particular patient, as conceptualized by Dr. Leon Gordis of Johns Hopkins University:

Level 1: "Would you have this done for yourself or for someone else in your immediate family?" Influenced by one's personal experience with the disease and capacity to deal with risk.

Level 2: "Would you make this recommendation for your own patients?" Also influenced by prior experience, but

TABLE 1.2. (continued)

<i>Study design</i>	<i>Description</i>	+	-
Nested case-control study	Analysis similar to case-control study, but subjects sampled from within cohort study.	For prospective studies, combines efficiency of case-control design with ability to demonstrate that exposure precedes disease.	See prospective cohort study.
Cross-sectional study (also called prevalence study)	Exposure and disease assessed at one point in time. May be repeated with different population samples at set time intervals (e.g., annual surveys).	Useful for measuring prevalence of an exposure or disease. Useful for generation of hypotheses and evaluating associations (as opposed to cause and effect). Repeated sampling design allows evaluation of population trends.	Exposure cannot be shown to precede disease. Inefficient for studying rare diseases.
Ecologic studies	Population-wide disease incidence or prevalence is compared with population-wide exposure estimates.	Useful for generating hypotheses. Useful for exposures that cannot be estimated on an individual level (e.g., ambient pollution).	Does not allow consideration of interindividual differences, which obscures confounding effects.
Case series or case reports	Descriptions of disease manifestations or therapy outcomes in single or multiple individual subjects, without controls; data often collected retrospectively.	May be the only feasible design for extremely rare diseases.	Lack control group. Subject to selection bias. Tend to lack information on confounders.
Preclinical studies: animal studies	Experimental design using animals, typically genetically homogeneous.	Large studies of animals (especially rodents) are useful for screening drugs and other chemicals for toxic or therapeutic effects.	May be inappropriate to extrapolate from rodent and other species to humans. Doses of chemicals used in toxicity studies may not be extrapolatable to doses likely to be experienced by humans.
Preclinical studies: laboratory studies below the whole-organism level	Experimental design utilizing controlled conditions, often involving effects of toxins or drugs on immortalized cancer cell lines or other cells.	Represent a level of control usually unattainable or unethical in humans. Generate hypotheses for human studies. Can elucidate biological mechanisms.	Lack organismal context, and therefore difficult to extrapolate to whole humans.

the strength of the scientific evidence may play a greater role.

Level 3: "Would you make an across-the-board recommendation for a population?" Must be based even more on rigorous assessment of the scientific evidence.

Level 1 is the level at which we all operate when we are making our own personal decisions regarding a procedure; it rests heavily on our own personal value systems and trade-offs. Nevertheless, it is important not to impose our own value systems on our patients. Level 2 is one in which clini-

cians engage in informed and shared decision making with patients. It is hoped that it involves reliance on strong evidence, although it is also heavily influenced by personal values of the patient if the decision is to be truly shared with the patient. Quick sound bites do not lend themselves to this format of informed decision making. By contrast, Level 3 involves an across-the-board recommendation for the entire population. Complexities are often sacrificed to strengthen the message. The messages are often sanitized of any mention of potential harms inherent in any test, procedure, or treatment. Here, therefore, recommendations should be based on particularly strong evidence.

TABLE 1.3. Levels of evidence.

I	Evidence obtained from at least one properly randomized controlled trial
II-1	Evidence obtained from well-designed controlled trials without randomization
II-2	Evidence obtained from well-designed cohort or case-control analytic studies, preferably from more than one center or research group
II-3	Evidence obtained from comparisons between times or places with or without the intervention; dramatic results in uncontrolled experiments (such as the results of treatment with penicillin in the 1940s) could also be included in this category
III	Opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees

Are We Practicing Evidence-Based Medicine?

The goal of using evidence in medicine is to come closest to practice that represents best practice and to produce optimal health outcomes. Thus, it is desirable to evaluate the impact of medical knowledge on actual practice, in terms of both the practices themselves and, ultimately, their public health impact. On one level, the impact of evidence-based guidelines can be assessed by measuring practitioners' beliefs and knowledge over a time period relevant to the introduction of new knowledge by means of surveys. However, such surveys may not fully reflect actual practice and are an indirect surrogate for health outcomes.

The translation of knowledge into practice is often measured using administrative datasets such as Medicare claims data, which are assumed to reflect some robust proportion of procedures performed on enrollees, for example, screening mammography examinations. Such data are more objective than physician self-report, but may not capture all procedures of interest, as enrollees may undergo procedures outside the Medicare reimbursement system. For example, Medicare analyses are usually restricted to procedures in the age 65+ population for which the U.S. government is billed.

Looking at effects of guidelines on health outcomes (such as cancer incidence and mortality) is of great interest. However, these endpoints are often the most difficult to evaluate with confidence in terms of their link to new knowledge, because so many other factors are likely to influence rates of disease. For the United States, the most comprehensive data on disease incidence and mortality are compiled by the SEER program (Surveillance, Epidemiology, and End Results). SEER is a national dataset that is designed to reflect the total cancer experience of the U.S. population. Despite these caveats, occasionally a breakthrough in cancer medicine results in clearly measurable improvements in outcomes. Feuer et al.¹⁷ reported on dramatic improvements in testicular cancer outcome statistics in SEER after the completion of a successful clinical trial of cisplatin, vinblastine, and bleomycin; improved survival rates then reached a plateau, apparently indicating the limits of diffusion of the results of the trial into medical practice.

Questions of impact of knowledge may be addressed by looking at rates of disease and mortality over a time frame relevant to the introduction of a given guideline, or to media coverage of, for example, a diagnosis of cancer in or a cancer screening or treatment procedure undergone by a celebrity. This approach is essentially an ecologic study design and is subject to the limitations described earlier. In one notable case, rates of breast-conserving surgery, which had been increasing (relative to mastectomies) in the 1980s, appeared to decline abruptly, albeit briefly, after widespread publicity about a mastectomy undergone by then First Lady Nancy Reagan. Nattinger et al.¹⁸ carefully documented this change by analyzing news reports and the appropriate time period of subsequent SEER data.

Despite this evidence, other unmeasured factors affecting these rates are undoubtedly still at play, and outside of the context of a controlled trial it is extremely difficult to establish a causal effect that an intervening factor may have had on population mortality rates.

Progress in fighting cancer is often measured in terms of SEER-derived statistics; again, however, it is difficult to

ascribe changes to a single factor. Recent reductions in deaths from breast cancer could be related to more widespread mammography screening, but improvements in breast cancer therapy are also likely to have an effect on mortality, and it is impossible to tease apart their effects on population-based mortality rates.

Another example of the use of national data to assess the impact of evidence-based medicine is that of colorectal cancer. The U.S. Preventive Services Task Force recommends screening for colorectal cancer by any of four methods; however, the reported prevalence of screening is below 50% in many states. As for the rates of disease, long-term declines in colorectal cancer incidence have slowed. Although screening is thought to play a role in reducing incidence and mortality, risk factors for colorectal cancer—physical inactivity and obesity—have increased in the population.¹⁹ Although it is not possible to separate the effects of screening, improvements in therapy, and risk factors completely, they do act in different directions; the increase in physical obesity could conceivably explain the slowing of declines in incidence.

A common error in interpreting population cancer statistics is in the use of 5-year survival as a gauge of progress against a disease. Five-year survival is an appropriate outcome in a trial of a therapy, where all subjects in the numerator and denominator of the survival rate have the disease and a comparison is made between two groups randomly assigned to treatment after their diagnosis. In the general population, however, 5-year survival is much more likely to be a function of the date of diagnosis relative to the course of the disease. As a result, 5-year survival is unrelated to mortality and is ultimately a misleading statistic in this context.²⁰ For example, changes in screening patterns can advance the date of diagnosis without changing risk of death, thus artifactually lengthening survival time.

Other relevant outcomes beyond physician practice but shy of hard health outcomes include smoking rates, which are known to be closely related to rates of lung and oral cancer as well as a number of other health outcomes and total mortality. The Behavioral Risk Factor Surveillance Survey and National Household Survey on Drug Abuse measure the prevalence of smoking in the United States and can be used to estimate the impact of smoking-cessation programs and tobacco-related policies.

Evidence-Based Medicine and Societal Issues

Given finite resources, the medical system cannot provide every intervention no matter how small its potential benefit. From a societal perspective, it is therefore important for clinicians to judge interventions based on a balance between magnitude of benefit, quality of evidence, and resources. That is, one must keep in balance two questions: (1) Does it work? and (2) Should we do it? Otherwise, we could diminish the net health of the community by diverting resources from highly effective intervention to more marginally effective ones. The methods for such prioritization, however, are not yet well established. Cost-effectiveness analysis and cost-utility analysis are tools that can help, but many value judgments are necessary that go beyond quality of evidence. In the meantime, adhering to evidence-based principles of

evaluating, for example, screening and diagnostic tools, may help eliminate ineffective redundancy and thus save costs while still achieving needed health outcomes.

Summary

This introduction has attempted to put evidence-based decision making in a useful, practical framework with special attention to issues relevant to the study and practice of oncology. We hope we have made it clear that evidence-based medicine is neither theoretical nihilism nor cookbook practice, in that it incorporates clinicians' knowledge and training with systematic methods for asking answerable questions, critically evaluating research, and taking into account patient values (thus marrying the tools of evidence-based medicine with the ethical concept of patient autonomy).

Resources

The landscape of medical research changes constantly, and thus the best resources for practitioners of evidence-based medicine are those that adapt databases, recommendations, and guidelines regularly to take into account new findings. Key online resources relevant to oncology are the Physicians' Data Query (PDQ) at <http://cancer.gov>, the public Website of the National Cancer Institute. The PDQ has several topical committees that meet regularly to develop and update Web-based resources and explicitly spell out their methodology for ranking evidence. The U.S. Agency for Healthcare Research and Quality (<http://www.ahrq.gov>) posts links to evidence-based guidelines, including their own U.S. Preventive Services Task Force, at the National Guidelines Clearinghouse (<http://www.guideline.gov>), and also offers access to comprehensive literature reviews on a wide variety of clinical questions. The Cochrane Library (<http://www.cochrane.org>) regularly updates its evidence-based databases on health care and publishes comprehensive literature reviews according to stringent rules of evidence.

Two journals relevant to general medicine and oncology exist to help summarize the vast sea of new research into a manageable format and according to an evidence-based approach: *ACP Journal Club* (published by the American College of Physicians) and *Cancer Treatment Reviews* (from Elsevier; this journal now incorporates the former *Evidence-Based Oncology*).

Further instruction in the general nuts and bolts of evidence-based medicine can be found in texts by the innovators of the field: David Sackett and colleagues (*Evidence-Based Medicine: How to Practice and Teach EBM*; Churchill Livingstone, 2000) and the JAMA Users' Guide to the Medical Literature: A Manual for Evidence-Based Clinical Practice. The JAMA guides are a compilation of a previously published series of articles in JAMA and can also be accessed online by subscription.

Principles of Chemotherapy

Grace K. Dy and Alex A. Adjei

During World War II, sailors who were accidentally exposed to nitrogen mustard following the explosion of a ship developed marrow and lymphoid hypoplasia.¹ This serendipitous discovery led to the first clinical trial conducted in 1942 using nitrogen mustard in patients with malignant lymphomas at Yale University.² This marked the beginning of a new era of research in the quest for effective and safe drugs used in cancer chemotherapy.

The term chemotherapy has been loosely applied to the myriad systemic therapeutic options in cancer treatment exclusive of irradiation and surgical approaches. In this chapter, we confine our discussion of chemotherapy to refer to the use of conventional cytotoxic agents. Use of targeted and biologic agents such as hormone or signal transduction manipulation and gene therapy is explored in other chapters.

Cancer Cell Population Kinetics

The discussion that follows briefly describes the various paradigms of tumor growth and response to cytotoxic agents to facilitate understanding of the rationale and basis for the approaches to cancer therapy with cytotoxic agents.

Skipper's Exponential Tumor Growth/Log-Kill Hypothesis

One of the pioneer investigations in tumor growth kinetics was made by Skipper and his colleagues,³ who described the first model of tumor growth kinetics. Despite its flaws and oversimplified nature, the empiric observations derived from this model underlie many of the tenets in cancer chemotherapy. A conclusion derived from his L1210 mouse leukemia model was the exponential (logarithmic) growth of tumor cells. Doubling time of cancer cells was proposed to be constant, yielding a straight line on a semilog plot (Figure 2.1). Another conclusion generated from their experiments was the log-kill hypothesis, which proposes that anticancer drugs act with first-order kinetics, and hence, assuming homogeneous sensitivity to the drug, they will eliminate a constant proportion rather than a constant number of tumor cells regardless of the initial size of the tumor; that is, magnitude of tumor cell kill is a logarithmic function.³ By this a posteriori reasoning, if sufficient drug is given, cure can be achieved when fewer than 1 tumor cell remains. Similarly, therapy against small-volume tumors or micrometastatic

disease should be easily successful in effecting cures. However, clinical experience in adjuvant chemotherapy has not borne out this deductive assumption as successfully as hoped.

Gompertzian Model of Tumor Growth

With further studies, it became clear that Skipper's model was oversimplified and applied only to the proliferating segment within the tumor. Some early-stage malignancies, such as testicular germ cell tumor, may behave in such a way when they are composed of proliferating cells highly responsive to chemotherapeutic agents. However, most human solid tumors do not respond to chemotherapy, contrary to what would have been expected if tumor growth was exponential. Rather, the experimental data in human solid tumors support the Gompertzian kinetics of tumor growth, akin to the sigmoid curve seen in microbial kinetics under a controlled environment, where the initial growth phase is steep at smaller volumes, eventually plateauing and decreasing with time once a critical mass is reached⁴ (Figure 2.2). As many anticancer agents are cell cycle specific and are usually most active against cells that are proliferating, a critical factor in drug responsiveness of tumors to cell-cycle-specific drugs depends on the particular phase the tumor is in its growth curve. This model also helps explain why, unless cure was effected, varying degrees of residual tumor volume result in similar relapse-free survival over time.

Norton–Simon Model

In Skipper's model, the exponential growth of tumors is presumed to be homogeneous. The Norton–Simon model takes into account the heterogeneity of a tumor cell population following the Gompertzian growth curve.^{5,6} The log kill would be greater for very small cancers than for larger tumors. However, smaller cancers also regrow faster. The greater fractional kill, such as against micrometastases in the adjuvant setting, is offset by fractional repopulation of tumor cells at the same fast rate. Thus, tumors are difficult to eradicate under this model. As already stated, this model predicts the observation that adjuvant chemotherapy does not have much impact on overall survival, as opposed to the improvement in disease-free survival. Survival can thus be improved only when tumor cell populations are eradicated or rendered

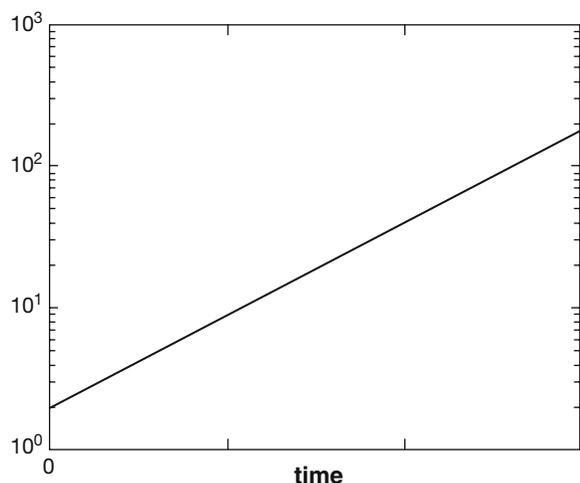

FIGURE 2.1. Skipper's model of tumor growth (x-axis, time for tumor growth; y-axis, tumor volume).

dormant during the early growth phase. Another implication is that effective therapy should be delivered at reduced intervals to maximize the chances of tumor eradication and to minimize tumor regrowth in between cycles of therapy.

Goldie and Coldman Hypothesis

An important corollary to tumor growth is the development of drug resistance resulting from spontaneous mutations that occur with cell proliferation, independent of the resistance inherent to the heterogeneity in cell kinetics described earlier. Goldie and Coldman had hypothesized that this occurs at a rate of 1 of 10^5 cells per gene.⁷ If 1 g tumor, the minimum size for detection, contains 10^9 cells, then such a tumor might contain 10^4 clones resistant to any given drug. However, resistance to two drugs would be seen in fewer than 1 cell in a 10-g (10^{10} cells) tumor. This idea is consistent with the known observation that combination chemotherapy is more effective than single-agent regimens. Nevertheless, single agents have remained successful in the treatment of

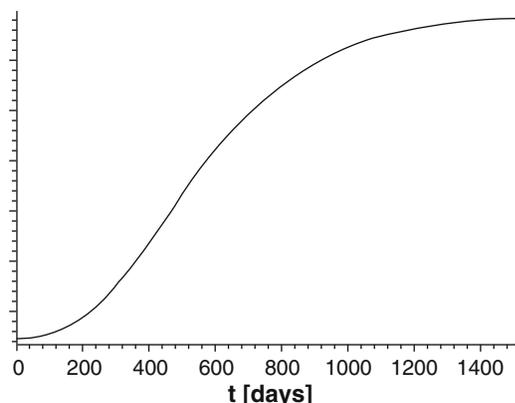

FIGURE 2.2. Gompertzian model of tumor growth (x-axis, time for tumor growth; y-axis, tumor volume).

certain tumors, such as Burkitt's lymphoma at sizes greater than 1 g.⁸ This hypothesis is one basis for the idea that chemotherapy should theoretically be started when tumor burden is smallest, to be effective; concomitant or alternating administration of noncross-resistant drugs is preferred to sequential chemotherapy. However, delaying therapy does not necessarily result in decreased responsiveness in many cases.^{9,10} Similarly, administration of chemotherapy preoperatively, although it may be predicted to be more beneficial based on this model, does not confer any significant improvement in the clinical outcomes in resectable early-stage breast cancer. This model also assumes a stepwise development of resistance to individual agents and thus does not account for multidrug resistance patterns.

Tumor cell growth kinetics are complex and poorly understood. There are no available models that accurately describe all aspects of clinical behavior of solid tumors. The heterogeneous genetic abnormalities of different tumors underlie their behavior, making it impossible to make broad predictions.

Chemotherapy Approaches in the Management of Cancers

Cancer chemotherapy has principally been used in the management of advanced or metastatic disease, following failed local therapies, or in disease for which no alternative therapy is effective. Chemotherapy is curative for several advanced human cancers, such as gestational trophoblastic disease, certain hematologic malignancies, or germ cell testicular cancer. However, most common solid tumors are not curable with current chemotherapeutic regimens when metastatic (Table 2.1).

The roles of chemotherapy are manifold: *induction* chemotherapy denotes its use as primary therapy when there is no alternative treatment available or subsequently suitable even with tumor response, such as in hematologic malignancies, where disease is systemic. As an adjunct in *combined modality therapy*, chemotherapy is *adjuvant* when systemic treatment is applied after the tumor has been controlled by an alternative modality, such as surgery and/or radiotherapy, or *neoadjuvant (primary)* chemotherapy when localized cancer will otherwise not be optimally managed if systemic chemotherapy is not used before definitive local therapy.

Dose Intensity Versus Dose Density

Multiple laboratory experiments have established the proportionate dose–response curve, such that log kill is greater for the regimen with a higher dose intensity (i.e., by increasing the dose level delivered over a standard time interval). The slope of the curve is often steeper for tumors with a higher growth fraction. This observation underlies one of the principles in cancer chemotherapy—the administration of the highest possible dose of drugs in the shortest possible time intervals. The latter is typically limited by the recovery period of host organ function, such as the gastrointestinal tract and, in particular, the bone marrow, and thus explains the familiar 14- to 28-day intervals between cycles of therapy.

Progress in understanding of tumor growth kinetics has led to the emergence of new concepts in the schedules and

TABLE 2.1. Responses of tumors to chemotherapy.

<i>Curable</i>	<i>Prolonged survival</i>	<i>Palliative/minimal</i>
Hodgkin's lymphoma	Non-Hodgkin's lymphoma	Multiple myeloma
Non-Hodgkin's lymphoma (e.g., Burkitt's, diffuse large cell)	(e.g., follicular)	Chronic leukemias
	Bladder cancer	Malignant melanoma
	Breast cancer	Renal cell carcinoma
Acute leukemias	Lung cancer	Glioblastoma multiforme
Testicular cancer	Colorectal cancer	Pancreatic carcinoma
Ovarian cancer	Oligodendrogliomas	Hepatocellular carcinoma
Choriocarcinoma		Head and neck cancers
Childhood cancers (e.g., rhabdomyosarcoma, Wilm's tumor, Ewing's sarcoma)		Esophageal carcinoma
		Gastric carcinoma
		Prostate carcinoma

dosing of cytotoxic agents. Dose intensity refers to the dose level or total amount of drug received over a fixed unit of time. It is a function of the magnitude of the dose level. Achieving a certain effective dose level is analogous to the concentration-dependent killing of some antibiotics, such as aminoglycosides, wherein increasing bactericidal activity is achieved with exposure to a higher dose until a threshold concentration of maximal efficacy is achieved. Dose intensity is an important concept derived from the well-observed steep dose-response effect of chemotherapy agents demonstrated in randomized trials such as in germ cell tumors.¹¹

However, achieving a higher dose intensity by administration of higher dose levels of chemotherapy is hampered by concomitant increase in frequency and severity of toxicities. In addition, this concept may not be applicable in metastatic solid tumors, when tumor burden is largest. This restriction is illustrated by the negative results of myeloablative doses of chemotherapy compared to conventional chemotherapy in women with metastatic breast carcinoma.¹² Moreover, it has been observed in vitro that one of the important determinants of cytotoxicity is the duration of drug exposure beyond a threshold drug concentration. Indeed, there may be a readily tolerable minimal dose level for tumors, as implied in a recent trial by the Cancer and Leukemia Group B (CALGB) trial. In that study, there was no survival benefit to the administration of a more dose-intense regimen of 5-fluorouracil, adriamycin, and cyclophosphamide (FAC) in the adjuvant setting among women whose tumors did not express the HER/2 neu oncprotein.¹³

In contrast, dose density refers to the total amount of drug received over a variable given period of time. To illustrate, giving 2x amount of drug in cycles of y days (A) is twice more dose intense than x drug in y days (B), whereas B is less dose dense than x drug given in y/2 days (C). C is as dose intense

and dose dense as A. Simply, dose density is a function of frequency of dose administration within a treatment cycle. Dose density is analogous to the time-dependent killing activity of penicillins and cephalosporins wherein bactericidal activity is directly related to the time of exposure above the minimum inhibitory concentration (MIC), after which it becomes independent of drug concentration. A tumor thus relapses when subtotal eradication upon initial drug administration leads to tumor growth and development of drug resistance in between treatment cycles when the interval between therapy is prolonged. The dose-dense therapy may inhibit tumor regrowth between cycles and limit the emergence of malignant cell populations resistant to chemotherapy. Dose-dense strategy is the logical conclusion derived from the Norton-Simon model of tumor growth and drug response. Moreover, recent preclinical studies have shown that frequent administration in vivo of low doses of chemotherapeutic drugs, so-called "metronomic" dosing, may affect tumor endothelium and inhibit tumor angiogenesis, thus resulting in a better therapeutic index with reduced significant side effects (e.g., myelosuppression) involving other tissues. In solid tumors, this may be exemplified by the successful use of weekly paclitaxel in metastatic breast cancer.¹⁴

Chemotherapeutic Drugs

Anticancer drugs may be subdivided into two large groups based on the dependence of their mechanism of action on the cell cycle (Table 2.2). Cell-cycle-nonspecific drugs, which include alkylating agents and most antitumor antibiotics, kill tumor cells in both the resting and cycling phases. On the other hand, it was previously mentioned that cell-cycle-specific drugs are most effective when tumor cells are

TABLE 2.2. Drugs according to cell-cycle effects.

<i>Cell cycle</i>	<i>Agents</i>
Cell cycle nonspecific	Nitrogen mustards, aziridines, nitrosoureas, alkyl alkane sulfonates, nonclassic alkylating agents, anthracyclines, actinomycins, anthracenediones
Cell cycle specific	
S	Bleomycin, antimetabolites, camptothecins, epipodophyllotoxins
G ₂	Bleomycin, epipodophyllotoxins
M	Vinca alkaloids, taxanes

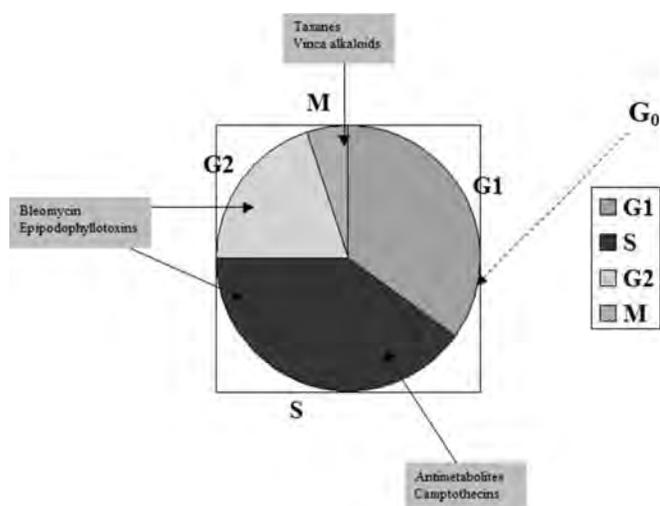

FIGURE 2.3. Cell-cycle-specific chemotherapeutic drugs and specific cell-cycle phase.

proliferating, that is, in cycles other than resting G₀ phase (Figure 2.3). Moreover, these drugs are usually most active in a specific phase of the cell cycle. Cell-cycle-specific drugs include the antimetabolites, antitubulin agents, and drugs targeting topoisomerase. Tables 2.3 and 2.4 describe common toxicities for each drug that is discussed in more detail in the subsequent sections.

Classic Alkylating Agents

Alkylating agents were the first class of agents to be clinically tested for cancer therapeutics. The alkylating agents form covalent bonds with nucleophilic cellular molecules, such as oxygen-, nitrogen-, phosphorus-, or sulfur-containing sites, through their alkyl groups. As a class, alkylating agents lack tumor selectivity but are generally active at very low doses. The bifunctional alkylating agents (two alkylating groups) not only alkylate but also crosslink DNA, leading to DNA template damage, subsequent cessation of DNA synthesis, and initiation of apoptosis upon recognition by cell-cycle checkpoint proteins such as p53. Alkylating agents thus are cytotoxic, teratogenic, and carcinogenic. Most secondary malignancies resulting from their use are acute leukemias.

Dose-dependent myelosuppression is the usual toxicity common to alkylating agents. Dose-dependent nausea and vomiting are frequently encountered. Gonadal atrophy and alopecia are also common sequelae of alkylating agent treatment. Because of the steep dose-response curve, alkylating agents are standardly included in myeloablative high-dose chemotherapy regimens in various hematologic malignancies. In such cases, pulmonary toxicity, veno-occlusive disease of the liver (nitrosoureas, busulfan, thiotepa, cyclophosphamide, mitomycin C), and neurotoxicity (lipophilic agents such as ifosfamide, nitrosourea, thiotepa, busulfan, nitrosourea) may arise and are life threatening.

The classic alkylating agents typically contain a chloroethyl group. They are classified as nitrogen mustards, aziridines, nitrosoureas, and alkyl alkane sulfonates. Non-classic monofunctional alkylating agents, on the other hand, feature a common N-methyl group, do not produce DNA crosslinks, and are essentially prodrugs requiring metabolic

transformation into active intermediates. Included in this latter group are procarbazine, dacarbazine, hexamethylmelamine, and temozolomide.

NITROGEN MUSTARDS

MECHLORETHAMINE

Nitrogen mustards have been the most commonly used alkylating agents. The prototype is the vesicant mechlorethamine. It has an extremely short half-life of 15 to 20 minutes, as it undergoes rapid hydrolysis in the plasma to reactive metabolites. Its chief uses currently are in the treatment of lymphoma and mycosis fungoides (topical). Derivatives of mechlorethamine that have gained broader clinical use are the oxazaphosphorines cyclophosphamide and ifosfamide, chlorambucil, and melphalan.

CYCLOPHOSPHAMIDE

Both cyclophosphamide and ifosfamide require metabolic transformation by the cytochrome P-450 mixed-function oxidases in hepatic microsomes into their reactive intermediates.¹⁵ They are also capable of induction of the microsomal enzymes responsible for their metabolism. In the case of cyclophosphamide, the intermediates 4-hydroxycyclophosphamide and aldosphosphamide that escape oxidation by aldehyde dehydrogenase are converted by tumor cells into acrolein and phosphoramidate mustard,¹⁶ the active alkylating agent that is responsible for the biologic effects of cyclophosphamide; this reaction is similar for ifosfamide. Because these metabolites are renally cleared, accumulation of acrolein in urine is responsible for hemorrhagic cystitis unique to these two agents,¹⁷ especially ifosfamide. Transitional cell carcinoma of the bladder developing as a late sequela has been described.¹⁸ Bladder toxicity may be reduced by hydration, frequent bladder emptying, and the use of thiol-containing agents such as *N*-acetyl cysteine (NAC) and mercaptoethane sulfonate (MESNA). These protectants are rich in sulfhydryl groups that bind and inactivate the charged toxic metabolites.

Cyclophosphamide can be administered orally or intravenously. Nausea and vomiting are usually delayed, occurring hours after drug administration. Relative sparing of the platelet count at doses less than 30 mg/kg is very characteristic. Moreover, it exhibits a stem cell-sparing effect even at high doses, in contrast to busulfan and melphalan, because of the high levels of aldehyde dehydrogenase in the early bone marrow progenitor cells. Cyclophosphamide is the most immunosuppressive anticancer agent available. Cardiac toxicity is dose limiting in high-dose administration,¹⁹ although no cumulative toxicity of low to moderate doses is evident. A toxic tubular effect has also been described wherein water retention, and an SIADH-like (syndrome of inappropriate antidiuretic hormone) picture can occur with the use of 50 mg/kg or higher doses.^{20,21} Cyclophosphamide is used in various settings, such as in breast cancer, bone marrow transplant, and non-Hodgkin's lymphoma (NHL), to name a few.

IFOSFAMIDE

Similar to cyclophosphamide, ifosfamide is well absorbed after oral administration. However, the oral metabolite chloroacetaldehyde is highly neurotoxic and hence the oral form is not commercially available.^{22,23} It has a lower affinity for its activating enzymes, and thus its transformation to alkylating

TABLE 2.3. Selected pharmacokinetic and toxicity features.

<i>Chemotherapeutic agent</i>	<i>Metabolism/excretion</i>	<i>Toxicity</i>	<i>Administration</i>	<i>Dose reduction in renal or liver dysfunction</i>
Classic alkylating agents	Chlorambucil	Myelosuppression, hyperuricemia, mild N&V, pulmonary fibrosis, seizures, gonadal toxicity, secondary malignancies	Oral	
	Cyclophosphamide	Myelosuppression, hemorrhagic cystitis, N&V, alopecia, headache, nasal congestion with rapid infusion, SIADH, cardiomyopathy, immunosuppression, gonadal toxicity, pulmonary fibrosis (high-dose), secondary malignancy	Infusion or oral	Clcr < 10mL/min: 25% reduction
	Ifosfamide	Myelosuppression, hemorrhagic cystitis, N&V, alopecia, metabolic acidosis, neurotoxicity (somnia), hallucinations, ataxia, neuropathy), arrhythmias, CHF, SIADH, Fanconi syndrome, gonadal toxicity, azotemia, secondary malignancy	Infusion or slow IV push	Ser 2.1–3.0 mg/dL: 25% to 50% reduction
	Mechlorethamine	Myelosuppression, severe N&V, dermatitis, thrombophlebitis, hyperuricemia, gonadal toxicity, secondary malignancy	Slow injection	
	Melphalan	Myelosuppression, mild N&V, vasculitis, mucositis, diarrhea, SIADH hypersensitivity reactions, gonadal toxicity, secondary malignancy	IV bolus, infusion or oral	Clcr 10–50 mL/min: 25% reduction Clcr < 10 mL/min: 50% reduction Clcr < 10 mL/min: 25% reduction
Mitomycin C	Myelosuppression, N&V, mucositis, HUS, DIC, microangiopathic hemolytic anemia, interstitial pneumonitis, thrombophlebitis, hepatic VOD, cardiomyopathy, bladder fibrosis (intravesical therapy)	Slow IV push or infusion, intravesical		
Thiotepa	Myelosuppression, mild N&V, hyperuricemia, dermatitis, secondary malignancy, hemorrhagic cystitis (intravesical therapy)	IV bolus or infusion, intrathecal, intravesical		
Nonclassic alkylating agents	Carmustine (BCNU)	Myelosuppression, severe N&V, thrombophlebitis, seizures (wafers), hepatotoxicity, nephrotoxicity, pulmonary fibrosis, infusion-related hypotension and arrhythmias at high doses, gonadal toxicity, secondary malignancy	IV infusion, wafer implant (glioblastoma)	
	Lomustine (CCNU)	Myelosuppression, severe N&V, gonadal toxicity, neurotoxicity (confusion, ataxia, dysarthria, lethargy), hepatotoxicity, nephrotoxicity, pulmonary fibrosis, secondary malignancy	Oral	Clcr 10–50 mL/min: 25% reduction Clcr < 10 mL/min: 50% reduction
	Streptozocin	Nephrotoxicity, N&V, elevated transaminases and/or mild cholestasis, hypoglycemia, secondary malignancy	IV bolus or infusion	Clcr 10–50 mL/min: 25% reduction Clcr < 10 mL/min: 50% reduction
	Busulfan	Myelosuppression, gonadal toxicity, secondary malignancy, mild N&V, skin hyperpigmentation (oral), hyperuricemia, cholestasis, hepatic VOD, seizures, bronchopulmonary dysplasia with pulmonary fibrosis, adrenal insufficiency	Oral or IV infusion	
	Procarbazine	Myelosuppression; N&V, hemolysis (G6PD deficiency), MAOI crises, flu-like syndrome, disulfiram reactions with alcohol; neurotoxicity (paresthesias, neuropathies, ataxia, confusion, seizures), gonadal toxicity, secondary malignancy	Oral	Consider dose reduction if bilirubin >3 mg/dl
	Dacarbazine	Myelosuppression, N&V, flu-like syndrome, photosensitivity	IV infusion	
	Altretamine	N&V, myelosuppression, neurotoxicity (neuropathy, ataxia, hallucinations), flu-like syndrome	Oral	
	Temozolomide	Myelosuppression, N&V, anorexia, headache, neurotoxicity (insomnia, somnolence, ataxia, hemiparesis, seizures), elevation of transaminases or cholestasis, peripheral edema	Oral	

Platinum compounds	Cisplatin	Renal	N&V, nephrotoxicity, electrolyte abnormalities, peripheral neuropathy, ototoxicity, myelosuppression, thromboembolic events, myocardial ischemia, ocular toxicity, thrombophlebitis, gonadal toxicity, mild elevation of transaminases or cholestasis, hypersensitivity reaction	IV infusion	Cldr 10–50 mL/min: 25% reduction Cldr < 10 mL/min: 50% reduction
	Carboplatin	Renal	Myelosuppression, N&V, nephrotoxicity, neuropathy, electrolyte abnormalities, mild elevation of transaminases or cholestasis, delayed hypersensitivity reaction	IV infusion	Calvert's formula
Antitumor antibiotics	Oxaliplatin	Renal	sensory > motor neuropathy, N&V, diarrhea, elevated liver transaminases, myelosuppression, nephrotoxicity, edema, hypersensitivity reaction	IV infusion	Consider in renal dysfunction
	Doxorubicin	Liver	Myelosuppression, mild N&V, mucositis, alopecia, cardiotoxicity, elevation of transaminases, radiation recall, hyperpigmentation, thrombophlebitis, urine discoloration	IV infusion, intraarterial, intravesical	Bilirubin 1.5–3 mg/dL: 50% reduction Bilirubin 3.1–5 mg/dL: 75% reduction
	Daunorubicin	Liver, renal	Myelosuppression, mild N&V, mucositis, alopecia, cardiotoxicity, elevation of transaminases, radiation recall, hyperpigmentation, urine discoloration	IV push or infusion	Bilirubin 2.1–3 mg/dL or AST 60–180 IU: 25% reduction Bilirubin 3.1–5 mg/dL or AST >180 IU: 50% reduction Bilirubin >5 mg/dL: omit use Serum creatinine \geq 2 mg/dL: 25% reduction
	Idarubicin	Liver, renal	Myelosuppression, mild N&V, mucositis, alopecia, elevation of transaminases or cholestasis, GI hemorrhage, cardiotoxicity, radiation recall, hyperpigmentation, urine discoloration, thrombophlebitis	Oral, slow IV push or infusion	Bilirubin 1.5–5 mg/dL or AST 60–180 IU: reduce dose 50%. Bilirubin >5 mg/dL or AST >180 IU: do not administer
	Epirubicin	Liver, renal	Myelosuppression, mild N&V, mucositis, cardiotoxicity, radiation recall, alopecia, hyperpigmentation, urine discoloration, thrombophlebitis, gonadal toxicity	IV infusion	Serum creatinine >5 mg/dl: consider dose reduction Bilirubin 1.2–3 mg/dL or AST 2–4 times the upper limit of normal: 50% reduction Bilirubin >3 mg/dL or AST >4 times the upper limit of normal: 75% reduction
	Mitoxantrone	Liver	Myelosuppression, mucositis, N&V, arrhythmias, cardiotoxicity (cumulative doses >140–160 mg/m ² cause CHF in ~10% of patients), elevated transaminases, urine discoloration, alopecia, secondary malignancy	IV infusion, intraperitoneal	Bilirubin 1.5–3 mg/dL: 50% reduction Bilirubin >3 mg/dl: 75% reduction
Antimetabolites	Dactinomycin	Liver	Myelosuppression, severe N&V, mucositis, cardiotoxicity, radiation recall, fatigue, hyperpigmentation, elevated transaminases, thrombophlebitis, hypocalcemia, hepatic VOD	Slow IV push	
	Bleomycin	Kidney, renal	Skin reactions (erythema, peeling, etc.), pneumonitis, pulmonary fibrosis, anaphylactoid reactions, Raynaud's phenomenon, arterial thrombosis, myocardial ischemia	Slow IV bolus, IM, SC or intracavitary injection	Cldr 10–50 mL/min: 25% reduction Cldr <10 mL/min: 50% reduction
	Methotrexate	Renal	Myelosuppression, mucositis, renal failure, uric acid nephropathy, elevation in transaminases or cholestasis, hepatic fibrosis, pneumonitis, serositis, neurotoxicity (high-dose or intrathecal), gonadal toxicity, vasculitis, thromboembolic disease	Oral, IV, IM, intrathecal	Cldr 61–80 mL/min: 25% reduction Cldr 51–60 mL/min: 30% reduction Cldr 10–50 mL/min: 50–70% reduction Cldr <10 mL/min: avoid use Bilirubin 3.1–5 mg/dL or AST >180 units: administer 75% of dose Bilirubin >5 mg/dL: do not use (continued)

TABLE 2.3. Selected pharmacokinetic and toxicity features. (continued)

<i>Chemotherapeutic agent</i>	<i>Metabolism/ excretion</i>	<i>Toxicity</i>	<i>Administration</i>	<i>Dose reduction in renal or liver dysfunction</i>
Raltitrexed	Renal	Fatigue/asthenia, N&V, mucositis, severe diarrhea, myelosuppression, elevated liver transaminases or cholestasis, edema	IV infusion	Clcr 55–65 mL/min: 25% reduction Clcr 25–54 mL/min: 50–75% reduction Clcr <25 mL/min: do not administer Consider in renal dysfunction
Pemetrexed	Renal	Myelosuppression, fatigue, mucositis, hand-foot syndrome, edema, elevated liver transaminases or cholestasis	IV infusion	Consider in renal dysfunction
5-Fluorouracil	Enzymatic catabolism	Myelosuppression, mucositis, hand-foot syndrome, acute coronary syndrome, GI ulcers, neurotoxicity, ocular symptoms	Slow IV bolus or infusion, topical, intraarterial IV, intra-arterial	Bilirubin >5 mg/dL: omit use
5-FUDR	Enzymatic catabolism	Hepatotoxicity, hand-foot syndrome, myelosuppression, mucositis, neurotoxicity, edema, acute coronary syndrome, headache, ocular symptoms	Oral	Clcr 30–50 mL/min: 25% reduction
Capecitabine	Enzymatic catabolism	Diarrhea, hand-foot syndrome, myelosuppression, acute coronary syndrome, neurotoxicity, ocular symptoms, elevated transaminases or cholestasis	Oral	Clcr <30 mL/min: do not use Consider in hepatic dysfunction
Cytarabine	Enzymatic deamination	Myelosuppression, N&V, GI ulcers, pancreatitis, cholestasis, hidradenitis, cerebellar dysfunction; with high-dose therapy: conjunctivitis, hand-foot syndrome, ARDS, elevated transaminases, hyperuricemia	IV infusion or bolus, IM, SC, intrathecal	Consider in hepatic dysfunction
Gemcitabine	Enzymatic deamination	Myelosuppression, N&V, flu-like symptoms, asthenia, fever, hemolytic-uremic syndrome, pneumonitis, elevated liver enzymes, somnolence, paresthesias	IV infusion	Consider in hepatic dysfunction
6-Mercaptopurine	Enzymatic; renal (with high-dose therapy) liver	Myelosuppression, mild N&V, mucositis, hepatotoxicity, crystalluria, hyperuricemia, pancreatitis	Oral	Consider in hepatic and renal dysfunction
6-thioguanine	Enzymatic; liver	Myelosuppression, N&V, mucositis, hepatotoxicity, hyperuricemia, crystalluria	Oral	Consider in hepatic and renal dysfunction
Fludarabine	Renal	Myelosuppression, autoimmune hemolytic anemia, edema, immunosuppression, fever, elevated liver enzymes, neurotoxicity (somnolence, neuropathy, confusion, cortical blindness, coma), tumor lysis syndrome	IV infusion	Clcr 30–70 mL/min: 20% reduction Clcr <30 mL/min: not recommended
Cladribine	Renal	Myelosuppression, immunosuppression, edema, fever, headache, dizziness, tumor lysis syndrome	IV infusion	
Pentostatin	Renal	Myelosuppression, immunosuppression, N&V, elevated liver enzymes, headache, lethargy, renal failure, acute pulmonary edema, ocular symptoms	IV infusion	Clcr <60 mL/min: administer 2 mg/m ² /dose

Antimicrotubule agents	Vincristine	Liver	Sensorimotor neurotoxicity, autonomic neuropathy(orthostatic hypotension/hypertension, ileus, constipation, bladder atony), seizures, alopecia, thrombophlebitis, hyperuricemia, SIADH, mild myelosuppression, ocular toxicity, ARDS	Bolus injection	Bilirubin 1.5–3.0 mg/dL or AST 60–180 units: 50% reduction. bilirubin 3.0–5.0 mg/dL: 75% reduction Serum bilirubin >5.0 mg/dL or AST >180 units: omit dose bilirubin 1.5–3.0 mg/dL or AST 60–180 units: 50% reduction. bilirubin 3.0–5.0 mg/dL: 75% reduction Serum bilirubin >5.0 mg/dL or AST >180 units: omit dose Serum bilirubin 2.1–3 mg/dL: 50% reduction Serum bilirubin >3 mg/dL: 75% reduction Liver
	Vinblastine	Liver	Myelosuppression, mucositis, neurotoxicity, hypertension, myocardial ischemia(esp. in comb w/cisplatin bleomycin), Raynaud's phenomenon, hyperuricemia, thrombophlebitis, SIADH, neuropathy, ARDS	Slow IV push or infusion	
	Vinorelbine	Liver	Myelosuppression, N&V, mucositis, constipation/diarrhea, elevated liver enzymes, fatigue, mild neurotoxicity, thrombophlebitis, SIADH, rare hemorrhagic cystitis	IV push or short infusion	
	Paclitaxel	Liver	Myelosuppression, hypersensitivity, neuropathy, myalgias, alopecia, cardiac arrhythmias (most commonly bradyarrhythmias), myocardial ischemia, myocardial dysfunction (with trastuzumab), mild elevation in liver transaminases, mucositis and diarrhea	IV infusion	
	Docetaxel	Liver	Myelosuppression, hypersensitivity, fluid retention, alopecia, skin rash, hand-foot syndrome, mucositis, diarrhea, fatigue, neuropathy, myalgia, arthralgias, mild elevation in liver transaminases, thrombophlebitis	IV infusion	Total bilirubin greater than or equal to the upper limit of normal (ULN), or AST (SGOT)/ALT (SGPT) >1.5 times the ULN concomitant with alkaline phosphatase >2.5 times the ULN: docetaxel should not be administered
Anti-topoisomerase agents	Topotecan	Renal	Myelosuppression, N&V, diarrhea, headache, fatigue, fever, alopecia, skin rash, hematuria, elevated liver enzymes	IV infusion	Clcr 20–39 mL/min: 50% reduction Clcr <20 mL/min: do not use
	Irinotecan	Liver	Myelosuppression, N&V, diarrhea, eosinophilia, elevated liver enzymes, fatigue, thrombophlebitis, cholinergic syndrome	IV infusion	
	Etoposide	Renal, liver	Myelosuppression, N&V, infusion-related hypotension, capillary leak syndrome, hypersensitivity, cerebral edema, elevation in liver transaminases, thrombophlebitis, secondary leukemias	IV bolus or infusion, oral	Clcr 10–50 mL/min: 25% reduction Clcr <10 mL/min: 50% reduction Bilirubin 1.5–3 mg/dL or AST 60–180 units: reduce dose by 50% Bilirubin >3 mg/dL or AST >180 units: reduce by 75%
	Teniposide	Liver	Myelosuppression, N&V, hypersensitivity, infusion-related hypotension, mild elevation in liver transaminases, secondary	IV infusion	

ARDS: acute respiratory distress syndrome

AST: aspartate transaminase

Clcr: creatinine clearance

DIC: disseminated intravascular coagulation

G6PD: glucose-6-phosphate dehydrogenase

HUS: hemolytic uremic syndrome

IM: intramuscular

IV: intravenous

MAOI: monoamine oxidase inhibitor

N&V: nausea and vomiting

SC: subcutaneous

SIADH: syndrome of inappropriate antidiuretic hormone secretion

VOD: veno-occlusive disease of the liver

TABLE 2.4. Frequency of adverse effects/toxicities.

Chemotherapeutic agent	M	N&V	Mucositis	Constipation	Diarrhea	Liver	Pulm	Renal/ bladder	CVS	Neuro	Alopecia	Skin	Fever	Weakness /fatigue	HSR

metabolites proceeds more slowly than that of cyclophosphamide. Ifosfamide is more likely than cyclophosphamide to produce renal damage, and a Fanconi-like syndrome has been described after ifosfamide therapy. Central nervous system (CNS) toxicities of varying degrees such as hallucinations, cerebellar ataxias, weakness, aphasia, seizures, and coma are more likely to occur in patients with renal impairment or low serum albumin levels receiving high-dose chemotherapy.²⁵ It has greater activity against sarcomas and testicular cancer.

AZIRIDINES

THIOTEPA

Thiotepa is a representative agent of the class of analogues of the closed-ring intermediates of the nitrogen mustards called aziridines. Thiotepa inhibits not only DNA but RNA and protein synthesis as well. It is primarily administered intravenously because of variable oral absorption. Intrathecal treatment of meningeal carcinomatosis and intravesical instillation for superficial transitional cell carcinoma (TCC) of the bladder is also used. It is extensively metabolized by the mixed-function oxygenases of the cytochrome P-450 system in the liver into the active desulfurated metabolite triethylenephosphoramide (TEPA). Both thiotepa and TEPA have cytotoxic activity, although nadirs in leukocytes and platelets correlate best with the AUC (area under the drug concentration–time curve) of thiotepa. It is used in breast and ovarian cancer, as well as in the high-dose transplant settings for these two malignancies. Mucositis, skin changes (bronzing, rash, hyperpigmentation), and altered mental status may be seen at high doses.

MITOMYCIN C

Mitomycin C belongs to the family of related antibiotics from *Streptomyces caespitosus*,²⁶ and thus can also be classified under the antitumor antibiotic group. The mitomycins are the only known naturally occurring compounds containing an aziridine ring. Biochemical reduction of its quinone moiety transforms the drug into a highly reactive alkylator, thus the term bioreductive alkylation.²⁷ Both aerobic and anaerobic mechanisms of activation exist, each giving rise to different reactive species, although alkylation may be more likely to occur in a hypoxic environment.²⁸ Its role as a radiosensitizer arises from this cytotoxicity in hypoxic cells. Although it is not currently used in first-line therapy of any malignancy, it is used in combined modality treatment of squamous cell carcinoma of the anus and head and neck malignancies. It is also intravesically administered for superficial bladder cancer.

NITROSOUREAS

CARMUSTINE AND LOMUSTINE

Because of their lipophilicity and ability to cross the blood–brain barrier, chloroethylnitrosoureas such as carmustine (BCNU) and lomustine (CCNU) are used principally for the treatment of brain tumors. They may also be used in certain regimens for lymphomas. At physiologic pH, the chloroethyldiazonium hydroxide molecules and isocyanates that arise from the spontaneous decomposition of BCNU alkylate DNA, inhibit enzymes involved in DNA and RNA synthesis, respectively.^{29–32} CCNU is relatively unionized at physiologic pH and is hepatically metabolized by the

cytochrome P-450 system into active intermediates. In contrast to other agents, nitrosoureas exhibit a characteristic delayed myelosuppression.³³ Onset of leukocyte and platelet depression occurs 3 to 4 weeks after drug administration. Platelet counts may reach nadir before neutrophil counts. Nadir typically occurs at 4 to 6 weeks and may persist for an additional 1 to 3 weeks. Transient elevation of the serum transaminases develops in the majority of patients within 1 week of BCNU administration. Hepatic veno-occlusive disease may be observed in up to 20% of patients receiving high-dose BCNU therapy. Pulmonary fibrosis and renal toxicity may be evident when a cumulative dose of 1,000 to 1,400 mg/m² is exceeded for both nitrosoureas.

STREPTOZOTOCIN

Unlike the other nitrosourea analogues, streptozotocin has no effect on RNA or protein synthesis. It does not form DNA crosslinks, although it can methylate DNA. This methyl-nitrosourea, isolated from *Streptomyces*, is remarkable for its lack of bone marrow toxicity.³⁴ When myelosuppression occurs, it is usually mild, with nadir occurring at 1 to 2 weeks. Nevertheless, when in combination with other cytotoxic agents, there is considerable synergism in regard to hematologic toxicity. Nausea and vomiting can be quite severe. Its diabetogenic effect in animals is correlated with its specific toxicity against pancreatic beta cells, hence its use in islet cell carcinoma of the pancreas. It has demonstrated clinically significant activity against islet cell carcinoma of the pancreas and carcinoid tumors.

ALKYL ALKANE SULFONATES

BUSULFAN

Busulfan is the major representative of this class of agents. Its lipophilicity and low protein-binding affinity account for its penetration into the CNS.³⁵ It reacts more extensively with the thiol groups of amino acids and proteins than do the nitrogen mustards.³⁶ It is selectively more toxic against myeloid than lymphoid cells, in contrast to nitrogen mustards and nitrosoureas.³⁷ It is well absorbed orally and has a short duration of action because of extensive hepatic conjugation with glutathione. Consequently, acetaminophen may potentiate host toxicity when given 72 hours before busulfan due to interference with hepatic metabolism. Its metabolism exhibits circadian rhythmicity, especially in children.³⁸ Prolonged bone marrow aplasia may be seen after its administration, attributed to its cytotoxicity against hematopoietic stem cells. Hyperpigmentation of the skin, especially the palmar creases, is not uncommon. Seizures and hepatic veno-occlusive disease occur in a substantial proportion of patients with high-dose therapy in the transplant setting. Prophylactic anticonvulsant therapy is thus recommended with high-dose busulfan. It is used as a component of most regimens for chronic myelogenous leukemia, although it is no longer the frontline therapy.

NONCLASSIC ALKYLATING AGENTS

PROCARBAZINE

Procarbazine (PCB) is widely distributed in most tissues, including the cerebrospinal fluid (CSF), with oral administration. It is a hydrazine analogue that inhibits DNA, RNA, and protein synthesis. An oral prodrug, its active end products and

the mechanism of their cytotoxicity remain unclear, although the free radical species that arise from the decomposition of methyl- or benzylazoxy intermediates generated by the hepatic cytochrome P-450 system seem to be the most likely candidates. Current evidence favors its role as a methylating agent. The importance of first-pass hepatic metabolism is demonstrated by the neurotoxicity and lack of antitumor activity with intravenous administration.³⁹ In contrast, the most common dose-limiting toxicity of PCB given orally is myelosuppression. Nausea and vomiting often abate with continued administration. Because it inhibits monoamine oxidase (MAO) and is in turn extensively metabolized by the hepatic microsomes, the potential for drug and food interactions is increased. Gonadal toxicity resulting in azoospermia or ovarian failure is not uncommon. Its immunosuppressive property may contribute to increased risk of infections.⁴⁰ It is primarily used in the treatment of Hodgkin's disease (MOPP regimen) and brain tumors.

DACARBAZINE

Dacarbazine (DTIC) is a dimethyltriazene prodrug that is administered intravenously. It is hepatically demethylated by the cytochrome P-450 mixed-function oxidase to form 5-(3-methyltriazeno)imidazole-4-carboxamide (MTIC), which tautomerizes to the methyl diazonium ion species that acts as the active methylating agent. It was originally developed as a purine antimetabolite. However, it is not cell cycle specific. Evidence is also sufficient to suggest that its antitumor activity does not result from inhibition of purine synthesis. DTIC inhibits DNA, RNA, and protein synthesis *in vitro*.⁴¹ Aside from its cytotoxicity, DTIC has antimetastatic properties *in vivo*, which may be related to its ability to enhance tumor immunogenicity.⁴² Unlike procarbazine, it has poor CSF penetration. Myelosuppression is dose-limiting.⁴³ It is an active single agent used in the treatment of metastatic melanoma and Hodgkin's lymphoma.

TEMOZOLOMIDE

Temozolomide (TMZ) is an oral imidazotetrazinone whose ring structure spontaneously opens under physiologic conditions to generate the monomethyl triazine MTIC, the same methylating metabolite formed by metabolic dealkylation of DTIC.⁴⁴ The spontaneous conversion to MTIC, as opposed to the inefficient and variable demethylation of DTIC to MTIC in humans, accounts for its advantage over DTIC. This conversion is pH dependent, acidic conditions favoring the closed stable form of TMZ. In contrast, MTIC rapidly degrades to the methyl diazonium ion at pH less than 7.0.⁴⁵ TMZ's lipophilicity accounts for its CNS penetration. It is used in the treatment of metastatic melanoma, high-grade gliomas, and anaplastic astrocytoma. It is also being investigated for treatment of brain metastases from lung cancer and other tumors.

Platinum Compounds

Antitumor activity of platinum compounds was extrapolated and tested from the initial observations of Rosenberg and coworkers on the inhibition of *Escherichia coli* growth by a current delivered between platinum electrodes.⁴⁶ The core structure of the intravenously administered platinum analogues cisplatin, carboplatin, and oxaliplatin is based on the

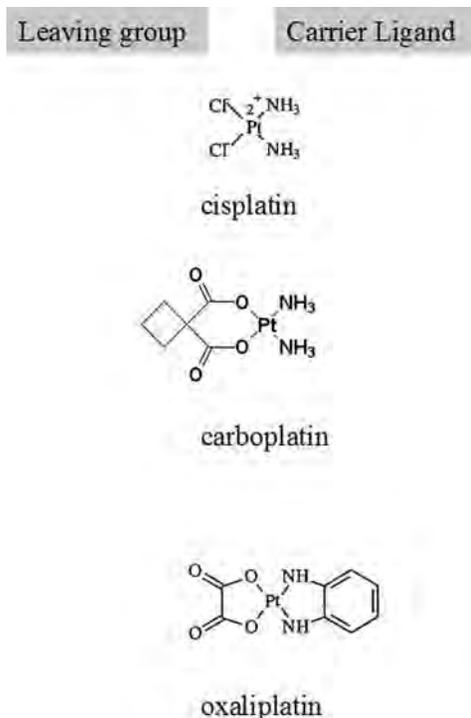

FIGURE 2.4. Structures of the platinum analogues.

cis configuration of platinum in its +2 oxidation state, designated as Pt(II). The cis isomers are cytotoxic whereas the trans isomers are much less potent. In addition to the oxidation state and isomeric configuration, clinical activity and toxicity of the platinum analogues seem to be related to the type of carrier ligand and leaving groups attached to the core cis-platinum structure. As shown in Figure 2.4, carboplatin differs from cisplatin by its cyclobutane dicarboxy leaving group, whereas oxaliplatin differs from carboplatin by its 1,2-diaminocyclohexane ring as its carrier ligand. Cisplatin undergoes an aquation reaction intracellularly wherein the chloride ions (the leaving groups) are displaced because of low intracellular chloride concentration. This reaction yields mono- and di-aquo platinum complexes that form strong covalent bonds with RNA as well as DNA and protein (in descending order of affinity), with intrastrand DNA crosslinks (also termed DNA adducts) being correlated with cytotoxicity and clinical outcomes.^{47,48} In the case of cisplatin, detection of cisplatin-induced DNA adducts initiates a nucleotide excision DNA repair pathway (NER) as well as a signaling cascade that results in apoptosis mediated by the mismatch repair proteins (MMR). Consequently, increased NER or defective MMR protein is associated with resistance.

CISPLATIN

All three compounds are primarily cleared by the kidneys, although the extent of this clearance as well as their toxicity profiles differ. Platinum compounds, particularly cisplatin, appear to inhibit cytochrome P-450 activity, which may account for drug interactions in combination regimens with other chemotherapeutic agents. Cisplatin is generally administered with forced saline diuresis, as nephrotoxicity is dose limiting and cumulative. Its high emetogenic potential also warrants the maintenance of adequate fluid hydration.

Nephrotoxicity is manifested early as potassium and magnesium wasting, in addition to a reduction in glomerular filtration rate. The electrolyte derangements may be ascribed to inhibition of the Na^+/K^+ ATPase activity as well as the Ca^{2+} channel in renal tubular tissue.^{49,50} Morphologic kidney damage is greatest in the renal tubules. Peripheral neuropathy, predominantly sensory, also commonly ensues after repeated administration and often may be irreversible. Approximately 85% of patients suffer this complication when cumulative dose exceeds $300\text{ mg}/\text{m}^2$.⁵¹ Cumulative and dose-dependent irreversible ototoxicity is not unusual. It is used as first-line agent in treating various malignancies, such as germ cell tumor, head and neck cancers, lung cancers, osteogenic sarcoma, genitourinary neoplasms, and upper gastrointestinal (GI) malignancies.⁵²

CARBOPLATIN

Carboplatin is 100 times less reactive than cisplatin in undergoing the intracellular aquation reaction. It requires 10-fold-higher drug concentrations and 7.5-fold-longer incubation time than cisplatin to induce the same degree of DNA damage. Unlike cisplatin, carboplatin is not significantly secreted by renal tubules. Its clearance is linearly related to the glomerular filtration rate (GFR). There is a good correlation between its AUC and dose-limiting thrombocytopenia. The AUC is the ratio of the amount of a drug that reaches the systemic circulation and the clearance of the drug. As carboplatin excretion has relatively simple pharmacokinetics, a formula relating the dose to AUC and renal function has been established. Calvert's formula [carboplatin dose (mg) = target AUC ($\text{mg}/\text{mL} \times \text{min}$) \times GFR (mL/min) + 25] uses the AUC and creatinine clearance to derive dose levels. Target AUC values of 5 and $7\text{ mg}/\text{mL} \times \text{minute}$ are recommended for single-agent carboplatin in previously treated and untreated patients, respectively. The efficacy of carboplatin appears to be suboptimal at AUCs below $5\text{ mg}/\text{mL} \times \text{min}$ and appears to plateau above an AUC of $7.5\text{ mg}/\text{mL} \times \text{minute}$. It is less emetogenic and neurotoxic than cisplatin, although more myelosuppressive.

As suggested previously, there is cross-reactivity between cisplatin and carboplatin and thus a similar reaction may be seen when one analogue is substituted for another. Carboplatin has confirmed activity for many of the diseases that are treated with cisplatin. It is of clinically equivalent efficacy as cisplatin in the treatment of non-small cell lung cancer (NSCLC), extensive-stage SCLC, and suboptimally debulked ovarian cancer. Cisplatin is clinically superior in treating germ cell, head and neck, and esophageal cancers.⁵²

OXALIPLATIN

Oxaliplatin is a third-generation platinum compound that undergoes spontaneous nonenzymatic conversion to its active metabolite. Oxaliplatin differs from both cisplatin and carboplatin by its unique carrier ligand, which is thought to cause reduced recognition and repair of oxaliplatin-DNA adducts.⁵³ It produces inter- and intrastrand DNA crosslinks more rapidly than cisplatin. It demonstrates both in vitro and in vivo activity against various tumor cell lines, even those resistant to cisplatin and carboplatin.⁵⁴ Although defects in certain MMR proteins, such as those seen in colorectal cancers, lead to cisplatin resistance, this is not the case with

oxaliplatin, which remains effective. Oxaliplatin is synergistic with fluorouracil (5-FU)/leucovorin in vitro, and its activity in vivo is significantly enhanced by combination with 5-FU. It is not nephrotoxic and has minimal hematologic, auditory, or cardiac toxicity. Certain toxicities are unique to oxaliplatin. Neurotoxicity, chiefly sensory neuropathy, is exacerbated or triggered by exposure to cold. Although dose limiting, this effect is generally reversible on discontinuation of oxaliplatin. Acute dysesthesias in the upper extremities and laryngopharyngeal region with episodes of difficulty breathing or swallowing may be observed within hours or the first few days after therapy. Diarrhea is more marked with combination chemotherapy, usually given in the regimen with 5-FU and leucovorin in metastatic colon cancer.

Antitumor Antibiotics and Related Synthetic Compounds

Most of the antitumor antibiotics were initially isolated from various *Streptomyces* species. Central to their cytotoxic profile is the presence of numerous mechanisms by which each individual antibiotic interacts with DNA. The variety of chemical structures present in each compound participate in multiple mechanisms responsible for their activity against cells. The polycyclic chromophore structure intercalates with DNA and is also responsible for conferring the characteristic bright color of these drugs. Ring structures, such as the quinone group, not only interfere with electron transport, but also bind metal cations, intercalate into DNA and RNA, and generate reactive oxidant species, to name a few actions. DNA-modifying enzymes, such as topoisomerases and helicases, are common cellular enzymes targeted by these drugs.

Dose-limiting toxicities are related to myelosuppression and mucositis. Variable susceptibility to congestive cardiomyopathy is an associated complication from cumulative dose administration of anthracyclines. Emetogenic potential is considerable. Reversible alopecia is not unusual. They are also among the most potent vesicants available, and thus scrupulous attention should be given during the administration of these agents to prevent tissue extravasation. Photosensitivity, hyperpigmentation, and pigmentation of the nails and urine are common. Another interesting toxicity is the radiation recall phenomenon. As the term suggests, pain, erythema, and blistering or ulceration occur on previous radiation sites within 3 to 7 days of administration of the antitumor antibiotic. This phenomenon may be observed on any epithelial surface and may thus manifest as dermatitis, enteritis, pneumonitis, or stomatitis. The drugs most commonly implicated are the anthracyclines doxorubicin and daunorubicin, dactinomycin, and bleomycin.

ANTHRACYCLINES

The anthracyclines doxorubicin and daunorubicin are commonly incorporated into standard therapy regimens for multiple cancer types, given their broad antitumor activity over a wide range of doses and administration schedules as well as the lack of antagonistic interactions with other commonly used chemotherapy agents.

Anthracyclines exert pleiotropic mechanisms by which they effect cytotoxicity. Aside from DNA intercalation, anthracyclines inhibit DNA topoisomerase II, an enzyme that

releases the torsional strain in DNA by actively inserting stable DNA strand breaks, facilitating the passage of one of the DNA strands through the other in the helix and then reannealing the strand break.⁵⁵ Anthracyclines form a ternary 'cleavable complex' with DNA topoisomerase II, which then 'traps' the DNA strand passage intermediates. This inhibition of topoisomerase II can be detected as protein-associated DNA single- and double-strand breaks linked to the enzyme. Another target is a group of nuclear enzymes, the helicases, that is critical in duplex DNA dissociation into single strands.⁵⁶ Their anthraquinone structure enables them to undergo one-electron reduction reactions catalyzed by flavin dehydrogenases or reductases. These reactions generate free radicals and other reactive oxidant species that damage intracellular macromolecules.⁵⁷ Moreover, certain signal transduction pathways, such as protein kinase C and the sphingomyelin pathway, can be modulated by anthracyclines, the end effects of which include apoptosis.^{58,59}

DOXORUBICIN

Doxorubicin is primarily hepatically metabolized. The liposomal formulation has a small volume of distribution and hence is mainly confined to the intravascular compartment. It has a slower plasma clearance and prolonged terminal half-life compared to the regular formulation. Doxorubicin can induce histamine release, manifesting as facial flushing. Atrial and ventricular dysrhythmia may arise acutely with anthracycline administration, although these are usually not life threatening. Congestive cardiomyopathy is a late complication, occurring at less than 5% with cumulative dosage of greater than 400 mg/m² with intermittent schedules, 550 mg/m² with weekly, or up to 800 to 1,000 mg/m² with continuous infusion schedules. Risk factors that predispose to earlier development of congestive heart failure are old age; cardiovascular disorder associated with increased left ventricular outflow tract gradients, such as uncontrolled hypertension, aortic stenosis, or underlying cardiomyopathy; history of congestive heart disease; and mediastinal irradiation.

EPIRUBICIN

Epirubicin is a derivative of doxorubicin. It is hepatically glucuronidated and its metabolites are excreted in bile. It was developed in efforts to reduce cardiotoxicity seen with doxorubicin. Epirubicin has a more favorable therapeutic index, with 30% less hematologic toxicity at equimolar doses. Risk of congestive heart failure, which may not differ from doxorubicin at equimyelosuppressive doses,⁶⁰ increases significantly with cumulative doses greater than 900 mg/m². Similar to doxorubicin, continuous infusion and weekly schedules are associated with decreased risk of cardiotoxicity. Epirubicin is used as a component of regimens used in adjuvant therapy in breast and gastric cancer.

DAUNORUBICIN

Daunorubicin was the prototype anthracycline studied in the 1960s. It is more lipid soluble than doxorubicin, owing to the absence of one hydroxyl group. As compared to doxorubicin, there is a lower incidence of mucositis and colonic perforation. The renal clearance is approximately twice that for doxorubicin, thus making dose adjustments in patients with hepatic dysfunction unnecessary in many situations. Cardiac

toxicity is likewise limiting. Its current use is mainly in the remission induction regimens for acute leukemias.

IDARUBICIN

Idarubicin is a 4-demethoxy derivative of daunorubicin that is orally bioavailable, has a longer half-life, and less potential for cardiotoxicity. Because of the alteration in its ring structure, it has a yellow color in aqueous solutions, as opposed to the characteristic red color of doxorubicin and daunorubicin. The primary metabolite of idarubicin, 13-idarubicinol, is cytotoxic and largely renally excreted. Although it has significant activity in the treatment of acute myelogenous leukemia (AML), it is less active against solid tumors.

ANTHRACENEDIONES

MITOXANTRONE

Mitoxantrone, a dark blue anthracenedione originally synthesized as a stable dye, intercalates nucleic acids and thus inhibits DNA and RNA synthesis. It also inhibits topoisomerase II by the formation of a cleavable complex, thus causing protein-associated single-strand DNA breaks.⁶¹ In spite of its quinone structure, free radical production is limited, and in one model, mitoxantrone inhibited the rate of lipid peroxidation induced by doxorubicin.⁶² This is clinically observed in the reduced severity of its cardiac effects in contrast to doxorubicin. It is used mainly in prostate and breast cancers, as well as leukemias and lymphomas.

BLEOMYCIN

Bleomycin is a cell-cycle-specific polypeptide antibiotic that requires a metal ion cofactor for its activity, such as copper or iron, without which single- and double-strand breaks (approximately 10:1) in DNA cannot be produced.⁶³ Inhibition of cell growth occurs at the S phase, although it can also induce a G₂ arrest.⁶⁴ It is a mixture of multiple glycopeptides, the predominant active component of which is the A2 peptide, comprising 70% of the commercial preparation.

Bleomycin has a short half-life.⁶⁵ Renal excretion is the primary route of eliminating up to 70% of unchanged drug after a given dose. It is inactivated in the tissues by the enzyme bleomycin hydrolase, the concentrations of which are lowest in skin and lung,⁶⁶ thus explaining the clinical toxicities encountered. Fever within the first 12 hours of administration is almost universally observed. Hypotension is seen with rapid intravenous infusions of higher doses. Anaphylactoid reactions have been described, mostly in lymphoma patients receiving their first dose.⁶⁷ The most feared complication, however, is pulmonary interstitial fibrosis, which appears to be cumulatively dose dependent at 300 units total dose.⁶⁶ Pulmonary fibrosis appears earlier in those with impaired renal function. Exposure to high oxygen tensions even after prior therapy with bleomycin is associated with increased risk of developing this pulmonary toxicity. Onset is unpredictable, as it may occur during treatment or after cessation of therapy, and may progress even after discontinuation of the drug.⁶⁸ It is used in curative regimens for testicular cancer and Hodgkin's lymphoma.

DACTINOMYCIN (ACTINOMYCIN D)

Actinomycin D has a tricyclic phenoxazone ring, which imparts its yellow color, attached to two symmetric cyclic

leucovorin. Polyglutamated MTX is a more potent and avid reversible inhibitor of DHFR than monoglutamated MTX. The ability to generate MTX polyglutamates seem to correlate with cytotoxicity in both murine and human tumor cells,^{70,71} whereas increasing concentration of reduced folates can competitively reverse MTX toxicity.

MTX is rapidly absorbed orally, although incompletely at higher doses. It has a rather long terminal half-life, up to 27 hours.⁷² CSF penetration at conventional doses is poor. It is thus administered intrathecally in prophylactic CNS therapy for ALL. MTX slowly penetrates third-space fluid collections such as pleural effusion and ascites. The half-life of MTX sequestered in these situations is further prolonged because of slow reentry into the bloodstream. Enhanced clinical toxicity may be observed if fluid collections are not drained before methotrexate therapy. MTX is primarily cleared by the kidneys within the first 12 hours after administration, mostly as unchanged drug. It should therefore be used cautiously in patients with renal insufficiency. In these circumstances, the enterohepatic circulation may assume a more important role in drug excretion,⁷³ and use of activated charcoal or cholestyramine may be tried to enhance plasma clearance through enhanced biliary excretion.^{74,75} Carboxypeptidase G, an enzyme that removes the terminal glutamate residue from MTX, leads to MTX inactivation and is another effective alternative.

STANDARD INTRAVENOUS ADMINISTRATION

Major toxicities are myelosuppression and mucositis. Gastrointestinal epithelial cells are more sensitive to the effects of MTX, being inhibited at half the concentrations required to inhibit DNA synthesis in the bone marrow.⁷⁶ Mucositis typically appears 3 to 5 days after treatment and precedes the fall in leukocytes or platelets by several days. Unless drug clearance is severely impaired, such as in renal failure, myelosuppression and mucositis are usually reversed within 2 weeks.

HIGH-DOSE THERAPY

High-dose MTX yields therapeutic concentrations in the CSF. Nephrotoxicity, manifested as oliguria and azotemia, is the major adverse effect of high-dose MTX therapy. Although MTX may be a direct tubular toxin per se, nephrotoxicity arising from high-dose therapy is mainly attributed to intratubular precipitation of MTX and its less-soluble metabolites, 7-OH MTX and 2,4-diamino-*N*-10-methyl pteric acid (DAMPA), in acidic urine. Vigorous hydration and urine alkalinization can diminish such complication. Some myelosuppression and mucositis may occur. Leucovorin rescue (described next) reduces the likelihood of systemic toxicity. Acute transient transaminase elevations commonly occur after high-dose therapy, but late occurrence of liver failure or cirrhosis has not been reported. Repeated courses of high-dose MTX therapy can result in encephalopathy, dementia, paresis, and seizures.

LEUCOVORIN RESCUE

Methotrexate blood levels should be assayed every 24 hours with high-dose therapy in patients with impaired renal function as well as patients who have had excessive toxicity with prior MTX therapy. Leucovorin rescue is initiated at 12 to 24 hours after the start of high-dose drug infusion and should

continue until MTX level is less than 50 nM/L. Leucovorin is typically administered as 10 mg/m² intravenously followed by oral doses given every 6 hours for 10 to 12 more doses. If MTX levels are above 500 nM/L, 1 μM/L, or 2 μM/L at 48 hours, a general guideline is that leucovorin should be administered at 15 mg/m², 100 mg/m², or 200 mg/m², respectively, every 6 hours over 48 more hours. Patients should be vigorously hydrated using bicarbonate-enriched fluids (2.5–3.5 L/m²/day IV fluids + 45–50 mEq bicarbonate/L IV fluid) to maintain high urine output (more than 100 mL/h) and alkaline urine (above pH 7.0) for 12 hours before and 48 hours after high-dose therapy (more than 1 g/m²) to avoid renal failure. MTX is used clinically in leukemia, lymphoma, breast cancer, head and neck cancer, osteogenic sarcoma, and choriocarcinoma.

RALTITREXED

Raltitrexed is a potent quinazoline analogue that selectively inhibits thymidylate synthase (TS). Similar to MTX, polyglutamation by folylpolyglutamyl synthetase (FPGS) is correlated with increasing cytotoxicity.⁷⁷ It is poorly absorbed orally. Its excretion, mostly as unchanged drug, is similarly correlated with creatinine clearance. Patients with insufficient folate intake may be at increased risk for clinical toxicity. Transient elevation of liver enzymes may be seen with its convenient IV dosing once every 3 weeks. It is an effective alternative to 5-FU-based therapy in patients with metastatic colorectal cancer. Another advantage over 5-FU is lesser frequency of mucositis. It also exhibits antitumor activity in non-small cell lung and breast cancers. It is approved in several countries in Europe, Canada, Asia, and Australia.

PEMETREXED

Pemetrexed is a pyrrolo-pyrimidine-based antifolate analogue whose main activity is inhibition of TS. It is transported into cells via the RFC, with transport kinetics similar to that of methotrexate. It binds to folate receptor-α with a very high affinity, similar to that of folic acid. Furthermore, cellular influx is also facilitated by the presence of high-affinity and highly specific transport systems for pemetrexed in malignant mesothelioma cell lines.⁷⁸ This transport system has a relatively low affinity for other inhibitors of DHFR or TS such as methotrexate and raltitrexed. Pemetrexed is likewise polyglutamated by FPGS to enhance intracellular concentration, and consequently, cytotoxicity. The polyglutamation reaction occurs 90- to 195-fold more efficiently with pemetrexed than methotrexate.⁷⁹ Polyglutamated pemetrexed is more than 60-fold more potent in its inhibition of TS than the monoglutamate. Its prolonged intracellular retention allows for bolus intermittent dosing schedules. At high concentrations, pemetrexed causes an S-phase block and apoptosis. Under the same conditions, it also exhibits multitarget inhibition of several crucial folate-requiring enzymes such as DHFR, GARFT, and, to a lesser extent, AICART and C1-FH₄ synthase.

Pemetrexed causes a rapid depletion of deoxythymidine-, deoxycytosine-, and deoxyguanosine triphosphates. Cells that rely on de novo purine synthesis and do not have purine salvage pathways are expected to be particularly sensitive to pemetrexed. It has been shown that pleural mesothelioma cells frequently (approximately 90%) exhibit codeletion of the gene coding for the enzyme methylthioadenosine phosphorylase (MTAP) with the CDKN2A gene.⁸⁰ Homozygous deletion

of CDKN2A gene, which encodes for the cell-cycle regulatory proteins p16 and p14ARF, may be seen in 75% of pleural mesotheliomas.⁸⁰ As MTAP catalyzes an important purine salvage pathway, the frequency of its codeletion with CDKN2A, as well as the presence of highly specific transport systems for pemetrexed in malignant mesothelioma, may in part account for its efficacy in this tumor type.

Folic acid has been shown to be 100- to 1,000-fold less effective than leucovorin in protecting tumor cells against the cytotoxic effects of pemetrexed.⁸¹ Nevertheless, folic acid reduces toxicity in mice while preserving the antitumor activity of pemetrexed. Myelosuppression and mucositis can be significantly ameliorated by folate and vitamin B₁₂ supplementation without any demonstrable reduction in antitumor efficacy.

Pemetrexed has demonstrated broad antitumor activity in a wide variety of solid tumors, including mesothelioma, non-small cell lung, breast, cervical, colorectal, head and neck, and bladder cancers in a variety of Phase II trials. It exhibits synergistic antitumor activity with alkylating agents, irinotecan, and gemcitabine.⁸² Promising activity has been demonstrated when pemetrexed is combined with cisplatin and gemcitabine.^{82,83} A pivotal Phase III trial indicates the superiority of pemetrexed in combination with cisplatin versus cisplatin alone in malignant pleural mesothelioma.⁸⁴ Pemetrexed demonstrated equivalent efficacy to docetaxel, but with significantly less toxicity, in second-line NSCLC.⁸⁵

Pyrimidine Antagonists

Pyrimidine antagonists comprise nucleic acid base analogues and their prodrugs as well as nucleoside analogues that generate substrates which ultimately become incorporated into the elongating DNA and RNA strand, thus inhibiting DNA, RNA, and ultimately protein, synthesis. All require intracellular anabolic conversion into active nucleotide substrates.

5-FLUOROURACIL

5-Fluorouracil (5-FU) is the simplest and most successful uracil derivative to date in clinical use. This fluoropyrimidine undergoes anabolic activation intracellularly into fluorodinated nucleosides and deoxynucleotides [fluorouridine monophosphate (FUMP); fluorouridine triphosphate, FUTP; fluorodeoxyuridine monophosphate, FdUMP; fluorodeoxyuridine triphosphate, FdUTP] (see Figure 2.5). FdUMP inhibits TS and prevents formation of, and consequently depletes the available pool of, thymidylate necessary for generating dTTP; as a result, FdUTP and dUTP become the "preferred" substrates of reactions catalyzed by DNA polymerase, affecting DNA stability. Moreover, incorporation of FUTP in RNA interferes with proper RNA synthesis and function. 5-Fluorodeoxyuridine (5-FUDR) or floxuridine is a fluoropyrimidine deoxynucleoside analogue that also undergoes similar metabolic conversion intracellularly to generate FUTP, FdUTP, and TS-inhibiting FdUMP. Genetic polymorphisms in TS may also affect treatment response. In vivo and in vitro studies have shown that lower TS activity is correlated with better antitumor response.

After intravenous administration, 5-FU readily penetrates the CSF and extracellular third-space fluid collections, such as ascites or pleural effusions. It has a short half-life (10–15 minutes). Both 5-FU and 5-FUDR are extensively catabolized

(more than 85%). The initial rate-limiting step in degradation involves the enzyme dihydropyrimidine dehydrogenase (DPD), which is widely expressed in tissues including the liver, GI mucosa, leukocytes, and kidney. Thus, 5-FU is poorly absorbed orally. Because of its size, the liver has the highest total content of DPD and is a major site of 5-FU metabolism. DPD is subject to genetic polymorphisms, with 8- to 21-fold intersubject variability. Those with low DPD activity are susceptible to severe toxicity. Greater first-pass effect (more than 90%) through the liver results in lower systemic drug levels (and, consequently, fewer side effects) with FUDR, making it the preferred agent for hepatic arterial infusion (HAI). When administered with IV bolus schedules, FUDR is catabolized to the predominant 5-FU form.⁸⁶ Several important interactions between 5-FU and other agents have been described. Leucovorin expands the pool of reduced folates to enhance the inhibition of TS. Methotrexate pretreatment increases the formation of 5-FU nucleotides. 5-FU may interfere with the repair of platinum-associated DNA damage. Ionizing radiation augments DNA damage. All these agents demonstrate preclinical as well as Phase III trial evidence for improvement in clinical activity.

Meta-analysis of several randomized trials comparing various 5-FU schedules of administration has shown the superiority of continuous infusion of 5-FU over bolus administration when given as a single agent.⁸⁷ Moreover, bolus drug administration cannot achieve effective radiosensitization, as this requires constant drug exposure given the short half-life of 5-FU. Clinical toxicities also have some correlation with schedule of administration. Myelosuppression, especially leukopenia, is more pronounced with IV bolus schedules than with continuous infusion. Mucositis along the GI tract can be debilitating and dose limiting, especially with continuous infusion. Other GI symptoms, such as nausea, vomiting, and anorexia, can also be more severe with continuous infusion. With HAI regimens, systemic toxicities of 5-FU are dose limiting whereas hepatitis is usually mild. On the other hand, local-regional toxicities such as gastritis, gastric ulcers, enteritis, hepatitis, cholestasis, or cholecystitis predominate with HAI using 5-FUDR. 5-FU is currently used for GI malignancies and esophageal, head and neck, and breast cancers. 5-FUDR is principally used for HAI therapy of GI adenocarcinoma metastatic to the liver.

CAPECITABINE

Capecitabine is an oral fluoropyrimidine carbamate precursor of 5-FU. It was developed to overcome the degradation of 5-FU in the GI tract when administered orally. With daily administration, it simulates continuous 5-FU IV infusion, without the inconvenience and morbidity associated with indwelling catheters. It is initially metabolized by hepatic carboxylesterase into 5'-deoxy-5-fluorocytidine, which in turn is converted to 5'-deoxy-5-fluorouridine (5'-dFUR) by the enzyme cytidine deaminase found in the liver as well as tumor tissues (Figure 2.6). The final step involves thymidine phosphorylase (TP), expressed at higher levels in tumor tissues than normal cells, which converts 5'-dFUR into 5'-FU. This preferential formation of 5-FU within tumor cells results in relatively low circulating plasma levels of 5-FU. Its current use is chiefly in the treatment of metastatic breast and colorectal cancer.

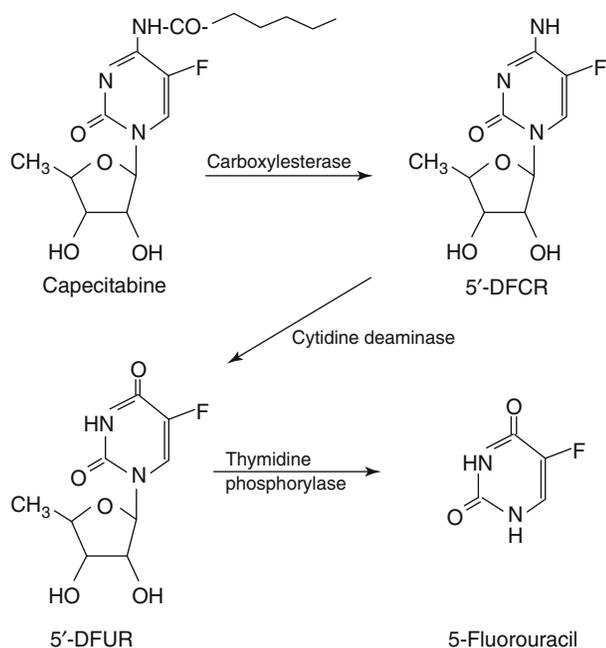

FIGURE 2.6. Metabolic activation of capecitabine (5'-DFCR, 5'-deoxy-5-fluorocytidine; 5'-DFUR, 5'-deoxy-5-fluorouridine).

CYTOSINE ARABINOSIDE

Cytosine arabinoside (Ara-C) is one of the cornerstone agents in AML therapy. It was originally extracted from the sponge *Cryptothethya crypta*. This cytosine analogue differs from the native cytosine by the substitution of the sugar moiety arabinose for ribose. It is intracellularly activated after phosphorylation by different kinases into its triphosphate form (Ara-CTP) such as deoxycytidine kinase, deoxycytidine monophosphate kinase, and nucleoside diphosphate kinase. Deoxycytidine kinase activity is highest during the S phase of the cell cycle and is the rate-limiting step in the anabolic conversion of various other nucleoside analogues. Ara-CTP then competes with and depletes the dCTP pool and reversibly inhibits DNA polymerase. More importantly, the degree of incorporation of ara-CTP into DNA, leading to chain termination and inhibition of DNA synthesis, correlates with cytotoxicity.⁷⁶ It also inhibits ribonucleotide reductase, the enzyme that catalyzes the synthesis of other deoxynucleoside triphosphates. Likewise, ara-C inhibits the formation of CDP-choline integral to the synthesis of membrane glycoproteins and glycolipids. Balancing these are deaminating reactions, catalyzed by cytidine deaminase and dCMP deaminase, that degrade the active ara-C metabolites. Cytidine deaminase is widely distributed in normal cells, including the liver, GI mucosa, and mature granulocytes.

Ara-C enters cells by a saturable carrier-mediated transport system in common with physiologic nucleosides. It has been shown that the transport system is the rate-limiting factor in the formation ara-CTP.⁸⁸ At drug levels above 10 $\mu\text{mol/L}$, passive diffusion occurs and the ability to accumulate ara-CTP becomes saturated. Thus, high-dose regimens may overcome resistance in some cases associated with deficiencies in the transport system. In spite of its water

solubility, ara-C penetrates the CNS quite effectively, 20% to 40% of plasma levels at steady state, to reach threshold cytotoxic levels for leukemia cells in the CSF at conventional doses. Because of the high concentrations of cytidine deaminase in the GI tract, oral administration yields significantly lower plasma levels, and therefore this route is precluded. Myelosuppression and GI toxicities are the major adverse effects of ara-C. Diarrhea and mucositis occur frequently. High-dose ara-C intensifies the severity of these toxicities. Moreover, certain syndromes unique to high-dose therapy are notable. Neurotoxicity in the form of cerebral-cerebellar dysfunction manifested as ataxia, dementia, slurred speech, and coma may lead to permanent disability in up to 40% of affected patients. An irreversible acute respiratory distress syndrome can occur in association with a high incidence of *Streptococcus viridans* pneumonia, especially in children. Steroid-responsive conjunctivitis is a frequent side effect. An unusual febrile state in conjunction with cutaneous eruption of plaques of nodules, termed neutrophilic eccrine hidradenitis, is also associated with high-dose therapy.

GEMCITABINE

Gemcitabine (2,2-difluorodeoxycytidine, dFdC) is the most important cytosine analogue currently in use for solid tumors. Cellular influx also occurs via the nucleoside transport system. Intracellular activation by deoxycytidine kinase is the rate-limiting step necessary for antitumor activity. The diphosphate form (dFdCDP) inhibits ribonucleotide reductase more effectively than ara-C,⁸⁹ whereas the triphosphate dFdCTP not only inhibits DNA polymerase but also leads to DNA strand termination upon its incorporation into the elongating DNA strand. Similar to ara-C, cytidine deaminase catalyzes the major catabolic pathway in degrading gemcitabine to difluorodeoxyuridine (dFdU). Deamination requires activation by dCTP, whose level in turn is reduced upon inhibition of ribonucleotide reductase by dFdCDP. Moreover, dFdCTP directly inhibits cytidine deaminase. The preclinical finding that prolonged exposure to gemcitabine leads to dramatically greater antitumor effect is consistent with the concept of self-potential leading to prolonged intracellular concentrations of its primary cytotoxic metabolite, dFdCTP. Affinity of gemcitabine for deoxycytidine kinase and cytidine deaminase is much lower than deoxycytidine itself. Nevertheless, gemcitabine is a better substrate for the nucleoside transporter of tumor cells and has greater affinity for deoxycytidine kinase than ara-C. dFdCTP has a longer half-life than ara-CTP. Moreover, dFdCDP is a more potent inhibitor of ribonucleotide reductase than ara-CTP. Gemcitabine enhances the formation of DNA adducts, and thus cytotoxicity, by cisplatin. It also potently sensitizes cells to ionizing radiation. This radiosensitization is dose- and time-dependent and is maximal when radiation follows gemcitabine exposure. Because dFdCTP is present intracellularly for several days after drug administration, gemcitabine is able to radiosensitize cells for several days after bolus administration. However, this also underlies the unwanted side effect of increased treatment-related morbidity and, in some cases, mortality.⁹⁰ Gemcitabine is currently used in pancreatic and non-small cell lung cancers and is active in breast, bladder, and ovarian cancers, lymphomas, and head and neck cancers.

Purine Antagonists

These purine analogues, similar to their pyrimidine counterparts, require metabolic conversion before activation, which results in inhibition of de novo purine synthesis, and are consequently incorporated into DNA. Some also inhibit DNA polymerase and ribonucleotide reductase. These drugs enter cells via the nucleoside transport system. Myelosuppression is the major toxicity shared by all these agents.

6-MERCAPTOPURINE AND THIOGUANINE

6-Mercaptopurine (6-MP) and thioguanine (6-TG) are analogues of hypoxanthine and guanine, respectively, wherein there is a substitution of a sulfhydryl group for the endogenous 6-OH position. Both are intracellularly anabolized through the hypoxanthine-guanine phosphoribosyl transferase (HGPRT) pathway to form 6-thioinosine monophosphate (TIMP) and 6-thioguanilic acid (TGMP), respectively, which inhibit de novo purine synthesis mediated by 5-phosphoribosyl-1 pyrophosphate (PRPP) amidotransferase. Cytotoxicity arises from the incorporation of 6-thioguanosine triphosphate (6-TGTP) and the deoxytriphosphate form into DNA and RNA, which triggers the mismatch repair pathway leading into apoptosis. In spite of these similarities, cross-resistance between these two agents is not complete, as 6-TG remains active in HGPRT-deficient cells resistant to 6-MP.⁹¹

Both 6-MP and 6-TG are converted to inactive metabolites by the enzyme thiopurine methyltransferase (TPMT), with 6-TG being more extensively S-methylated than 6-MP. Genetic polymorphisms in the TPMT gene associated with reduced enzyme activity have been described. 6-TG is also inactivated upon deamination by the enzyme guanase. 6-MP, unlike 6-TG, is catabolized by xanthine oxidase, high concentrations of which can be found in the intestinal mucosa and liver. Both 6-MP and 6-TG have poor and variable oral bioavailability that is further reduced with food intake. In the case of 6-MP, this arises from the large first-pass effect as the drug is metabolized by xanthine oxidase. Allopurinol, a xanthine oxidase inhibitor, prevents catabolism of 6-MP. Moreover, concomitant allopurinol intake increases 6-MP bioavailability fivefold.⁹² Dose reduction of 6-MP is thus warranted in patients taking allopurinol.

Anorexia, nausea, and vomiting may occur, especially among adults, more commonly with 6-MP than 6-TG. Hepatotoxicity, usually in the form of reversible cholestatic jaundice, has been reported for either drug. Acute hepatic necrosis may also ensue with high-dose 6-MP therapy, whereas fatal veno-occlusive disease has been reported with 6-TG. High-dose therapy with 6-MP or 6-TG can cause tubular precipitation and crystalluria. 6-MP is used in ALL whereas 6-TG is active in AML.

FLUDARABINE

Fludarabine is a 2-fluoromonophosphate derivative of adenosine arabinoside (ara-A) that is relatively water soluble and resistant to rapid deamination by adenosine deaminase (ADA). Upon dephosphorylation in plasma to 2-fluoro-ara-A, intracellular rephosphorylation by deoxycytidine kinase to its active form, 9- β -D-arabinofuranosyl-2-fluoro-adenine triphosphate (F-ara-ATP), is necessary for cytotoxicity. F-ara-ATP inhibits several important enzymes in DNA replication,

including DNA polymerase and ribonucleotide reductase. Its incorporation into DNA leads to DNA chain termination, primarily at the 3'-end, in contrast to ara-C, which is incorporated into 5'-termini. It demonstrates synergism with ara-C and cisplatin.^{93,94}

Fludarabine is cleared primarily by the kidneys. Although it has good oral bioavailability, an oral formulation is not yet available for commercial use. Myelosuppression is dose related and may be cumulative. Development of autoimmune hemolytic anemia may occur most commonly during the first three cycles of treatment. Fever occurs in approximately 25% of patients, although about one-third of these patients have a serious documented infection. Increased risk for opportunistic infections is in consequence to significant and protracted reduction in CD4+ T cells; hence, prophylaxis against *Pneumocystis pneumonia* is required. Pulmonary toxicity, manifested as fever, cough, and interstitial pneumonitis, has also been associated with this drug. Fludarabine is active not only against actively dividing cells but also in malignancies with low growth fraction such as chronic lymphocytic leukemia (CLL) and low-grade lymphomas.

CLADRIBINE

Cladribine (2-CdA) is a deoxyadenosine analogue with a chloride attached to the 2-position of the adenine ring that renders it resistant to breakdown by ADA. Intracellular phosphorylation by deoxycytidine kinase to the active 5'-triphosphate (2-CdATP) results in incorporation into DNA, leading to DNA chain termination and strand breaks; inhibition of DNA polymerases and ribonucleotide reductase ultimately results in inhibition of DNA synthesis. Cells with a high ratio of deoxycytidine kinase to deoxynucleotidase activity, such as lymphocytes, are particularly sensitive to the effects of cladribine. Similar to fludarabine, cladribine is cytotoxic to both actively dividing and nondividing cells. In resting cells, 2-CdATP seem to initiate the caspase cascade leading to apoptosis.⁹⁵

Bioavailability of cladribine administered subcutaneously reaches nearly 100%. It can penetrate the blood-brain barrier, the CSF concentrations reaching about 25% of the plasma concentrations during continuous IV infusion. Cladribine is renally cleared and hence, should be used with caution in patients with renal insufficiency. Similar to fludarabine, it increases the intracellular concentrations of ara-CTP and probably other pyrimidine analogues as well. Immunosuppression results from prolonged suppression of CD4+ T lymphocytes; thus, opportunistic infections, in addition to myelosuppression, are the major adverse complications with this drug. Cladribine is highly active in the treatment of hairy cell leukemia, Waldenström's macroglobulinemia, indolent lymphomas, and leukemias. Its activity in fludarabine-resistant cases however, is much diminished.

PENTOSTATIN

Pentostatin, or 2'-deoxycoformycin, is an adenosine analogue originally isolated from *Streptomyces antibioticus* but is now synthetically derived. It is a potent inhibitor of ADA, leading to high levels of deoxyadenosine and its triphosphate, which in turn inhibit ribonucleotide reductase in a negative feedback loop. Cells with high levels of deoxynucleoside kinase activity over 5-nucleotidase activity, such as lymphocytes,

are most susceptible to the effects of ADA inhibition.⁹⁶ Postulated mechanisms of cytotoxicity are similar to the other adenosine analogues. In addition, it also prevents methylation reactions mediated by S-adenosylhomocysteine hydrolase.

Renal elimination accounts for most of the clearance of pentostatin (more than 90%). Pentostatin is per se a nephrotoxic agent, and renal failure is dose limiting. Opportunistic infections arising from immunosuppression may occur. Nausea and vomiting are the most common nonhematologic toxicities. It is highly active in hairy cell leukemia, Waldenström's macroglobulinemia, indolent lymphomas, and leukemias.

Microtubule-Targeting Drugs

Microtubules are integral components of the mitotic spindle apparatus during metaphase in dividing cells. They are also involved in many nonmitotic functions such as intracellular scaffolding, locomotion and chemotaxis, secretory processes, anchorage of subcellular organelles, and neurotransmission. They are composed of tubulin heterodimers that assemble into 13 protofilaments aligned side by side around a hollow central core. Posttranslation modification after tubulin polymerization accounts for the functional diversity of microtubules in various tissues.

There is a constant flux between the microtubule and the intracellular pool of tubulin. Each tubulin molecule is associated with two molecules of guanosine triphosphate (GTP). GTP is found only at the rapidly growing, or plus end, of the microtubule. Its hydrolysis after tubulin polymerization is not essential for microtubule growth at the plus end; however, hydrolysis of GTP does lower the concentration of the free tubulin subunit required for net polymerization at the plus end. The plus end switches spontaneously and rapidly between slow growth and rapidly shrinking states.⁹⁷ This "dynamic instability" occurs once the GTP "cap" is lost from the end of microtubule upon hydrolysis and depolymerization occurs. In contrast, the "minus end" is where net disassociation occurs because protofilaments align slowly at this end.

Vinca Alkaloids

Most antimicrotubules agents are alkaloids, structurally complex plant-derived organic bases. Vinca alkaloids are the first widely used class of antimicrotubule agents in cancer chemotherapy. They are cell-cycle-specific vesicants derived from the pink periwinkle plant, *Catharanthus roseus* (L.) G. Don. Vincristine and vinblastine are the two representative compounds. Vinorelbine is a vinblastine semisynthetic derivative with broad antitumor activity as a single agent that may not be completely cross-resistant with vincristine and vinblastine. Their antitumor and toxicity spectra vary significantly. This variability may arise from different tubulin isotypes, lipophilicity, or cellular retention.

Cytotoxicity of vinca alkaloids is principally related to the microtubular depolymerization by inhibiting microtubule assembly, resulting in metaphase arrest in G₂ and M cell-cycle phases in dividing cells. This explanation is oversimplified, as the lowest drug concentration that induces metaphase arrest and antiproliferative effects results in little or no dis-

ruption of the mitotic spindle apparatus or depolymerization. The vinca alkaloids have pleiotropic biologic effects not necessarily related to their effects on microtubules, such as inhibiting purine, DNA, RNA, and protein synthesis. They are also potent inhibitors of angiogenesis. As microtubules function in cell processes other than mitosis, vinca alkaloids also affect cells in the nonmitotic phases of the cell cycle.

These vinca alkaloids are primarily eliminated by hepatic metabolism and biliary excretion. Hepatic metabolism is principally mediated by P-450 CYP3A. Agents that can increase toxicity include L-asparaginase and CYP3A inhibitors such as erythromycin. On the other hand, they can reduce the bioavailability of certain drugs such as digoxin and phenytoin. Vinca alkaloids are administered intravenously. Vinorelbine is orally bioavailable, although a commercial formulation is not yet available. Vincristine has the longest terminal half-life and the lowest clearance rate, whereas vinorelbine has the shortest half-life and the highest clearance rate. Vinca alkaloids should never be administered intrathecally, as the global dissolution of brain and spinal cord neurofilaments that ensues is fatal.

VINCRIStINE

Vincristine has the greatest affinity for tubulin and has the highest degree of intracellular accumulation among the vinca alkaloids. These characteristics, together with its pharmacokinetic properties, are implicated in the associated neurotoxicity. Neurotoxicity is cumulative and the severity is related to total dose and duration of therapy. Motor dysfunction is usually irreversible. Autonomic neuropathy may be manifest as ileus, constipation, urinary retention, orthostatic hypotension, or hypertension. Central effects, such as seizure and blindness, have been reported. Aside from drug discontinuation or dose/schedule modification, approaches to prevent or reduce neuropathy include the use of folic acid and glutamic acid. Severe myelosuppression is rare. In therapy, vincristine is unique in that a single maximum dose delivered is typically limited to 2 mg to prevent and/or delay the development of neurotoxicity. It is an integral component in chemotherapy regimens for lymphomas, Ewing's sarcoma, rhabdomyosarcoma, leukemias, and neuroblastoma.

VINBLASTINE AND VINOReLBINE

Neurologic effects are much less common and severe with vinblastine and least with vinorelbine. Myelosuppression, especially neutropenia, is the major dose-limiting toxicity of both vinblastine and vinorelbine. Mucositis and stomatitis happen more frequently with vinblastine than vincristine. Constipation, as with vincristine, occurs frequently. Vinblastine is an important component for regimens used in testicular carcinomas and lymphomas. Vinorelbine has demonstrated activity in advanced non-small cell lung cancer, breast cancer, and ovarian carcinomas as well as lymphomas.

TAXANES

Taxanes affect microtubules through a mechanism of action unique from the vinca alkaloids. Unlike the vinca alkaloids, which facilitate microtubule depolymerization, taxanes shift the dynamic equilibrium toward microtubule assembly,

prevent depolymerization, and therefore suppress microtubular reorganization. The binding site for taxanes is different from that for vinca alkaloids, GTP, podophyllotoxins, and colchicine. Sustained mitotic arrest at the metaphase–anaphase boundary, apoptosis, and antiangiogenesis may be observed even at low concentrations where increase in microtubule bundling is not seen. Taxanes also exert inhibitory effects on nonmitotic cell-cycle phases, attesting to the myriad functions subserved by microtubules. They have also been shown to be effective radiosensitizers. This radiosensitizing effect is most likely related to their ability to cause cell-cycle arrest in the G₂ and M phases of the cell cycle, when tumor cells are highly susceptible to the effects of radiation. Taxanes are intravenously administered because of poor oral bioavailability, due in part to the constitutive overexpression of P-glycoprotein in enterocytes as well as the first-pass metabolism in the liver and/or intestines. They are widely distributed to almost all tissues and third-space fluid collections except the CNS. Plasma protein binding is high (more than 90%), and elimination half-lives are long. The principal route of metabolism is through the hepatic cytochrome P-450 system. Biliary excretion is the main route of elimination as renal clearance accounts for less than 10%. Dose reductions are therefore necessary in patients with hepatic dysfunction. Reversible and noncumulative neutropenia is the principal toxicity of the taxanes in clinical use.

PACLITAXEL

The prototype taxane, paclitaxel, is a complex alkaloid ester initially isolated from the bark of the Pacific yew tree, *Taxus brevifolia*. It is currently a semisynthetic derivative from 10-deacetylbaccatin III and other precursors found in the needles of other more abundant *Taxus* species, such as the European yew, *Taxus baccata*. Paclitaxel binds to the N-terminal 31 amino acids of the β -tubulin subunit of the tubulin oligomers.⁹⁸ Aside from its effects on the microtubular system, in vitro experiments also showed inhibition of endothelial cell proliferation, motility, and invasiveness in a dose-dependent manner. Paclitaxel also inhibits the production of matrix metalloproteinases, which are enzymes that degrade matrix and thereby contribute to tumor invasiveness.

Clinical activity and toxicity of paclitaxel is highly dose- and schedule-dependent. Early clinical studies of paclitaxel were limited to 24-hour infusion schedules largely due to the severity of hypersensitivity reactions on shorter infusion schedules. However, the development of effective premedication regimens enabled reevaluation of shorter infusion schedules. The extensive distribution and high affinity of taxanes to peripheral tissue may explain the lack of significant differences in antitumor activity between the short and protracted infusion schedules. Patients treated with higher doses and/or shorter infusion schedules are more prone to neurotoxicity as compared to those treated with longer infusion. In contrast, both dose and duration of infusion are directly proportional to the degree of myelosuppression. Weekly treatment (80–100 mg/m²/week), although more inconvenient than the conventional once every 3 weeks schedule (135 mg/m² over 24 hours or 175 mg/m² over 3 hours), has gained clinical acceptance. Weekly administration not only results in dose-dense therapy, it achieves a higher dose intensity, total cumulative dose over a 3-week period

being higher than could be given in one dose. Weekly administration results in less myelosuppression and allows for better control of toxicities, as a dose may be omitted but treatment resumed the following week. This regimen results in sustained exposure of tumor cells to paclitaxel and simulates “metronomic” dosing as well that enhances its antiangiogenic activity.

The severity of myelosuppression seems to be related to prolonged infusions. Because of poor aqueous solubility, paclitaxel is formulated in polyoxyethylated castor oil (cremophor EL), which leaches the plasticizer out of polyvinylchloride containers and tubings. Cremophor, known to induce histamine release, is most likely responsible for the well-recognized hypersensitivity reactions seen with paclitaxel. Major anaphylactoid manifestations include bronchospasm, urticaria, and hypotension that usually occurs within 2 to 3 minutes after administration. The taxane structure itself may be contributory. Before the routine use of premedication with antihistamines and corticosteroids, severe acute hypersensitivity reactions occurred in 20% to 30% of patients treated with paclitaxel in early Phase I trials. With standard premedication, the incidence of major hypersensitivity reactions nowadays is low (less than 5%) and similar for the 3- or 24-hour infusion. Particularly pertinent to paclitaxel is its effect on atrioventricular conduction, as it causes bradyarrhythmias, which are mostly reversible and asymptomatic. A direct causal relationship observed between paclitaxel and ventricular and atrial tachycardias has yet to be proven. Combination of paclitaxel and doxorubicin results in a higher frequency of congestive heart failure than would have been expected from an equivalent cumulative dose of doxorubicin given alone.

DOCETAXEL

Docetaxel is a more water-soluble taxane semisynthetically derived from 10-deacetylbaccatin III, obtained from the needles of the European yew (*Taxus baccata*). It is more potent than paclitaxel and has nearly twofold-higher affinity for the β -tubulin subunit. In comparative studies, docetaxel has been found to be 1.3- to 12-fold more cytotoxic in vitro than paclitaxel. It has linear pharmacokinetics at clinically relevant doses, and its maximal activity can be achieved with fairly rapid infusion, in contrast to paclitaxel. Schedule-dependent activity thus seems not to be evident with docetaxel. It is highly protein bound, primarily to α -acid glycoprotein. CYP3A4 and CYP 3A5 constitute the major cytochrome P-450 isoforms responsible for the bulk of its metabolism.

Major anaphylactoid reactions induced by docetaxel are similar to those seen with paclitaxel although, unlike paclitaxel, docetaxel is suspended in a polysorbate 80 formulation. Whether the polysorbate or the taxane moiety itself or both are responsible for the hypersensitivity reactions is unclear. With corticosteroid and histamine antagonist premedication, incidence of major hypersensitivity reactions is reduced to 1% to 3%. Peripheral neuropathy is less common and less severe with docetaxel. Unlike paclitaxel, adverse cardiovascular events such as arrhythmias are rare with its use, and docetaxel can be combined with anthracyclines without excessive cardiac toxicity. On the other hand, fluid retention mimicking capillary leak syndrome characterized by edema,

pleural effusions, ascites, or anasarca is noted with docetaxel, particularly at cumulative doses that exceed 400 mg/m². Docetaxel also causes an erythematous, pruritic maculopapular rash over the forearms and hands in up to 75% of patients. It is associated with palmar-plantar erythrodysesthesia that may respond to cooling or pyridoxine. Premedication with corticosteroids has been shown to reduce the incidence of dermatologic toxicities and fluid retention.

Drugs Targeting Topoisomerase

Unwinding of the DNA helix generates a torsional strain from supercoiling of the helix above and below the region of ongoing nucleic acid during DNA replication, transcription, or recombination. DNA topoisomerase I is a ubiquitous nuclear enzyme that relaxes this torsional strain by catalyzing a transient single-stranded nick in the DNA. This results in covalent linkage of the enzyme to the 3'-terminus of the cleaved DNA. It also reanneals the strand break after passage of the intact single strand through the gap in the cleaved DNA strand. Topoisomerase I is expressed in both mitotic and non-mitotic cells alike throughout the cell cycle, with higher levels of its mRNA and the topoisomerase protein found in malignant tumors than in their normal tissue counterparts.^{99,100}

Topoisomerase II exists in two isoforms in mammalian cells. Although topoisomerase II β is expressed throughout the cell cycle, expression of topoisomerase II α is cell cycle specific, highest during G₂-M phases of the cell cycle, and its concentrations are higher in rapidly proliferating cells. The α -isoenzyme is preferentially targeted by the topoisomerase II inhibitors at drug concentrations reached with standard doses. Unlike topoisomerase I, topoisomerase II is energy cofactor dependent, requiring ATP and magnesium for its catalytic activity. It becomes covalently attached to the 5'-terminus of the cleaved DNA. It then facilitates strand passage through another and thereafter religates the strand break. Furthermore, it can create double-stranded DNA gaps, orchestrate concerted strand passage, and can catalyze "unknotting" or decatenation of intertwined DNA, attesting to its role in mitosis.

Topoisomerase I-Targeting Agents

Camptothecin (CPT), a naturally occurring, relatively water-insoluble alkaloid extract from the bark and wood of the Chinese tree *Camptotheca acuminata*, is the prototype topoisomerase I-targeting agent. Its clinical development was halted early due to its toxicity and only upon the introduction of water-soluble forms was it reintroduced into clinical testing. The analogues have greater in vivo and in vitro activity and less severe and more predictable toxicity than camptothecin. All CPT analogues exhibit stereospecific-inhibition of topoisomerase I activity, with the naturally occurring S-isomer being up to 100 times more biologically active than the R-isomer. Nevertheless, they differ from classic enzyme inhibitors by not merely preventing the function of topoisomerase alone; CPTs trap the enzyme in a covalent complex bound to DNA, leading to persistence of single-strand breaks and accumulation of stabilized cleavable complexes, which by themselves are not lethal because the strand breaks are

reversible upon drug removal. Active DNA synthesis is a crucial component to CPT-induced cytotoxicity,¹⁰¹⁻¹⁰³ making camptothecins relatively S-phase-specific agents, although non-S-phase-specific cytotoxicity has been described. According to the fork collision model,¹⁰² lethal damage to DNA occurs once a DNA replication fork encounters a cleavable complex, resulting in a cytotoxic double-stranded break in DNA. CPTs thus are more aptly termed topoisomerase I-targeting agents.

All CPTs undergo a rapid, reversible, pH-dependent, nonenzymatic hydrolysis of the lactone ring to generate the less-active open-ring hydroxy carboxylate in aqueous solutions. The latter species predominate at physiologic or alkaline pH. This finding is clinically relevant because the low pH in the bladder favors the active closed lactone ring species that can cause severe hemorrhagic cystitis. Among the CPT analogues, irinotecan is structurally unique in that it lacks direct activity per se. It is a prodrug that must undergo cleavage of its bulky dipiperidino side chain by a carboxylesterase-converting enzyme to produce the metabolite SN-38 for biologic activity.

TOPOTECAN

Topotecan was the first water-soluble CPT analogue approved for clinical use. It has a relatively higher CNS penetration than most other CPTs, due in part to its low plasma protein binding. Schedule-dependent synergism with radiation (concurrent, preradiation, or within 30 minutes after radiation) in vitro has been observed. Renal excretion is the main route of drug elimination. Dosage adjustments are recommended for patients with moderate renal impairment (20–39 mL/min). Hepatic metabolism by cytochrome P-450 enzymes is minimal. At the standard dose of 1.5 mg/m²/day for 5 consecutive days every 3 weeks, noncumulative and reversible neutropenia is the most common dose-limiting toxicity, with grade 4 neutropenia occurring in 81%, febrile neutropenia in 26%, grade 4 thrombocytopenia in 26%, and severe anemia (Hb less than 8 g/dL) in 40%. Topotecan is approved for use in cisplatin-refractory ovarian cancer, recurrent small cell lung cancer failing frontline chemotherapy, and leukemias.

IRINOTECAN

As mentioned earlier, irinotecan (CPT-11) has little inherent antitumor activity in vitro. Its water-insoluble deesterification metabolite SN-38 is 1,000-fold more potent than the parent compound. SN-38 has a longer half-life and high binding affinity to plasma proteins, especially albumin. In contrast with topotecan and other CPT analogues, the lactone form of SN-38 is preferentially stabilized by albumin, hence the equilibrium is shifted toward the formation of the lactone in physiologic conditions. Although SN-38 formation occurs in the plasma and intestinal mucosa, conversion of irinotecan to SN-38 predominates in the liver. Moreover, differential activity of carboxylesterase in malignant tissues may contribute to tumor sensitivity to this agent.¹⁰⁴ SN-38 undergoes glucuronidation in the liver mediated by UGT1A1 isoform of hepatic uridine diphosphate glucuronosyltransferase. UGT1A1 expression is highly variable, and its activity varies 17- to 52-fold among individuals. UGT1A1 activity is deficient in patients with Gilbert's syndrome, which can occur in up to 15% of the population. Biliary excretion of SN-

38 and irinotecan is the major route of elimination. Enterohepatic recirculation occurs as the glucuronidated SN-38 metabolite can be deconjugated by bacterial β -glucuronidases, thereby increasing exposure of the intestinal epithelium to SN-38. Ability to conjugate SN-38 and bilirubin, the endogenous substrate, is inversely related to myelosuppression, suggesting that agents that induce UGT activity, such as phenobarbital, may improve the therapeutic index of CPT-11. Certain polymorphisms of UGT1A1, such as in the promoter region with Gilbert's syndrome, have been correlated with decreased glucuronidating activity, resulting in increased risk for myelosuppression and diarrhea. Further elucidation of such polymorphisms and other pharmacogenetic variables will hopefully enable clinicians to better predict drug responses and toxicities. CPT-11 is approved for frontline therapy in metastatic colorectal carcinoma in combination with 5-FU and leucovorin.

DNA Topoisomerase II Inhibitors

The podophyllotoxins are extracts of the mayapple or mandrake plant, *Podophyllum peltatum*, long known in folk medicine. Two glycosidic derivatives, etoposide (VP-16) and teniposide (VM-26), are currently in clinical use. The main mechanism of cytotoxicity was initially ascribed to tubulin-binding properties, at sites distinct from vinca alkaloids that result in inhibition of microtubule assembly and consequent S-G₂ phase block and cell death. However, new evidence demonstrates that the antimicrotubular effects occur only at concentrations severalfold higher than were not reached with clinically relevant doses. Moreover, the epipodophyllotoxins produce both single- and double-strand DNA breaks that were distinct from the cellular changes seen with antimicrotubule agents.¹⁰⁵ Epipodophyllotoxins, and anthracyclines as well, bind to topoisomerase II, stabilize the enzyme-DNA complex (termed cleavable or cleavage complex), and inhibit the reannealing of the cleaved DNA, thus resulting in both single- and double-stranded DNA strands. Similar to topoisomerase I inhibitors, replication fork collision with this cleavable complex increases the degree of lethal DNA fragmentation that ultimately leads to apoptosis.

ETOPOSIDE

VP-16 is available in both intravenous and oral formulations. Mean oral bioavailability is 50%, and nonlinear at doses beyond 200 to 250 mg/m². It exhibits high plasma protein binding such that patients with low serum albumin seem to be at risk for associated toxicities. It is eliminated by both renal and hepatic mechanisms. Up to 40% of unchanged drug is cleared through the kidneys. Dose reduction is recommended in patients with impaired creatinine clearance. Administration of cisplatin before VP-16 reduces VP-16 clearance, likely secondary to the effects on cytochrome P-450. Sequence-dependent synergism and reduced myelosuppression are also observed when paclitaxel administration precedes VP-16. VP-16 phosphate is a water-soluble prodrug that is completely and rapidly converted to VP-16. Its chief advantage lies in the reduced incidence of hypersensitivity reactions and better safety and tolerability profile. Pharmacokinetic, toxicity, and antitumor activity of VP-16 apply to VP-16 phosphate. Single-agent randomized studies demon-

strate its marked schedule-dependent activity such that multiple daily divided-dose schedules result in higher rates of response and survival than continuous administration of the same total dose over 1 day. Antitumor activity seems to correlate with the duration of exposure above a threshold concentration; this is not seen in combination regimens.

TENIPOSIDE

VM-26 is more extensively metabolized by the liver, although its plasma clearance is slower than VP-16. It has an even higher degree of protein binding than VP-16 (99% versus 94%). Although CSF penetration is low, VM-26 is generally considered more clinically effective than VP-16 in the treatment of gliomas. Although it is only available for IV administration, this formulation may be administered orally, with a bioavailability of approximately 40%.

Noncumulative myelosuppression, chiefly neutropenia, is the principal dose-limiting toxicity of the epipodophyllotoxins. Nausea and vomiting are the main gastrointestinal toxicities, although usually mild to moderate in severity. Mucositis may be seen with high-dose VP-16 therapy. Other side effects seen with high-dose therapy are metabolic acidosis and reversible hepatotoxicity. Rapid infusion may result in transient hypotension. Hypersensitivity reactions, seen in less than 2% of patients receiving IV VM-26 and VP-16 but not oral VP-16, may result in part from the diluent used and occurs more frequently with rapid infusion. Incidence of secondary leukemias ranges from 0.37% to 4.7% and appears to be dose related. VP-16 is approved for use in small cell lung carcinoma and testicular carcinomas. VM-26 is used as part of the induction therapy of refractory childhood acute lymphoblastic leukemias.

Pharmacogenetics

One of the important factors affecting antitumor efficacy and clinical toxicity of cancer chemotherapeutic drugs and their complex interaction is an individual's genotype. It has been observed as early as the 1950s that responses to certain drugs may be heritable. The field of pharmacogenetics, which studies the genetic basis for interindividual variability in drug response, classically involved investigations on drug metabolism but currently also encompasses various pharmacokinetic and pharmacodynamic elements that participate in determining drug response. The ensuing discussion highlights selected pharmacogenetic variables well recognized in current clinical practice of cancer chemotherapy.

Thiopurine Methyltransferase

Thiopurine methyltransferase (TPMT) is a methylating enzyme whose gene is encoded on chromosome 6. It plays an important role in the catabolism of 6-MP and its prodrug azathioprine, thus preventing generation of thioguanine nucleotides. Early studies revealed that TPMT activity is inherited as an autosomal codominant trait.¹⁰⁶ About 1 in 300 individuals carry two mutant TPMT alleles, thus resulting in deficient activity. Approximately 10% of the population are heterozygotes with intermediate TPMT activity.¹⁰⁷ It has been shown that the various single-nucleotide polymor-

phisms do not result in altered levels of mRNA or TPMT protein. However, these mutations render the translated protein susceptible to degradation through the ubiquitin-proteasome system, decreasing the half-life to 30 minutes compared to 18 hours for the wild-type protein.¹⁰⁸ TPMT*3A, TPMT*3C, and TPMT*2 mutant alleles, which harbor point mutations resulting in amino acid substitutions, account for more than 95% of deficient TPMT activity among whites.

As there is no endogenous substrate for TPMT, individuals with defective enzyme activity are asymptomatic until exposure to thiopurine drugs results in severe myelosuppression that may be life threatening. On the other hand, individuals with high or high-normal TPMT are relatively resistant to the action of thiopurine drugs and thus may not achieve clinical remission if these drugs are used at standard dosages. An allele with increased TPMT activity has been described. TPMT activity can be influenced by various factors such as age and renal function. TPMT activity in red blood cells serves as a surrogate marker for TPMT activity in other tissues.

Dihydropyrimidine Dehydrogenase

Dihydropyrimidine dehydrogenase (DPD) catalyzes the initial rate-limiting step in the catabolism of endogenous pyrimidines and 5-FU. It is encoded on chromosome 1. DPD activity is inherited as an autosomal codominant trait. Approximately 0.1% of the population carry homozygous inactivating mutations whereas 3% are heterozygotes. DPD activity has a normal distribution in the population and there is manifold interindividual variability, although not obviously age- or gender-related. The most common mutant allele, DPYD*2A, results from a G to A transition that leads to deletion of exon 14 and thus ending with a truncated protein, which is subsequently degraded by the ubiquitin-proteasome system.

Individuals with deficient DPD activity experience profound systemic toxicity (myelosuppression, diarrhea, neurotoxicity) upon exposure to 5-FU, which may potentially result in fatalities. Assessment of DPD activity in human peripheral blood mononuclear cells correlates well with total body enzyme activity. On the other hand, high level of DPD mRNA expression in colorectal tumors confers resistance to 5-FU.¹⁰⁹

Uridine Diphosphate Glucuronosyltransferase

Uridine diphosphate glucuronosyltransferase (UGT) is an enzyme that catalyzes the phase II catabolic reaction in which uridine diphosphate glucuronic acid is conjugated with drugs or poorly soluble endogenous substrates. There are two gene families (UGT1 and UGT2), each of which has various isoforms. The most important of these isoforms is UGT1A1, which is encoded on chromosome 2q37. Polymorphisms of the gene encoding UGT1A1 give rise to the hyperbilirubinemia phenotype of the rare Crigler-Najjar syndrome and the relatively common Gilbert syndrome.

UGT1A1 plays an important role in the metabolism of the active metabolite of irinotecan, SN38 by changing it into the more polar SN 38 glucuronide, which is mainly excreted in the bile. Reduced UGT1A1 expression, often associated with elevated levels of unconjugated bilirubin, is inherited in an

autosomal-recessive pattern. Polymorphisms in the number of TA repeats in the promoter region, which is inversely related to UGT1A1 enzyme activity, constitute the most common abnormality. The wild-type promoter region has a (TA)₆TAA sequence whereas the most common mutation results in an extra TA, thus the sequence becoming (TA)₇TAA (UGT1A1*28). Patients with Gilbert syndrome are homozygous for this promoter variation, which leads to a 70% reduction in UGT1A1 expression. (TA)₇TAA homozygosity occurs in about 0.5% to 23% in various populations. Other mutations in the promoter region of UGT1A1 gene alter transcription and have been associated with deficient or increased UGT1A1 activity.

Patients with the UGT1A1*28 allele are susceptible to severe, at times life-threatening, toxicities of irinotecan, mainly leukopenia and diarrhea.

Principles of Radiation Oncology

Timothy J. Kinsella, Jason Sohn, and Barry Wessels

The medical specialty of radiation oncology has evolved significantly over the past 50 years, having begun as a subspecialty within diagnostic radiology in the 1930s and 1940s. Today, more than 50% of newly diagnosed cancer patients receive radiation therapy, typically as a part of curative combined modality treatment with surgery and/or chemotherapy. Additionally, a majority of patients who present with metastatic disease or who develop metastases following initial cancer treatment require palliative radiation therapy. As such, the radiation oncologist plays a major role in the management of most adult cancers and certain groups of pediatric and adolescent cancers. The intent of this chapter is to provide an overview of radiation biology, newer approaches to radiation treatment planning, the use of specialized applications of radiation therapy, and the mechanisms of drug–radiation interactions leading to radiosensitization, as well as the evolving area of *targeted* radiation therapy. It is hoped that this overview provides the necessary fundamental knowledge of radiation oncology for the reader (particularly nonradiation oncologists) to then better understand the rationale for the use of radiation therapy in specific cancers as detailed in other chapters throughout this textbook.

The Biologic Basis of Radiation Oncology

The Concept of Therapeutic Ratio

Shortly after the turn of the last century, radiation therapy began as a new modality for cancer treatment based on the discovery of X-rays by Roentgen and radium by the Curies. The pioneering use of X-rays and radium in the first two decades of the 20th century involved the use of large single doses of radiation therapy delivered in short treatment intervals, which, although resulting in a reduction of the tumor mass, was also associated with severe acute and late normal tissue toxicities. The concept of radiation dose fractionation (i.e., the use of smaller radiation doses given in multiple, typically daily, fractions) over several weeks evolved from an *in vivo* experiment in the 1920s using the testes of a rabbit as a model system for *tumor* proliferation.¹ These early French radiobiologists found that multiple radiation treatments compared to a large single dose of radiation resulted in sterility (the desired effect) without producing severe injury to the surrounding scrotum. The initial clinical use of radiation dose fractionation was then applied to patients with head and neck

cancers as early as the 1930s, with improved tumor responses and reduced acute and late normal tissue toxicities.^{2,3} Thus, the concept of a therapeutic ratio or index for radiation therapy was initially recognized more than 75 years ago.

The concept of the therapeutic ratio for radiation therapy, which compares the radiation dose–response curves for both tumor control rates and normal tissue(s) complication rates, is illustrated in three separate panels in Figure 3.1. The upper panel represents a theoretical optimal therapeutic ratio, where the tumor control curve lies always to the left of the normal tissue complication curve, whereas the middle panel shows an unacceptable therapeutic ratio in which the tumor control and normal tissue complication curves are reversed. Obviously, it would be easy to recommend the clinical use of radiation therapy for this idealized situation depicted in the upper panel. Conversely, in the middle panel, the radiation oncologist would need to carefully weight the type (acute, late) and grade (severity) of expected normal tissue(s) complications before recommending radiation therapy. Indeed, as illustrated in the section on radiation treatment planning (later in this chapter), the current use of three-dimensional conformal radiation treatment (3-D CRT), intensity-modulated radiation treatment (IMRT) planning, and image guided radiation therapy (IGRT) allows the radiation oncologist to quantitate the dose–volume histograms for each normal tissue included in the treatment volume so as to change an unacceptable therapeutic ratio (middle panel) to the bottom panel in Figure 3.1, which is the most realistic graph of tumor control and normal tissue injury as a function of radiation dose as found in many clinical settings. In actuality, for most common solid cancers the curves are not parallel, and the tumor control curve for most solid tumors is less steep than the normal tissue injury curves. Actual dose–response curves derived from *in vivo* experimental data or from clinical trials in humans are often more variable than the illustration in the bottom panel of Figure 3.1, particularly depending on the tumor type. Indeed, as is presented in other chapters on specific tumor types throughout this textbook, it is only by carefully designed and controlled clinical trials that the concept of a therapeutic ratio for radiation therapy can be quantitated for a specific tumor type.

Radiation Interactions with Biologic Materials

Ionizing radiation deposits energy as it traverses various types of biologic materials or media (e.g., air, soft tissue, bone) within a human. The interaction of ionizing radiation with

these biologics is a random process, with the frequency and density of energy deposition termed the linear energy transfer (LET). As human cells and tissues (as well as tumors) are principally considered to be dilute aqueous (water) solutions containing biomolecules, the localized but randomly distributed energy depositions from ionizing radiation can have either direct effects on important biomolecules such as DNA

or indirect effects produced by intermediate radiation products resulting from interactions with water, which constitutes up to 90% of a cell or tissue as calculated on a weight basis. The most highly reactive species produced by the radiolysis of water is the hydroxyl radical ($\bullet\text{OH}$), although there are many other types of free radicals produced by ionizing radiation, including DNA free radicals resulting from direct ionizations. These free radicals are generated within 10^{-2} to 10^{-12} seconds and subsequently cause chemical damage to DNA. It has been determined that ionizing radiation-induced cell killing in mammalian cells (including human tumor cells) results from a greater contribution ($\approx 70\%$) of initial indirect ionizing effects on water than direct effects on essential biomolecules, principally DNA. These ionizing radiation-produced free radicals are highly reactive chemically within the cell and undergo a cascade of reactions to either acquire new electrons or to rid themselves of unpaired electrons, typically resulting in breakage of chemical bonds in DNA in very localized areas, called clusters, or multiply damaged sites. Because DNA is considered to be the most essential cellular biomolecule, the types of DNA damage caused by this sequence of initial energy deposition, production of free radicals and subsequent *clustered* breakage of chemical bonds can include DNA single-strand breaks (SSB), DNA double-strand breaks (DSB), DNA crosslinks, and DNA base damage. The creation of a DSB and, more specifically, an unrepaired DSB is considered the most cytotoxic DNA lesion resulting from ionizing radiation damage.^{4,5} The molecular and biochemical processes involved in ionizing radiation damage and repair in human normal and malignant tissues are reviewed in the next section.

At the cellular level, the biologic effects of these initial physical interactions of ionizing radiation with biologic materials and the secondary chemical effects (i.e., DNA effects) can result in a cell's loss of reproductive capability. Functionally, the consequence of this reproductive loss can result in terminal differentiation, accelerated senescence, necrosis, or apoptosis.^{6,7} A cell that has been lethally damaged by ionizing radiation may undergo a few cell divisions before death, and this lethally damaged cell's progeny are also destined to die. In the radiation biology laboratory, the radiation sensitivity of a cell (both normal and malignant) can be quantitated by analysis of cell survival curves. A radiation survival curve plots the fraction of cells surviving on a log scale against the radiation dose given (in cGy or Gy) on a linear scale (Figure 3.2). Survival is determined by the ability of a cell to form a macroscopic colony, usually defined as more than 50 cells ($\approx 5-6$ cell divisions). A typical radiation survival curve for a mammalian cell population has an initial "shoulder" in the low-dose region (up to 1-3 Gy), followed by a terminal exponential slope. The importance of this exponential relation is that, for a given radiation dose increment, a constant proportion (not a constant number) of cells are killed by ionizing radiation.^{6,7} The *shoulder* region indicates a reduced efficiency of cell killing or, conversely, a higher efficiency of repair of sublethal or potentially lethal ionizing radiation damage. The resulting survival curve for mammalian cells based on a standard clonogenic survival assay is best described by a linear quadratic (LQ) model, according to the following formula:

$$S = e^{-(\alpha D + \beta D^2)}$$

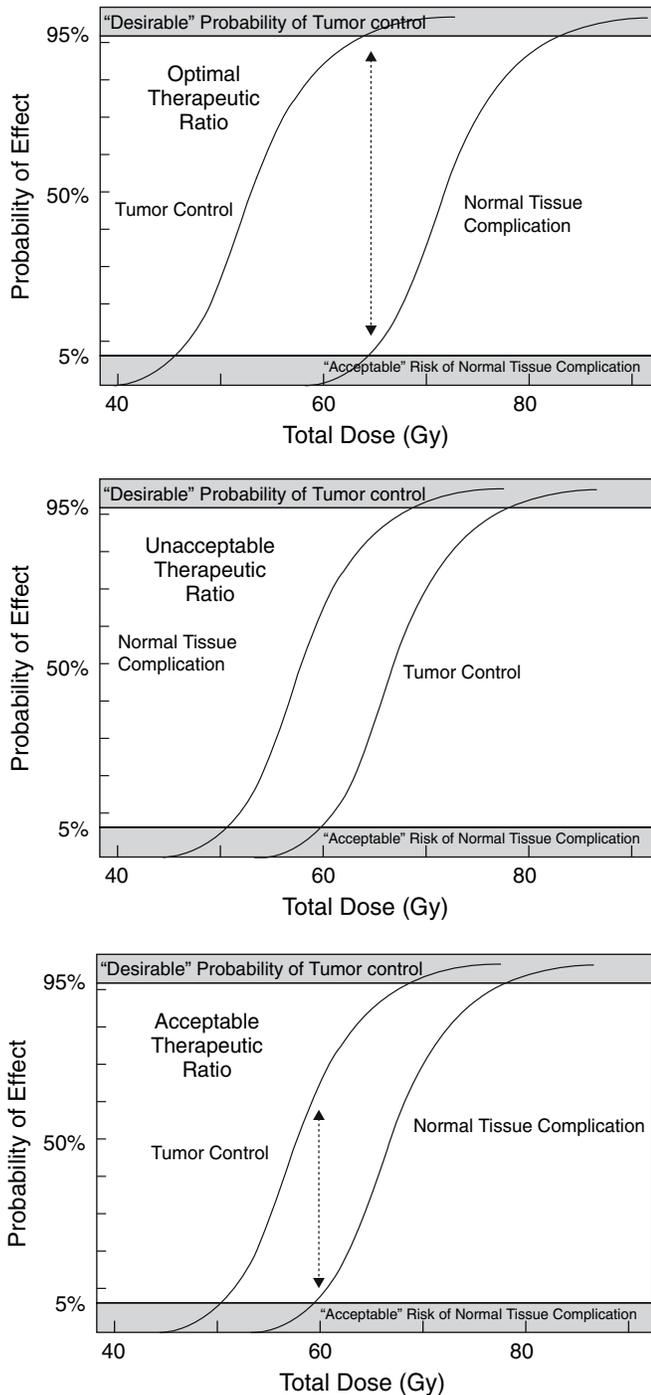

FIGURE 3.1. The concept of therapeutic ratio for radiation therapy under conditions in which the relationship between the normal tissue tolerance and tumor control dose-response curves is optimal (*upper panel*), unacceptable (*middle panel*), and acceptable (*lower panel*).

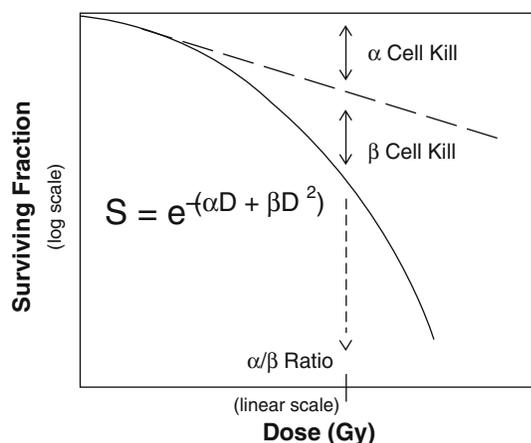

FIGURE 3.2. Log-linear illustration of in vitro radiation survival of a typical human cancer cell line showing an initial shoulder (a cell kill) at lower doses (usually 1–2 Gy) followed by a terminal slope (B-cell kill) at higher doses (≥ 3 Gy).

where S = surviving fraction, α = initial “repairable” radiation damage, β = irreparable radiation damage, and D = ionizing radiation dose measured in grays (Gy).

Interestingly, this two-parameter (α , β) exponential model is reproduced when multiple fractions of ionizing radiation are given to either a normal or malignant cell population if the time interval between radiation doses (fractions) is sufficient to allow for initial radiation damage repair (usually 1–3 hours). However, the differential effects of ionizing radiation on cell kill in a malignant versus a normal cell population are not completely explained by this LQ model or any other mathematical model, as discussed later.

The discussion on radiation interactions at the cellular level so far has concerned sparsely ionizing radiation (low LET), such as produced by photons or high-energy electrons that are generated by linear accelerators used clinically for most cancers treated today. High linear energy transfer (high-LET) radiation can also be used clinically and involves the use of charged particles such as alpha particles and pi mesons. Additionally, intermediate-LET sources such as neutrons and protons are also used clinically, with a recent resurgence of interest in proton radiation therapy in the United States and Japan.^{8,9} Because of these different LET radiation sources, the parameter of relative biologic effectiveness (RBE) is used in experimental radiation biology and clinical radiation therapy. The RBE is the dose ratio of different LET sources to produce the same biologic effect. Typically, with high- or intermediate-LET radiation, the radiation survival curve has a reduced or absent “shoulder” and a steeper exponential slope. The general explanation of the change in radiation survival (α , β parameters) with use of intermediate- to high- and intermediate-LET radiations compared to low-LET radiation is that the ionizing energy deposition is so dense with high- and intermediate-LET radiations that the DNA damage cannot be repaired as efficiently. There may also be less effect from the oxygenation state of a cell or tissue with high LET. However, as discussed later, the advantage of intermediate- and high-LET radiations in the radiation survival curve may not be easily translated to the clinic, as one must carefully weight the RBE of the tumor and the RBE of normal tissues. Thus, the therapeutic gain for a specific tumor and specific dose-

limiting normal tissues may not be improved with high- or intermediate-LET radiation compared to low-LET radiation. Clinically, this is clearly the case for neutron beam irradiation, based on the past 20 years of human testing. As such, the recent renewed interest in proton beam irradiation should be tempered until prospective clinical data are available for specific patient groups in which proton beam treatments are compared to the standard of use of photons from conventional linear accelerators.⁹

Molecular and Cellular Radiation Biology

Repair of Ionizing Radiation Damage: Cellular and Molecular Mechanisms

As mentioned, ionizing radiation can cause a variety of lesions through direct interactions with DNA or, more commonly, through damage induced in adjacent water molecules within a cell or adjacent cells. These damages to DNA include damage to the deoxyribose backbone, base damage, single-strand breaks (SSBs), and double-strand breaks (DSBs).⁴ Because exposure to ionizing radiation was inevitable during evolution, human cells have developed multiple repair pathways to handle the diverse types of DNA damage created by ionizing radiation.⁵ Understanding these complex and sometimes redundant repair pathways in human cells has been a major focus in radiation biology during the past 10 to 15 years that will continue in the future.¹⁰ These studies on radiation repair pathways also have many links to ionizing radiation effects on the cell cycle, which is discussed later in this chapter.

REPAIR OF BASE DAMAGE AND DNA SINGLE-STRAND BREAKS

Repair of ionizing radiation-induced base damage involves a sequence of biochemical processes termed base excision repair (BER). DNA single-strand breaks (SSBs) are one of the most common lesions occurring in human cells, either spontaneously or as intermediates of enzymatic repair of base damage during BER. In BER, a single damaged base or locally multiply damaged bases are recognized and removed by specific glycosylases, resulting in apurinic or apyrimidinic (AP) sites that require cleavage by an AP endonuclease, followed by resynthesis using the complementary strand as a template, and finally by ligation of the repaired strand.^{11,12} Ionizing radiation-induced DNA SSB repair is completed in steps similar to BER, in which a normal DNA strand serves as a template for repair. When DNA SSBs caused directly by ionizing radiation or arising as BER intermediates are not promptly and efficiently processed, the presence of clusters of damaged sites and of stalled replication forks can then result in DSBs.⁴

The availability of cellular models characterized by deficiencies in specific DNA repair proteins have proved to be good models to clarify the molecular mechanisms underlying BER and SSB repair.¹⁰ For example, it has been shown that transfection of the human gene XRCC1 (X-ray repair cross-complementing gene 1) can correct mouse cells that have a deficiency in rejoining DNA SSB induced by ionizing radiation and alkylating agents. The XRCC1 protein acts as a scaffolding protein, which binds tightly to at least three other factors involved in BER and DNA SSB repair mechanisms

including DNA ligase III, DNA polymerase β , and poly (ADP-ribose) polymerase (PARP).¹² The importance of XRCC1 in the response of a human cell population to DNA damage has been the subject recently of several studies evaluating whether polymorphism of the human XRCC1 gene contributes significantly to an increased cancer risk in selected populations.¹² Indeed, a genetic change in a single amino acid at codon 399 has been linked to an increased risk of several types of gastrointestinal cancers (gastric, pancreatic, colorectal) as well as breast cancer. Additionally, functional analysis of these polymorphisms suggest that these variants of XRCC1 may contribute to a hypersensitivity to ionizing radiation.¹²

REPAIR OF DNA DOUBLE-STRAND BREAKS

It is well recognized that the most important lesion caused by ionizing radiation is a DSB.^{4,5} Unrepaired or misrepaired DSBs can produce chromosomal deletions, translocations, and acentric/dicentric chromosomes, which result in cell lethality or genetic instability. Unlike repair of DNA SSB where the complementary normal DNA strand serves as a template, DSB repair is a more complicated process and can involve homologous recombination (HR) or nonhomologous end joining (NHEJ). Typically, ionizing radiation induces DNA DSBs where one or both DNA ends have a protruding DNA single-strand overhang. It is known from genetic and biochemical studies in radiosensitive yeast mutants that only one unrepaired (or misrepaired) DSB can result in cellular lethality.^{5,10} The induction of DSBs by ionizing radiation shows a linear function with dose whereas the kinetics of unrepaired (unrejoined) DSBs has a linear quadratic (α , β) relationship with dose.¹³ With low radiation doses, the quadratic component is insignificant. Thus, the survival curve for a DSB repair-proficient cell would have an initial "shoulder" (α component) at low radiation doses followed by a terminal exponential slope (β component), as previously illustrated in Figure 3.2. In contrast, the "shoulder" region is normally not observed in DSB repair-deficient cells, such as normal skin fibroblasts or normal lymphocytes from patients affected with the autosomal recessive disease ataxia telangiectasia (AT). DSB repair (including both HR and NHEJ) is presumably the fundamental process that mechanistically explains the previously described cellular responses to ionizing radiation damage termed sublethal damage repair (SLDR) and potentially lethal damage repair (PLDR).⁴ However, in spite of numerous attempts to define DSB repair and survival following ionizing radiation in mathematical terms (such as the LQ model), other contributing factors such as cell-cycle checkpoints, hypoxia, genetic background diversity (polymorphism), induction of apoptosis, and bystander effects (e.g., autocrine or paracrine pathways) may significantly influence the survival response of a cell or tissue (including normal and malignant). These complex genetic and biochemical interactions are not easily simulated by mathematical modeling.

Homologous recombination (HR) is one of two major repair pathways in humans for repair of ionizing radiation-induced DSB. There are three general mechanisms for HR-mediated DSB repair.^{5,14,15} Two of the HR mechanisms, termed gene conversion and break-induced homology, require homology with a separate DNA molecule (Figure 3.3). The other HR mechanism, single-strand annealing, requires only local homology on one end of the DSB (Figure 3.4). All three

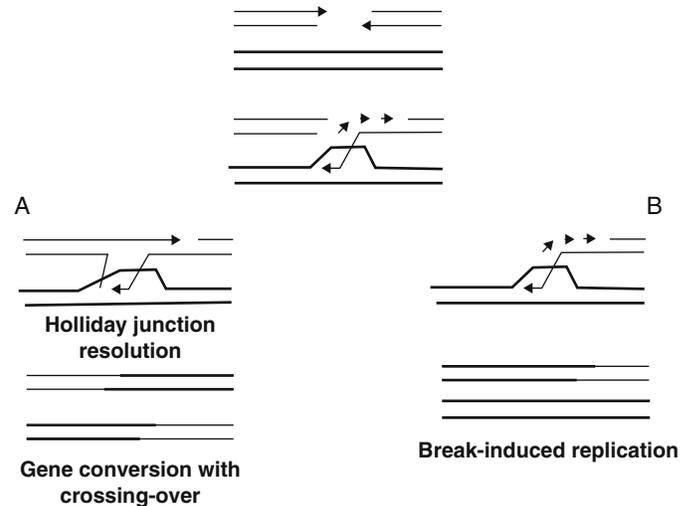

FIGURE 3.3. Various pathways of homologous recombination (HR). After 3'-Protruding DNA Single Strand (3'-PSS) are created (*arrowheads*), they invade a homologous region on another DNA molecule. Replication fork capture (A) results in the formation of a Holliday junction, with its subsequent resolution either with crossing-over (shown) or in the absence of cross-over events. When no replication fork capture occurs (B), the recombination follows the break-induced replication pathway.

HR mechanisms require a 3'-DNA single-strand overhang (3'-PSS). During gene conversion and break-induced replication, 3'-PSSs are created on both ends of a DSB. One then anneals to a homologous region on a sister chromatid, a homologous chromosome, or elsewhere to other chromosomes. New DNA synthesis is next initiated at the 3'-ends and proceeds to the 3'-PSS on the other end of the DSB. At this point, HR can proceed in two different directions, including (a) a Holliday junction (gene conversion), which results from the 3'-PSS annealing to the newly synthesized strand (Figure 3.3A), or (b) the replication fork proceeds until the end of the chromosome without encountering the other end of the DSB (break-induced replication; Figure 3.3B). The third HR mechanism, single-strand annealing, can be synthesis-dependent or

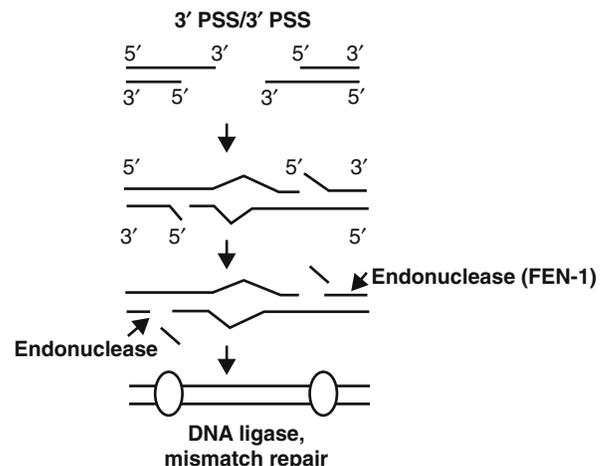

FIGURE 3.4. Single-strand annealing repairs double-strand breaks (DSBs) that contain both ends having 3'-PSS. Flap endonuclease (FEN-1) removes the mispaired DNA strand.

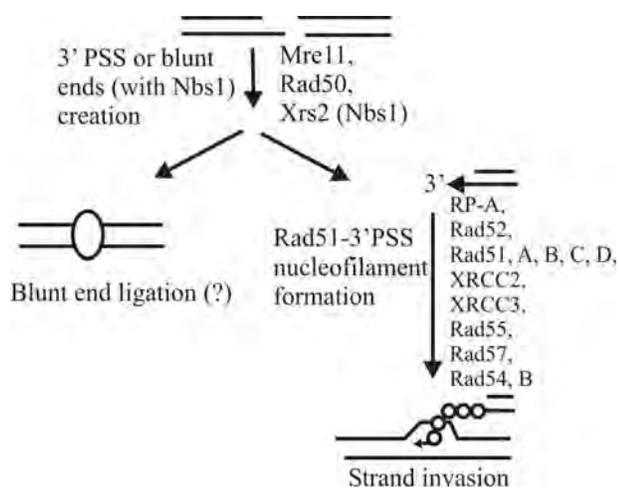

FIGURE 3.5. Proteins involved in the homologous recombination (HR) pathways of DSB repair: homology search and strand invasion. Taken from combined data obtained on yeast and vertebrate models.

-independent (Figure 3.4). Both types of single-strand annealing utilize local homology on the 3'-PSSs of both ends of the DSB. Annealing of the two 3'-PSSs results in a flap of one strand with synthesis-independent annealing or in a gap with synthesis-dependent annealing. The flap is subsequently removed by a 3'→5' exonuclease or a flap endonuclease while a gap is filled by a DNA polymerase.

All three HR mechanisms require the gene products (proteins) of the RAD52 epistasis group (RAD50, 51, 52, 54, 57, 58, and 59) as well as participation of the gene products.¹⁵ The Mre11 protein is thought to be a primary sensor of ionizing radiation induced DSB with subsequent recruitment of Rad50 and Xrs2 proteins in yeast and the Nijmegen breakage syndrome (Nbs1) protein in humans (Figure 3.5). The resulting complex of Mre11, Rad50, and Nbs1 is believed to generate 3'-PSS DNA lesions where several homologues of the yeast RAD51 gene (Figure 3.5) next interact with each other in a complex process to facilitate DNA strand migration, invasion, and finally repair.

In contrast, nonhomologous end joining (NHEJ) recombinational repair does not require extended homology between the ends of a DSB. DSB rejoining can proceed with a limited number of base pairings at the site of the break. In humans, the complex of repair proteins for NHEJ involves Ku70, Ku80, DNA-dependent protein kinase catalytic subunit (DNA PKcs), DNA ligase IV, and X-ray cross-complementation (XRCC) 4. According to a current model (Figure 3.6), the Ku70–Ku80 dimer initially binds to the ends of a DSB, and this dimer acts as a helicase to result in local unwinding at the DSB end.¹⁵ DNA PKcs is then recruited near the sites of each end of the DSB followed by the XRCC4/DNA ligase IV complex to repair DSBs created by restriction enzymes. NHEJ can be divided into several pathways, depending on the type of DNA lesion detected. Rejoining of DNA DSB containing four base pair complementary ends created by restriction endonucleases is very efficient and precise. However, when the DSB ends are not complementary, repair is less efficient and may result in small insertions or deletions in the repair of noncomplementary (*difficult*) DSBs.

It is not clearly understood how human cells choose the pathway for DSB repair.¹⁰ Two models have been proposed to

explain how a cell might regulate whether HR or NHEJ pathways are used following ionizing radiation-induced DSBs. According to the first model, NHEJ is the major pathway active during the G₁ and early S phases of the cell cycle.¹⁶ As sister chromatids occur during late S and G₂ phases, HR is the major DSB repair pathway at these cell-cycle phases.⁵ The second model involves a direct competition for DNA DSB ends between the sensors of NHEJ and HR (see Figures 3.5, 3.6). Evidence for the first model is derived from murine *scid* cells, which lack NHEJ but can repair DSBs during the G₂ phase via HR pathways.¹⁷ Evidence for the second model is found in human cells where the human Rad52 protein and the Ku70–Ku80 protein complex have been shown to compete to protect DNA DSB ends against exonuclease activity.¹⁸ Additionally, the p53 tumor suppressor gene also appears to play a role in a human cell decision between NHEJ and HR following ionizing radiation damage.¹⁰ It has been shown that human cells lacking functional p53 (either by null mutations or by mutant p53 expression) display up to 20-fold-higher rates of HR following ionizing radiation damage than cells expressing wild-type p53. Because p53 regulates the transcription and posttranslational activity of RAD51, it may be that the Rad51 protein plays a pivotal role in channeling DSB repair via the NHEJ pathway. Thus, these data suggest that the choice between NHEJ and HR is a function of cell-cycle phase, homologue availability, and the genetic background of a cell (e.g., p53 status).

The consequences of incomplete or faulty DNA repair of ionizing radiation damage may result in carcinogenesis in human normal cells or in the development of ionizing radiation resistance in human tumor cells. A number of genes whose products are involved in DSB repair have been found mutated in many different human cancers. For example, loss of heterozygosity (LOH) of RAD51, RAD52, and RAD54 have been found in human breast carcinomas. Additionally, nearly two-thirds of human pancreas cancers have overexpression of

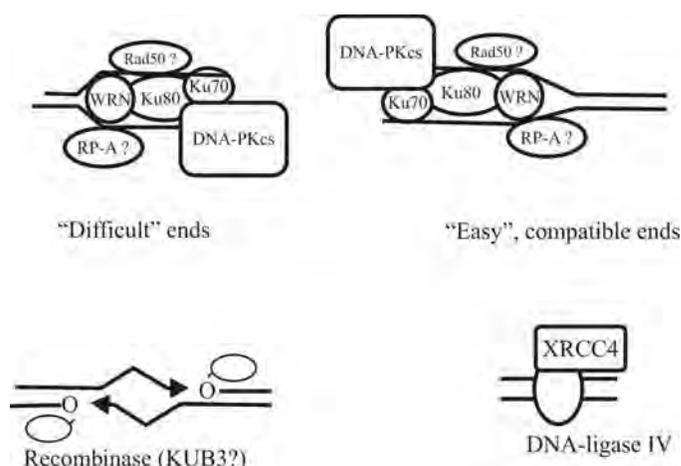

FIGURE 3.6. A model for nonhomologous end joining (NHEJ) involving DNA-PK. The Ku80/Ku70 complex senses and binds to DSB ends and recruits DNA-PKcs. Ku-associated helicase activity (WRN in the presence of RP-A?) is activated, and the Ku-complex migrates into the double helix with the Ku80 protein heading first in the 5'-direction of the broken end of DNA. It is speculated that, depending on the type of the DSB, either the XRCC4/DNA ligase IV complex or other proteins (i.e., nucleases and recombinases) are recruited to aid in the rejoining of the four broken ends of DNA.

the Rad51 protein, which could lead to cellular resistance to ionizing radiation damage and the development of tumor heterogeneity.

There is an ongoing search for new proteins responsible for ionizing radiation-induced DNA damage detection and repair.^{10,15} During the past decade, several important DNA repair genes were discovered, mutations of which led to defects in DNA repair and extreme sensitivity to ionizing radiation. The X-ray cross-complementing (XRCC) genes were identified in humans and subsequently nine genetic complementation groups were recognized. As mentioned previously, the product of the XRCC1 gene was found to be important for DNA SSB repair. XRCC2 and XRCC3 gene products are part of the RAD51 family and are essential for the HR pathway in DNA DSB repair. XRCC4 to XRCC7 genes initially appeared to be involved in the NHEJ pathway for DNA DSB repair and were later sequenced to reveal that XRCC4 was DNA ligase IV, XRCC5 was Ku80, XRCC6 was Ku70, and XRCC7 was found to be DNA PKcs. Mutants within the XRCC8 complementation group show phenotypic similarities with ataxia telangiectasia (AT) and the Nijmegen breakage syndrome (NBS) with extreme sensitivity to ionizing radiation and to topoisomerase 1 inhibitors. Finally, the XRCC9 gene (also called Fanconi anemia G group) shows marked sensitivity to ionizing radiation and DNA crosslinking agents as well as spontaneous chromosome instability.

During the past few years, the RAD24 gene group members were identified to also include RAD9, RAD17, MEC3, and DDC1 genes. The products of this RAD24 epistaxis group appear to have regulatory roles that connect ionizing radiation-induced DNA repair and cell-cycle progression. It is also recognized that products of the tumor suppressor genes such as BRCA1, ATM, and p53 interact with RAD50 and RAD51 gene products to complete the complex process of DNA DSB damage recognition and repair.

Clearly, the field of DNA DSB repair is complex and is an area of intense research for the discipline of radiation oncology.^{5,10,15} Although our knowledge of these complex interactions leading to DNA DSB repair is probably still quite rudimentary, translational radiation biologists/oncologists are beginning to explore how some of these genes or protein products might be therapeutic targets for modifying the ionizing radiation response in resistant human cancers. These translational approaches to novel "targeted" therapy in radiation oncology are discussed later in this chapter. The effects on ionizing radiation damage and repair on cell-cycle checkpoints are described in the next subsection.

Ionizing Radiation Effects on the Cell Cycle

It has been known for several decades that ionizing radiation leads to a prolongation of the cell cycle and can result in an arrest in the G₁, G₂, and S phases.^{7,19,20} Because ionizing radiation causes a variety of DNA damage, it was initially inferred that these cell-cycle arrests (now called *checkpoints*) were essential for the repair of these different types of DNA damage. However, over the past 10 to 15 years, the biology of the cell cycle has become better understood as a complex but finely regulated process involving many factors, particularly the cyclins and cyclin-dependent kinases (CDKs).¹⁹ Progression through the cell cycle is promoted by a number of CDKs that are complexed with specific regulatory proteins called

cyclins, and these complexes drive the cell cycle. Additionally, there are a corresponding number of cell-cycle inhibitory proteins (CDKIs), which serve as negative regulators of the cell cycle. To date, at least nine structurally related CDKs have been identified along with more than 20 cyclins. The CDK–cyclin complexes themselves are activated by phosphorylation at specific sites, although not all these CDK–cyclin complexes have clearly defined cell-cycle regulatory roles. It is also now recognized that the G₀ phase is not a "quiescent" phase as initially termed. Indeed, cellular growth functions occur during G₀, and subsequent entry from G₀ into the cell cycle (G₁) is tightly regulated at the restriction point. This point is thought to divide the early and late G₁ phase of the cell cycle. A current model of the human cell cycle and the major cyclins, CDKs, and CDKIs is depicted in Figure 3.7.

The arrest of cells at the G₁ checkpoint following ionizing radiation damage is best understood at the present time. The retinoblastoma tumor suppressor gene product (Rb) governs the G₁–S phase transition.²¹ In its active state, Rb is hypophosphorylated and forms an inhibitory complex with the E2F transcription factors. The activity of Rb is modulated by the sequential phosphorylation by CDK 4/6–cyclin D and CDK2–cyclin E. An ionizing radiation-induced G₁ arrest results from a specific CDKI, p21^{waf1/cip1}, which prevents key events such as the phosphorylation of Rb and activation of E2F transcription factors. Importantly, p21^{waf1} is induced at the transcriptional level by wild-type p53, which accumulates in irradiated cells and causes a cell-cycle arrest in both G₁ and G₂.^{22,23} While the p53-mediated G₁ arrest is primarily due to the induction of p21, a p53-mediated G₂ arrest involves induction of both p21 and 14-3-3 σ , a protein that normally sequesters cyclin B–Cdc2 complexes in the nucleus.

Following recovery of a G₁ checkpoint, cyclin E binds to CDK2, and this active complex completely hyperphosphorylates Rb (pRb), which releases the E2F complex and fully activates the E2F transcription factors.²⁴ The irradiated cell then proceeds into S-phase transcription of a range of targets involved in chemotherapy-based radiosensitization. These drug–radiation targets include ribonucleotide reductase (RR), thymidylate synthase (TS), and thymidine kinase (TK). The interactions of radiosensitizing drugs such as RR inhibitors (gemcitabine, hydroxyurea) and TS inhibitors (flurorpyrimidines), as well as drugs activated by TK (flurorpyrimidines, halogenated pyrimidine analogues), are used clinically to enhance radiation cytotoxicity. These drug–radiation combinations are discussed later in this chapter (see following section on Mechanisms of Interaction with Conventional Chemotherapy).

Early in S phase, cyclins D and E are targeted by ubiquitination for proteasome degradation. The production of cyclin A and the subsequent complex of cyclin A–CDK2 enables S-phase progression, with the production of other enzymes and proteins involved in DNA synthesis, including histones and proliferating cell nuclear antigen (PCNA). Ionizing radiation can also induce an S-phase (or replication) checkpoint, which involves activation of ataxia telangiectasia mutated (ATM) and ATM and Rad-3 related (ATR) kinases with subsequent activation of Chk1 and Chk2.²⁵ The phosphorylation (activation) of Chk1 and Chk2 inhibits phosphorylation of Cdc2 and blocks progression into G₂ and entry into mitosis (M phase).

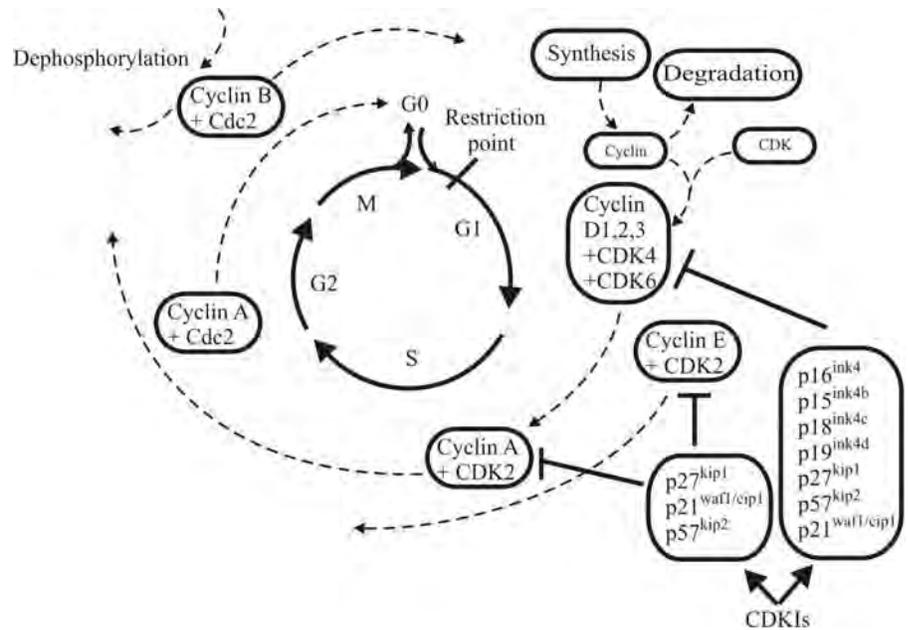

FIGURE 3.7. Current model of the cell cycle. The cell cycle is regulated by cyclins, cyclin-dependent kinases (CDKs), and cyclin-dependent kinase inhibitors (CDKIs). The cell cycle is divided into four distinct phases: G_1 , S, G_2 , and M. G_0 represents exit from the cell cycle in which the cell performs its routine functions, including the important function of cell growth. The progression of cell through the cell cycle is driven by CDKs, which are positively and negatively regulated by cyclins and CDKIs, respectively. The restriction point governs the transition point beyond which a cell's progression through the cell cycle is independent of external stimuli.

A clear understanding of the role of the G_2 checkpoints to ionizing radiation damage and repair is lacking at the present time.²⁶ From genetic studies in yeast using *Saccharomyces cerevisiae*, the RAD9, RAD17, RAD24, and MEC3 genes are required for a G_2 arrest. In human cells, the DNA mismatch repair proteins MLH1 and MSH2 also appear to play a role in the G_2 arrest following ionizing radiation damage.²⁷ Based on the dramatic increase in our understanding of ionizing radiation effects on G_1 and S-phase checkpoints over the past few years, it is anticipated that the signaling pathways for recognition of ionizing radiation damage during G_2 and M will be better understood in the near future.¹⁹

Ionizing Radiation-Induced Apoptosis

It is well established that a principal mechanism of cell death following ionizing radiation damage involves necrosis.^{6,7} More recently, radiation research has also focused on apoptosis as an alternative cell death mechanism following ionizing radiation.^{6,7} Apoptosis is an active, energy-dependent process in which the cell participates in its own destruction (i.e., programmed cell death).²⁸ Apoptosis is characterized morphologically by cell shrinkage, cell membrane blebbing, chromatin condensation, and finally by fragmentation into apoptotic bodies. The molecular sequence or cascade of apoptosis involves the early release of cytochrome C from mitochondria, activation of an apoptotic protease-activating factor (Apaf-1), activation of caspase 9, and subsequent cleavage of downstream (effector) caspases in a self-amplifying cascade. The apoptotic cascade degrades several essential cellular proteins including β -actin, laminin, and polyadenosine 5'-diphosphate-ribosyl polymerase (PARP).²⁹ This cascade is regulated by members of the Bcl-2 family of proteins, which are either antiapoptotic (Bcl-2, Bcl-xL, Bcl-W) or proapoptotic (BAD, Bax, Bak).^{28,29} Bcl-2 or Bcl-xL proteins bind and inhibit Apaf-1, which prevents the activation of caspases. However, in the presence of excess Bax, Bcl-2 may be displaced from Apaf-1, allowing caspase cleavage and activation.

The effects of ionizing radiation on apoptosis and cell-cycle arrests are interrelated, as evidenced by the central role of p53.³⁰ In addition to the effects of ionizing radiation-induced p53 protein expression on both the G_1 arrest and G_2 arrest as detailed in the prior section, p53 is also critical in the induction of apoptosis. For example, human tumor cells with certain mutations in the p53 gene are resistant to undergoing apoptosis following ionizing radiation. Another example of this interrelationship of cell-cycle arrest and apoptosis following ionizing radiation damage is demonstrated in isogenic human colon cancer cell lines that differ only in their p21 protein status. Wild-type p21 cells undergo a G_1 and G_2 cell-cycle arrest with enhanced clonogenic survival following ionizing radiation, whereas cells lacking the p21 protein do not undergo these cell-cycle arrests and proceed to apoptosis.

Ionizing Radiation Interaction with Oxygen

It has long been recognized that cellular and tissue oxygenation is a major determinant of radiosensitivity.^{31,32} For several decades, oxygen was considered to be a radiation dose modifier as in vitro/in vivo radiobiology data suggested that the oxygen enhancement ratio (OER) is 2.5–3.0 for low-LET radiation (X-rays, photons) and 1.5–2.0 for intermediate-LET radiation (protons). More recently, experimental and limited clinical data suggest that the OER for both low- and intermediate-LET radiation are lower at lower doses typically used daily in treating human cancers. Although the underlying mechanism of the oxygen-modifying effect is not exactly known, the leading model suggests that cellular oxygen acts as a radiosensitizer by forming radicals such as peroxides in DNA, resulting in a fixation or persistence of ionizing radiation (IR) damage.

It is now known that two different forms of hypoxia exist in human cancers. Chronic hypoxia results from a tumor outgrowth of its blood supply, and variable levels or gradients of chronically low oxygen tension exist beyond the physiologic diffusion distance of oxygen through the interstitial (extra-vascular) tissue compartment.³³ It is hypothesized that these

chronic hypoxic tumor areas (volumes) contain clonogenic and radioresistant hypoxic tumor cells. It is also recognized that reoxygenation of these chronically hypoxic tumor cells can occur, at least experimentally.^{33,34} A second type of tumor hypoxia also exists and is termed acute or perfusion-limited hypoxia. Acute tumor hypoxia results from transient alterations in tumor vasculature.³⁴

Over the past decade, several clinical studies have demonstrated that hypoxic tissue (defined as areas of oxygen tension less than 2.5 mmHg) exist in up to 50% to 60% of a wide range of locally advanced solid tumors including primary brain tumors, soft tissue sarcomas, and melanoma as well as carcinomas of the breast, head and neck, pancreas, and cervix.³⁵ Although trials of several hypoxic radiosensitizers have been negative, it is now realized that proper patient (tumor) selection was not performed in the design of these trials.³⁶ Current trials such as the accelerated radiotherapy, carbogen, and nicotinamide (ARCON) trials in Europe, particularly in head and neck cancer and bladder cancers, are selecting patients with biochemically confirmed hypoxic tumors for testing this approach.³⁷

Hypoxia also causes altered gene expression in human tumors with associated changes in tumor microenvironment. The best characterized transcription factor is hypoxia-inducible factor 1 (HIF-1).³⁸ The changes in gene expression in hypoxic tumors are similar to changes in normal cells to adapt to a hypoxic stress such as trauma and subsequent wound healing. However, these hypoxia-regulated genes, when upregulated in human tumors, lead to resistance not only to radiation therapy but also to different types of

chemotherapy.³⁹ The clinical targeting of HIF-1 α to selectively kill or inhibit hypoxic tumor cells is now in early trials using drugs such as radamycin.³⁹ The advantage of targeting HIF-1 is the observed rapid response to changes in oxygenation, making it a good target for both acute and chronic hypoxic tumor cells. Such new targeted approaches in radiation oncology are discussed later in this chapter.

Radiation Treatment Planning

Three-Dimensional Conformal Radiation Therapy

Since computers were used for single plane treatment planning in the 1970s to 1980s, treatment planning systems have become further developed along with advances in computer hardware. These dramatic increases in computing power have allowed multiplane treatment planning to become practical. Once the planning systems became capable of handling large amounts of computed tomography (CT)-derived patient data, calculation algorithms were developed to account for the full scattering component of radiation transport in various human tissues.

The development of accurate three-dimensional dose calculations and 3-D rendering of patient anatomy provided the tool to sculpt a tumoricidal dose distribution conformed to a tumor (target) volume and to minimize dose to all other normal tissue (Figure 3.8). From these considerations, the term 3-D conformal radiation therapy (3-D CRT) gained rapid

FIGURE 3.8. A tumor in the pancreas was treated with three-dimensional (3-D) conformal radiation therapy (CRT). Organs spared were kidneys, liver, spinal cord, and small bowel. Five noncoplanar beams were used for treatment. Each beam was conformed to the target volume with multileaf collimator as shown above to maximize the conformity. Three-dimensional rendering can assist the planner to optimize the beam angle.

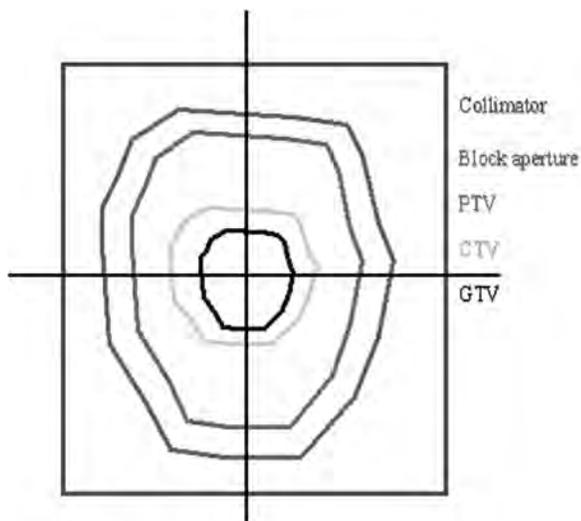

FIGURE 3.9. International Commission on Radiation Units and Measurements (ICRU) reports 50 and 62 introduced the volume definitions for radiation therapy treatment planning (see References 41, 42). Outer ring, block aperture; second from outer ring, planning target volume; third ring, clinical target volume; inside ring, gross target volume.

utility and acceptance⁴⁰ Once dose could be highly conformed to the target volume, the margin of the target had to be more accurately determined; this has been accomplished by using multimodality imaging and carefully defining treatment and normal treatment volumes. The International Commission on Radiation Units and Measurements (ICRU) Reports 50 and 62 introduced the definition of volumes (Figure 3.9).^{41,42} The gross target volume (GTV) is defined as the clinically palpable volume or, more typically, as visualized by imaging. It may consist of the primary tumor, metastatic lymphadenopathy, and local tumor extension. The clinical target volume (CTV) includes the tissue surrounding the GTV that might have microscopic malignant disease or “at-risk” regional lymph nodes. More than one CTV can be defined. The planning target volume (PTV) includes GTV and/or CTV plus a margin to account for variations in treatment delivery, including variations in treatment setup, patient motion during treatment, and organ motion. These ICRU reports also reviewed the definition of normal organs to be spared. Organs at risk (OAR) are defined as critical normal tissues, such as the spinal cord, whose radiation sensitivity may significantly influence treatment planning and/or the prescribed dose. After planning has been performed, a dose–volume histogram (DVH) can be generated from the plan (Figure 3.10). The DVH provides the information: dose versus volume of a specified organ. This information is very useful for radiobiologic studies. However, it does not provide spatial dose informa-

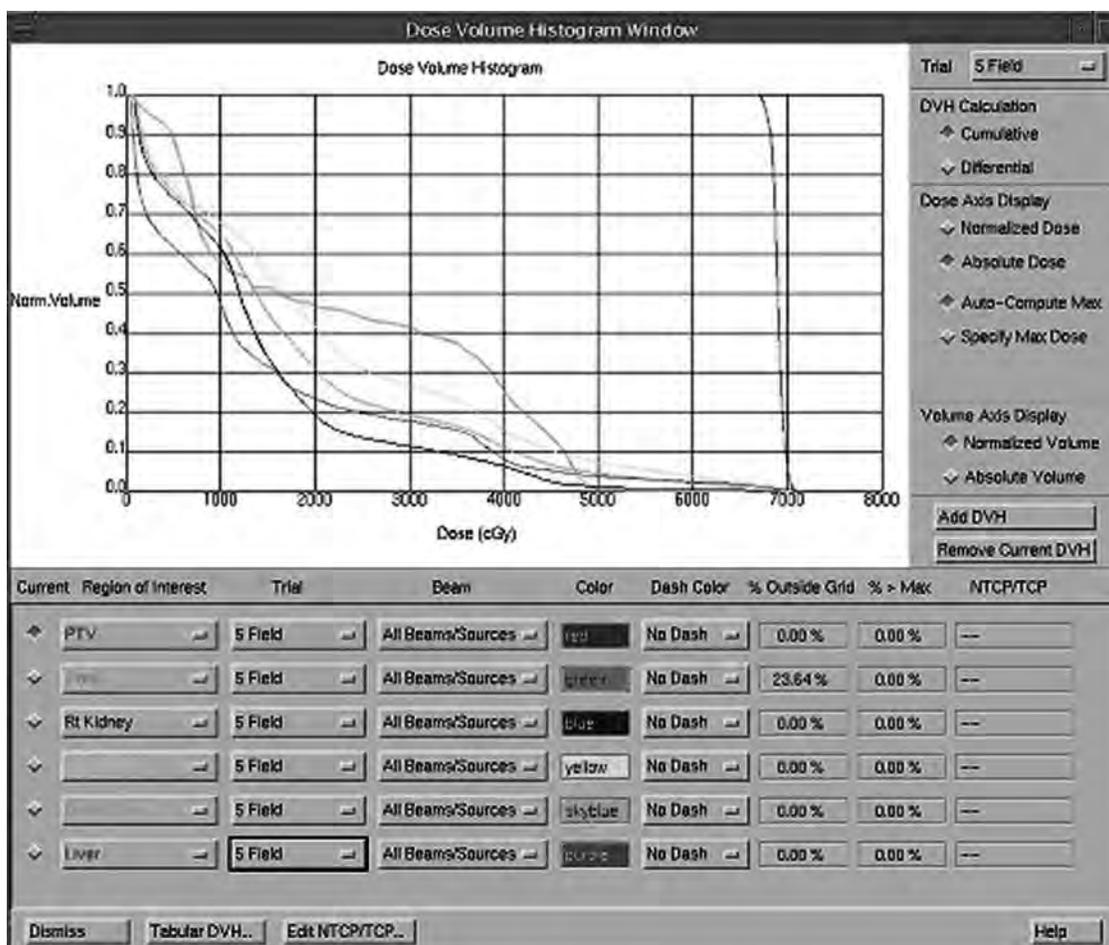

FIGURE 3.10. Three-dimensional treatment planning provided a tool for analyzing dose distribution in various organs interested. This tool is very useful in the analysis of the biologic consequences of the optimized irradiation.

tion. It can be used to complement the graphic isodose displays used in treatment planning by comparing the amount of dose given to specified organ volume. High dose conformity can enable the radiation oncologist to seek dose escalation to the target volume for possibly better radiobiologic advantages and an improved therapeutic gain, as previously described in Figure 3.1.

Intensity-Modulated Radiation Therapy

Three-dimensional CRT is used to optimize the radiation delivery to irregularly shaped volumes by manually setting individual beam angles. Intensity-modulated radiation therapy (IMRT) is a new approach to 3-D CRT. Clinical definition of complex treatment volumes often requires concave dose distributions. IMRT has been found to be most useful in this regard.⁴³ Radiation dose delivery to a target volume by IMRT is performed by the superposition of multiple “beamlets” from each treatment angle. Full dose uniformity is achieved by the summation of individual beams of small field size where the central axis is frequently blocked by complex multileaf collimator (MLC) patterns. The dose is figuratively painted in by discrete amounts wherever needed to maintain dose uniformity in a defined volume. Typically, in the optimization process using IMRT for radiation dose delivery, the relevant physical and geometric information of the irradiated object and radiation source serve as input data. Then, dose distribution may be calculated using the input data for volumes that have specific geometric characteristics. This dose calculation is known as a forward treatment planning process. However, an inverse treatment planning process is used to create IMRT plans. The inverse planning process essentially starts with a precise prescription of the goals of an ideal plan, and the planning system optimizes input data to meet these conditions. In addition to the availability of the physical parameters of the irradiated object (tumor volume), the relevant information about the capabilities and specifications of the available treatment machine may be inserted into the planning system. After the physician prescribes the desired doses to the different volumes including GTV, PTV, and adjacent dose-limiting normal tissues, the inverse planning system provides a delivery method to execute the prescription accurately with a specific treatment machine. The resultant computerized solutions appear as radiation intensities from the sources as a function of source location, which results in a dose function that is used in the delivery of targeted irradiation.

As shown in Figure 3.11, this head and neck treatment plan provides a sample of IMRT inverse planning process. This specific case shows a target volume for a patient with a base-of-tongue primary cancer where the GTV has been outlined and resulting in a corresponding PTV with expanded margins generated around it. The PTV has been prescribed to a uniform dose distribution of 7,200 cGy. Regional “at-risk” lymph nodes are also treated to the minimum dose of 5,400 cGy. Here, there are unique features of IMRT compared to the conventional radiation therapy, in that the IMRT can deliver different doses to multiple targets simultaneously. This method may eliminate the necessity of boost plans to deliver different doses to multiple targets. The fractional doses per day to physically defined target volumes can be made to vary. The daily doses should be selected carefully in view of the radiobiologic

consideration. Most clinical experience is based on the same fractional doses, although total doses specific to multiple target sites and critical structures may be different.

Critical normal tissues such as the spinal cord and right parotid can be “spared” (see Figure 3.11) to doses of 4,300 and 2,200 cGy, which should result in no significant late toxicities. Once all objectives are determined, the inverse treatment planning system is able to optimize the dose distributions that satisfy the initial objectives. Most planning systems have used an intermediate step before giving a deliverable plan with a delivery machine. This intermediate step provides users with several options: which treatment delivery machine is being selected, how many intensity levels are to be used, and what is the basic prescription of multiple beam directions (gantry angles).

Current IMRT delivery methods have been implemented by MLCs installed on conventional linear accelerators, tomotherapy, and physical beam modulators.⁴⁴ Multileaf collimators include conventional MLCs that accompany the installation on most modern linear accelerators and specifically designed MLCs which have been attached to the gantry for IMRT use. There are two methods used for delivering modulated beams using MLCs: step-and-shoot and sliding window techniques.⁴⁴ The step-and-shoot method delivers dose to the target by a series of small beams. At each gantry angle, MLCs constantly form a series of segments to deliver a modulated beam. During the time of MLC movements between segments, the radiation beams are cycled to an off position automatically by the programmed accelerator software without further human interaction. However, the sliding window technique starts with all leaves closed from one side of a radiation field and opens the leaves in a dynamic pattern. The speed of each pair of leaves depends on the dose intensity desired. The radiation beams are continually on during the MLC movement.

Image-Guided Radiation Therapy

In the past, large target margins and treatment volume were used to accommodate the positioning error and organ motion associated with radiation therapy treatment. Because highly conformal radiation therapy can now be delivered, accurate target determinations (i.e., CTV, GTV, PTV) have become a very important issue. Various image modalities can now guide highly conformal therapy such as IMRT by locating the target before daily fractionated radiation therapy. Ultrasound imaging is often used for internal target positioning, mostly for localized prostate cancers.⁴⁵ However, because the ultrasound cannot penetrate air or bone, its use is limited to certain anatomic sites. Additionally, ultrasound, similar to CT, does not provide any functional information on tumor biology.

Traditionally, the determination of tumor volumes for radiation treatment planning, as well as determining responses following radiation therapy, has been limited to imaging techniques such as CT and magnetic resonance imaging (MRI) scanning. Based on these scanning techniques, we now can deliver higher radiation doses using 3-D CRT and IMRT techniques in certain situations such as localized prostate cancer⁴⁶ and head and neck cancers,⁴⁷ which translate into improved local tumor control and survival. With the

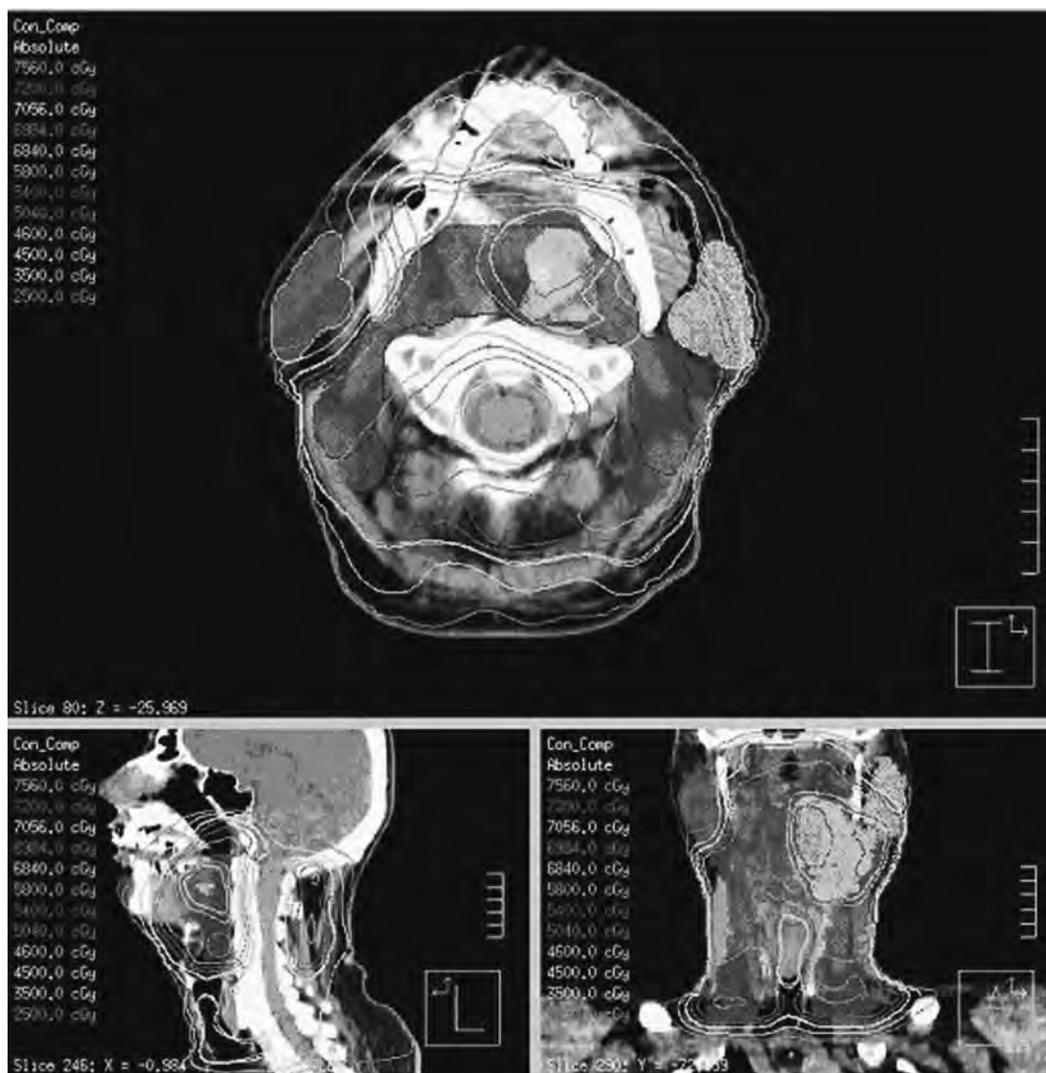

FIGURE 3.11. The orthogonal images for a head and neck cancer show the dose distribution from an intensity-modulated radiation treatment (IMRT) plan with nine beams at equally spaced gantry

angles. Markedly reduced doses to the spinal cord (4,300 cGy) and the right parotid (2,200 cGy) are noted, while delivering 7,200 cGy to the primary tumor and 5,400 cGy to the at-risk lymph nodes.

clinical development of positron emission tomography (PET), single-photon emission computed tomography (SPECT), and magnetic resonance spectroscopy (MRS), radiation oncologists are attempting to integrate these function imaging techniques into radiation treatment planning. This evolving field of image-guided radiation therapy (IGRT) holds the potential to radically alter the way radiation therapy is used to treat cancer over the next decade. A comprehensive overview was recently published.⁴⁸

Specialized Applications of Radiation Therapy

Systemic Radiation Therapy

Targeted radiation therapy combines principles of systemic and local therapy. Advantages of these approaches are to treat disease in multiple locations and to target microscopic sub-clinical disease. The rate of the uptake and retention of

radioactivity to kill tumor cells relative to that of the normal tissues determines the efficiency of this treatment approach.

Systemic radiation therapy can be categorized into two forms: radioimmunotherapy and systemic unsealed radiation therapy.^{49,50} Radioimmunotherapy uses antibodies, antibody fragments, or compounds as carriers to guide radiation to the target(s). The systemic unsealed radiation therapy can be administered by intravenous, oral, intratumoral, peritoneal, or intrathecal routes. These approaches are intended to concentrate the radioactivity into the target(s) and to deliver a therapeutic radiation dose. The applications of radioimmunotherapy are currently under way to treat lymphomas, leukemias, and some solid tumors with ^{131}I , ^{90}Y , ^{153}Lu , ^{186}Re , and several alpha-emitting radionuclides.⁴⁹ Other forms of systemic radiation therapy often use electron-emitting radioactive material. The most typical treatments using ^{131}I , ^{89}Sr , ^{32}P , and ^{153}Sm are for hyperthyroidism, differentiated thyroid cancer, painful skeletal metastases, polycythemia vera, malignant cysts, and neuroendocrine tumors.⁵⁰ These

treatments are usually well tolerated without causing long-term effects, such as cancer or infertility. Several ongoing and new initiatives to explore the use of targeted therapy to be used as conditioning regimens for bone marrow transplant instead of nonspecific total-body irradiation show strong potential for reducing the side effects associated with the transplant process.⁵¹

Brachytherapy

Brachytherapy is the clinical procedure that inserts small encapsulated radioactive sources into the treatment (tumor) volume. Radioactive sources are continuously irradiating the treatment volume by an exponentially decaying dose rate. From each source, the therapeutic range is usually in the millimeter (mm) to centimeter (cm) range. Therefore, it provides a superior localization of dose to the tumor volume compared to the conventional external radiation therapy. There are two different methods in brachytherapy: an intracavitary approach where radioactive sources are implanted in body cavities in close proximity of the treatment volume, and an interstitial approach in which the sources are directly implanted in the treatment volume. Typically, the intracavitary implant is temporary. On the other hand, interstitial implant can be temporary or permanent. Most gynecologic tumors have been treated with brachytherapy using long-lived ¹³⁷Ce sources.⁵² Recently, more brachytherapeutic applications to other anatomic sites have been introduced. These new applications include prostate seed implant for localized prostate cancers, intravascular irradiation to prevent coronary artery restenosis, and “mammo-site” breast irradiation as briefly discussed next.

Palladium-103 and ¹²⁵I seeds are used for the prostate seed implant procedure.^{53,54} Accurate seed placement within the prostate, the most important task, is achieved by using transrectal ultrasonography, which provides accuracy and precision. The treatment procedure requires extensive treatment planning to localize each source and produce a combined plan for all sources. There are usually two steps to complete the treatment planning process for permanent seed implants: preplanning the target volume and intraoperative planning. Preplanning is performed with ultrasound images acquired before the surgery. Based on this plan, the strength of the seeds to be ordered, the number, and proposed seed placement may be preplanned. The premise of intraoperative planning is that preplanning is not necessary. All planning can be done in the operating room with real-time images. Advantages of the preplanning approach include: preevaluation of whether this treatment can be deliverable, more planning time to optimize the seed placement for ideal dose distribution, and minimization of ordering unnecessary seeds. The dosimetric goals of prostate cancer implant therapy are to deliver sufficient dose to the prostate and to spare the rectum, bladder, and other adjacent critical structures. These goals are achieved with optimizing the strength and the number of seeds.⁵⁴

Intravascular brachytherapy has been introduced to treat coronary restenosis.^{55,56} After a percutaneous coronary transluminal angioplasty (PCTA) is performed to reopen the blockage within the coronary artery, a radioactive source (¹⁹²Ir, ¹²⁵I, ⁹⁰Sr, or ³²P) may be positioned in the area of the restenosis. Depending on the selection of radioactive source, the treat-

ment time varies from 3 to 25 minutes.⁵⁵ Due to the presence of the radiation-delivering catheter, minimizing the treatment time to restore maximum blood flow is a factor for consideration of source selection as well as other factors; other factors include the dose distribution in inhomogeneous tissue (calcified plaque versus normal tissue), and the artery diameter.⁵⁶

Mammo-site brachytherapy is considered as an alternative to a standard 5-week external radiation therapy course for breast cancers.^{57,58} This procedure shortens the treatment time to just 5 days. A specific device has been designed for this procedure, consisting of a hollow catheter to which an inflatable balloon is attached. It is temporarily implanted into the lumpectomy site. Beads of radioactive iridium are inserted into the catheter within the inflated balloon, which helps the catheter to be centered so that the dose can be uniformly delivered to the lumpectomy surface. The actual treatment takes typically two 15-minute sessions per day for 5 days. The catheter stays in place over the entire course of treatment. The preliminary clinical results with respect to local control and breast cosmesis are encouraging.⁵⁸

Intraoperative Radiotherapy

Intraoperative radiation therapy (IORT) delivers a large single dose of 10 to 20 Gy to a tumor bed following surgical resection, during which the normal organs are physically moved out of the pathway of the radiation beam.⁵⁹ Intraoperative radiation therapy using X-ray beams was first described more than 80 years ago. However, refinements in techniques for IORT delivery and the generation of relevant large animal and human data on normal tissue tolerances to these large single doses of radiation therapy have ushered in a modern era for IORT.^{60,61} It is now widely used for abdominal, pelvic, and retroperitoneal carcinomas and sarcomas as well as for some thoracic malignancies, extremity sarcomas, and head and neck cancers. The clinical experience to these tumor sites from large cancer centers throughout the world was recently summarized.⁶² Linear accelerators designed for external radiation therapy have been adapted to deliver electron beams with IORT applicators, which collimate the electron beams according to the size and the slope of the treating area. Presently, dedicated mobile IORT machines are also used. These machines generate electron beams only. Therefore, shielding issues are minimal, and the machines are designed to be suitable for use in regular operating rooms.

Stereotactic Radiation Therapy

Stereotactic radiosurgery has been used worldwide as a primary or secondary procedure to treat both malignant and benign tumors. Typically, patients with brain metastases are treated following delivery of whole-brain irradiation.^{63,64} The clinical results including appropriate patient selection are discussed in detail in the chapter on Brain Metastases. The target (tumor) volumes for this procedure are small, typically less than 30 cm³ (less than 4 cm diameter). To achieve this goal, intracranial stereotactic positioning systems are designed to achieve accurate target localization and have also enabled effective nonsurgical treatment of arteriovenous malformations, acoustic neuromas, and primary brain tumors, in addition to brain metastases.

Stereotactic radiation therapy to well-defined intracranial lesions can be performed in single or multiple fractions. The

type of tumor can determine the choice of fractionation.^{63,64} Most centers perform radiosurgery on an outpatient basis. Treatment process starts with the fixation of a stereotactic frame on the patient's skull. Light sedation and local anesthetic applied before frame fixation are adequate for the patient's comfort throughout the treatment day. The patient with the frame goes through contrast-enhanced CT and/or MRI imaging with thin serial cuts (1–2 mm thick) taken in the region of the tumor. These scans are imported into a treatment planning software, where image segmentation is performed for volumetric evaluation and three-dimensional reconstruction.

There are two approaches for stereotactic radiosurgery: linear accelerator based and the gamma knife. With the first approach, tertiary micro-multileaf collimator and circular cones have been developed and adapted to a standard linear accelerator where 6MV photons are typically used. The cone sizes for linear-based stereotactic radiosurgery range from 0.5 to 3.5 cm. The second technical approach to stereotactic radiosurgery uses the gamma knife (Elekta). This machine uses 201 cobalt sources (⁶⁰Co) and collimates the radiation beams using specially designed cranial helmets with 201 apertures and four different diameters (4, 8, 14, and 18 mm). The treatment is delivered with a combination of these helmets to conform the radiation distribution.

Whether a linear accelerator or a gamma knife is used, the radiation beams are arranged to intersect at a common point within the brain. The beam intersection volume is determined by the collimation system selected to encompass the target, and this produces a high-dose falloff just outside the intersection volume. Therefore, precise determination of the target volume is very important to deliver effective doses to the tumor(s). Noncoplanar arc beams are often used with linear accelerator-based stereotactic radiosurgery compared to stationary beams with the gamma knife.

Heavy Charged Particle Radiation Therapy

Heavy charged particles have two distinct characteristics compared to photons or electrons.⁸ Dose distributions are highly localized, and the shallow depth sparing effect is significant due to the domination of the Bragg peak. This shallow depth sparing is much more significant than high-energy photons generated by linear accelerators. Additionally, the depth dose after the Bragg peak diminishes nearly to zero. As the Bragg peak depth depends on the incident energy, varying the energy of the primary beam can easily modulate the maximum dose depth. In addition to the advantage in depth dose distribution, the lateral dose gradient is significant at the beam edge.

As previously discussed, heavy charged particles also have a higher radiobiological effectiveness (RBE) and lower oxygen enhancement ratio (OER) because of higher linear energy transfer (LET). These factors may provide more radiobiologic advantages in addition to the physics described above. Recently, isocentrically mounted proton therapy machines are emerging as a competitive radiation therapy modality, as dose conformality has become more of a central issue.^{8,9} It is possible that the new, clinically oriented proton therapy machines can deliver conformal radiation to the target that will be superior to the current IMRT methods using linear

accelerators. However, carefully designed clinical trials are needed to evaluate these potential advantages to proton beam radiation therapy. For small targets, gamma knife irradiation with full frame immobilization represents the current "gold standard" by which other irradiation modalities are to be measured and compared.

Drug–Radiation Interactions and New Approaches to “Targeted” Radiation Therapy

Mechanisms of Interaction with Conventional Chemotherapy

The concomitant use of conventional chemotherapy agents such as the fluoropyrimidines and the platinum analogues during radiation therapy is the standard of care for neoadjuvant, postoperative adjuvant and definitive therapy in the treatment of locally advanced cancers of the head and neck, lung, and throughout the gastrointestinal tract, including esophageal, gastric, pancreas, rectal, and anal cancers. The results of various Phase 3 clinical trials of concomitant combined modality therapy using these drugs are reviewed throughout this textbook under the disease-specific sites. Indeed, the success of these concomitant combined modality treatments for the locally advanced cancers is probably the most significant advances in cancer therapy during the past 10 to 15 years.^{65–67} Surprisingly, in spite of such success, the cellular and molecular mechanisms of interaction resulting in tumor radiosensitization remain poorly understood. Although an in-depth review of our current understanding of the greater than additive interactions of conventional chemotherapy drugs is beyond the scope of the chapter, the reader is referred to three recent reviews.^{65–67} A brief overview of these drug–radiation interactions is summarized as follows.

5-Fluorouracil (5-FU) is clearly the most commonly used drug as a radiosensitizer, with the principal mechanism of sensitization related to inhibition of thymidylate synthase (TS) with subsequent progression through the G₁ checkpoint (restriction point) into S phase with altered (perturbed) triphosphate pools and reduced DNA repair.⁶⁸ As such, tumors with high levels (overexpression) of TS, which are known to be clinically resistant to 5-FU cytotoxicity, are probably also resistant to 5-FU-based radiosensitization. Two other enzymes involved in nucleoside metabolism including dihydropyrimidine dehydrogenase (DPD), a 5-FU catabolic enzyme, and thymidine phosphorylase (TP) may also be key regulators of fluoropyrimidine radiosensitization, including the use of oral prodrugs such as UFT and capecitabine.⁶⁶

Chemotherapy drugs that target ribonucleotide reductase (RR), the rate-limiting enzyme in deoxynucleotide metabolism, can also result in clinical radiosensitization.^{66,67} These drugs include hydroxyurea (HU) and gemcitabine (dFdCyd). It is known that ionizing radiation can cause a posttranscriptional overexpression of RR⁶⁹ and that the mechanism of radiosensitization appears to be progression into S phase under altered triphosphate pools (particularly dATP).⁷⁰

The platinum analogues, including cisplatin, carboplatin, and oxaliplatin, are also commonly used as clinical radiosensitizers in head and neck cancers, non-small cell lung cancers,

bladder cancers, and locally advanced cervical cancers. Several potential mechanisms of drug–radiation interactions with the platinum analogues have been proposed, including enhanced formation of toxic platinum–DNA adducts and crosslinks in the presence of IR free radicals; cell-cycle arrest at G₂/M with reduced DNA repair; and enhanced cellular platinum uptake by IR.⁶⁸

Although the enhanced local control and improved survival rates have convinced the oncology community to consider these concomitant combined modality approaches as the current standard of care for many locally advanced solid tumors, there is also an enhancement in both acute (e.g., mucositis, myelosuppression) and late (e.g., esophageal, bowel strictures) normal tissue toxicities. Thus, more carefully designed clinical trials are still needed to measure the therapeutic gain and to test in patients the proposed mechanisms of these drug–radiation interactions leading to radiosensitization using noninvasive imaging techniques including PET and MR spectroscopy. Even in this era of molecularly targeted therapy, the oncology community should not overlook the success of these drug–radiation interactions and should continue to study the molecular targets of these leading to radiosensitization.

Mechanisms of Interaction with Bioreductive Drugs

As discussed earlier, hypoxic tumor cells exist in many common solid tumors and represent a therapeutically resistant tumor cell population that may limit the curability of these tumors to different chemotherapy drug classes as well as to radiation therapy. However, the presence of these hypoxic cell populations in tumors also represents an exploitable difference to enhance the therapeutic gain as normal tissues do not have such acute and/or chronically hypoxic cells. One approach to exploit hypoxia for a therapeutic gain is to use bioreductive drugs with radiation therapy to selectively kill the hypoxic cell population.

The development of bioreductive drugs has been an area of extensive preclinical research and clinical testing for more than 25 years, but even today there are no clinically proven bioreductive drugs approached in the United States for use with radiation therapy alone nor with chemoradiotherapy. Two recent review articles detailed the development and testing of these various nitroheterocyclic compounds.^{71,72} At the present time, nimorazole is used in some European countries as a radiosensitizer in head and neck cancers based on a Phase III trial,⁷³ and tirapazamine is in Phase II and III testing combined with radiotherapy alone, cisplatin-based chemotherapy, and combined cisplatin/radiation therapy in the United States.⁷²

Growth Factor Receptor Targeting for Radiosensitization

Over all the past several years, the potential therapeutic targeting of growth factor receptors on tumor cells is an area of active preclinical research and early clinical testing. Two key targets to enhance radiosensitization in human cancers are the epidermal growth factor (EGF) family and vascular endothelial growth factor (VEGF). For a comprehensive dis-

ussion of these approaches to radiosensitization, the reader is referred to two recent reviews.^{74,75}

The epidermal growth factor receptor family has four transmembrane receptor tyrosine kinases, including HER2, HER3, HER4, and epidermal growth factor receptor (EGFR), which are involved in cell proliferation and survival responses, mediated through ligand binding. EGRF is known to be overexpressed in a majority of several tumors including non-small cell lung cancer, head and neck cancers, and glioblastoma multiforme. Clinical studies confirm that EGRF overexpression is associated with clinical radioresistance in these tumors. HER2 overexpression in breast cancer is also associated with clinical radioresistance. Thus, targeting the EGFR family clearly has the potential for radiosensitization. The preliminary results of a Phase III clinical trial comparing radiation therapy + the chimeric monoclonal antibody against EGRF (Cetuximab, Erbitux, ImClone Systems, New York, NY, and Bristol-Myers Squibb Company, Princeton, NJ, USA) were recently reported showing improved local control and survival at 2 and 3 years.⁷⁶ Although encouraging, several criticisms in trial design and the lower than expected local control and survival data in the radiation therapy alone, necessitate further clinical testing.

A second developmental area of tumor targeting involves targeting the tumor vasculature. It is recognized that tumor progression during radiation therapy is a major reason for radiation failures. The ability of a tumor to progress during radiation therapy is dependent on the continued formation of new tumor blood vessels. Consequently, by targeting tumor vasculature, one attempts to disrupt the proangiogenic balance between the tumor and its endothelial and vascular stromal cells.⁷⁵ Because VEGF is an important proangiogenic tumor growth factor, a considerable amount of emphasis has been placed on VEGF inhibition in preclinical testing with radiation therapy using protein- or receptor-targeted antibodies or using VEGF receptor signaling inhibitors including the cyclooxygenase 2 inhibitors.⁷⁷

Two other approaches that attempt to target tumor growth and enhance tumor response to ionizing radiation involve targeting tumor oncogenes such as *Ras*⁷⁸ and the nuclear transcription factor NF- κ B.⁷⁹ As no clinical data are available on these potential targeted therapies, the reader is referred to two recent reviews of the preclinical research and proposed clinical testing.^{78,79}

Targeting DNA Repair for Tumor Radiosensitization

As reviewed previously in this chapter, recent advances in our understanding of DNA repair have shown genetic and epigenetic changes in several common human cancers, which result in alterations in IR damage recognition and damage repair processes. DNA mismatch repair (MMR) is a postreplicational process whose genes/proteins are not only capable of recognizing and processing single DNA base-pair mismatches and insertion-deletion loops during DNA replication, but also DNA adducts resulting from several types of chemotherapy drugs including the platinum analogues, alkylating/methylating drugs including procarbazine and temozolomide, and various nucleoside analogues including the fluoropyrimidines, gemcitabine, and the purine analogues, 6-thioguanine (6-TG) and 6-mercaptopurine (6-MP).⁸⁰ MMR is also involved

in processing IR damage.⁸¹ As such, MMR-deficient human tumors resulting from genetic defects [e.g., human nonpolyposis colorectal cancers (HNPCC)] or from epigenetic silencing (methylation) of hMLH1 and hMSH2 genes (e.g., found in 15%–30% of colon, gastric, endometrial, high-grade glioma, and ovarian and breast cancers) show clinical resistance to these chemotherapeutic agents as well as IR.^{80–82} One approach to target these MMR-deficient human cancers for radiosensitization involves the use of the halogenated thymidine analogues such as iododeoxyuridine (IUDR), which are incorporated into DNA in place of thymidine and enhance DNA damage following IR exposure. MMR-deficient tumor cells fail to effectively remove IUDR DNA, unlike normal (MMR⁺) cells, allowing for preferential tumor radiosensitization without enhancing normal tissue toxicity as recently shown in vivo.⁸³ A clinical trial of this approach using an oral prodrug of IUDR (IPdR) and radiation therapy in MMR-deficient (“resistant”) human cancers is ongoing.

Another potential area for “targeted” radiosensitization involves the use of inhibitory drugs or proteins directed at double-strand break repair. As stated earlier, RAD51 is overexpressed in several clinically radioresistant tumors such as pancreas cancer. Additionally, ionizing radiation treatment can induce expression of RAD51 RNA and RAD51 protein-mediated homologous recombination of double-strand breaks in both normal and human tumor cells. At present, imatinib mesylate (Gleevec; Novartis) is a potential candidate for clinical testing of inhibiting RAD51 at its tyrosine 315 phosphorylating site.⁸⁴

Principles of Surgical Therapy in Oncology

Michael S. Sabel, Kathleen M. Diehl,
and Alfred E. Chang

History of Surgical Oncology

The role of surgery in the treatment of cancer has seen a dramatic change over the past century, from that of the only chance for cure to becoming one weapon in an armamentarium of oncologic therapies. As the role of surgery changes, so has the role of the surgeon, evolving from *cancer surgeon* to *surgical oncologist*. This role continues to evolve, as the management of cancer is altered by increased knowledge of genetics, molecular biology, and tumor immunology. Although surgery has historically been the first line of defense against a tumor, the escalating use of neoadjuvant therapies often shifts surgery to the second or third line. The role of surgery has expanded from that of purely therapeutic to include both palliation and prophylaxis. Inasmuch as surgeons are the ones with direct access to tumors, they have cemented their role as physician-scientists, investigating novel molecular and immunologic therapies. As new discoveries continue to transform our approach to cancer, the field of surgical oncology will continue to evolve (Table 4.1).

The surgical treatment of superficial cancers is clearly not a new concept. Some of the oldest medical records in existence, Egyptian papyri dating back to 1700 B.C., describe the cauterization of the breast.¹ Celsus and Galen, Roman physicians of the first and second centuries A.D., wrote about breast cancer operations, and the Greek physician Lenoidas described a mastectomy for breast cancer, including the use of cauterization for hemostasis, in the 5th century A.D. Surgery was obviously limited to superficial tumors, and even that approach was halted throughout the dark ages of medicine. Ultimately the humoral theories of disease (blood, phlegm, white bile, and black bile) were replaced by scientific experimentation, and the principles of modern medicine began to take shape.

The principles of surgical oncology, along with several other fields, found their start with John Hunter (1728–1793), often referred to as the father of surgery. He first described many of the concepts of surgical oncology, including the idea that cancer could be a localized process that was potentially amenable to surgical cure. He stressed the need for total removal of the cancer along with the potential areas of lymphatic spread a century before Halsted's theory. These theories would not realize themselves, however, until the surgery itself became more feasible through a better understanding of anatomy and pathology through autopsies, the introduction

of general anesthesia in 1842, and the principles of antiseptics, first described by Lister in 1867. This knowledge allowed surgical oncology to expand beyond superficial tumors, such as breast cancer, to the treatment of intraabdominal malignancies.

The next few decades would see the description of several major operations for cancer, including many by Theodore Billroth of Vienna, who could probably be considered the first surgical oncologist. He is most well known for the first successful partial gastrectomy for cancer (1881), but he also described the first total laryngectomy (1873), the first hemipelvectomy (1891), and the first suprapubic removal of a bladder tumor.² Other notable milestones include the resection of colon cancer (Weir, 1885),³ the radical mastectomy (Halsted, 1891),⁴ the radical hysterectomy for cancer (Kelly, 1895),⁵ the first radical neck dissection (Crile, 1906),⁶ and the first abdominoperineal resection for rectal cancer (Miles, 1908).⁷

Throughout the first half of the 20th century, surgery remained the mainstay of cancer treatment. Although these major operations were not without significant mortality and morbidity, the risks of surgery were still outweighed by the potential for cure or palliation of symptoms. It is during this time that the phrase *cancer surgeon* was popularized, as the only major advances in cancer care were surgical. Cancer surgeons were in abundance at the major medical centers and were the clinical leaders at the few dedicated cancer centers.

The mid-20th century saw advances in cancer therapies outside the realm of surgery. Roentgen's discovery of X-rays in 1896 ultimately led to radiation treatments for surface cancers such as those of the cervix, head and neck, or breast. Chemotherapy entered the scene with the discovery of the alkylating agent nitrogen mustard in WWII,⁸ the folic acid antagonists reported by Farber in 1948,⁹ and the concept of hormonal alteration proposed by Nobel laureate Charles Huggins in 1941.¹⁰ It soon became apparent that cancer could be treated using more than one modality. It was at this time that the field of oncology began to mature, with clinical chemotherapists becoming known as oncologists. James Ewing, a pathologist who had experimented with immunotherapy, chemotherapy, and radium, established the multidisciplinary approach to the treatment of cancer with his book entitled *Neoplastic Diseases*.

In the mid-1960s, the term *surgical oncology* first arose; however, this phrase served to differentiate not between

TABLE 4.1. Important milestones in surgical oncology.

1600–1700 B.C.	Egyptians use cautery to destroy breast cancer.
400 B.C.	Hippocrates describes the clinical symptoms of cancer and coins the terms “carcinoma” and “sarcoma.”
1st and 2nd century A.D.	Roman physicians use surgery to treat breast cancer.
5th century A.D.	The Greek physician Lenoidas first describes a mastectomy as a treatment of breast cancer.
1760s	John Hunter, the “Father of Scientific Surgery,” describes principles of surgical oncology including cancer as local disease and lymphatic spread.
1775	Percival Pott describes scrotal cancer in chimney sweeps, first identifying a specific etiology of cancer.
1809	The first modern elective surgery for an abdominal cancer is performed: the removal of a 22-lb ovarian tumor by Ephraim MacDowell.
1829	Joseph Recamier first describes the principles of tumor metastasis.
1846	The first major cancer operation is performed under general anesthesia: the excision of the submaxillary gland and part of the tongue by John Collins Warren.
1867	Lister describes the principles of antiseptics and introduces carbolic acid, greatly reducing the morbidity of surgery.
1873	First total laryngectomy for laryngeal cancer by Theodore Billroth.
1881	First partial gastrectomy for cancer by Theodore Billroth.
1885	First colectomy for colon cancer by Robert Weir.
1887	New York Cancer Hospital becomes the first hospital in the United States specifically for cancer treatment.
1891	First hemipelvectomy by Theodore Billroth, first radical mastectomy for breast cancer by William Halsted.
1896	Roentgen discovers X-rays, ultimately leading to radiation oncology; G.T. Beason performs the first oophorectomy as hormonal treatment for breast cancer.
1906	First abdominoperineal resection for rectal cancer by W. Ernest Miles.
1909	Theodore Kocher first describes thyroid surgery.
1913	Both the American Association for the Advancement of Cancer (which would become the American Cancer Society) and the American College of Surgeons are established.
1919	James Ewing publishes <i>Neoplastic Diseases</i> , promoting the concept of the multidisciplinary treatment of cancer.
1927	First resection of pulmonary metastases by George Divis.
1935	First pancreaticoduodenectomy for pancreatic cancer by Allen O. Whipple.
1940	The James Ewing Society is established to “further our knowledge of cancer.”
1940s	Chemotherapy begins with the discovery of nitrogen mustards and folic acid antagonists.
1957	The initiation of the National Surgical Adjuvant Breast Project (NSABP).
1960s	Dr. Walter Lawrence establishes a division of surgical oncology at the Medical College of Virginia.
1975	The Society of Surgical Oncology (SSO) is established.
1978	The term <i>surgical oncologist</i> is defined by the SSO and NCI, and the SSO formulates guidelines for postresidency surgical oncology training.
1998	The American Board of Surgery establishes the Advisory Council for Surgical Oncology. The American College of Surgeons Oncology Group (ACOSOG) is established.

cancer surgeons and general surgeons but rather between surgeons and oncologists. Although the fields of medical oncology and radiation oncology were quickly acknowledged as legitimate subspecialties, the field of surgical oncology had difficulty separating from general surgery. Most well-trained general surgeons felt capable of performing the majority of cancer operations, and so subspecialization was limited to university hospitals that allowed such a focus. In the mid-1960s, the Medical College of Virginia was the first university department of surgery to establish a formal division of surgical oncology under the auspices of Dr. Walter Lawrence. By 1986, 38% of university surgery departments had done the same.¹¹ Despite the territorial conflicts between general surgeons, whose workload continues to be devoted in large part to cancer, and the surgical oncologist, the field continued to emerge as a surgical subspecialty. In 1975, the Society of Surgical Oncology (SSO) was established from the James Ewing Society, a group of alumni who had trained at the Memorial Sloan-Kettering Cancer Center and gathered in New York for

both scientific and social purposes. Although not a purely surgical society, it was dominated by surgeons and was established with the premise that its members would continue to be true to the inspiration of Dr. Ewing and his multidisciplinary approach to cancer. In conjunction with the National Cancer Institute (NCI), the SSO defined a surgical oncologist as an individual who is a fully qualified general surgeon who has had additional training and experience in all aspects of oncology, is capable of collaborating well with other oncology disciplines, has a full-time commitment to oncology, and serves the important role of leader of his fellow general surgeons in the care of the cancer patient.

Goals of Cancer Surgery

With the expansion of the multidisciplinary approach to cancer, the role of the surgeon has changed significantly. In addition to the well-established curative role, surgeons are

often asked to obtain tissue for diagnosis and staging, debulk tumors as part of multimodality therapy, palliate incurable patients, or prevent cancer by the surgical removal of nonessential organs. As the management of cancer is altered by new discoveries in genetics, molecular biology, immunology, and improved therapeutics, so too will the functions of the surgical oncologist change. With our increased understanding of the genetic predisposition to cancer, the surgeon is increasingly being asked to remove healthy organs to prevent malignancy. However, as other effective methods of prevention are developed, such as chemoprevention or gene therapy, this role will certainly diminish. Improving imaging technologies may have diminished the need for surgical intervention for staging (such as in Hodgkin's lymphoma), but the expanded use of neoadjuvant therapies often requires interventions to accurately assess response to therapy. In addition, harvesting tumors may become increasingly important for molecular staging as well as identifying molecular targets for specific therapies. It is therefore imperative for surgical oncologists to remain up-to-date on the newest approaches to cancer therapy, both multidisciplinary and experimental, and be prepared to adapt to the changing requirements for surgery.

Curative Surgery

Surgery for Primary Cancers

The major objective for surgery of the primary cancer is to achieve optimal *local control* of the lesion. Local control is defined as the elimination of the neoplastic process and establishing a milieu in which local tumor recurrence is minimized. Historically, this was achieved with radical extirpative surgeries that shaped the surgical oncologists' major objective, namely, avoiding a local recurrence. Before William Halsted's description of the radical mastectomy, surgical

treatment of breast cancer resulted in a dismal local control rate of less than 30%. The reason why Halsted's procedure was adopted as a standard approach was because he achieved greater than 90% local control, despite the fact that the overall survival of his patients was not improved.⁴ The latter was due to the locally advanced stage of the patients who were treated in those days. This consideration ushered in the concept of en bloc removal of adjacent tissue when removing a primary cancer. Halsted's mastectomy involved the removal of adjacent skin (often necessitating a skin graft), underlying pectoral muscles, and axillary lymph nodes (Figure 4.1).

One of the major principles of surgical therapy of the primary tumor is to obtain adequate *negative margins* around the primary tumor, which could mean different operative approaches depending on the tumor type and its local involvement with adjacent structures. For example, the removal of a primary colon cancer that involves an adjacent loop of small bowel or bladder requires the en bloc resection of the primary tumor along with removal of the involved segment of small bowel and bladder wall. This approach avoids violation of the primary tumor margins that could lead to tumor spillage and possible implantation of malignant cells in the surrounding normal tissues. Aside from biopsies of the primary tumor, the lesion should not be entered during a definitive resection. In fact, any biopsy tract or incision that was performed before the tumor resection should be included in the procedure to reduce the risk of local recurrence (Figure 4.2).

The risk of local recurrence for all solid malignancies is clearly increased if negative margins are not achieved. The adequacy of the negative margin has been defined for most tumor types either from retrospective clinical experience or prospective clinical trials. For example, a 5-cm margin is an adequate bowel margin for primary colon cancers that has been established from clinical experience. Likewise, it is accepted that a 2-cm distal margin for rectal cancers results

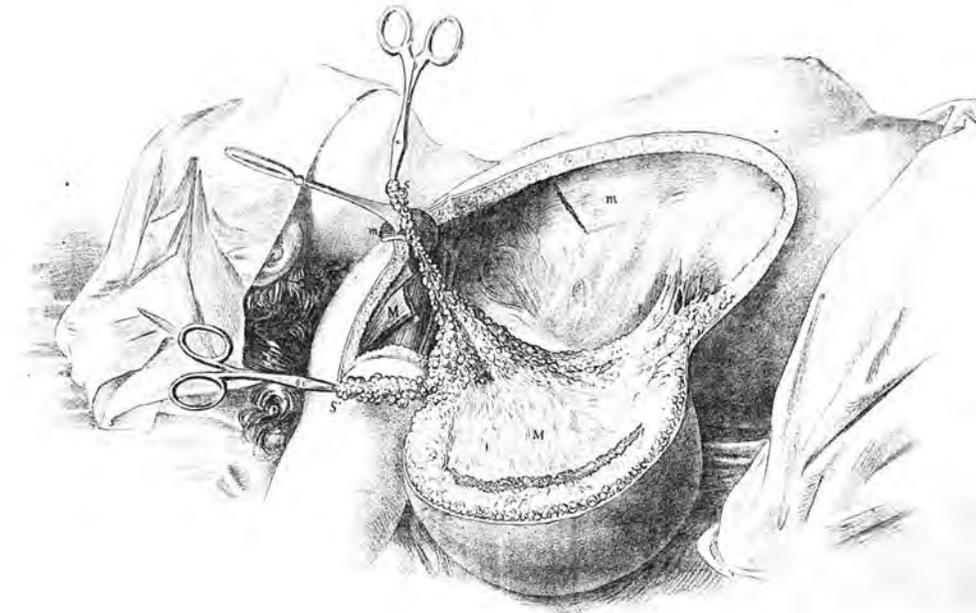

FIGURE 4.1. Original drawing of the radical mastectomy reported by William S. Halsted in 1894. Introduction of this operation led to improved local control in the treatment of breast cancer. (From Halsted,⁴ by permission of *Annals of Surgery*.)

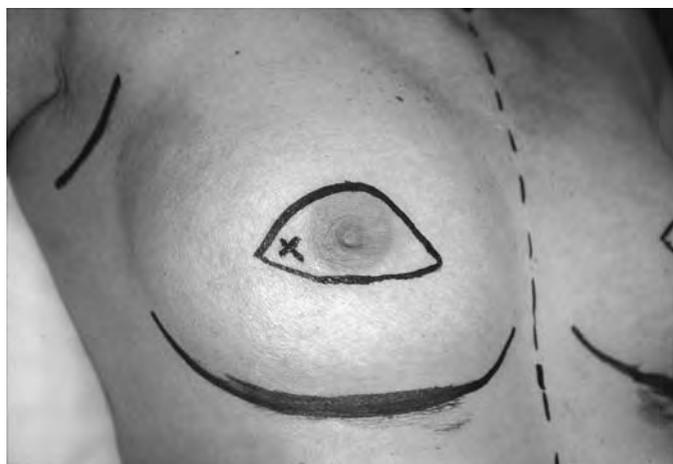

FIGURE 4.2. Location of core-needle biopsy site (x) in a patient undergoing a skin-sparing mastectomy for breast cancer. The biopsy site is incorporated in the elliptical skin incision to be removed en bloc with the specimen.

in adequate local control. Through several prospective, randomized clinical trials, the margins of excision for primary cutaneous melanomas differ according to the thickness of the primary (see Chapter 60). It was a commonly held notion that the development of a local recurrence would in itself result in metastatic disease with decreased overall survival. However, this has not been borne out in the context of prospective trials as described here.

The emergence of multimodal therapy has dramatically affected the surgical approach to many primary cancers, especially when surgical resection of the tumor is combined with radiotherapy. Local control is significantly improved after surgical resection of breast, rectal, sarcoma, head and neck, and pancreatic primary cancers. In fact, the addition of radiation therapy as an adjunctive therapy has allowed for less-radical procedures to be performed with an improvement in the quality of life of patients. A prime example of this is in breast cancer. Several clinical trials have demonstrated that the overall survival of patients with invasive breast cancer was comparable if treated by mastectomy versus lumpectomy plus adjuvant radiotherapy (see Chapter 55). This realization has resulted in better cosmesis and quality of life. In the National Surgical Adjuvant Breast and Bowel Project protocol, B-06, local recurrence in breast cancer patients did not affect overall survival.¹² In this seminal study, women with stage I or II breast cancer were randomized to total mastectomy with axillary node dissection, lumpectomy, and axillary node dissection followed by breast irradiation, or lumpectomy and axillary node dissection without irradiation. There was a significantly greater local relapse of tumor in women who underwent lumpectomy who did not receive breast irradiation versus those who received it (10% versus 39%, respectively, P less than 0.001). However, there was no difference in overall survival between any of the randomized groups. This study demonstrated the improved local control achieved with irradiation combined with lumpectomy.

Another example of how irradiation has altered surgical management of cancers is with extremity sarcomas. Before the 1970s, amputation was the standard surgical therapy of extremity soft tissue sarcomas because of the excessive local

relapse rate with wide excisions. In a landmark trial conducted at the National Cancer Institute, subjects with high-grade soft tissue sarcomas were randomized to receive amputation versus limb-sparing surgery plus radiotherapy.¹³ All subjects received postoperative chemotherapy. Despite a higher local recurrence rate in the limb salvage group, there were no significant differences in overall survival between the randomized groups. This study paved the way for offering limb salvage procedures for patients with soft tissue sarcomas.

As the field of multimodality therapy has developed, the role of surgery as primary therapy for certain solid malignancies has changed. The concept of neoadjuvant therapy where chemotherapy and/or radiation therapy is administered before surgical resection has become standard care for some tumors. A prime example of this is the treatment of anal squamous cell cancers. Before the 1970s, the primary therapy for this cancer was an abdominoperineal resection, which involves removal of the rectum and creation of a permanent colostomy. The discovery of effective chemoradiation therapy for this tumor has resulted in a high percentage of complete responses in many patients who then require having only excisional biopsies of residual scar.^{14,15} This change has spared patients from having an abdominoperineal resection, which is now reserved for those who fail to completely respond to chemoradiation or who subsequently relapse. Another example is the treatment of childhood rhabdomyosarcomas. In breast cancer, the use of neoadjuvant chemotherapy has been able to render many more women to be candidates for breast-sparing surgery who may not have been initially because of large tumor size.^{16,17} Postoperative adjuvant therapies involving chemotherapy and/or radiation therapy have also become standard approaches in many solid tumors, resulting in improved local control and overall survival.

Surgical Resection of Regional Lymph Nodes

The regional lymph nodes represent the most prevalent site of metastasis for solid tumors. Because of this, the involvement of the regional lymph nodes represents an important prognostic factor in the staging of the cancer patient. For this reason, the removal of the regional lymph nodes is often performed at the time of resection of the primary cancer. Besides staging information, a regional lymphadenectomy provides *regional control* of the cancer. Examples of this are patients with melanoma who have tumor metastatic to lymph nodes. It is well documented that the removal of these regional lymph nodes can result in long-term survival benefit in approximately 20% to 40% of individuals depending upon the extent of nodal involvement. Hence, the removal of regional lymph nodes can be therapeutic.

The controversies regarding regional lymphadenectomy for solid malignancies have related to the timing of the procedure as well as the extent of the procedure. For some visceral solid tumors such as gastric and pancreatic cancers, the extent of lymphadenectomy at the time of primary tumor resection has been hypothesized to be important in optimizing local and regional control and has an impact on improving overall survival. This concept has not been borne out in prospective randomized trials of gastric cancer in which the extent of lymphadenectomy has been examined (see Chapter

42). Based on these trials, the more-extended lymphadenectomy appears to result in more accurate staging of patients at a cost of increased morbidity. For nonvisceral solid tumors such as melanoma, breast cancers, and head and neck squamous cancers, the *elective* removal of regional lymph nodes at the time of primary tumor resection has been postulated to result in better survival outcomes compared to taking the wait-and-watch approach. The latter involves performing a lymphadenectomy only when the patient relapses in a nodal basin that would then necessitate a therapeutic lymph node dissection. In prospective randomized clinical studies evaluating elective versus therapeutic lymph node dissection in various tumor types, there was no survival advantage for performing elective lymph node dissections (Table 4.2).¹⁸⁻²⁵ It is apparent from these controversies that the initial removal of regional lymph nodes is most important for its staging impact, rather than its therapeutic effect. The introduction of *selective lymphadenectomy* based upon the concept of the

sentinel lymph node has dramatically improved our ability to stage the regional lymph nodes of certain cancers. This is reviewed in more detail in the Diagnosis and Staging section of this chapter.

Surgical Resection of Metastatic Disease

The resection of *isolated* metastases in patients with solid malignancies should always be a consideration when technically feasible. The term *isolated* metastasis implies that there are no other sites of metastatic disease present as assessed by clinical and imaging modalities. Hence, the selection of candidate patients for surgical resection requires a thorough evaluation of the individual's disease status, preoperative medical status, and assessment of the feasibility of resecting the metastatic site with a negative margin. This process ends up identifying a small subset of patients who would be surgical candidates. Although there are no prospective randomized

clinical studies documenting the survival benefit of surgical resection of isolated metastases, there is a significant body of retrospective evidence indicating that this approach can result in significant long-term benefit in patients with either lung or liver metastases. Aside from the regional lymph nodes, both lung and liver represent the next most common sites to which solid tumors metastasize.

The resection of metastases to the lung in patients with osteogenic or soft tissue sarcomas has been established from numerous retrospective reports. Both osteogenic and soft tissue sarcomas have a propensity to metastasize to the lung as the only site. Computed tomography studies of the lung are capable of identifying lesions that are a few millimeters in size. Multiple wedge excisions can be performed utilizing stapling devices without compromise of pulmonary function. Pulmonary metastasectomies for bone and soft tissue sarcoma can result in 5-year overall survival rates of approximately 35% if all disease is resected.^{26,27} The resection of metastases for adenocarcinomas is not so well documented. Primary adenocarcinomas often metastasize to multiple sites and do not result in isolated lung metastases. When they are confined to the lung, the metastases are often too numerous to consider wedge resections. There are retrospective reports indicating that, in select patients with metastatic adenocarcinomas to the lung (i.e., colorectal primaries), resection can result in long-term survival benefit.^{28,29}

A large body of retrospective evidence documents the benefit of resecting isolated liver metastases; this is especially the case for colorectal primary cancers. These cancers appear to have a pattern of spread that involves the liver as the initial site of metastasis. Resection of solitary or multiple colorectal liver metastases has resulted in a 25% to 40% overall 5-year survival rate, depending on the extent of liver involvement. Factors that have been associated with better survival are node-negative primary cancers, prolonged disease-free interval from time of primary resection to diagnosis of liver metastases, negative margins of hepatic resection, and fewer numbers of hepatic metastases (see Chapter 95). Current trials are under way to determine if adjuvant therapies given after hepatic metastasectomies further improve survival in this patient group. Besides colorectal liver metastases, the resection of noncolorectal liver metastases also can be therapeutic or palliative for selected individuals. For example, the resection of functional neuroendocrine metastases to the liver can result in palliation and prolonged survival of patients.³⁰ These tumors tend to be indolent in their growth rate; however, the symptoms associated with the metastatic lesion can often be detrimental to the quality of life of the patient. For other nonneuroendocrine, noncolorectal liver metastases, resection can result in survival benefit as well. Patients with isolated genitourinary or gynecologic primary malignancies with a prolonged disease-free interval have been reported to benefit from aggressive resection of hepatic metastases.³¹

Both liver and lung represent the majority of the evidence that resection of visceral metastases can result in long-term survival. These results have been observed usually in the absence of adjuvant systemic therapies. Our current concept that solid malignancies are systemic at their onset (i.e., breast cancer) would have us surmise that, with the presence of bulky visceral metastases, there must also be micrometastatic disease present at the time the bulky disease is resected.

Nevertheless, approximately 20% to 25% of individuals remain disease free for many years. This finding begs the notion that perhaps an immune mechanism is involved in preventing disease relapse in a subset of these patients. Besides liver and lung sites, there are clearly anecdotes and published series indicating that the resection of isolated metastases to skin, bowel, adrenal glands, pancreas, and other sites can result in survival benefit. One of the roles of the surgical oncologist is to know when it is appropriate to offer surgical resection of metastatic disease as a palliative or therapeutic option.

Diagnosis and Staging

In addition to operating for curative purposes, the surgical oncologist will often operate for the purpose of obtaining tissue for diagnosis or staging or for monitoring response to therapy. Biopsies for diagnosis can be done with fine-needle aspiration, core-needle biopsy, or incisional or excisional biopsy.

Fine-Needle Aspiration

Fine-needle aspirations obtain cell suspensions suitable for cytology or flow cytometry. This technique can be helpful in aspirating a thyroid nodule, sometimes a breast lump, or a lymph node whenever lymphoma is not primary in the differential diagnosis. The advantages to fine-needle aspiration include the lack of a scar, lack of need for anesthetic, good patient tolerance of the procedure, and the relatively fast turnover of cytology in obtaining a diagnosis. Cell-surface receptors cannot be evaluated, and cytology cannot distinguish between invasive and noninvasive cancers. A fine-needle aspiration should be done only when the determination of atypical or malignant cells will help in diagnosis or treatment, such as proceeding with a thyroid lobectomy or documenting whether a lesion is recurrent cancer in a patient with a known history of the disease. Although a determination of cell abnormality and malignancy can be done, it is usually not sufficient for determining the definitive diagnosis of a primary neoplasm, with the possible exception of abnormal cytology on brushings from an endoscopic examination in a patient with a pancreatic head mass or bile duct stricture. Because of the possibility of false-positive results, cytology is not considered sufficient for proceeding with a major surgical resection such as a mastectomy. In such instances, a method of biopsy that yields definitive histology should be obtained.

Core-Needle Biopsy

Core-needle biopsies can be done percutaneously by palpating a mass or lymph node or by radiologic guidance. Core biopsy material yields tissue architecture, including the diagnosis of malignancy, the tissue of origin of the primary tumor, whether a tumor is noninvasive or invasive, and cell-surface receptors. Advantages include the ability to do the biopsy under local anesthesia, minimal scarring, and improved patient tolerance of the procedure. Care should be taken to keep the entry point for the needle in a location that can be incorporated in a definitive resection of the mass in the event the result shows a malignancy (Figure 4.2). A core-needle

biopsy when diagnostic can allow planning for either neoadjuvant or adjuvant therapies or for surgical resection. For example, a core-needle biopsy of a large breast mass can allow neoadjuvant chemotherapy of a breast malignancy and possibly downstage the patient to being a breast conservation candidate, particularly when an excisional biopsy would be cosmetically unacceptable and obligate a mastectomy. Thus, it is usually the procedure of choice for making a pathologic diagnosis in many areas of oncology. For large soft tissue tumors or bone lesions, core biopsies should be the first method to consider to obtain a diagnosis.^{32,33} However, core needle biopsies often do not yield sufficient tissue for making a diagnosis of primary lymphoma, which often requires incisional or excisional biopsies.

Incisional Biopsy

Incisional biopsies are usually done when a needle biopsy is nondiagnostic or technically not feasible. Common examples include a pancreatic mass in which attempts at obtaining cytology by endoscopic brushings or fine-needle aspiration via endoscopic ultrasound have been nondiagnostic, or for a retroperitoneal mass that is potentially a lymphoma. For these intraabdominal tumors, the minimally invasive laparoscopic approach offers advantages of obtaining adequate tissue material as well as staging information that might not be appreciated by imaging modalities. For tumors outside the abdomen, care should be taken in planning an incisional biopsy to keep the biopsy within the area of the definitive operation. Biopsies of the extremity should be done along the line of the long axis of the extremity (Figure 4.3). An improperly placed trans-

verse incision on the extremity can lead to an unnecessarily morbid procedure because the definitive resection must achieve negative margins around the area of previous dissection (Figure 4.4). Impeccable hemostasis should be obtained during incisional biopsy procedures because the complication of a postoperative hematoma can lead to the dissemination of tumor cells into tissue planes well beyond the area that would be resected for definitive surgical therapy. For large cutaneous lesions, a *punch biopsy* represents a form of incisional biopsy that will sample all layers of the skin including the subcutaneous fat (Figure 4.5A). This procedure can be performed under local anesthesia in the outpatient setting using disposable punch biopsy tools (Figure 4.5B).

Excisional Biopsy

Smaller tumors are often more amenable to excisional biopsy. Excisional biopsy implies the removal of the entire skin lesion or lump. Small, particularly superficial, mobile tumors can be difficult to obtain with an adequate needle biopsy. Small masses or skin lesions on the extremity or trunk that are potentially malignant are often best approached with an excisional biopsy, as it allows definitive diagnosis without risking violation of tissue planes. Disadvantages include the resultant scar, the need for anesthetic, and the potential need for reexcision for margins. It is important to orientate excisional biopsy specimens in three dimensions for the pathologist to determine margins if surgical reexcision is needed. The precautions regarding orientation of incisions, not violating tissue planes, and hemostasis are the same as mentioned in the previous section on incisional biopsies.

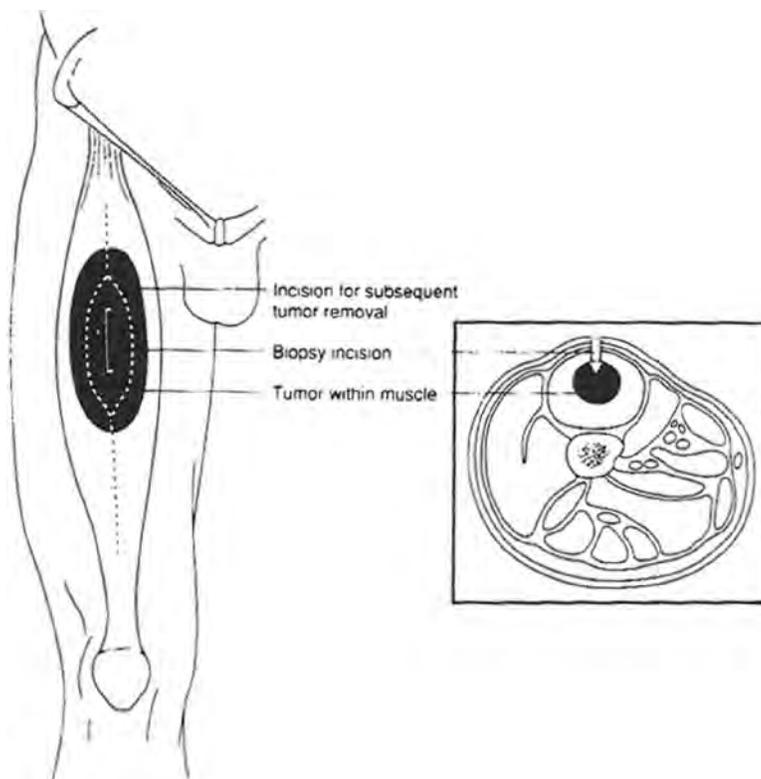

FIGURE 4.3. Placement of an incisional biopsy incision in a patient with an extremity soft tissue tumor. These incisions should be placed parallel to the long axis of the extremity. [By permission of Sondak VK. In: Greenfield LJ, et al. (eds). *Surgery Scientific Principles and Practice*. Philadelphia: Lippincott: Williams & Wilkins, 1993.]

FIGURE 4.4. Improperly placed transverse incision of a large soft tissue tumor. The tumor proved to be a high-grade sarcoma, with the subsequent wide excision being compromised because of the initial procedure.

Care should be taken, when biopsying more than one lesion of the same patient, to use separate instrument setups between biopsies in the event that not all the lesions are malignant to avoid cross-contamination of malignant cells between surgical sites. In this setting, precise labeling of each biopsy specimen is needed in the event that only one of the biopsied lesions is malignant to correctly identify the area to be further treated. It is also important to ensure proper handling of specimens. For example, lymph node tissue obtained for the potential diagnosis of lymphoma should go to pathology fresh to procure part of the specimen for flow cytometry.

In addition to obtaining biopsies to make a diagnosis, the surgical oncologist is increasingly called on to do a biopsy to assess response to adjuvant therapy because routine imaging studies do not always reflect what is happening at the tissue level. For example, necrotic tumor may still show as a mass on CT or mammography. In some protocols, serial biopsies are obtained to assess response to therapy; this is most often done as a core-needle biopsy.

Sentinel Lymph Node Biopsy

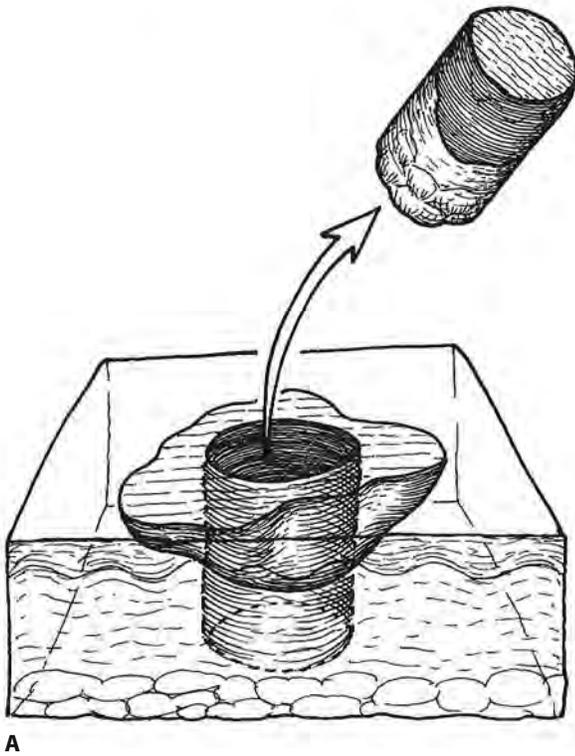

Increasingly, attempts at a more minimal approach to lymph node staging are being done with selective lymphadenectomy, also known as sentinel lymph node mapping or biopsy. The principle underlying this approach assumes that a cancer will

metastasize to one or more *sentinel nodes* in the regional lymph node basin(s) as defined by the anatomic distribution of lymphatic vessels present within and adjacent to the tumor (Figure 4.6).³⁴ One can determine whether the lymph node basin is involved with tumor by removing the sentinel lymph nodes and performing careful histologic examination of the nodes. Negative sentinel nodes predict fairly accurately that the remaining nodes within that basin will also be uninvolved with tumor, thereby avoiding the need for a regional lymphadenectomy and its attendant complications. This method has become the standard of care for staging patients with invasive breast cancer or melanoma (greater than 1 mm thickness) and is increasingly being evaluated in other malignancies such as head and neck, lung, gynecologic (i.e., cervical cancer), and gastrointestinal malignancies (i.e., colorectal and gastric cancers). The sixth edition of the American Joint Commission on Cancer staging guidelines has been revised to reflect the identification of micrometastasis to lymph nodes in melanoma and breast cancer (see Chapters 55 and 60).

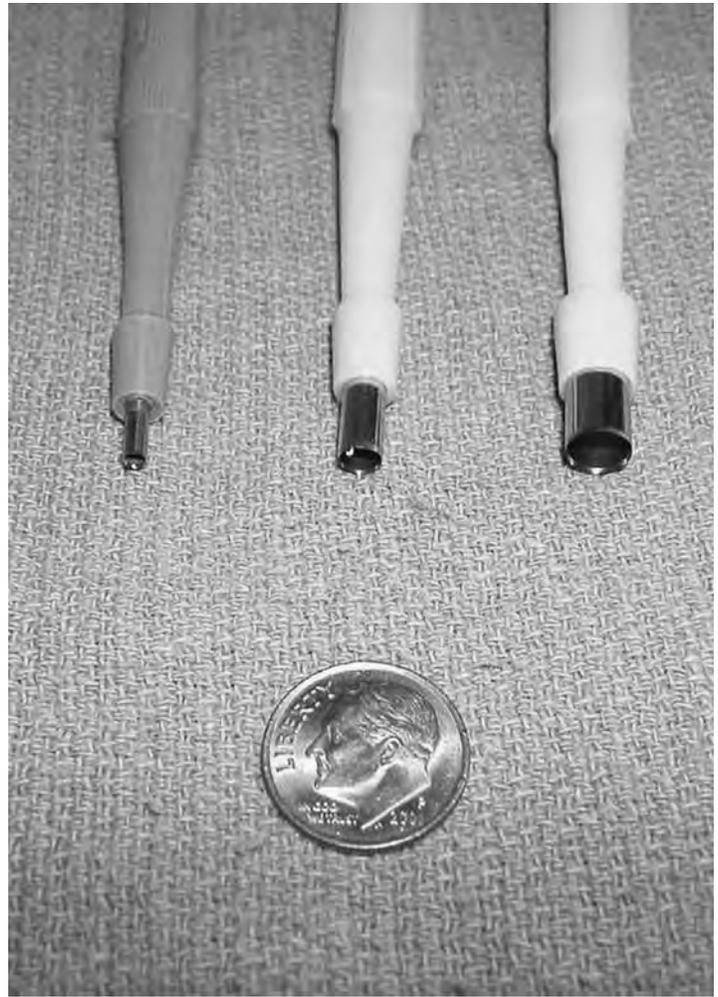

Complete lymph node dissections of the affected lymph node basin should be performed for positive sentinel lymph nodes. Continued questions remain regarding the incorporation of sentinel lymph node biopsy into melanoma treatment, including whether this method of staging and treating lymph node basins affects overall or disease-free survival (as is being evaluated in the Multicenter Selective Lymphadenectomy Trial), the natural history of microscopic sentinel node metastasis, and whether survival is affected by lymphadenectomy or treatments with interferon alpha-2b in these patients (as is being evaluated in the Sunbelt Melanoma Trial).³⁵ Sentinel lymph node biopsy has been accepted as accurately staging the clinically negative axilla in early-stage breast cancer patients with accuracy rates of 97% or greater. Currently, all patients with histologically proven metastasis to the sentinel node undergo completion axillary lymph node dissection.

Cancer Prevention

With the exponential increase in our understanding of inherited genetic mutations and the identification of patients who are predisposed to malignant transformation, surgical therapy has expanded beyond the therapy of established tumors and into the prevention of cancer. Prophylaxis is not a new concept in surgical oncology. Patients with chronic inflammatory diseases are known to be at high risk of subsequent malignant transformation. This realization typically prompts close surveillance and surgical resection at the first identification of premalignant changes. However, with the ability to perform genetic screening for relevant mutations, cancer prevention can be implemented before the onset of symptoms or histologic changes. With the decoding of the entire human genome, it is likely that more genes responsible for specific cancers will be identified, and the potential role for prevention will expand. Although many interventions may ultimately be nonsurgical (such as tamoxifen for the chemoprevention of breast cancer), the role of surgical therapy remains a primary option in the prevention of cancer. It is for this reason that all surgical oncologists must be aware of those high-risk situations that require surgery to prevent subsequent malignant disease (Table 4.3).

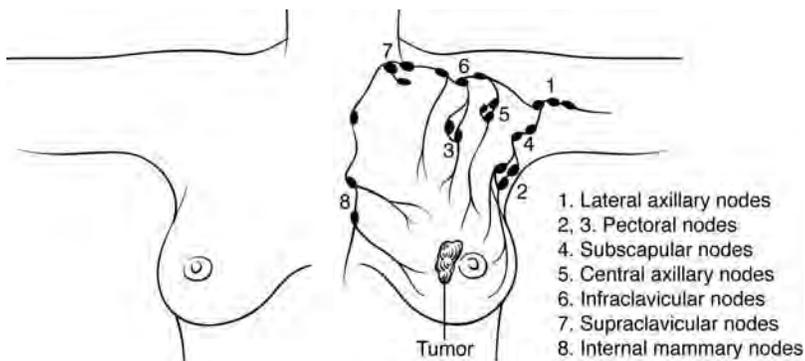

FIGURE 4.6. Schematic diagram illustrating the lymphatic drainage of the breast and sentinel lymph nodes.

TABLE 4.3. Potential indications for prophylactic organ removal.

<i>Prophylactic surgery</i>	<i>Potential indications</i>
Bilateral mastectomy (patients with no history of cancer)	BRCA1 or BRCA2 mutation Atypical hyperplasia or lobular carcinoma in situ (LCIS) Familial breast cancer
Bilateral mastectomy (patients with unilateral breast cancer)	BRCA1 or BRCA2 mutation Familial breast cancer or age of diagnosis less than 40 years History of atypical hyperplasia or LCIS followed by unilateral breast CA Difficult to evaluate contralateral breast
Bilateral oophorectomy in patients with no history of cancer	BRCA1 mutation Familial ovarian cancer Hereditary nonpolyposis colorectal cancer
Bilateral oophorectomy in addition to other abdominal cancer surgeries (postmenopausal women)	Hysterectomy for endometrial cancer Colon resection for colon cancer
Thyroidectomy	RET proto-oncogene mutation Multiple endocrine neoplasia type 2A (MEN 2A) Multiple endocrine neoplasia type 2B (MEN 2B) Familial non-MEN medullary thyroid carcinoma (FMTC)
Total proctocolectomy	Familial adenomatous polyposis (FAP) or APC mutation Ulcerative colitis Hereditary nonpolyposis colorectal carcinoma (HNPCC) germ-line mutation

Colorectal Cancer

One of the earliest examples of surgical prophylaxis is the recommendation for total proctocolectomy for subsets of patients with chronic ulcerative colitis. Patients with pancolitis, onset of disease at a young age, and a long duration of colitis are at high risk of developing colorectal cancer.³⁶ Other clinical diseases of the large intestine also illustrate the role of proctocolectomy in cancer prevention. Familial adenomatous polyposis coli (FAP) syndrome, defined by the diffuse involvement of the colon and rectum with adenomatous polyps often in the second or third decade of life, almost always predisposes to colorectal cancer if the large intestine is left in place. However, the role of screening and prophylactic proctocolectomy changed dramatically with the identification of the gene responsible for FAP, the adenomatous polyposis coli (APC) gene, located on the long arm of chromosome 5 (5q21).³⁷ Now, children of families in which an APC mutation has been identified can have genetic testing before polyps become evident. Carriers can have screening and surgical resection once polyps appear, usually in the late teens or early twenties. Although not ideal, the palatability of proctocolectomy in this population was furthered with the description of the total abdominal colectomy, mucosal proctectomy, and ileoanal pouch anastomosis.³⁸

As we identify additional syndromes and genes that carry an increased risk of colorectal cancer, the potential role of screening and prophylactic surgery also expands. Hereditary nonpolyposis colorectal carcinoma (HNPCC), or Lynch syndrome, is an autosomal dominant disorder that is estimated to be responsible for 5% to 10% of all colorectal cancers. Although the carcinomas arise from benign adenomas, HNPCC is not characterized by a large number of polyps. Two Lynch syndromes have been described. Lynch syndrome I features an early age onset of cancer, often metachronous. Lynch syndrome II involves cancers not only of the small and large intestine but also endometrial, ovarian, renal, gastric, and hepatobiliary. Although the genes responsible for HNPCC

have been identified, namely hMSH1, hMLH1, hPMS1, and hPMS2, these mutations do not have a 100% penetrance; thus, cancer will not develop in all carriers. Prophylactic surgery is recommended for some but not all carriers, but aggressive screening should be implemented and a subtotal colectomy should be performed if a cancer develops.^{39,40}

Breast Cancer

Another example of prophylactic surgery is the bilateral mastectomy for women at high risk of developing breast cancer. Before the identification of the BRCA genes, prophylactic mastectomies were typically reserved as an option for women with lobular carcinoma in situ (LCIS). However, with the identification of BRCA1 and BRCA2, the role of prophylactic mastectomies has been greatly expanded. For women with BRCA1 or BRCA2 mutations, the lifetime probability of breast cancer is between 40% and 85%.⁴¹⁻⁴³ Because mastectomy cannot remove all breast tissue, women can expect a 90% to 94% risk reduction with prophylactic surgery.⁴⁴ Schrag et al. calculated the estimated gain in life expectancy after prophylactic surgery versus no operation in women with either a BRCA1 or BRCA2 mutation and found a 30-year-old woman would be expected to gain 2.9 to 5.3 years of life, depending on her family history.⁴⁵ However, potential benefits of prophylactic mastectomy must be weighed against quality of life issues and the morbidity of the surgery.⁴⁶ In addition, other methods for prophylaxis, such as tamoxifen chemoprevention or bilateral oophorectomy, must be considered. Along with the increased risk of breast cancer with BRCA1/2 mutations, the risk of ovarian cancer is also increased. Bilateral oophorectomy after childbearing is complete not only reduces the risk of ovarian cancer⁴⁷ but may also decrease the risk of breast cancer.⁴⁸ A detailed discussion must be held with each patient considering bilateral mastectomies regarding the risks and benefits, the knowns and unknowns. It is becoming increasingly important that today's surgical oncologist have a clear understanding of genetics and inherited risk.

Medullary Thyroid Cancer

Increased genetic knowledge has also changed our approach to thyroid cancer. Medullary thyroid cancer (MTC) is a well-established component of multiple endocrine neoplasia syndrome type 2a (MEN 2a) or type 2b (MEN 2b). Previously, family members at risk for MEN 2 underwent annual screening for elevated calcitonin levels; however, this only detected MTC after it developed. In 1993 it was identified that mutations in the RET proto-oncogene were present in almost all cases of MEN 2a and 2b. Now family members of MEN patients can be screened for the presence of a RET mutation. Those without the mutation need not undergo additional screening, whereas those with the mutation should undergo total thyroidectomy at a young age (6 years for MEN 2a, infancy for MEN 2b).⁴⁹

Palliation

Surgical intervention is sometimes required in the patient with unresectable advanced cancer for palliative indications. The common indications for palliation in this setting are pain, bleeding, obstruction, malnutrition, or infection. The surgeon needs to consider several factors regarding each situation as to whether the surgical intervention will add significantly to the quality of life of the patient. These factors include the expected survival of the individual, the potential morbidity of the procedure, the likelihood that the procedure will palliate the patient, and whether there are alternative nonsurgical methods of palliation.

The acute onset of pain, bleeding, or obstruction represents a potential oncologic emergency. This topic is covered in more detail in Chapter 74 (Surgical Emergencies). Probably the most common oncologic emergency that the surgeon con-

fronts is the obstruction of a hollow viscus, which can give rise to an acute abdomen, perforation of the viscus, and possibly bleeding. The hollow viscus could be the bowel, biliary tree, endobronchial tree, ureters, or bladder. There are surgical interventions that can be employed to address these problems, and in certain instances, nonsurgical approaches with stents that are effective.

Malnutrition is a common problem in the cancer patient, especially one with advanced, unresectable disease. Nutrition can be supplemented or replaced by intravenous hyperalimentation or enteral feedings via a gastrostomy or jejunostomy tube. Commonly, the surgeon is involved in placement of vascular access for hyperalimentation. If the gastrointestinal tract is functional, the surgeon may be called upon to place a feeding tube for enteral nutrition. The nutritional support of the cancer patient as well as aspects of vascular access are reviewed in more detail in Chapters 82 and 85.

Occasionally, the surgeon is involved in palliating pain caused by a metastatic lesion compressing an organ or adjacent nerves. Examples include cutaneous or subcutaneous melanoma metastases, a large ulcerating breast cancer, or a recurrent intraabdominal sarcoma mass. As indicated previously, the surgeon needs to assess the relative risk-to-benefit ratio in resecting a symptomatic mass, knowing that it will not affect the overall survival of the patient. If the quality of life of the individual can be improved at an acceptable operative risk, then the surgical intervention is warranted.

Surgical Considerations in the Cancer Patient

There are special considerations when planning operative procedures on cancer patients beyond the normal planning done for the same operation on a nononcologic patient (Table 4.4).

TABLE 4.4. Special considerations in the cancer patient.

<i>Oncologic factors</i>	<i>Potential associated problems</i>
Tumor-specific factors:	
Gastrointestinal	Obstruction and aspiration risk; gastrointestinal bleeding; bowel perforation
Head and neck/mediastinal	Reduced oral intake; superior vena cava obstruction; airway compromise; difficulty with ventilation or intubation
Cerebral tumors/brain metastasis	Decreased mental status; syndrome of inappropriate secretion of antidiuretic hormone; increased intracerebral pressures
Paraneoplastic syndromes	Syndrome of inappropriate secretion of antidiuretic hormone; hypercalcemia
Cancer factors:	
Cachexia/malnutrition	Increased infection; fluid and electrolyte management; wound healing
Hypercoagulability	Venous thrombosis; superior vena cava syndrome; pulmonary embolism
Bone metastasis	Hypercalcemia; increased fracture risk; potential for cord compression; potential for difficulty with intubation
Treatment-specific factors:	
Steroids	Gastritis and gastrointestinal bleeding; diabetes; adrenal insufficiency; difficulties with wound healing
Chemotherapy	Neutropenia and anemia; pulmonary fibrosis; cardiac dysfunction; stomatitis; alteration in mucosal integrity of the gastrointestinal tract; constipation; bowel perforation; nausea; vomiting; diarrhea; hypercoagulability
Radiation therapy	Pulmonary fibrosis; difficulty with wound healing
Tamoxifen	Hypercoagulability

These considerations include cancer syndromes affecting nutrition, debilitated performance status, hypercoagulability, paraneoplastic syndromes, tumor-specific effects, and effects of chemotherapy or radiation therapy.

Tumor-Specific Effects

Alteration of physiologic function or distortion of normal anatomy may occur due to specific tumor effects. For example, tumors of the mediastinum or neck may cause venous congestion, superior vena cava obstruction, airway compression, or tracheal deviation that may make establishment of an airway or ventilatory management difficult. Gastrointestinal tumors may cause obstruction, causing an aspiration risk. Cerebral tumors or brain metastases can cause changes in mental status, syndrome of inappropriate secretion of antidiuretic hormone making perioperative fluid management difficult, or may cause an increased intercerebral pressure that affects anesthesia management of the patient.

Paraneoplastic Syndromes

Paraneoplastic syndromes such as hyponatremia due to inappropriate secretion of antidiuretic hormone such as seen in small cell lung cancers, prostate, pancreas, and other cancers, or hypercalcemia such as seen in squamous cell carcinomas of the lung, breast, or kidney, will alter nutritional and fluid and electrolyte management. Although mild hyponatremia can be associated with mild symptoms such as nausea and headaches, severe, acute hyponatremia can lead to more severe symptoms, even seizures or coma. Hypercalcemia is most often associated with bone metastasis, but it may be related to a paraneoplastic syndrome and can lead to neuromuscular symptoms such as weakness and fatigue and gastrointestinal symptoms such as nausea, ileus, and abdominal pain. Severe hypercalcemia can disturb cardiac conductivity. Given the tendency to malnutrition and low serum albumin in cancer patients, serum calcium levels are often best determined by measuring ionized calcium.

Malnutrition

A hallmark warning sign of cancer is unexplained weight loss. Malnutrition has long been recognized in surgery as being related to an increased risk of infection, with difficulties in perioperative electrolyte and fluid management, and with difficulties in wound healing postoperatively. A large National Veterans Affairs Surgical Risk Study identified the preoperative serum albumin level as the single most important predictor of 30-day mortality.⁵⁰ Cancer cachexia is a syndrome of malnutrition with muscle wasting, protein malnutrition with myopathy, incomplete nutrient utilization, glucose intolerance, and anemia with decreased nutrient absorption. Its causes are multifactorial. Cancer, or its treatment, can cause alterations in taste, stomatitis, dysphagia, anorexia, nausea and vomiting, alterations in intestinal tract absorptive surface area, gastroparesis, constipation, pancreatic insufficiency, or pain, fatigue, and depression, which in turn can lead to impaired oral intake. Gastrointestinal tumor with associated obstruction or head and neck tumors can interfere with, or prohibit, oral intake. In addition, tumor- or treatment-associated diarrhea, fistulas, or nephrotic syndrome can lead to

increased nutrient loss. An assessment of nutritional status can be done by assessing for a recent weight loss of 10% or more from prediagnosis weight, current caloric intake, or by measuring albumin, prealbumin serum transferrin, or cutaneous testing for anergy.

Hypercoagulability

Cancer is associated with hypercoagulability and an increased risk of venous thrombosis or pulmonary embolism. This susceptibility can be compounded by decreased mobility resulting from fatigue and diminished functional status, or by pain related to the operative procedure. Operations particularly of risk include operations of the abdomen, pelvis, hip, or leg. Surgery that is of long duration, which uses laparoscopy, or has a degree of postoperative immobilization adds additional risk. Cancer patients have twice the risk of postoperative venous thrombosis, and three times the risk of fatal pulmonary embolism, as noncancer patients undergoing the same procedure.⁵¹ Patients at a higher risk are those with a history of previous myeloproliferative disorders such as polycythemia vera and primary thrombocytosis, or a history of obesity, varicose veins, cardiac dysfunction, indwelling central venous catheters, inflammatory bowel disease, nephrotic syndrome, pregnancy, or estrogen use, or treatment with tamoxifen or chemotherapy. Treatment with tamoxifen induces hypercoagulability with an associated two- to three-fold greater risk of venous thrombosis. This risk is increased even more in women undergoing treatment with both chemotherapy and tamoxifen.^{52,53} Chemotherapy has been shown to increase the risk of thromboembolism up to 7% in early-stage breast cancer patients.^{52,54}

A history of hypercoagulable abnormalities should be ascertained, such as activated protein C resistance (factor V, Leiden); prothrombin variant 20210A; antiphospholipid antibodies (lupus anticoagulant and anticardiolipin antibody); deficiency or dysfunction of antithrombin, protein C, protein S, or heparin cofactor II; dysfibrinogenemia; decreased levels of plasminogen and plasminogen activators; heparin-induced thrombocytopenia; or hyperhomocystinemia.⁵⁵

Cancer patients older than 40 years undergoing major surgery without prophylaxis have a risk of deep venous thrombosis of 10% to 20% and a risk of fatal pulmonary embolism of 0.2% to 5.0%.¹⁰ Although most clinical trials show pneumatic compression devices to be similar in effectiveness to prophylactic doses of subcutaneous heparin, their effectiveness is directly dependent on compliance with their use, and most clinicians recognize that, in practice, pneumatic compression devices are only on the patient a portion of the time they are nonambulatory and therefore they are not as effective.⁵⁶ The sixth American College of Chest Physicians consensus conference in 2000 recommended the following: (1) oncology patients more than 40 years old undergoing major surgery, or nonmajor surgery in patients more than 60 years old, with no other risk factors, receive pneumatic compression devices or low molecular weight heparin; (2) oncology patients more than 40 years old undergoing major surgery and additional risk factors receive pneumatic compression devices and prophylactic low molecular weight heparin; and (3) low-dose coumadin for patients with central venous catheters. They did not recommend routine continuation of anticoagulation after discharge for surgical patients;

however, many clinical studies are under way regarding the efficacy of continued prolonged anticoagulation after discharge from a surgical procedure.

Chemotherapy Considerations

Agents such as adriamycin can affect cardiac function, and an assessment of functional status, a review of systems looking for decreased exercise tolerance, dyspnea, edema, orthopnea, etc., should be elicited. On physical examination, particular attention should be paid to signs of edema, tachycardia, or arrhythmias. At minimum, a 12-lead EKG should be done on any patient who has received adriamycin before undergoing a surgical procedure to look for conduction changes. An echocardiogram for an evaluation of function should be done for any symptomatic patients before any major surgical procedure in patients who have received an adriamycin-based chemotherapy. An evaluation of respiratory symptoms should be elicited in patients who have undergone radiation to the thorax or treatment with bleomycin-based chemotherapy to evaluate for pulmonary fibrosis. Treatment with corticosteroids can lead to diabetes or adrenal insufficiency requiring monitoring of glucose levels postoperatively and potential treatment with stress dose steroids and the implications for glucose control perioperatively. Treatment with steroids can also lead to gastritis and gastrointestinal bleeding or mask symptoms of peritonitis, making evaluation of abdominal pain difficult. Chemotherapy can also affect the gastrointestinal tract, with bowel perforation having been reported in patients undergoing treatment with cytosine arabinoside, taxol, and interleukin 2. In addition it should be remembered that oncology patients will still succumb to and need to be treated for the same illnesses as nononcologic patients such as cholecystitis and appendicitis; however, treatment with steroids, or immunosuppressive agents such as seen in patients after bone marrow transplantation, and the potential for neutropenic colitis in those undergoing chemotherapy can make evaluation of these more common diseases more difficult.⁵⁷

Elderly Patient

In addition, the readers are reminded that older or elderly patients will increasingly make up the population of patients with cancer. Currently 60% of all malignancies, and 70% of all cancer deaths, occur in people over the age of 65.⁵⁸ In addition to the previously mentioned considerations, assessment of the older patient should include evaluation of activities of daily living, depression, cognitive function, current medications and potential medication interactions, and available social support.⁵⁹⁻⁶²

Clinical Trials: Role of the Surgical Oncologist

At the very heart of evidence-based medicine, and nowhere is this truer than in oncology, are clinical trials. Although the early trials initiated by the National Cancer Institute (NCI) in the mid-1970s primarily considered nonsurgical issues (leukemia, lymphoma, stage IV disease), surgeons quickly became involved in significant roles in clinical oncology trials, such as the National Surgical Adjuvant Breast Project (NSABP), which has answered, and continues to

answer, many important questions regarding the optimal surgical and adjuvant therapy of breast and colon cancer. Today, most cooperative groups include surgery committees to address ongoing questions regarding the surgical management of a variety of malignancies. The prominent role of surgery in the design and implementation of clinical oncology trials is best exemplified by the establishment of the American College of Surgeons Oncology Group (ACOSOG) to evaluate the surgical management of patients with malignant solid tumors. Created in May 1998 under the leadership of Dr. Samuel Wells, the ACOSOG is 1 of 10 cooperative groups funded by the NCI to develop and coordinate multiinstitutional clinical trials.

As surgical oncologists, our obligation is not only to the patient who is sitting before us in the office, but to the progression of patients who will follow. The improved success and decreased morbidity of the treatments that we offer today are only possible because of the involvement of surgeons and their patients in clinical trials of the past. As the newest discoveries in all fields of oncology will have a direct impact on the surgical therapy, it is imperative that surgeons continue to play prominent roles as both leaders and participants in multidisciplinary cooperative group trials. All surgical oncologists should not only incorporate clinical trials into their practice but strongly encourage the participation of the general surgical community.

Principles of Targeted and Biological Therapies

Stephen R.D. Johnston, Sue Chua,
and Charles Swanton

Development of Targeted Therapies

One of the characteristics of the malignant phenotype is the ability of cells to grow in an autonomous manner. Various components of the proliferative and/or survival signaling pathways can become constitutively activated or deregulated in human cancers.¹ Many studies have attempted to show that a given molecular change is the key event involved in the pathogenesis of a specific cancer. Such information may not only provide a better understanding of cancer but may allow a novel target to be identified for therapeutic intervention.

With our ever-increasing understanding of the pathogenesis of cancer, there are now a plethora of potential molecular targets in human cancer cells that are being utilized for the development of novel anticancer therapies (Table 5.1). Perhaps the oldest and most established targeted therapy is endocrine treatment for breast and prostate cancer, taking advantage of the estrogen receptor (ER) and androgen receptor (AR) that can readily be detected in many breast and prostate carcinomas, respectively. More recently, peptide growth factor receptors (EGFR and HER2) have become viable targets in human solid epithelial tumors such as lung, head and neck, breast, and colon cancer. The unraveling of the signal transduction cascade within cells has resulted in various small molecule signal transduction inhibitors (STIs) entering clinical development, whereas the complex protein interactions that regulate the cell cycle may allow various modulators to be developed to restore cell-cycle control in aberrantly behaving malignant cells. Likewise the ability to effectively trigger programmed cell death (apoptosis) in cancer cells adapted to prolonged survival is a promising new approach for the future. Finally, the capacity for malignant cells to acquire a blood supply is a key event in the growth of human tumors, and drugs are being developed that target either the endothelial cell or the vascular growth factor pathways. The principles and current status of targeted therapies in each of these six areas are reviewed in this chapter. However, a common theme to all these approaches is the need to confirm that a given molecular target is specifically involved in the pathogenesis of that cancer, to develop an assay to reliably detect the target in tumors, and to show that interrupting its function gives the desired anticancer effect.

Target Identification

Some of the problems of target identification in cancer are illustrated by considering kinases, regulatory enzymes that are integral to most signaling events inside cells. In cancer, these may be either pivotal or permissive for the pathogenesis of the malignant phenotype.² Pivotal kinases are often critical to tumor growth and maintenance and may be subject to activation by mutation, gene amplification, or translocation (i.e., p210BCR-ABL in chronic myeloid leukemia), whereas permissive kinases are not mutated or amplified but still may have a role in signal transduction pathways important in neoplastic growth. One of the challenges has been to identify pivotal kinases for anticancer drug development and to select patients with aberrations in these critical signaling pathways for inclusion in early clinical trials. To do this, robust biologic assays are required that will readily identify potential targets in cancer cells.

High-throughput screening using cDNA microarrays and techniques such as comparative genomic hybridization have been extensively employed to analyze gene expression in human tumors, thereby identifying novel targets for therapeutic drug development.³ Target identification and validation have been supported by tissue microarray profiling that allows the analysis of DNA, RNA, or protein levels in thousands of tumor specimens at a time to identify the frequency of molecular alterations in a population of patients with a given cancer type. In future, complex proteomic techniques using mass spectrometry will allow the identification of potential protein drug targets that are differentially expressed between tumor and normal tissue. Preclinical studies are important to determine what a gene product-protein target does in the cell, and moreover what the consequences are of inhibiting its expression or function, respectively. The technique of synthetic short interfering RNAs (siRNA) that lead to the degradation of complementary mRNA, thereby silencing gene expression, is a helpful new tool in analyzing the functional significance of certain gene products. Similarly, high-throughput screens using siRNAs in mammalian cells are in progress to identify molecular regulators that are involved in the acquisition of the malignant phenotype and also in the development of drug resistance.

TABLE 5.1. Targets for the development of novel anticancer therapies.

<i>Molecular target</i>	<i>Anticancer therapeutic strategy</i>	<i>Tumor type and stage of clinical development</i>
Steroid hormone receptor		
ER	Anti-estrogen (tamoxifen, fulvestrant),	Approved breast
AR	Aromatase inhibitor, LHRH agonist	Approved prostate
	Antiandrogen (flutamide), LHRH agonist	
Growth factor receptor		
EGFR	MoAb (cetuximab)	Approved colon; Phs III H&N, NSCLC.
	TKI (gefitinib, erlotinib)	Approved NSCLC; Phs III breast
	MoAb (trastuzumab)	Approved Breast
HER2	TKI (lapatinib, canertinib)	Phs III breast, renal
Oncogenic kinase		
BCR-ABL	TKI (imatinib)	Approved CML, GIST
Signal transduction pathway		
Ras	FTIs (tipifarnib, lonafarnib)	Phs III MDS, CML, breast, NSCLC
Raf	B-RAF Kinase Inhib (BAY43-9006)	Phs II Melanoma
MEK	MEK Kinase Inhib (PD0325901)	Phs I
m-TOR	mTOR Antag (temsirolimus, everolimus)	Phs III breast, renal
Cell cycle		
Cdk2	CDKI (flavopiridol, UCN-01, E7070)	Phs I
Proteasome	Proteasome Inhib (bortezomib)	Approved Myeloma
Histone deacetylase	HDACI (FR901228, MS-27-275)	Phs I
Apoptosis regulators		
TRAIL	MoAb	Phs I
Bcl-2	Antisense (G3139)	Phs II NHL
P53	P53 (ONXY-015, INGN201, Nutlin)	Phs II H&N, phs I
Caspase XIAP, FLIP	Sphingosine kinase (phenoxodiol)	Phs II breast, prostate
Angiogenesis		
Endothelial cell	Endo Inhib (thalidomide, TNP-740)	Phs II renal, H&N
VEGF	Endostatin, angiostatin Antisense (angiozyme) MoAb (bevacizumab)	Phs I
	TKI (SU11248, PTK787) MoAb (2C7)	Phs I
VEGF-R	Integrin Inhib (cilengitide) MMPI (marimastat, BAY12-9566)	Approved Colon, phs II H&N
Integrins		Phs I
		Phs I
		Phs I
		Phs III NSCLC, gastric

Approach to Targeting

Pharmacologic or biologic methods are usually employed in preclinical studies to establish the effect of altering the expression of the target gene or of interfering with the function of the target protein. Most approaches have utilized either small molecule inhibitors (often detected in screening assays) or monoclonal antibodies (MAbs) to interfere with the function of the target protein. In general, small molecule inhibitors have a short half-life and are orally delivered on a continuous long-term basis. However, side effects can be common and potentially troublesome, especially if there is a broader substrate for related cellular proteins/kinases. By contrast, MAbs have a longer half-life with a more acceptable toxicity profile, although they require regular intravenous administration. Monoclonal antibodies usually target surface receptors and may also lead to receptor downregulation, although there is the additional theoretical potential for direct tumor cell cytotoxicity via complement and antibody (antibody-mediated cellular cytotoxicity, ADCC). Side effects may relate to hypersensitivity reactions, with the potential

also to develop human antimono-clonal antibodies (HAMAs) that may limit effectiveness. Other approaches to targeting include the use of antisense technology to inhibit target messenger RNA that is transcribed from a given gene, although a key limiting factor is appropriate delivery of nucleic acids to the tumor cell. The use of viral vectors in targeted therapy approaches to modify/replace or inhibit target genes has therefore attracted much attention, and this method has been used to replace or stabilize key tumor suppressor proteins that may regulate cell survival and apoptosis.

Targeted Therapies

Hormone Receptor-Targeted Therapies

Targeting hormonal growth pathways has been an effective strategy in the management of various tumors such as breast, prostate, and endometrial cancers. Early approaches were directed at surgical ablation of the glands supplying these

hormonal stimuli (i.e., ovariectomy for breast cancer and orchiectomy for prostate cancer), but over the past 30 years a large number of medical agents have become available based on an increasing understanding of molecular endocrinology.

BREAST CANCER

Medical endocrine strategies in breast cancer are designed to counteract the proliferative effects of estrogen in ER-positive breast cancer, either with drugs that compete with estrogen for ER and block its effect (i.e., antiestrogens), or strategies that induce estrogen deprivation and remove the proliferative signal [i.e., oophorectomy or gonadotropin-releasing hormone (GnRH) agonists in premenopausal women, and aromatase inhibitors in postmenopausal women]. Tamoxifen is a non-steroidal estrogen receptor (ER) antagonist that inhibits breast cancer growth by competitive antagonism of ER, although its actions are complex as a result of partial estrogenic agonist effects, which in some tissues (i.e., bone) can be beneficial but which in others may be harmful, increasing the risk of uterine cancer and thromboembolism. Oral aromatase inhibitors prevent conversion of adrenal androgens (androstenedione and testosterone) into estradiol (E_1) and estrone (E_2) by the cytochrome P-450 enzyme aromatase. Alternative endocrine approaches are also being developed, including steroidal antiestrogens that selectively downregulate expression of ER.⁴

PROSTATE CANCER

Normal prostate cells and tumor cells are sensitive to androgens, which are produced by two major sources: the testicles, which produce testosterone (95% of all androgens), and the adrenal glands, which produce dehydroandrosterone, dehydroandrosterone sulfate, and androstenedione. Both are under the influence of luteinizing hormone (LH), which in turn is controlled by GnRH produced by the hypothalamus. Testosterone levels have a negative feedback effect on GnRH release from the hypothalamus. Targeted endocrine medical treatment of prostate cancers aims to decrease the activity of androgens on the AR, either with antiandrogens (i.e., non-steroidal agents such as flutamide, bicalutamide) that competitively block dihydrotestosterone (DHT) binding to AR, and subsequent activation of AR-regulated genes, or by suppression of LH secretion (i.e., using specific LH agonists that ultimately inhibit LH secretion, thus reducing androgen production).

Growth Factor Receptor-Targeted Therapies

In human cancer cells, aberrant signaling through the epidermal growth factor receptor (EGFR) has been associated with neoplastic cell proliferation, resistance to apoptosis, migration and stromal invasion, and enhanced angiogenesis. The EGFR (or ErbB-1) is part of a subfamily of four closely related receptors that include HER-2/*neu* (ErbB-2), HER-3 (ErbB-3), and HER-4 (ErbB-4).⁵ These receptors exist as inactive transmembrane monomers in cells, and dimerize after ligand activation either by homo- or heterodimerization between EGFR and another member of the ErbB receptor family. This dimerization results in activation of the intracellular tyrosine kinase domain through autophosphorylation, which in turn

initiates a cascade of downstream signaling pathways that include Ras and mitogen-activated protein kinase (MAPK). In cancer cells, various mechanisms for activation of EGFR or related ErbB pathways include receptor overexpression (e.g., as a result of gene amplification in the case of HER-2), receptor mutation (e.g., truncated EGFR that lacks the extracellular domain but has a constitutively activated tyrosine kinase domain that functions independent of ligand), increased autocrine or paracrine expression of the various receptor ligands [e.g., transforming growth factor- α (TGF- α), amphiregulin, heparin-binding EGF], or decreased receptor turnover.

Studies have shown that EGFR or HER-2 overexpression in cancer is often associated with a poorer prognosis and resistance to conventional therapies including hormonal therapy, cytotoxic drugs, and radiotherapy.⁶ Consequently, EGFR and related receptors represent an attractive target for the development of novel cancer therapeutics. The two most promising approaches have been MAb against the extracellular ligand-binding domain of the receptor and small molecule inhibitors of the receptor intracellular tyrosine kinase enzymatic activity (TKIs).

INHIBITION OF EXTRACELLULAR DOMAIN GROWTH FACTOR RECEPTOR: MONOCLONAL ANTIBODIES

Cetuximab (C225 or Erbitux) is a chimeric antibody that binds to EGFR, inhibiting downstream signaling and promoting receptor internalization, and significant growth inhibition has been observed in a variety of human cancer xenograft models.⁶ Additive effects were seen when cetuximab was combined with various cytotoxic agents and with ionizing radiation. The clinical development has focused on selecting patients with EGFR-overexpressing tumors, and Phase II/III trials have been conducted in head and neck cancer,⁷ colorectal cancer,⁸ and advanced non-small cell lung cancer⁹ (Table 5.2). These latter studies have investigated whether addition of cetuximab can enhance the activity of conventional therapies for these tumor types. Recent data demonstrate that cetuximab, in addition to irinotecan in patients with irinotecan-refractory metastatic colorectal cancer, improves median survival and time to progression.⁸

HER2 gene amplification occurs in 25% to 30% of breast tumors and contributes to cell growth and malignant transformation, rendering tumors more resistant to both endocrine and conventional chemotherapies.¹⁰ Trastuzumab (Herceptin) is a humanized MAb directed against HER2 and, when administered as a weekly intravenous infusion, gave clinical response rates of 35% as first-line therapy for patients with HER2+ve metastatic breast cancer.¹¹ One of the central principles is the appropriate selection of patients with HER2+ve tumors, and validated assays have been developed to identify either HER2 overexpression by immunohistochemistry or HER2 gene amplification by fluorescence in situ hybridization (FISH). The addition of trastuzumab to taxane- or anthracycline-based chemotherapy enhanced both objective response and time to disease progression, which in turn significantly improved overall survival in advanced breast cancer (median, 25 versus 20 months, $P < 0.046$).¹² As such, this represented one of the first examples of modern targeted therapies successfully modifying disease outcome.

INHIBITION OF INTRACELLULAR SIGNALING: TYROSINE KINASE INHIBITORS

IMATINIB MESYLATE (STI-571 OR GLIVEC)

When growth factor receptors are bound by their natural ligand, they undergo dimerization with subsequent activation of receptor tyrosine kinase activity, which in turn phosphorylates downstream signal transduction cascades. Small molecule tyrosine kinase inhibitors (TKIs) specifically target the receptor's internal tyrosine kinase domain. The first to prove effective in the clinic was imatinib mesylate (STI-571 or Gleevec), which targets a small family of tyrosine kinases including ABL, Kit, and platelet-derived growth factor receptor (PDGF), as well as certain oncogenic mutants of these proteins such as the *bcr-abl* oncogene found in chronic myeloid leukemia.¹³ The success of this therapy relates to the dominant role that these pivotal kinases play in the pathogenesis of certain tumors; that is, 90% of gastrointestinal stromal tumors (GIST) exhibit aberrant signal transduction through KIT, primarily through activating point mutations in exon 11 that encodes the intracellular region of the protein, with evidence that KIT activation is an early tumorigenic event in most GIST tumors.¹⁴ KIT mutations were a strong predictor of response to imatinib in early clinical trials and produced significantly prolonged survival.¹⁵ The high level of efficacy appeared independent of tumor bulk and failure of prior chemotherapy, with objective responses in 54% of patients and stable disease in an additional 28% to 37%.^{16,17} This molecularly targeted therapy has transformed the management of this previously intractable disease.

GEFITINIB (IRESSA)

Several small molecule inhibitors of EGFR tyrosine kinase are in development, including the synthetic anilinoquinazoline gefitinib (Iressa), which is an orally active, potent, and selective inhibitor of EGFR-TK. In experimental models gefitinib induced dose-dependent antiproliferative effects that delayed tumor growth.¹⁸ The effects appeared mainly cytostatic, and additional studies suggested that, when given in combination with cytotoxic drugs, gefitinib could enhance their antitumor activity.¹⁹ This interaction did not always appear to be dependent on overexpression of EGFR, and the mechanism for any enhanced cytotoxic effect remains unclear.

Evidence of efficacy in Phase II non-small cell lung cancer (NSCLC) studies led to the accelerated approval for gefitinib by the U.S. Food and Drug Administration (FDA) for the treatment of NSCLC in patients previously treated with chemotherapy^{20,21} (Table 5.3). However, two Phase III randomized trials, INTACT-1 and INTACT-2 (Table 5.4), that compared platinum-based chemotherapy and gefitinib to chemotherapy alone in chemotherapy-naïve NSCLC patients, failed to demonstrate a survival advantage for the addition of targeted therapy, despite the preclinical evidence for an additive benefit for gefitinib-chemotherapy combinations.²² Several theories have been proposed to explain the failure of these trials, including the possibility that cytostatic effects of targeted therapy may abrogate the cytotoxic effects of cycle-dependent chemotherapy. Unlike the trastuzumab studies, where patients were selected based on HER2 status, there were insufficient data at the time to predict which biologic markers may correlate with response to gefitinib. This failing may have severely reduced the chance of success in the Phase III setting, which contained patients with a heterogeneous selection of tumor phenotypes.

Clinical trials have been undertaken with gefitinib in other tumor types, including breast cancer. There have been three Phase II monotherapy studies of gefitinib in patients with advanced breast cancer.^{23–25} Overall, the data are relatively disappointing with low clinical response rates. The only trial to report a significant number of responses included patients with ER+ve tamoxifen-resistant breast cancer,²⁵ the setting in which preclinical models had shown evidence of

activity for gefitinib.²⁶ More research is required to establish tumor phenotypes in responding versus nonresponding patients.²⁷

ERLOTINIB (TARCEVA)

Erlotinib is an ErbB1 TKI that binds reversibly to the adenosine triphosphate (ATP) hydrophobic pocket. Table 5.3 summarizes data from recent Phase II trials in advanced NSCLC with erlotinib. A Phase II study in 56 patients with EGFR-positive NSCLC refractory to platinum-based therapy gave a response rate of 11% for erlotinib 150mg/day.²⁸ Results of Phase III combination studies of erlotinib with carboplatin and paclitaxel (TRIBUTE) or gemcitabine and cisplatin (TALENT) in NSCLC demonstrated no significant survival benefit or differences in time to progression.^{29,30} However, the NCI Canadian BR21 placebo-controlled Phase III trial of erlotinib in NSCLC patients failing one or two prior chemotherapy regimens demonstrated prolonged survival in the erlotinib arm (6.7 versus 4.7 months).³¹ Ongoing trials are investigating the activity for the combination of two targeted therapies in NSCLC, erlotinib and the VEGF antibody bevacizumab (avastin). Phase II data in other tumor types have revealed response rates in pretreated patients with ovary and head and neck tumors between 11% and 13%, although Phase II monotherapy trials in breast cancer have been relatively

disappointing.³² Important activity in previously treated glioblastoma multiforme was demonstrated in a Phase II study (with 8 of 49 patients achieving a partial response).

CANERTINIB DIHYDROCHLORIDE (CI-1033); LAPATINIB (GW 572016)

Canertinib dihydrochloride (CI-1033) is a selective and irreversible pan-erbB inhibitor. Activity has been demonstrated in Phase I studies with an acceptable side-effect profile, and Phase II studies are under way in breast and renal cancer.³³ Lapatinib (GW 572016) is a dual inhibitor of EGFR and HER2³⁴ that has shown responses in trastuzumab-resistant breast cancer patients.³⁵ Further studies of lapatinib in combination with either endocrine or cytotoxic therapy are ongoing in breast cancer.

Signal Transduction-Targeted Therapies

Elucidation of the signal transduction cascade downstream from growth factors and membrane receptor tyrosine kinases has revealed several key proteins involved in this malignant transformation, including the guanine nucleotide-binding proteins encoded by the *ras* proto-oncogene (Figure 5.1). Following posttranslational processing and addition of a hydrophobic 15-carbon farnesyl moiety, Ras is localized to the

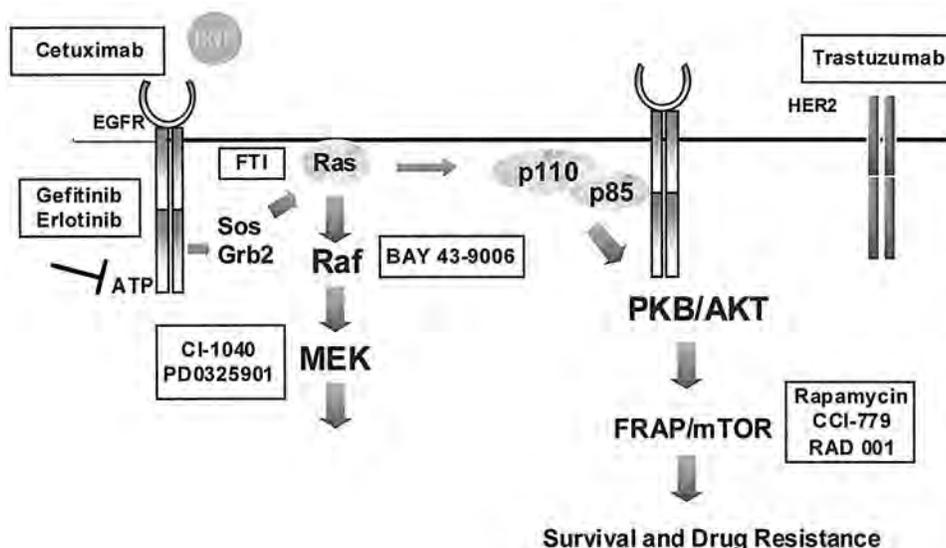

FIGURE 5.1. The signal transduction inhibitors.

inner plasma membrane and acts as a molecular switch that plays a crucial role in linking tyrosine kinase activation at the cell membrane to downstream cytoplasmic and nuclear targets, ultimately resulting in cell differentiation, proliferation, and survival.³⁶ Farnesylation has attracted attention because of its critical role for Ras signaling,³⁷ and farnesyl transferase inhibitors (FTIs) were initially developed as a novel therapy to target aberrant Ras function in cancer.

FARNESYLTRANSFERASE INHIBITORS

As farnesyltransferase inhibitors (FTIs) have been developed and entered clinical trials, a fundamental research goal has been to understand their exact mechanism of action. Although FTIs clearly inhibit Ras farnesylation, it is unclear whether the antiproliferative effects of these compounds result exclusively from their effects on Ras alone. Other targets for FTIs include RhoB, a 21-kDa protein that regulates receptor trafficking and cell motility, and two centromere-associated proteins (CENP-E and CENP-F) that play a role in attaching centromeres to microtubules in early G₂ phase.³⁸

The FTI lonafarnib (SCH66336 or sarasar) is a tricyclic compound that inhibits the growth of several tumor cell lines as well as *K-ras*-transformed xenografts *in vivo*.³⁹ In human xenograft studies a wide variety of tumors including colon, bladder, lung, prostate, and pancreas were growth inhibited in a dose-dependent manner, while prophylactic administration of SCH66336 delayed both tumor onset and growth.⁴⁰ In patients with solid tumors, efficacy has been reported in early Phase I clinical studies in a variety of tumor types including lung and head and neck cancer,⁴¹ and confirmation of biologic efficacy has been demonstrated by inhibition of prenylation of prelamin A in buccal mucosa cells in treated patients⁴² (Table 5.5). Based on promising preclinical evidence that

lonafarnib may synergize with taxane-based chemotherapy,⁴³ randomized Phase II/III trials were initiated in NSCLC to investigate whether lonafarnib could further enhance the efficacy of standard taxane platinum-based chemotherapy. Tipifarnib (R115777 or zarnebra) is an imidazole-containing heterocyclic compound that is a potent and selective, orally active, nonpeptidomimetic inhibitor of the farnesyl protein transferase (FPTase) enzyme.⁴⁴ There is considerable evidence that tipifarnib may have promising activity in hematologic malignancies, in particular, newly diagnosed acute myelogenous leukemia (AML) and myelodysplasia (MDS)^{45,46} (see Table 5.5).

In view of the higher incidence of Ras mutations in gastrointestinal malignancies, two randomized double-blind placebo-controlled Phase III trials of tipifarnib were conducted in colorectal and pancreatic cancer. There was no significant improvement in overall survival versus best supportive care for tipifarnib as monotherapy in advanced refractory colorectal cancer,⁴⁷ or for gemcitabine plus tipifarnib versus gemcitabine plus placebo in 688 patients with advanced pancreatic cancer.⁴⁸ Although several Phase I studies have assessed combinations of FTIs with various cytotoxic agents, it remains unclear whether they will significantly enhance the efficacy of standard cytotoxic regimens. Several issues have arisen, including competing toxicities (i.e., myelosuppression) and uncertainty on the optimal sequence/schedule for FTI-chemotherapy combinations. There may be more promise for combining FTIs with noncytotoxic therapies. In breast cancer, preclinical data have shown additive or synergistic interactions of FTIs with endocrine therapy,⁴⁹ and in view of this, randomized Phase II studies of both tipifarnib and lonafarnib with letrozole are in progress. Evidence has also emerged that FTIs may be radiosensitizers in selected cancer cell lines, and Phase I trials have investigated the feasibility of this combined modality in

TABLE 5.5. FTI Phase I/II clinical trials.

Drug	Author	Dose range	Schedule	No. patients (pts)	Dose-limiting toxicities	Clinical/biological activity
SCH 66336 Lonafarnib	Adjei et al. ⁵¹ Solid tumors	25–400 mg bid	7 days oral (q21)	20	Nausea, vomiting, diarrhea	Inhibition of prelamin A farnesylation in buccal mucosal cells; PR in 1 pt with non-small cell lung Ca; 8 pts stable for 5–10 cycles
	Eskens et al. ⁵⁰ Head and neck cancer Lung cancer	25–300 mg bid	Continuous oral	24	Neutropenia, thrombocytopenia, vomiting, confusion	Stable disease lasting >9 months in 2 pts (thyroid Ca, pseudomyxoma peritonei)

both lung and head and neck cancer. The true role for FTIs in cancer therapy thus remains to be determined.

M-TOR INHIBITORS: TARGETING THE PI3K/AKT PATHWAY

The mammalian target of rapamycin (mTOR) is a downstream effector of the phosphatidylinositol 3-kinase (PI3-K)/Akt (protein kinase B) signaling pathway that mediates cell survival, proliferation, and drug resistance (see Figure 5.1). The immunosuppressant rapamycin, together with the analogues CCI-779 (temsirolimus) and RAD-001 (everolimus), are specific inhibitors of mTOR that act by binding to the immunophilin FK506, thus blocking the action of p70S6 kinase and 4E-binding protein 1, which regulate transition through the G₁ phase of the cell cycle. In preclinical experiments, cell lines from breast, prostate, small cell lung cancer, melanoma, T-cell leukemia, and glioblastoma were especially sensitive to CCI-779.⁵⁰ In particular, breast cancer and prostate cell lines that had a constitutively activated PI3-K/Akt pathway due to either upstream HER2 overexpression, loss of the PTEN suppressor gene, or Akt overexpression were markedly more sensitive to CCI-779 than resistant lines that lacked these features.⁵¹

CCI-779 has an acceptable toxicity profile in Phase I studies with reports of neutropenia, rash, fever, hypertriglyceridemia, mucositis, and fatigue as the main toxicities, with clinical activity seen in patients with NSCLC, breast, and renal cell carcinoma.⁵² Phase II studies in patients with advanced renal cell carcinoma demonstrated that CCI-779 was well tolerated with objective response rates of 7%, minor responses of 29%, and disease stabilized in 40% of patients.⁵³ This trial precipitated a randomized Phase III study comparing CCI-779 with interferon-alpha or the combination in poor prognosis renal cell carcinoma. Single-agent activity has also been documented in locally advanced or metastatic breast cancer in patients who have failed prior anthracyclines or taxanes.⁵⁴ Phase I studies of RAD-001 have demonstrated a similar toxicity profile to CCI-779.⁵⁵

RAF KINASE INHIBITORS: BAY 43-9006

RAF kinase is a critical signaling molecule downstream of RAS (see Figure 5.1). Activating mutations in BRAF (a RAF family member) occur in two-thirds of melanomas and at lower frequencies in other cancers.⁵⁶ Promising Phase I data with the orally active RAF kinase inhibitor BAY 43-9006 in combination with chemotherapy have been reported, with stable disease for at least 12 weeks in 38 of 115 (33%) patients. Toxicities included skin rash, hand-foot syndrome, diarrhea, and fatigue. Phase II trials are in progress in melanoma with continuous monotherapy dosing of 400 mg bid,⁵⁷ and in combination with carboplatin and paclitaxel.⁵⁸

INTERVENTION OF THE MAPK PATHWAY BY TARGETING MEK: CI-1040 AND PD0325901

CI-1040 inhibits MEK allosterically at micromolar concentrations and is administered orally, thereby preventing activation of MAPK. The lack of sequence homology of the drug interaction site with other kinases increases the specificity of this small molecule inhibitor. CI-1040 is well tolerated in Phase I trials, with 98% of adverse events being only of grade 1 or 2 in severity (diarrhea, fatigue, rash, and vomiting).⁵⁹ Dis-

appointing Phase II results were seen in patients with breast, lung, colon, and pancreatic carcinoma.⁶⁰ CI-1040 was limited by poor solubility, high metabolic clearance, and low bioavailability and was unable to consistently lead to more than 90% inhibition of the target in biopsied tumors. This result precipitated the development of PD0325901, a second-generation non-ATP-competitive allosteric MEK inhibitor. Preclinical studies have demonstrated promising activity with greater solubility, improved metabolic stability and bioavailability, and longer duration of MEK inhibition than its parent compound, and clinical trials are in progress.

Cell-Cycle-Targeted Therapies

The cell cycle is regulated by a number of key proteins that appear to be frequently inactivated or aberrantly expressed in human cancer. The cyclin D and E family of proteins, together with their cyclin-dependent kinase (cdk) partners (cdk4 and -6) phosphorylate the retinoblastoma (Rb) tumor suppressor protein, which regulates G₁/S transition and commitment to cell-cycle transition (Figure 5.2). Cyclin/cdk activity is restrained by cdk inhibitors (CKIs) of the p16^{ink4a} and the p21^{cip1} family of proteins. The appropriate interaction of the cyclin/cdk families and the CKIs regulate the cell-cycle checkpoints at the G₁/S and G₂/M transitions, ensuring faithful chromosome replication and separation to preserve genetic stability. Failure of these checkpoints to arrest cells in response to certain stimuli is characteristic of cancer cells and is due to the frequent genetic aberration in expression and function of cell-cycle regulatory proteins in transformed cells.

The greater understanding of the cell cycle has led to the development of a number of compounds that might restore the control of cell division in cancer cells. In particular, two strategies are now being explored in the clinic. First, compounds have been developed to mimic the action of CKIs by interfering with action of the cdk molecules.⁶¹ Second, pharmacologic agents have been developed to target the proteasome or histone deacetylases, thereby interfering with the degradation and expression of key molecules that regulate the cell-cycle checkpoint.

CDK INHIBITORS

FLAVOPIRIDOL

Flavopiridol targets the ATP-binding pocket of cdk2 and arrest cells at either the G₁/S or G₂/M checkpoints and may inhibit other cdk's including cdk1, cdk7, and cdk9. The initial Phase I trial explored a 72-hour continuous infusion of flavopiridol, but dose-limiting toxicities included secretory diarrhea and symptomatic hypotension⁶² (Table 5.6). In three separate phase II studies with this schedule, objective tumor responses were rare, although disease stabilization was seen in a number of patients.⁶³⁻⁶⁵ Previous preclinical studies had shown synergy and induction of apoptosis when flavopiridol was combined with standard cytotoxic therapies,⁶⁶ and clinical activity using combination therapy has been seen in patients previously resistant to the given cytotoxic drug alone.^{67,68} Preclinical evidence of synergism with paclitaxel therapy followed by flavopiridol in animal models further supported clinical studies of this combination,⁶⁹ and Phase I combination studies have demonstrated promising activity in lung, esophagus, and prostate cancer.⁷⁰ Thus, although cdk

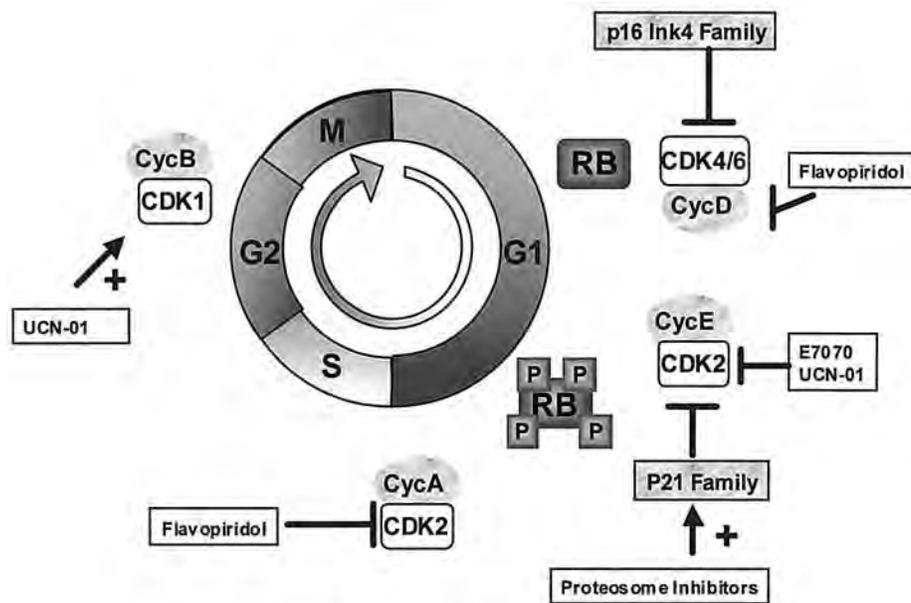

FIGURE 5.2. Cell-cycle-targeted therapies.

inhibitors alone may only have a cytostatic effect, combined therapy may prove more promising in enhancing their anti-cancer mode of action.

UCN-01

UCN-01 is a cell-cycle modulator with a number of complex effects resulting in both G₁/S arrest and aberrant entry into M phase. These cell-cycle kinetics are associated with an increased p27^{kip2}-cdk2 interaction, Rb hypophosphorylation, and cdk1 activation due to chk1 inhibition. Phase I trials examined a 72-hour continuous infusion schedule, with dose-limiting toxicities that included nausea, hypotension, hyper-

glycemia, and pulmonary toxicity, and evidence for activity was seen in two patients with melanoma and lymphoma.

E7070

E7070 is a novel sulphonamide compound that inhibits the activation of cyclin E-cdk2 complexes and in vitro has demonstrated activity against both colon and lung cancer xenografts. A number of Phase I studies have investigated different schedules. The main dose-limiting toxicity has been myelosuppression; alopecia, stomatitis, and diarrhea have also been reported.^{71,72} Tumor stabilizations were seen in some of these studies, but documented tumor regressions

were rare in phase II monotherapy trials conducted in non-small cell lung cancer⁷³ and in colorectal cancer⁷⁴ with E7070.

PROTEOSOME INHIBITORS

Protein concentrations within the cell may be altered by post-translational modification leading to polyubiquitination followed by proteasome-mediated degradation. Prevention of ubiquitination and proteasome-mediated degradation of cell-cycle proteins has been explored as a novel targeted anticancer therapy.⁷⁵ Bortezomib (PS-341 or velcade) is a potent and selective proteasome inhibitor that prevents the degradation of the CKIs p21 and p27. In addition, key apoptosis-related proteins are degraded by the proteasome such as I κ B, an inhibitor of the transcription factor NF κ B that regulates various apoptotic processes.

In 2003, the FDA approved the use of bortezomib in patients with multiple myeloma who have received two previous lines of treatment, partly due to the results of a large multicenter phase II trial in 202 patients with relapsed refractory multiple myeloma that demonstrated a 35% response rate with a median survival of 17.8 months.^{76,77} A phase III trial comparing bortezomib with high-dose oral dexamethasone in relapsed or refractory multiple myeloma was terminated prematurely following the recommendation of an independent data monitoring committee to allow patients receiving high-dose dexamethasone to choose bortezomib therapy. Combination studies with cytotoxic agents are also under way, with promising activity already demonstrated.⁷⁷

HISTONE DEACETYLASE (HDAC) INHIBITORS

Inside the nucleus of cells, histone acetylation–deacetylation modifies the chromatin structure and association between DNA and nucleosomes, thus modulating access for nuclear transcription factors such as E₂F that are involved in initiating transcription of genes essential for S-phase entry.

Inhibitors of histone deacetylase result in G₁ cell-cycle arrest and cell differentiation and appear to have anticancer effects including induction of apoptosis in transformed cells⁷⁹ and enhanced expression of the cdk inhibitor p21.⁸⁰ Two compounds have entered early clinical trials, depsipeptide (FR901228) and the synthetic benzamide derivative MS-27-275.

Apoptosis-Targeted Therapies

Apoptosis, or programmed cell death, in normal human tissues has an essential role in controlling overall cell number. In many human tumors apoptosis is impaired, contributing to cellular transformation. Triggering of apoptosis is determined by the ratio of pro- and antiapoptotic proteins, in particular, members of the Bcl2 family, the intracellular antiapoptotic proteins (IAPs), tumor necrosis factor (TNF)-related apoptosis-inducing ligand (TRAIL), and the caspase family. Although cytotoxic chemotherapy drugs can induce apoptosis in malignant cells, resistance to chemotherapy may in some instances relate to alteration in the molecular pathways that regulate apoptosis.

There are two major apoptotic pathways that can be triggered in cells: the extrinsic death-receptor-induced extrinsic pathway, and the intrinsic mitochondrial apoptosome-mediated pathway (Figure 5.3). The extrinsic pathway is regulated by members of the TNF superfamily, FASL (FAS ligand), TNF, and TRAIL. These “death receptors” signal through the “death-inducing signaling complex” (DISC), leading to caspase activation and apoptosis. The intrinsic mitochondrial apoptosome pathway is controlled by members of the Bcl2 family. The proapoptotic members of this family (e.g., BAX, BAK, BIM, and BID) precipitate the release of cytochrome *c* from mitochondria, which promotes the formation of the apoptosome (cytochrome *c*/APAF1/caspase 9) complex. Members of the Bcl2 family that inhibit the cytochrome *c* pathway include

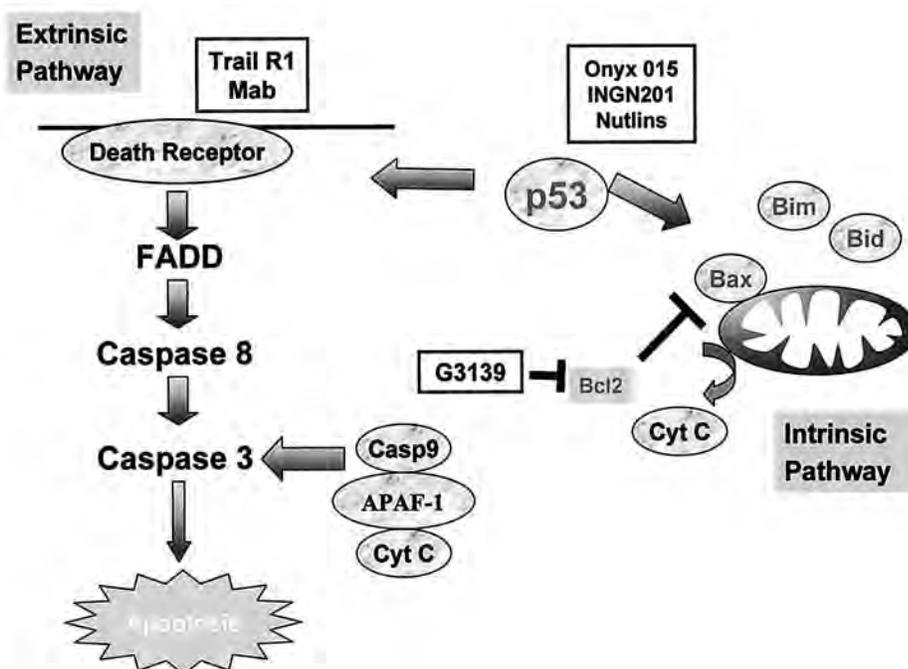

FIGURE 5.3. Apoptosis-targeted therapies.

Bcl2 itself, Bclxl, and Bclw. P53 can regulate both the intrinsic pathway by promoting the transcription of BAX and the extrinsic pathway through upregulation of the death receptor. Apoptosis is also suppressed by the IAPs (inhibitors of apoptosis). Members of this family include XIAP, IAP1, IAP2, and survivin. These proteins interact with and inhibit selected effector caspases. IAP suppressors have also been identified and include Smac/DIABLO and XAF1.

Many of the targeted therapies mentioned above act in part through the promotion of apoptosis; for example, the proteasome inhibitor bortezomib and the histone deacetylase inhibitor suberoylanilide hydroxamic acid (SAHA) precipitate apoptosis in tumor cells. Similarly, flavopiridol-mediated inhibition of the cell-cycle kinase, cdk1, enhances the cytotoxicity of doxorubicin in MCF7 human breast carcinoma xenografts through the suppression of survivin phosphorylation.⁸¹ However, some of the more direct therapies targeting components of the apoptosis pathway are discussed next.

Strategies to Modulate Apoptosis

TRAILR1 MONOCLONAL ANTIBODY

This MAb targets TRAILR1 expressed on human cancer cells and induces apoptosis in human tumor cell lines. Although initial studies suggested that TRAIL activation preferentially leads to apoptosis of tumor cells over normal cells, recent data suggest that human hepatocytes may also be sensitive to TRAIL activity.⁸² Phase I studies are currently in progress.

ANTISENSE Bcl2 STRATEGIES: G3139

G3139 is an antisense phosphorothioate oligonucleotide that suppresses the expression of the antiapoptotic protein Bcl2. Results of a trial of 21 patients with non-Hodgkin's lymphoma treated with subcutaneous G3139 demonstrated a response rate of 14% with a further 43% exhibiting stable disease.⁸³ Phase III trials are in progress.

STRATEGIES TARGETING p53: ONYX-015, INGN 201, NUTLINS

ONYX-015 is a mutant adenovirus with a loss-of-function mutation of the adenoviral E1B gene product. The wild-type viral gene product E1B inactivates p53. ONYX-015 selectively replicates in p53-deficient tumor cells leading to cytolysis. The virus is unable to replicate in cells with wild-type p53.⁸⁴ Promising results have been demonstrated in phase I and II trials, and also in combination with chemotherapy agents.⁸⁵ Regional delivery of ONYX-015 has been attempted in different tumor types. A Phase II trial of intratumoral ONYX-015 in combination with cisplatin and 5-fluorouracil in patients with recurrent head and neck cancer demonstrated objective tumor responses with an acceptable toxicity profile.⁸⁶ Furthermore, biopsies revealed selective adenoviral replication and necrosis within some tumor specimens. Intratumoral injection has also been attempted in patients with breast cancer chest wall recurrence. Hepatic artery infusion of ONYX-015 in a Phase I/II study of 35 patients with liver metastases secondary to colorectal carcinoma demonstrated antitumoral activity,⁸⁷ while a Phase I trial of intraperitoneal regional delivery of ONYX-015 was conducted in refractory ovarian cancer.⁸⁸

INGN 201 is a replication incompetent adenovirus vector in which the E₁ region has been replaced by wild-type p53 gene under the control of a cytomegalovirus promoter. Preclinical studies demonstrated anticancer properties in head and neck tumor cell lines and xenografts. A Phase I trial of stereotactic intratumoral injection of INGN 201 into recurrent glioma demonstrated minimal toxicity and the transfer of p53 to astrocytic tumor cells that led to transcriptionally active p53, with upregulation of target genes such as p21^{cip1} and apoptosis in subsets of cells. Phase II studies in patients with advanced recurrent squamous cell carcinoma of the head and neck treated with intralesional INGN 201 indicate that the virus is well tolerated.⁸⁹ Disease stabilized in 6 of 17 patients with nonresectable disease, and 2 of 17 patients exhibited partial responses. Paradoxically, efficacy appeared independent of p53 status.

Mdm2 inhibits p53 by promoting p53 nuclear export, impeding the interaction of transcription factors with the activation domain of p53 and triggering the degradation of p53 via the ubiquitin-proteasome pathway. Nutlins are a family of synthetic compounds that can successively displace Mdm2 from the N-terminus of p53, thereby promoting p53 activity.⁹⁰ This is an exciting technical development for the manipulation of protein-protein interactions by small molecules. Furthermore, it raises the possibility of activating p53 in tumors that retain normal p53, thereby promoting apoptotic pathways.

TARGETING SPHINGOSINE KINASE ACTIVITY: PHENOXODIOL

Sphingosine kinase promotes the activity of the caspase inhibitory proteins XIAP and FLIP. The isoflavone phenoxodiol targets a regulator of sphingosine kinase thereby reducing XIAP and FLIP activity. Phase Ib/II data have recently been presented demonstrating promising activity of oral phenoxodiol in hormone refractory prostate cancer and late-stage ovarian cancer refractory to chemotherapy.^{90,92}

Angiogenesis

Folkman first postulated that angiogenesis (the formation of new blood vessels from the preexisting vascular bed) is required for tumor progression.⁹³ Initially, malignant cells derive their nutrients from the normal host vessels by diffusion, but tumor growth is limited beyond 1 to 2 mm without new blood vessel growth.⁹⁴ Neovascularization is initiated by increased permeability of preexisting vessels in response to vascular endothelial growth factor (VEGF) produced by the tumor; this allows for the extravasation of plasma proteins that lay down the matrix upon which activated growth factor-secreting endothelial cells migrate. Proteolytic degradation of the extracellular matrix and basement membrane then enables endothelial cells to form new capillaries. Normally, perivascular cells are attracted and form basal lumina around the vessels, thus limiting endothelial cell proliferation and decreasing their dependence on VEGF-A. However, in tumors, pericytes have a decreased association with new blood vessels, which as a consequence are leaky due to an imbalance of appropriate proangiogenic and antiangiogenic controls that control the so-called angiogenic switch. Hypoxia stimulates the tumor cells to generate proangiogenic factors, including vascular endothelial growth factor (VEGF), fibro-

blast growth factor (FGF), transforming growth factor-beta (TGF- β), and tumor necrosis factor-alpha (TNF- α). VEGF and FGF are considered the most important factors for tumor angiogenesis.

Tumor vascularization has been found to correlate with growth and metastatic potential in some tumor types, and microvessel density has been shown to be an adverse prognostic factor of distant disease and survival.⁹⁵ Consequently, antiangiogenesis has been a new strategy for the development of anticancer treatment. The characterization of natural inhibitors and promoters of angiogenesis has led to the development of novel compounds that potentially interfere with various steps required for angiogenesis (Table 5.6, Figure 5.4). In principle, these approaches involve either targeting the endothelial cell, targeting activators of angiogenesis, or targeting the extracellular matrix.

TARGETING THE ENDOTHELIAL CELL (THALIDOMIDE, TNP-740, ENDOSTATIN, ANGIOSTATIN)

Thalidomide has been found to have immunomodulating and antiangiogenic properties by impeding VEGF- and bFGF-dependent angiogenesis through inhibition of TNF, interleukin (IL)-12, and IL-6 and stimulation of IL-2, interferon, and CD8+ T cells. Clinical activity has been seen in refractory multiple myeloma, myelodysplasia, Kaposi's sarcoma, renal cell cancer, colorectal cancer, and recurrent glioblastomas. No benefit has been demonstrated in Phase III trials of metastatic breast and head and neck malignancies. The thalidomide analogue, CC-5013, has increased potency and efficacy with less sedation, constipation, and neuropathy and has demonstrated promising activity in Phase I trials of patients with advanced solid cancers.⁹⁶

TNP-470 is a potent endothelial inhibitor *in vitro*, and animal models have demonstrated the broadest anticancer range of any known agent. In clinical trials, TNP-470 has shown evidence of antitumor effect both as monotherapy with responses observed in relapsed or refractory malignancies⁹⁷ and in combination with chemotherapy.⁹⁸

The clinical observation that the removal of the primary tumor can lead to the rapid growth of previously dormant micrometastases led to the discovery of angiostatin and endostatin, two potent endogenous antiangiogenic agents. Endostatin is a 20-kDa C-terminal fragment of collagen XVIII found in vessel walls and basement membranes. Recombinant human endostatin inhibited endothelial cell proliferation and tumor growth in preclinical studies, and in a subsequent Phase II trial there were 23 patients with stable disease and 2 with minor responses of the 37 evaluable patients.⁹⁹ Angiostatin is a 38-kDa internal fragment of plasminogen, which has subsequently been shown to induce dormancy and regression of tumor models. Angiostatin binds to ATP synthase on the surface of human endothelial cells, induces apoptosis in endothelial cells and tumor cells, inhibits endothelial migration and tubule formation, and inhibits matrix-enhanced plasminogen activation. A Phase I trial in patients with advanced cancer demonstrated that it was well tolerated, with some patients (7 of 24) achieving long-term stable disease.¹⁰⁰

TARGETING ACTIVATORS OF ANGIOGENESIS

Vascular endothelial growth factor (VEGF-A), a critical regulator of physiologic angiogenesis during embryogenesis and skeletal growth, is also important in the pathologic angiogenesis of tumor growth. VEGF-A is a multifunctional cytokine expressed by many tumor cells, promoting microvascular permeability, endothelial cell migration, division, and survival, and inhibiting apoptosis. Oxygen tension/hypoxia, growth factors, oncogenes, inflammatory cytokines, and various hormones regulate the level of VEGF-A. The effects of VEGF are mediated in part by two receptor tyrosine kinases (RTKs), VEGFR-1 (flt-1) and VEGFR-2 (flk-1), which are expressed on endothelial cells. The level of VEGF-A expression in cancer cells has been found to correlate with tumor size, metastasis, poor disease free-survival (DFS), and overall survival (OS).¹⁰¹ Consequently, VEGF and its receptors

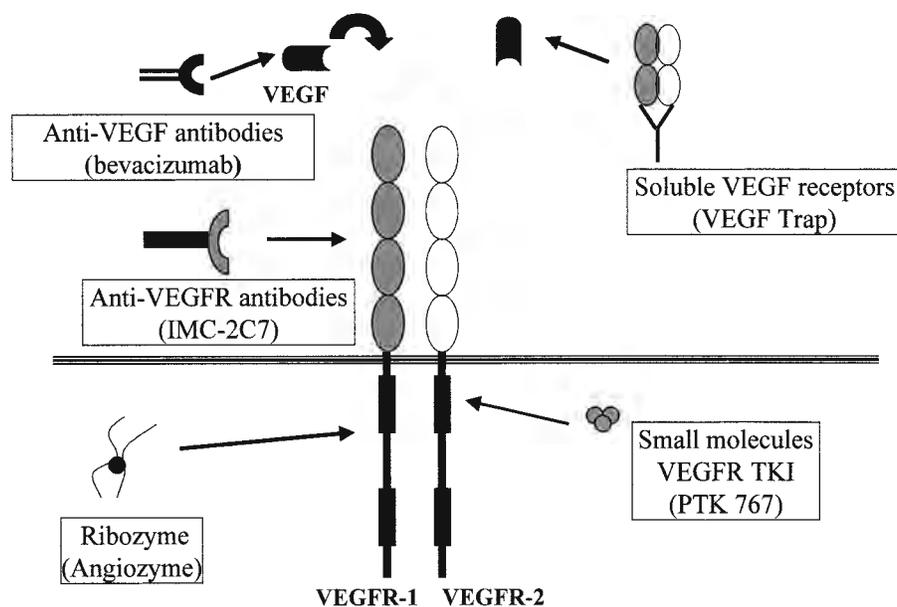

FIGURE 5.4. Inhibitors of angiogenesis.

have been investigated for antiangiogenesis therapies in various malignancies. Different strategies have been designed to inhibit VEGF function, including inhibition of endogenous tumor VEGF secretion (antisense), neutralizing VEGF in the microcirculation, or preventing VEGF binding to its receptor (antibodies), and targeting subsequent signal transduction by VEGF (small molecule receptor tyrosine kinase inhibitors) (see Figure 5.4).

Ribozymes are RNA molecules that can recognize RNA sequences and cleave specific sites on other RNA molecules. Angiozyme, a synthetic ribozyme that targets the VEGFR-1 mRNA, was well tolerated in a Phase I/II study of patients with refractory solid tumors,¹⁰² and further trials are in progress. Bevacizumab (avastin) is a recombinant anti-VEGF humanized MAb,¹⁰³ which, in patients with untreated metastatic colorectal cancer given in combination with chemotherapy, showed a significant increase in response rate and time to progression compared with chemotherapy alone, with a 4.7-month prolongation of overall survival.¹⁰⁴ This result represents the first clinical validation for antiangiogenesis therapy as an effective cancer treatment, and recent similar studies in untreated advanced non-small cell lung cancer have demonstrated improved response rates and time to progression with the addition of bevacizumab.¹⁰⁵ Finally, several different small molecules targeting VEGF receptor tyrosine kinases have been developed, each with a different selectivity profile (Table 5.7); these include SU5416 (intravenously administered), SU6668, SU11248, and PTK 787.^{106,107}

TARGETING THE EXTRACELLULAR MATRIX

The matrix metalloproteinases (MMPs) are a family of zinc-dependent endopeptidases that mediate degradation of extracellular matrix expressed by tumor cells or stroma.¹⁰⁸ They are synthesized as inactive zymogens (pro-MMP) and activated by proteinase cleavage. Their activity is regulated by endogenous inhibitors such as β 2-macroglobulin, thrombospondin-2, tissue inhibitors of metalloproteinases (TIMPs), and small molecules with TIMP-like domains. MMPs can promote tumor progression by increasing cell growth, migration, invasion, metastasis, and angiogenesis. Several different approaches have been developed to inhibit the activity of MMPs, including antisense mRNA or ribozyme technology.¹⁰⁹ Integrins are a group of heterodimeric transmembrane receptors that mediate cell-cell and cell-ECM interactions. Vitaxin, a humanized derivative of a mouse LM609 MAb, was developed to inhibit the MMP-2 interaction with integrin $\alpha_v\beta_3$, although its instability precluded further development.¹¹⁰ Cilengitide (EMD 121974) is a synthetic cyclic pentapeptide small molecule inhibitor of $\alpha_v\beta_3$ and $\alpha_v\beta_5$, which in a Phase I trial gave prolonged stable disease in 3 of 37 patients.¹¹¹ Finally, MMP enzymatic inhibitors (MMPI) have been developed. Marimastat was the first orally available MMPI and has been tested in several phase III trials in glioblastoma, breast, ovarian, and small and non-small cell lung cancers. These trials were discontinued because marimastat failed to demonstrate superiority over placebo or standard chemotherapy. However, in a Phase III placebo-controlled trial in patients with advanced gastric cancer, marimastat showed significant improvement in OS (2-year survival, 5% versus 18%) and PFS over placebo-treated patients. These benefits remained significant even after

longer follow-up.¹¹² Other MMPIs in development are listed in Table 5.7.

Clinical Development of Targeted/Biologic Therapies

Clinical Trial Design

Clinical trials aim to identify effective drugs for further studies, while also allowing discontinuation of ineffective drugs in an ethical and efficient way. Traditional phase I/II/III clinical trials for cytotoxic agents assume that (1) the agent will reduce the size of the tumor in a dose-dependent manner; (2) the agent will have toxicities that are dose dependent; and (3) reduction in tumor size will lead to improved overall survival and/or improved quality of life. In contrast, newer targeted agents may not have an objective effect on tumor size other than tumor stabilization or metastasis prevention. There may not be a dose-dependent effect, and toxicities may only be modest.¹¹³ Consequently, there are limitations in testing target-based agents with conventional trials designed for cytotoxic drugs, and alternative endpoints/trial designs are required.

Phase I: Biologic Endpoints and Surrogate Markers

Phase I trials are small studies aimed at finding the optimal dose of a drug using schedules determined from preclinical models. In conventional trials with cytotoxic agents, maximal tolerated dose (MTD) is often used to define the optimal dose rather than using the dose that has a quantifiable therapeutic effect. The dose of the agent is escalated in cohorts of three to six patients until there is unacceptable toxicity in two or more patients. The design of phase I trials is based on the assumption that the efficacy and toxicity of the drug increases as the dose increases and that the mechanism of toxicity and tumor effect are the same. Pharmacokinetic studies are included in Phase I trials but are not required to determine the optimal dose of a cytotoxic agent.

Due to their selective effect, targeted agents have the potential to achieve maximum biologic effect with minimal side effects. Therefore, the optimal dose in Phase I trials may need to be defined by a biologic endpoint rather than toxicity. Their wider therapeutic ratio may in some cases make it difficult to determine the MTD. Furthermore, the mechanisms of toxicity and biologic effect may differ, and therefore, MTD cannot be used to define the optimal dose. Conversely, others contend that unless the MTD and intratumoral pharmacodynamics of the novel agent are determined in Phase I and II clinical trials, Phase III trials run the risk of inadequate dosing and suboptimal target inhibition.²

Consequently, biologic endpoints in tumor and surrogate tissue rather than dose-limiting toxicity are often used to define the optimal dose of targeted agents for subsequent clinical trials. This characterization requires a biologic understanding of the target, a specific and reproducible assay for target inhibition, knowledge of the distribution of the target in the tissues of interest, accessibility of the appropriate tissue, and demonstration that the tissue is a valid surrogate for the tissue of interest. Phase I trials with targeted agents aim to define the dose or concentration of a drug that

TABLE 5.7. Antiangiogenesis therapies.

<i>Agent</i>	<i>Mechanism of action</i>	<i>Trial</i>	<i>Major toxicity</i>
TNP-740	Synthetic analogue of fumagillin; inhibition of Ets-1	Phase II advanced cancer, lymphomas and acute leukemia	Cerebellar dysfunction
Thalidomide	Unknown	Phase I malignant glioma & melanoma Phase II non-small cell lung cancer; phase II in CRC, lymphoma, MDS, liver, CLL, NSCLC Phase III prostate, myeloma, RCC	Fatigue, somnolence, myelosuppression, peripheral neuropathy, thromboembolism (in combination with chemotherapy)
Squalamine	Inhibition sodium-hydrogen exchanger, NHE3	Phase I solid tumors; phase II non-small cell lung cancer and solid tumors	
Combretastatin	Induction of apoptosis in proliferating endothelial cells	Phase I solid tumors; phase II to begin in mid-2000	
Endostatin		Phase I advanced neuroendocrine and melanoma	Rash
Angiostatin		Phase I advanced tumors	Erythema
Anti-VEGF antibody (bevacizumab)	Humanized mAb to VEGF	Phase II metastatic RCC, advanced prostate, NSCLC, colorectal and other solid tumours	Thrombosis, proteinuria, hypertension
Anti-VEGFR-2 (IMC-2C7)	Antibody to VEGFR-2	Preclinical	
Soluble VEGFR-1 (VEGF TRAP)	Inhibition of VEGF signaling by sequestration of VEGF and possibly formation of inactive heterodimers with cell-surface VEGF receptors	Phase I advanced tumors	Hypertension, fatigue, proteinuria
Ribozyme (angiozyme)	Cleavage of mRNA of VEGFR-1	Phase I/II refractory solid tumors	
SU11248	Small molecule inhibitor of VEGFR-2, PDGFR, KIT and FLT-3	Phase I advanced solid tumors	Asthenia, thrombocytopenia, neutropenia, skin discoloration, depigmentation
SU6668	Small molecule blocker of VEGF-receptor, FGF, and PDGF receptor signaling	Phase I in selected advanced tumors	Asthenia, thrombocytopenia, hypertension, diarrhea
PTK787/ZK22584	Inhibition of VEGFR-1,2,3 TKI	Phase I/ II with chemotherapy in CRC	Fatigue, neuropathy, diarrhea
Cilengitide (EMD121974)	Small molecule inhibitor of $\alpha_v\beta_3$ and $\alpha_v\beta_5$	Phase I advanced tumors	
Marimastat	Synthetic inhibitor that blocks TNF—a convertase; inhibitor of MMPs	Phase I pancreatic cancer; phase III NSCLC, small cell lung cancer and breast cancer; phase I GBM	Musculoskeletal pain and joint swelling
Prinomastat (AG-3340)	Synthetic MMP inhibitor	Phase III NSCLC, hormone refractory prostate, pancreatic, and small cell lung cancer	
Metastat (COL-3)	MMP inhibitor and tetracycline derivative	Phase I/II brain, Kaposi's sarcoma	Lupus, anemia
Neovastat (AE941)	Natural MMP inhibitor; derivative of shark cartilage	Phase II multiple myeloma, Phase III renal cell cancer, Phase III non-small cell lung cancer	
BMS-275291	Synthetic MMP inhibitor	Phase I	

provides maximal target inhibition.¹¹⁴ Because determining target inhibition within the tumor is technically demanding, the sampling of normal or surrogate tissues has been an alternative approach. Examples of surrogate tissue use include the measurement of p70S6 kinase activity in peripheral blood mononuclear cells after treatment with an mTOR inhibitor, the assessment of EGFR and ERK/MEK phosphorylation status in skin biopsies after treatment with EGFR tyrosine

kinase inhibitors, or assessment of prelamin A farnesylation in buccal mucosal cells following FTI treatment.⁴² However, reliance on surrogate endpoints to determine the efficacy of these targeted therapies has attracted criticism because the pharmacodynamics within normal tissue may not reflect target inhibition within the tumor mass. For example, clinical trials investigating the activities of the EGFR inhibitors have failed to adequately assess the intratumoral pharmaco-

dynamics before and after drug exposure.² Therefore, negative trial data may simply reflect inadequate drug dosage and tumor tissue concentrations of these agents rather than drug inactivity, which raises serious questions over the interpretation of negative clinical trial data unless proof of target inhibition is documented within tumor specimens rather than surrogate tissues.

Noninvasive functional imaging techniques that can quantify the level of target function *in vivo* are under investigation and include dynamic contrast-enhanced MRI (DCE MRI) for measuring tumor vascularization and vascular permeability with angiogenesis inhibitors and positron emission tomography (PET) to monitor metabolic changes in uptake of ¹⁸F-fluoro-2-deoxy-D-glucose (¹⁸FDG) within the tumor mass. Other functional modalities include doppler ultrasound and dynamic infrared imaging of vascular perfusion patterns.¹¹⁵

Phase II

The primary aim of a Phase II trial is to define the spectrum of antitumor activity for the new drug using the optimal dose and schedule determined from Phase I trials. With cytotoxic drugs, the traditional endpoint is response rate as measured by the percentage decrease in size of the tumor compared to the pretreatment size. However, objective response rate may not be an ideal endpoint for target-based agents because of their cytostatic properties. To overcome this difficulty, alternative endpoints have been used in Phase II clinical studies of targeted therapies. These include the following:

- Pharmacodynamic endpoints: for example, quantifying posttranslational changes in biological markers in either tumor or surrogate tissues
- Functional imaging studies to assess treatment response at the tumor site (FDG-PET or dynamic contrast-enhanced MRI)
- Assessment of time to disease progression and the proportion of patients with disease progression
- Quality of life (regarded as a secondary endpoint for cytotoxic agents)¹¹³

None of these endpoints has been well validated.^{116,117} An alternative approach to clinical trials investigating the activity of targeted therapies is the use of the randomized discontinuation design. All patients are enrolled to receive the drug for an initial 2- to 4-month period. Patients with progressive disease, toxicity, or noncompliance during this period are removed from the study. The remaining patients are then randomized to continue the drug or a placebo. The endpoint is the percentage of patients that remain with stable disease in the randomized period. The advantages of this method are that it can overcome the slow accrual of trials that offer treatment or placebo upfront, eligibility criteria can be relatively broad, and enrichment of the randomized group may increase the efficiency of the trial.¹¹⁸ Other Phase II trial designs include utilizing the patient as the internal control, whereby a single cohort of patients with progressive disease is treated with a cytostatic agent to determine whether the agent slows the rate of disease progression with reference to the pretreatment rate of progression. Similarly, neoadjuvant treatment can provide a valuable system with tumor sampling for

molecular analysis that can be performed at progressive time points during treatment.

PHASE III

The aim of Phase III trials is to determine efficacy or clinical benefit of a new regimen versus a standard therapy in a randomized study. Endpoints are usually progression-free survival or overall survival. With target-based agents, the traditional designs should remain relatively unchanged. It is important that the drug dose that optimally inhibits the target in question within patient tumor specimens be defined in advance of Phase III studies.

PATIENT SELECTION

The target should be critical to the biology of tumor [e.g., *bcr-abl* in chronic myeloid leukemia (CML)], and the targeted agent should be used in a biologically relevant population. Disease stage may also need to be considered in patient selection, as some agents may be less active in the advanced setting and more effective in patients with minimal disease. Many Phase III clinical trials conducted (with the exception of the trastuzumab and imatinib studies) have not selected patients based on target expression. It is noteworthy that had the Phase III study investigating the addition of trastuzumab to chemotherapy in patients with metastatic breast cancer not selected patients based on HER2 overexpression, the trial would have been negative.

At the same time, our understanding of the molecular profile in a tumor that may predict response to targeted therapies remains naive. Little is known about resistance to targeted therapies to guide appropriate strategies of combining different inhibitors together to inhibit redundant or parallel signaling pathways, thus maximizing clinical benefit. Future trials of targeted therapies must incorporate a prospective analysis of tumor tissue during treatment so that response can be correlated with the molecular phenotype (either through microarray or proteomic techniques), thus identifying predictive markers for future studies.

Conclusion: Challenges for the Future

Designing clinical trials to investigate the activity of these novel agents and optimize their use in a defined patient population are critical challenges to the success of targeted therapy. There remains much cause for optimism and enthusiasm, particularly following the notable successes in the past few years that have made it to the clinic, such as trastuzumab for breast cancer, bevacizumab for colorectal cancer, imatinib mesylate for CML and GIST, and gefitinib for lung cancer.

The field is moving fast, with an exploding knowledge base of molecular abnormalities in cancer and an increasing array of molecules that can target abnormal or overexpressed onco-proteins. As reviewed here, targeted therapies include a wide spectrum of approaches that are applicable to many different cancers, and the principles which govern their development are evolving as we learn how to utilize these novel agents. Within the next decade we should find out whether we make a paradigm shift in the treatment and prevention of cancer by translating scientific progress into clinical practice. Many truly believe that we will.

Biologic Principles of Hematopoietic Stem Cell Transplantation

Robert J. Soiffer

During the past 25 years, hematopoietic stem cell transplantation (HSCT) has become accepted as routine treatment for many patients with hematologic malignancies. Traditionally, the primary biologic objectives of HSCT for malignant disease and marrow disorders include the following:

- Delivery of chemotherapy/radiotherapy sufficient to destroy tumor cells
- Infusion of a source of hematopoietic stem cells to replace damaged lymphoid or myeloid progenitors
- Establishment of organ graft tolerance to prevent rejection of donor cells
- Induction of graft-versus-tumor (GVT) activity by allogeneic immune effector cells

Recent laboratory and clinical observations on the biology of transplantation have challenged many of the fundamental beliefs and practices established over the past quarter century. Insights into graft-versus-host disease (GVHD), graft-versus-leukemia (GVL) activity, stem cell engraftment, donor selection, minimal residual disease (MRD), infectious complications, and treatment-related organ dysfunction all have contributed to revisions and refinements in the current approach to potential transplant recipients.

Indications for Transplantation

For many diseases, the indications for transplantation were established in an era when standard treatment approaches had very little hope of producing cures or extended long-term survival. As both nontransplant therapeutic options and transplant-related methodologies have evolved, continued reassessment is needed to determine the place of transplantation in the design of treatment algorithms.

It is a common misconception that research in transplantation is bereft of comparative clinical trials. It is true that many reported Phase 2 trials are difficult to interpret in the absence of rigorously defined control groups. Single institution case-control studies are only of limited value. However, the establishment of well-organized data repositories such as the International Bone Marrow Transplant Registry (IBMTR) and the European Bone Marrow Transplant (EBMT) registry have led to large retrospective observational

studies using standardized data collection tools across many centers. The reports emerging from these studies have proven useful in assessing the value of specific transplant strategies. However, these registry analyses do not take the place of rigorously conducted randomized trials. Indeed, there have been a number of randomized trials conducted in transplantation, although many have been underpowered to detect small, but significant, differences because of limited patient availability.

Transplant indications can be divided into three groups based on the objective evidence that supports its use. The first group includes those diseases for which results from prospective randomized trials are available to guide treatment decisions. The most definitive randomized study supporting transplantation was the PARMA trial, conducted in patients undergoing autologous HSCT for non-Hodgkin's lymphoma (Figure 6.1).¹ Patients with relapsed NHL were treated with two cycles of salvage chemotherapy upon study entry. Those patients exhibiting a response were randomized to receive either high-dose chemotherapy and autologous bone marrow transplantation or four more cycles of chemotherapy. With extended follow-up in each arm, both disease-free survival and overall survival were far superior for patients undergoing transplantation. In another randomized trial conducted in Europe at the same time, a survival advantage was demonstrated for patients with recurrent multiple myeloma randomized to autologous transplantation compared to conventional therapy. This finding was recently confirmed in another large randomized study.^{2,3}

The importance of randomized trials is not limited to positive studies. The highly publicized randomized trials in breast cancer patients with metastatic disease or with more than 10 positive nodes failed to demonstrate any survival advantage for autologous transplantation.⁴⁻⁶ Participation in these studies was critical in helping to determine that high-dose chemotherapy and autologous HSCT, which had become *standard* treatment for many patients with advanced disease, offered no clear-cut advantage to conventional therapy. Still, proponents of transplant point to the lower relapse rates in the transplant arm and argue that if toxicity could be eliminated, high-dose therapy might still offer advantages.

It is also important not to blindly extrapolate the results of positive studies to distinctly different clinical scenarios. For example, the encouraging results with autologous transplantation for intermediate-grade NHL in second remission

prompted its use for patients thought to be at high risk for relapse in first remission. However, when a prospective randomized study was performed in these first remission patients, no clear benefit of transplantation could be demonstrated except perhaps in patients with very high international prognostic index (IPI) scores.⁷⁻⁹

There have also been circumstances in which different randomized studies have yielded conflicting results, as is most clearly the case for patients with acute myelogenous leukemia (AML) and acute lymphoblastic leukemia (ALL) in first complete remission (CRI). Many of these trials were designed so that patients with HLA-identical donors were allocated (truly genetically selected) for allogeneic transplantation whereas those without donors were randomized to autologous transplantation or further chemotherapy. In some of these trials, allogeneic transplantation held a modest advantage when analyzed on an intention-to-treat basis. In other trials, no significant differences in disease-free survival (DFS) between the treatment arms could be found.¹⁰⁻¹³ More recent data on the prognostic implications of certain chromosome abnormalities associated with AML and ALL have influenced thinking on who should undergo transplantation in first remission. General agreement exists that patients with adverse cytogenetics (such as monosomy 7 or multiple complex abnormalities in AML or the Philadelphia chromosome in ALL) should undergo HSCT in CRI. Patients with favorable cytogenetics [such as t(8;21) or inv16] are usually not offered transplantation in first remission. Transplant decisions for patients with intermediate-risk cytogenetics in AML and ALL are more difficult and require careful deliberation with the patient and his/her family.

The second group of transplant indications includes those diseases for which a cure rate has been established with HSCT that is superior to that obtained with conventional therapy but for which prospective randomized trials have not been conducted. This group includes patients with recurrent acute

leukemia, recurrent Hodgkin's disease, low-grade lymphoma, chronic lymphocytic leukemia (CLL), aplastic anemia, and chronic myelogenous leukemia (CML).¹⁴⁻²⁴ CML deserves special consideration since the introduction of imatinib into practice in 2001.²⁵⁻²⁷ In the pre-imatinib era, cure rates were less than 5% and median survival was 5 to 6 years with either hydroxyurea or interferon, the mainstays of therapy. In contrast, for patients under 50 years of age with an HLA-identical sibling donor, HSCT performed in the first year after diagnosis of stable-phase CML cures more than 70% of patients.^{28,29} DFS for patients with unrelated donors appears to exceed 50% to 60% in identical circumstances.¹⁶ For these younger patients with CML, it could be safely argued that HSCT offered the only hope for cure. However, this conclusion did not necessarily mean that HSCT was an obvious choice for all these patients, because there was a very real possibility that transplantation would dramatically shorten the lifespan of a subset of patients as a result of transplant-related complications. In the current imatinib era, the transplant decisions faced by physicians and patients cannot necessarily be based on a reproducible median survival of 5 to 6 years without HSCT. It is not known what the median survival will be for newly diagnosed patients treated with imatinib. Despite the early data that indicate imatinib is superior to interferon in inducing hematologic and cytogenetic remissions, the duration of these responses is not known.^{30,31} Development of drug resistance has been identified in a number of patients.^{32,33} At this point, it is too early to know how imatinib should change the approach to transplantation for CML.

The third group of transplant indications includes those diseases for which transplantation benefits some individuals but for which sufficient follow-up is not yet available in enough patients to determine the proper role of HSCT in disease management. Diseases that fall into this category include hemoglobinopathies, autoimmune disorders, and renal cell carcinoma.³⁴⁻³⁶ Transplantation for these indications should be considered investigational.

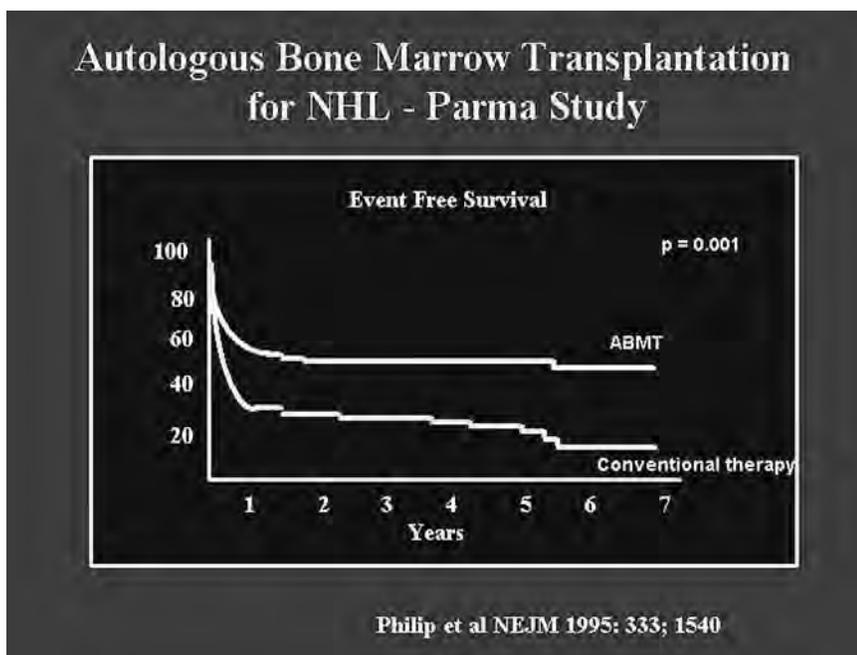

FIGURE 6.1. Randomized study of high-dose chemotherapy with autologous transplantation versus chemotherapy. Event-free survival in patients undergoing transplantation is superior to that in those receiving chemotherapy alone for recurrent chemotherapy-sensitive intermediate-grade non-Hodgkin's lymphoma. (Adapted from Philip et al.,¹ by permission of *New England Journal of Medicine*.)

Sources of Hematopoietic Stem Cells

Hematopoietic stem cells for transplantation can be obtained from bone marrow (BM) or peripheral blood (PB). Bone marrow was the traditional source for stem cells until the 1980s. At that time, antibodies were developed that could recognize CD34+ hematopoietic progenitors, and it was recognized that these CD34+ cells circulate in PB. Moreover, the number of these CD34+ cells in the periphery increased during recovery from myelosuppressive chemotherapy and after administration of growth factors, particularly granulocyte colony-stimulating growth factor (G-CSF).^{37–39} Strategies to mobilize stem cells from the marrow out into PB with chemotherapy, growth factors, or a combination of the two were developed. Full lymphohematopoietic reconstitution was observed after ablation and infusion of these mobilized PB stem cells in the autologous transplant setting. Using mobilized PB containing a minimum of 2.0×10^6 CD34+ cells/kg, engraftment of both neutrophils and platelets is considerably more rapid than when BM is used.^{40,41} For autologous transplantation, mobilized PB has replaced BM as the stem cell source in most centers. It is notable, however, that the use of peripheral blood stem cells (PBSCs) has not led to improved survival after autologous transplantation but has been associated with decreased duration of hospitalization.

Physicians were initially reluctant to use PB for allogeneic transplantation as it was feared that the increased number of T lymphocytes infused with PB would increase the incidence and severity of graft-versus-host-disease (GVHD). The first trials published in the 1990s demonstrated rapid engraftment without apparent increases in GVHD.^{42,43} A number of randomized trials comparing allogeneic PBSC versus BM have been reported, as have a meta-analysis and registry data.^{44–49} As in the autologous setting, neutrophil and platelet engraftment were more rapid with PBSCs. There have been conflicting reports on the risk of acute GVHD posed by PBSCs. In a randomized trial involving 350 patients, both acute GVHD (grade II–IV) and severe acute GVHD (grade III–IV) were significantly increased in the PBSC group (52% versus 39%, $P = 0.014$ and 28% versus 16%, $P = 0.01$, respectively).⁵⁰ Other trials have found differences in acute GVHD that were not statistically significant. An IBMTR/EBMT retrospective review of 288 PBSC and 536 BM transplants revealed a borderline increase in grades II–IV acute GVHD [relative risk (RR), 1.19; 95% CI, 0.9–1.56].⁵¹ A meta-analysis of 15 studies (9 cohorts, 5 randomized trials, and 1 database review) suggested that use of PBSCs did increase risk of acute GVHD (RR, 1.16; 95% CI, 1.04–1.28).⁴⁶

A number of studies have suggested a higher incidence of chronic GVHD with PB.^{44–46,51} An updated meta-analysis of the randomized trials demonstrated an overall relative risk of 1.57 (95% CI, 1.28–1.94) for chronic GVHD after PBSC when compared with bone marrow transfer (BMT). The explanation for the increase in chronic GVHD may lie with the increase in the number of T cells infused, although there may be an association between the development of chronic GVHD and the number of CD34 cells infused.^{52,53}

It has been speculated that the larger number of T cells infused with mobilized peripheral blood might translate into improved immune reconstitution and a reduction in disease relapse posttransplant. In several studies, higher levels of B cells and T cells were noted after PBSC compared to BMT,⁵⁴

with the increase in T-cell number associated with a lower incidence of confirmed infections (RR, 0.59; $P < 0.001$).⁵⁵ With regard to relapse, several randomized studies have demonstrated a decrease in the rate of relapse after PBSC compared to BMT.^{48,49} In the largest U.S. randomized trial, the hazard ratio for relapse was 0.49 (95% CI, 0.38–1.28) among patients transplanted with PBSCs.⁴⁴ Unfortunately, despite these effects on lymphoid recovery and disease relapse, most randomized studies have yet to demonstrate a convincing improvement in overall survival for PBSCs.

All the comparative studies of PBSCs and BM referenced previously have involved related donors. For unrelated donors, a single-arm cohort of PBSC resulted in outcomes similar to that noted with BMT.⁵⁶ Comparative rates of engraftment, acute and chronic GVHD, and survival in the unrelated setting await completion of large multiinstitutional randomized studies now under way.

If there turns out to be no survival advantage to PBSC compared with BMT in the allogeneic setting, policies regarding donor source may be determined by quality of life or economic issues. Donor preference for either PBSC or BM donation has been evaluated in one series of allogeneic donors with no differences in self-reported quality of life measures; however, patients randomized to donate autologous PBSC or BM have preferred PBSC collection.^{57,58} Because of the reduction in hospital stay associated with PBSC, costs have been lower in comparative analyses although these studies did not factor in the potentially added economic burden of a higher incidence of chronic GVHD.⁵⁹

Conditioning Regimens

The conditioning regimen administered before stem cell infusion plays several potential roles in promoting the success of transplantation. Cyto-reduction of the endogenous malignancy with high-dose chemo/radiotherapy has traditionally been central to transplantation and is the major mode by which autologous transplantation benefits patients. Typical conditioning regimens for autologous transplantation include cyclophosphamide/total-body irradiation (Cy/TBI), cyclophosphamide/busulfan (Bu/Cy), cyclophosphamide/BCNU/VP-16 (CBV), BCNU/etoposide, ara-C, melphalan (BEAM), VP-16/busulfan, and cyclophosphamide/thiotepa/carboplatin (CTCb). It is not clear if one particular regimen is superior in a particular clinical circumstance, although it is generally assumed that results with current standard regimens are reasonably equivalent.

For allogeneic transplantation, the conditioning regimen not only reduces the disease burden but also suppresses the host to facilitate donor engraftment. The most common ablative combinations have been cyclophosphamide/total-body irradiation or cyclophosphamide/busulfan. Several randomized studies of Cy/TBI and Bu/Cy have been conducted in patients with AML and CML.^{60–62} Socie et al. summarized the long-term results of four of these studies.⁶³ With more than 7 years of follow-up in each study, no differences in long-term outcome were noted for patients with CML. They noted a nonsignificant 10% improvement for AML patients receiving Cy/TBI compared to Bu/Cy. The development of intravenous busulfan and strict pharmacokinetic monitoring to target

TABLE 6.1. Comparison of autologous and allogeneic transplantation.

	<i>Autologous</i>	<i>Allogeneic</i>
Advantages	1. No HLA matching requirement 2. No graft-versus-host disease (GVHD) 3. No need for immunosuppression	1. Stem cells have not been exposed to chemotherapy 2. Stem cells free of tumor 3. Graft-versus-tumor activity
Disadvantages	1. ? Stem cell damage from prior therapy leading to delayed engraftment or myelodysplasia 2. ? Graft contamination with tumor 3. No graft-versus-tumor effect <i>Lower risk of complications</i> <i>Higher risk of relapse</i>	1. Donor availability uncertain 2. GVHD 3. Infectious complications <i>Higher risk of complications</i> <i>Lower risk of relapse</i>

plasma levels of the drug has helped optimize efficacy and limit toxicity of the Bu/Cy regimen.^{28,64}

Attempts to escalate doses of the conditioning have been disappointing. In several studies in which TBI dose intensity was increased to more than 1,500 cGy, modest decreases in relapse rates were offset by increases in regimen-related morbidity and mortality.⁶⁵⁻⁶⁷ The introduction of monoclonal antibodies directed at marrow elements linked to radioisotopes in hopes of targeting only marrow and not vital organs may offer hope of providing truly selective myeloablation.⁶⁸

The lack of benefit of conditioning regimen dose intensification and the recognition of the contribution of graft-versus-tumor activity to disease eradication prompted the development of low-dose, nonmyeloablative regimens. These regimens are designed not to have direct antitumor activity but rather to provide sufficient host suppression to permit engraftment of donor hematopoietic and lymphoid effector cells. Many regimens ranging from nearly myeloablative to minimally myelosuppressive have been piloted. Most regimens have combined a purine analogue, such as fludarabine, with an alkylating agent or low-dose TBI with or without anti-T-cell antibodies such as thymoglobulin or alemtuzumab.⁶⁹⁻⁷³ Studies indicate that these nonmyeloablative regimens can facilitate full donor engraftment with much decreased upfront toxicity, allowing transplantation to be performed in older patients or those with contraindications to high-dose therapy. Unfortunately, GVHD still is a problem. One-hundred-day transplant-related mortality is low in recipients of nonmyeloablative conditioning, but later morbidity and mortality, usually from GVHD, can be substantial.⁷⁴ Several retrospective comparative studies have suggested similar overall outcomes in recipients of myeloablative and nonmyeloablative transplants, but prospective randomized studies are needed to determine the impact of these less-intensive regimens on toxicity and disease control.

Potential Obstacles to Successful Transplantation

There are three major hurdles that must be overcome for HSCT to be successful: (1) identification of a suitable donor, (2) prevention and effective treatment of transplant-related complications, and (3) sustained eradication of underlying disease.

Identification of a Suitable Donor

Donor choice can have a profound influence on transplant outcome. Patients may receive either autologous or allogeneic stem cells. Pros and cons of each donor source are displayed in Table 6.1.

AUTOLOGOUS TRANSPLANTATION

A major issue facing investigators surrounding autologous transplantation is the potential of tumor cell contamination. The aim of purging in autologous transplantation is to eliminate any contaminating malignant cells and leave intact the hematopoietic stem cells that are necessary for engraftment. Most clinical studies in lymphoma and myeloma have demonstrated that purging can deplete malignant cells in vitro without significantly impairing hematologic reconstitution,⁷⁵⁻⁷⁷ but studies in AML using immunologic or chemical methods have been associated with delayed hematopoietic recovery (Figure 6.2).^{78,79} The rationale for removing tumor cells from hematopoietic cells might therefore appear compelling, yet the issue of purging remains highly controversial. Both positive (CD34+ columns) and negative (exposure ex vivo to antibodies directed at tumor cells) selection techniques for tumor cell purging are available. However, purging has not as

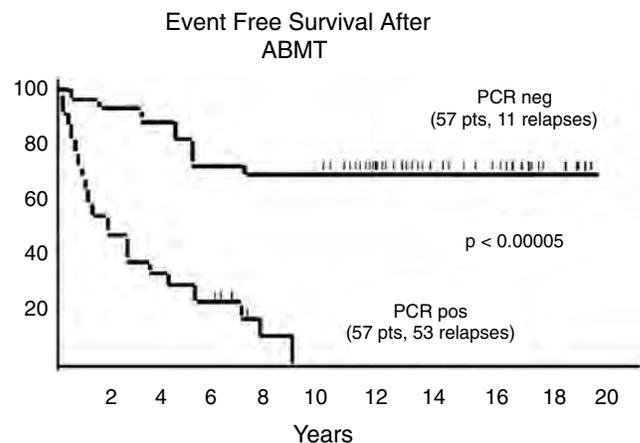

FIGURE 6.2. Successful purging of tumor cells from autologous marrow is associated with improved survival after transplantation. Patients whose marrows had no detectable lymphoma cells by polymerase chain reaction studies after immunologic purging had superior survival compared to patients with persistent evidence of disease. (Courtesy of J. Gribben.)

yet been universally adopted because there are no convincing data in Phase 2 trials that patients receiving purged marrow fare better than those receiving unpurged cells. A retrospective analysis of the European Blood and Marrow Transplant Lymphoma Registry compared the outcome of 270 patients whose BM had been purged and with the outcome of 270 case-matched control patients.⁸⁰ A variety of purging methodologies was used. Patients with low-grade lymphoma did not have a significantly improved progression-free survival if the BM was purged ($P = 0.18$), but they did have a significantly improved overall survival ($P = 0.0018$). In multiple myeloma, a Phase III randomized trial using purged versus unpurged autologous PBSC was performed using CD34 selection.⁸¹ After CD34 selection, tumor burden was reduced by a median of 3.1 log, with 54% of CD34-selected products having no detectable tumor. There was no improvement in disease-free or overall survival.

Data indicate, however, that contamination of the stem cell inoculum with tumor cells contributes to posttransplant relapse. In studies at the Dana-Farber Cancer Institute, polymerase chain reaction (PCR) amplification of the t(14;18) was used to detect residual lymphoma cells in the BM before and after purging to assess whether efficient purging had any impact on disease-free survival.⁸² In this study, patients with B-cell non-Hodgkin lymphoma and the bcl-2 translocation were studied. Residual lymphoma cells were detected in all patients in the harvested autologous BM. Following three cycles of immunologic purging using the anti-B-cell mAbs and complement-mediated lysis, PCR amplification detected residual lymphoma cells in 50% of patients. Patients who were infused with a source of hematopoietic cells that was free of detectable lymphoma cells had improved outcome compared to those who had residual detectable lymphoma (see Figure 6.2). This finding was independent of degree of BM infiltration at the time of BM harvest or remission status at the time of autologous BMT. Further evidence supporting the contribution of contaminating tumor cells to posttransplant relapse comes from gene marking studies in AML and neuroblastoma.⁸³⁻⁸⁵

ALLOGENEIC DONORS

When allogeneic transplantation is contemplated, an HLA-identical or closely matched donor must be found. The major HLA loci are located on chromosome 6 and are closely linked.⁸⁶ Because every individual inherits one chromosome 6 from their mother and one from their father, the chance of any one sibling being a match is one in four. A *complete* match between donor and recipient was considered identity of both alleles at HLA-A, HLA-B, and HLA-DR loci. Other major loci, such as HLA-C and HLA-DQ, can influence outcome and must be checked when performing a search for an unrelated donor. Indeed, HLA-C identity is now considered as important as a match at HLA-A, -B, and -DR.⁸⁷⁻⁹⁰ Accurate HLA typing is essential. Serologic methods are no longer adequate. It is imperative that molecular techniques using site-specific oligonucleotide probes and direct sequencing be employed. The formation of the National Marrow Donor Registry (NMDR) has made possible thousands of unrelated transplants in the United States. More than 4 million people are registered as potential donors with the NMDP. The likelihood of finding an HLA-A, -B, and -DR

match is 65% to 70%, although finding a donor is more difficult in minority populations. It can take weeks to many months between the time a search is initiated and a donor is identified, medically cleared, and ultimately donates.

Even when a "complete" match is found, complications such as GVHD can still be substantial. The reason for this is that minor HLA antigens, which can influence graft rejection or GVHD, cannot be easily typed.⁹¹⁻⁹³ Moreover, these minor antigens likely are not found on chromosome 6; therefore, a complete match of HLA major loci does not necessarily translate into a complete match of minor loci. Results of allogeneic transplantation using unrelated donors have been slightly worse than those of matched related transplants, but with improvements in typing, the gap has narrowed.⁹⁴

Sometimes it is possible to identify more than one potential donor either within a family or through the NMDP. The most important characteristic in choosing a donor is HLA identity. The greater the HLA disparity, the greater the risk of GVHD, graft failure, and adverse outcome. Other factors that may increase GVHD include the use of female multiparous donors for male recipients (a minor HLA antigen located on the Y chromosome has recently been identified), older donor age, and prior cytomegalovirus (CMV) exposure.^{95,96} ABO compatibility is desirable but is not a prerequisite for transplantation. ABO incompatibility may lead to hemolysis and delayed red cell engraftment.⁹⁷

Transplantation of hematopoietic stem cells from haploidentical family members has been associated with increased risks of GVHD and graft failure.^{98,99} Historically, outcome has been poor. Recent studies of infusion of large numbers of haploidentical peripheral blood stem cells exhaustively depleted of T cells through positive selection of CD34+ stem cells has been reported to result in high rates of engraftment and low rates of GVHD.¹⁰⁰ Despite T-cell depletion, relapse rates have been low, particularly in patients with AML. It now appears that mismatching of KIR receptor on donor NK cells and KIR ligand on recipient cells may actually promote cell-mediated destruction of AML cells and recipient antigen-presenting cells, leading to lower relapse rates without GVHD.^{101,102}

Recent studies have demonstrated that umbilical cord blood (UCB) is very rich in stem cells but low in alloreactive T cells. As a consequence, it was hypothesized that these cells might support engraftment with less GVHD. A series of studies have confirmed that engraftment can be obtained with unrelated UCB with a reduced risk of GVHD, even when partially HLA-mismatched unrelated transplants donor cells used.¹⁰³⁻¹⁰⁷ However, because the number of stem cells per kilogram recipient weight is relatively low in cord blood products, engraftment is slow. The number of cells available for transplantation from cord blood may make it difficult to utilize these products with large adult recipients. Strategies currently under investigation to address low cord blood cellularity include the use of multiple disparate products and expansion of stem cells *ex vivo* before infusion.¹⁰⁸ UCB transplantation should be considered for patients for whom traditional related or unrelated products are not available.

Transplant-Related Complications

When evaluating patients for potential complications of transplantation, it is critical to have a full understanding of

the entire treatment course to assemble a reasonable differential diagnosis. Factors that must be taken into account include donor source (allogeneic or autologous), interval post-transplant (early versus late), type of GVHD prophylaxis, infectious prophylaxis, current use of immunosuppressive medications, ablative regimen, and duration of granulocytopenia. The three major categories of transplant-related toxicities are (1) treatment-related organ damage, (2) infectious complications, and (3) graft-versus-host disease.

ORGAN DAMAGE

Damage can be manifested early or late after transplantation. Some of the more commonly recognized organ toxicities that are not clearly attributable to infection or GVHD are discussed next.

IDIOPATHIC PNEUMONIA SYNDROME (IPS)/DIFFUSE ALVEOLAR HEMORRHAGE (DAH)/ENGRAFTMENT SYNDROME

These processes usually occur during the transplant hospitalization around the time of neutrophil recovery, more commonly after allogeneic HSCT.¹⁰⁹⁻¹¹¹ These terms may represent slightly different manifestations of the same poorly understood entity. By definition, they have no clearly identified infectious etiology. Onset can be insidious, but decompensation can be sudden. Radiographic findings can be nonspecific. Mortality is extremely high in patients who require mechanical ventilation. Elevated circulating and bronchoalveolar lavage (BAL) levels of tumor necrosis factor (TNF) and other cytokines have been observed.^{112,113} Early intervention with high-dose steroids (1 g IV solumedrol) even before diagnostic studies are performed may be lifesaving.¹¹⁴ New agents, including TNF blockers such as etanercept (Enbrel), are being studied in clinical trials.¹¹⁵

INTERSTITIAL PNEUMONITIS (IP)

Interstitial pneumonitis (IP) often occurs 2 to 6 months after transplant. IP may present as a delayed inflammatory response to a conditioning agent, such as BCNU. In these circumstances, complete responses can be obtained with a steroid dose of 1 mg/kg. IP can be steadily progressive and fatal, particularly after allo-HSCT. IP must be distinguished from infectious pneumonitis.

HEPATIC VENO-OCCLUSIVE DISEASE (VOD)

VOD is a clinical syndrome characterized by painful hepatomegaly, jaundice, ascites, fluid retention, and weight gain.^{116,117} The onset is usually before day + 35 after stem cell reinfusion, and other causes of these symptoms and signs are absent. VOD develops in 2% to 40% of patients after SCT and ranges in severity from mild, reversible disease to a severe syndrome associated with multiorgan failure and death, with established severe VOD shown to have a mortality rate approaching 100% by day + 100 post-SCT. VOD is believed to be caused by primary conditioning regimen-induced injury to sinusoidal endothelial cells and hepatocytes with subsequent damage to the central veins in zone 3 of the hepatic acinus.¹¹⁸ Early changes include deposition of fibrinogen, factor VIII, and fibrin within venular walls and sinusoids. As the process of venular microthrombosis, fibrin deposition, ischemia, and fibrogenesis advances, widespread zonal disruption leads to portal hypertension, hepatorenal syndrome, multiorgan failure, and death. Despite therapeutic interven-

tions, including the use of antithrombotic and thrombolytic agents such as prostaglandin E₁ and tissue-plasminogen activator (t-PA) with or without concurrent heparin, little success has been achieved in the treatment of severe VOD. Recently, the use of defibrotide (DF), a single-stranded polydeoxyribonucleotide that has specific aptameric-binding sites on vascular endothelium, has shown promise in the treatment of VOD.^{119,120} DF upregulates the release of prostacyclin (PGI₂), prostaglandin E₂, thrombomodulin (TM), and t-PA both in vitro and in vivo. Moreover, it has been shown to decrease thrombin generation, tissue factor expression, plasminogen activator inhibitor (PAI)-1 release, and endothelin activity.

HEMOLYTIC-UREMIC SYNDROME (HUS)/

THROMBOTIC THROMBOCYTOPENIC PURPURA (TTP)

Both HUS and, less commonly, TTP can occur after either allo- or autotransplant. HUS/TTP presents 2 to 12 months posttransplant. HUS is manifest by nonimmune-mediated hemolytic anemia characterized by schistocytes on smear, mild azotemia, and mild hypertension.^{121,122} It is likely precipitated by endothelial damage caused by the ablative regimen or by medications such as cyclosporine, tacrolimus, or sirolimus. HUS is usually self-limited, and treatment is supportive. Plasmapheresis is generally not indicated but isolated reports have indicated some benefit.

CARDIOMYOPATHY

Cardiac dysfunction can occasionally be observed after HSCT. It usually presents shortly after completion of conditioning and has been linked with cyclophosphamide.¹²³ It can present as myopericarditis. If patients can be managed through the acute episodes, there may not be permanent dysfunction. Long-term cardiac complications are uncommon and usually can be related to previous anthracycline exposure.

NEUROLOGIC DYSFUNCTION

Neurologic dysfunction can be an unrecognized problem after HSCT. Potential issues include memory disturbance and learning disability secondary to irradiation, Guillain-Barre syndrome, limbic encephalitis, cyclosporine/tacrolimus-associated hypertensive encephalopathy and seizures, and peripheral neuropathies.¹²⁴

CATARACTS

Cataracts often develop in patients 1 to 5 years after transplant.¹²⁵ The incidence is increased in patients who received TBI and those on prolonged steroid therapy for GVHD.

INFECTION

Infection is a major cause of morbidity and mortality after transplantation. There are numerous predisposing factors that increase the risk of infection after HSCT, including the following:

- Prolonged granulocytopenia
- Disruption of mucosal barriers
- Extensive use of antibiotics
- Prolonged placement of indwelling venous access
- Delayed recovery of cellular immunity
- Impaired antibody production
- Use of immunosuppressive medications to treat or prevent GVHD

- Immune defects associated with underlying malignancy
- Suppression of immune responses by GVHD itself

It is important to have an understanding of the typical time course associated with risk of developing specific infections after HSCT.¹²⁶ It is critical to anticipate the development of infection, and considerable attention has been paid to prophylaxis and preemptive therapy. Examples are detailed here:

1. Bacterial: During the transplant hospitalization, gut decontamination with oral nonabsorbable antibiotics is often employed along with systemic agents such as a quinolone. If patients become febrile while neutropenic, typical broad-spectrum coverage is employed. For outpatients with chronic GVHD on steroids, oral antibiotics targeting encapsulated organisms are frequently prescribed on a chronic basis for suppression. Although routine immunoglobulin (IgG) administration is not recommended after transplant, it is recommended that patients whose IgG levels are consistently very low should receive replacement therapy.

2. Fungal: There are data indicating that prophylactic fluconazole can prevent *Candida* infections and may improve long-term survival after transplant.^{127,128} Amphotericin B or a liposomal derivative has been routinely administered for fever and neutropenia unresponsive to antibacterial antibiotics. The newly available voriconazole may ultimately be substituted for amphotericin in this setting.^{129,130} Moreover, its oral administration and activity against *Aspergillus* may lead to it being more widely adopted as fungal prophylaxis after discharge for patients on steroids for GVHD.

3. *Pneumocystis carinii*: *Pneumocystis carinii* pneumonia (PCP) can develop as early as 1 month after transplant. Prophylaxis should be instituted no later than 30 days post-HSCT and be continued for approximately a year or longer if the patient remains on steroids for GVHD. Trimethoprim-sulfamethoxazole is the most efficacious agent. For patients with allergies or cytopenias, atovaquone or other agents (dapson, pentamidine) may be substituted, but coverage should never be omitted. Practitioners should be aware of development of PCP in the months after discontinuation of prophylaxis.

4. Viral: Herpesviruses (HSV, VZV, EBV, HHV-6, and, most importantly, CMV) present the largest viral problem after transplant. HSV-induced mucositis can be completely prevented with acyclovir administration during the transplant hospital stay. Many centers will continue acyclovir for 1 year to prevent varicella-zoster virus (VZV) infections, which occur in 30% to 40% of patients not receiving prophylaxis.¹³¹ CMV usually occurs 2 to 6 months after transplant and is more common in allotransplant recipients. Patients at highest risk are those who are CMV seropositive and receive cells from a seronegative donor.¹³² In this circumstance, no anti-CMV immunity is transferred. CMV-filtered, or better still, CMV-negative blood products are essential to prevent nosocomial transmission. Data exist that demonstrate that treatment of patients preemptively with gancyclovir when CMV reactivation can be detected in blood or BAL fluid (before actual development of invasive infection) will reduce the risk of subsequent CMV pneumonitis and improve survival.¹³³⁻¹³⁶

Vaccinations are routinely administered to patients 1 and 2 years after HSCT. Diphtheria tetanus, inactivated polio, MMR (measles-mumps-rubella), hepatitis B, pneumococcal, and *Hemophilus influenzae* vaccine are often given.¹³⁷ The ability to make antibody is impaired post-HSCT and vaccinations are therefore usually delayed until the 1-year anniversary. Recent data suggest that vaccination of the donor before transplant may allow earlier transfer of immunity to the patient.¹³⁸

Graft-Versus-Host Disease

GVHD causes complications after allogeneic HSCT as a direct result of organ damage and as a consequence of infectious complications prompted by GVHD therapy. GVHD can be classified as acute or chronic based on timing of onset and clinical features. Acute GVHD usually develops within the first 2 months of BMT and affects mainly the skin, gastrointestinal (GI) tract, and liver.¹³⁹ The current standard grading system for acute GVHD is based on the degree of involvement of these three organs (Table 6.2). When pharmacologic immunosup-

TABLE 6.2. Acute GVHD scoring.

Extent of organ involvement	Skin	Liver	Gut
Stage			
1	Rash on less than 25% of skin	Bilirubin 2–3 mg/dL	Diarrhea more than 500 mL/day or persistent nausea
2	Rash on 25%–50% of skin	Bilirubin 3–6 mg/dL	Diarrhea more than 1000 mL/day
3	Rash on more than 50% of skin	Bilirubin 6–15 mg/dL	Diarrhea more than 1500 mL/day
4	Generalized erythroderma with bullous formation	Bilirubin more than 15 mg/dL	Severe abdominal pain with or without ileus
Grade			
I	Stage 1–2	None	None
II	Stage 3 or 4	Stage 1 or 2	Stage 1
III	—	Stage 2–3 or	Stage 2–4
IV	Stage 4	Stage 4	—

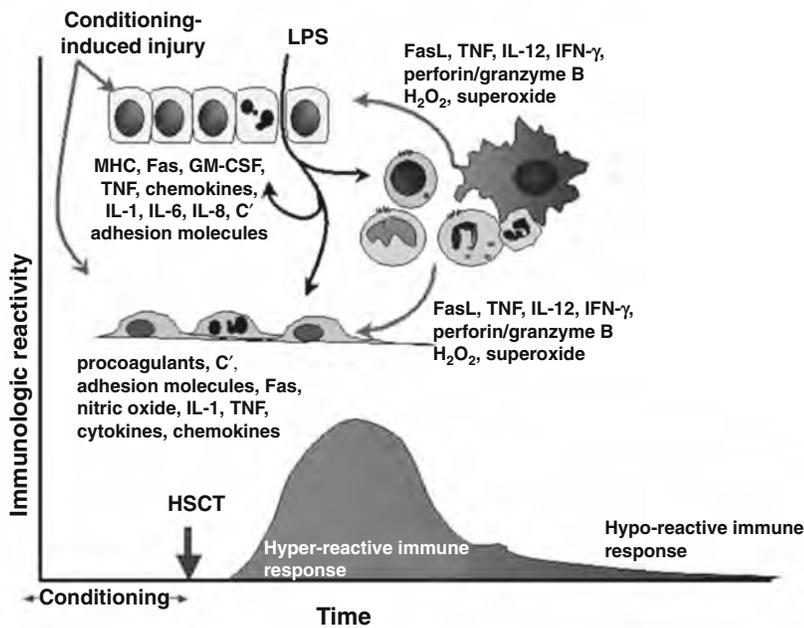

FIGURE 6.3. Pathophysiology of acute graft-versus-host disease (GVHD). The cytokine theory of acute GVHD pathogenesis involves release of proinflammatory cytokines after conditioning regimen-induced injury, which then leads to stimulation of alloreactive effector cells, which then leads to the further release of cytokines and tissue injury. (Courtesy of J. Antin.)

pression is used as GVHD prophylaxis after myeloablative transplant, moderate to severe acute GVHD (grades II–IV) occurs in 25% to 60% of matched related donor transplant recipients and up to 45% to 70% in unrelated donor recipients. Development of grade II–IV acute GVHD is associated with decreased survival in patients after allogeneic BMT.^{140–143}

Chronic GVHD has a later onset than acute GVHD and is often clinically distinct.¹⁴⁴ Chronic GVHD may resemble an autoimmune collagen vascular disease. Patients can manifest sclerodermatous skin changes, keratoconjunctivitis, sicca syndrome, lichenoid oral mucosal lesions, esophageal and vaginal strictures, liver disease, and pulmonary insufficiency. Despite immunosuppressive agents, approximately 30% to 50% of patients develop chronic GVHD after conventional myeloablative HLA-identical sibling BMT. The incidence of chronic GVHD may be even higher after allogeneic transplantation using unmanipulated peripheral blood stem cells.^{45,46,51,52} Chronic GVHD may be classified as subclinical or clinical, limited or extensive. Although subclinical or clinically limited chronic GVHD often resolves spontaneously with minimal intervention, extensive chronic GVHD requires prolonged immunosuppressive treatment and is associated with significant morbidity and mortality. More than 50% of patients with extensive chronic GVHD will die, mostly secondary to infections resulting from severe immune dysfunction.

Large single-institution and registry series have identified factors that place patients at higher risk for the development of GVHD. For acute GVHD, these include HLA incompatibility, use of an unrelated donor, prior donor allosensitization through pregnancy or blood transfusion, older patient or donor age, recipient CMV seropositivity, and increased intensity of the ablative regimen. For chronic GVHD, prior acute GVHD is the major risk factor, but also important are use of peripheral blood stem cells, histoincompatibility, and the prior use of corticosteroids.^{95,145–147}

GVHD PATHOPHYSIOLOGY

The pathophysiology of GVHD has received extensive attention. It is recognized that donor T cells are critical mediators in the graft-versus-host reaction. However, recent animal research suggests that the pathophysiology of acute GVHD is far more complex and that it involves intricate interactions between cellular and cytokine components of the immune system (Figure 6.3).^{148,149} Acute GVHD is now believed to occur in three phases: (1) tissue damage from conditioning regimen, (2) donor T-cell activation phase, and (3) inflammatory effector phase. In the earliest phase of GVHD, inflammatory cytokines are released from host tissue in response to damage by the pretransplant conditioning regimen. These cytokines, including interleukin 1 (IL-1) and tumor necrosis factor- α , upregulate the expression of adhesion molecules and host major histocompatibility complex (MHC) antigens and enhance recognition of the host tissue by mature donor T lymphocytes. During the second phase, donor T cells of the T-helper 1 (Th1) subset are activated upon recognition of alloantigens and secrete cytokines such as interleukin 2 and interferon- α . IL-2 plays a central role in the recruitment of other T cells, cytotoxic T lymphocytes (CTLs), natural killer (NK) cells, monocytes, and macrophages.

GVHD PROPHYLAXIS

T cells remain the prime target for most current therapeutic strategies in GVHD prophylaxis in humans. Effective approaches for the prevention and treatment of GVHD involve direct blockade of T-cell function. These methods have included the downregulation of T lymphocytes by inhibiting cellular proliferation (methotrexate), inhibition of de novo purine synthesis (mycophenolate mofetil), suppression of IL-2 secretion by blocking calcineurin activity (cyclosporine, tacrolimus), interfering with downstream growth signaling pathways (rapamycin), reduction of T-cell

responsiveness by blocking the IL-2 receptor (dacluzimab), and generation of immunosuppressive cytokines (extracorporeal photopheresis).¹⁵⁰⁻¹⁵⁶ Combination therapy with methotrexate and a calcineurin inhibitor, albeit flawed, remains the gold standard for GVHD prophylaxis.¹⁵⁷⁻¹⁶⁰ The recent combination of tacrolimus and sirolimus (rapamycin) has shown significant promise in recipients of HLA-matched unrelated and related transplants.¹⁶¹

The most effective means for GVHD prophylaxis has been ex vivo depletion of T cells from the donor inoculum.¹⁶² Donor T-cell depletion (TCD), when it was first introduced in the early 1980s, offered the potential for prevention of GVHD without the morbidity associated with immunosuppressive drugs such as methotrexate and cyclosporine. Numerous TCD methods have been utilized over the past two decades; these have included negative selection techniques using monoclonal antibody(ies) plus complement, immunotoxins, counterflow centrifugal elutriation, soybean lectin agglutination, and, more recently, positive selection through CD34+ columns.¹⁶³⁻¹⁶⁶ Most early trials documented that TCD could substantially limit acute and chronic GVHD. However, this reduction in GVHD did not translate into improved overall survival because of unexpected high rates of graft failure, Epstein-Barr virus (EBV)-associated lymphoproliferative disorders (EBV-LPD), and disease recurrence following TCD-BMT (Table 6.3).¹⁶⁷⁻¹⁷⁰ It is believed that certain sets of donor cells removed in the purging process are also important for graft maintenance, viral surveillance, and elimination of residual leukemia cells that have survived the high-dose ablative conditioning regimen. Despite the problems associated with T-cell depletion, there remains great interest in developing and improving this technology, particularly for recipients of mismatched or unrelated grafts. Reasonable applications for TCD may include those patients at high risk for GVHD (unrelated or mismatched grafts) or patients with comorbid medical conditions who might have a high risk of complications after conventional BMT. TCD may be ideal for patients with diseases where GVL activity is less critical, such as first remission acute leukemia. In the future, studies need to assess the potential role of T-cell depletion when mobilized PBSCs are used for allogeneic transplantation, particularly with respect to its effect on chronic GVHD. It would be ideal to be able to manipulate different lymphoid subgroups responsible for GVHD and GVL, but whether these processes can be effectively separated at a clinical level remains unknown.

GVHD TREATMENT

Once established, administration of corticosteroids is the most effective approach to the treatment of both acute and

chronic GVHD. Complete responses occur in 25% to 40% of patients. Addition of other agents to corticosteroids or increasing the steroid dose has not improved response rates or outcomes.^{171,172} A comparative trial of 2 and 10 mg/kg/day of methylprednisolone demonstrated no advantage of the higher dose in terms of response or survival.¹⁷³ For acute GVHD, calcineurin inhibitors such as cyclosporine and tacrolimus are useful in patients who did not receive these agents initially as prophylaxis.¹⁷⁴ Serotherapy with antithymocyte globulin (ATG) can produce responses, although subsequent infection rates are high and survival does not appear to be improved. Other anti-T-cell antibodies with distinct specificities have been studied. Responses have been reported, but these antibodies have not proven superior to steroids alone. Medications aimed at blocking T-cell proliferation (mycophenolate mofetil) or activation (rapamycin) appear to induce responses in single-arm trials, but these agents have not yet been studied fully in randomized trials. Targeting cytokine receptors such as IL-2 (dacluzimab, denileukin difitox), IL-1 (IL-1RA), and tumor necrosis factor- α (TNF- α) (infliximab) have yielded promising results in small uncontrolled trials but have not proven to add benefit in randomized trials.^{150-156,175,176}

Treatment of extensive chronic GVHD with immunosuppressive therapy has been even less rewarding than that of acute GVHD. Although the combination of cyclosporine and prednisone is the treatment of choice in many centers, a recent randomized trial failed to show any survival advantage.¹⁷⁷ Encouraging uncontrolled trials with thalidomide have been reported, but subsequent randomized studies did not demonstrate significant benefit.^{178,179} Both psoralen plus ultraviolet A (PUVA) therapy and extracorporeal photopheresis (ECP) have been reported to be effective in acute and particularly chronic GVHD.^{180,181} Randomized studies are currently under way to evaluate the value of ECP. The overall disappointing results of immunosuppressive therapy for chronic GVHD make other efforts, such as prevention of infection and physical therapy, even more critical to maintenance of patient well-being.

Sustained Eradication of Disease

The goal of HSCT for malignant disease or marrow disorders is sustained eradication of disease. This result can be obtained in certain circumstances with high-dose chemotherapy. However, it is clear from preclinical models and clinical studies that immune-mediated allogeneic effects, termed graft-versus-tumor (GVT) or graft-versus-leukemia (GVL) effects, are central to the therapeutic effect of allogeneic

TABLE 6.3. Pros and cons of T-cell depletion.

<i>Advantages</i>	<i>Disadvantages</i>
Decreased incidence of acute and chronic GVHD	Higher incidence of graft failure
Reduced or no requirement for posttransplant immunosuppression as GVHD prophylaxis	Loss of GVL activity (higher incidence of disease relapse, especially with CML)
Decreased organ toxicity	Delayed immune reconstitution
Lower early transplant-related mortality	Increased risk for posttransplant EBV-associated lymphoproliferative disorder

HSCT.¹⁸² Evidence to support the existence of GVL activity has come from several sources. First, a higher relapse rate has been noted in recipients of syngeneic transplants compared with allogeneic transplants from sibling donors, suggesting that the genetic/immunologic discrepancy between donor and host plays a role in disease control.^{140,183} Second, a reduced risk of relapse is observed in patients who develop GVHD after HSCT.¹⁸⁴ Third, relapse rates are higher in recipients of T-cell-depleted grafts where alloreactive T cells are removed.¹⁶⁷ Fourth, withdrawal of immunosuppression in some patients who have relapsed after transplant can induce a remission.¹⁸⁵ All these lines of evidence still only provided indirect evidence of the existence of GVL activity. Direct evidence was finally obtained when donor lymphocyte infusions (DLI) were successfully used to treat patients with CML who had relapsed after BMT.

Many reports confirmed the efficacy of DLI in inducing remissions in patients who have relapsed after transplant, particularly in patients with CML.^{186–188} DLI induces complete cytogenetic remissions in more than 70% in patients with CML when treated in either cytogenetic or hematologic relapse. Responses are noted in other diseases, including multiple myeloma, MDS, CLL, and low-grade lymphoma. Acute leukemia and advanced CML may be less sensitive to DLI. DLI can cause GVHD. However, it is exciting to note that DLI can induce remissions in the absence of GVHD, demonstrating that GVL and GVHD can be separable.¹⁸⁹ The dramatic activity of DLI is what has led to the exploration of nonmyeloablative conditioning regimens in clinical situations that rely predominantly on GVL activity for therapeutic benefit. It is hoped that current efforts to identify targets of DLI will lead to generation of vaccines that can be tested in clinical trials.^{190,191}

Evaluation of Tumor Markers: An Evidence-Based Guide for Determination of Clinical Utility

Daniel F. Hayes

A tumor marker is clinically useful if its results serve to separate a large heterogeneous population into smaller populations with more precisely predictable outcomes. In theory, if this separation is both reliable and disparate, one can apply therapy more efficiently to the population by exposing those most likely to need and benefit from the therapy while ensuring that the other group avoids needless toxicities. In essence, the term *tumor marker* has come to describe a variety of molecules or processes that differ from the norm in either malignant cells, tissues, or fluids in patients with malignancies. Assessing these alterations from normal can be used to place patients into categories that are distinguished by different outcomes, either in the absence of specific therapy or after various treatments are applied.

Tumor markers can include changes at the genetic level (for example, mutations, deletions, or amplifications), at the transcriptional level (for example, over- or underexpression), at the translational or posttranslational level (for example, increased or decreased quantities of protein, or abnormal glycosylation of proteins), and/or at the functional level (for example, histologic description of cellular grade or presence of neovascularization). Each of these can be assessed by one or more assays, which can be performed using one or more methods with differing reagents. This enormous heterogeneity of approaches is the root of considerable confusion regarding the true value, in clinical terms, of a given tumor marker.

The *molecular revolution* is now well into its fourth decade. Yet, in spite of impressive advances in our understanding of the biology of human malignancy and in the technology of investigating molecular processes, the number of clinically useful products from these advances is disappointing. For example, in 1995, the American Society of Clinical Oncology (ASCO) convened a panel of experts to establish guidelines for the use of tumor markers in colon and breast carcinoma. Although the Expert Panel reviewed many putative markers (including both tissue-based and circulating

markers), their ultimate recommendations were surprisingly sparse (Table 7.1).¹⁻³

Why are the ASCO guidelines so conservative? In reviewing the available literature, the Panel recognized that the science of clinical tumor marker investigation has been haphazard and relatively chaotic. Too often, studies of tumor markers are more inclined to be “fishing expeditions” with the hope that something interesting will be detected with statistical significance, rather than being prospective, hypothesis-driven investigations. In light of this confusion, several authors of the Guidelines separately developed a proposal for a framework in which previously published tumor marker studies might be critically evaluated in an evidence-based manner.⁴ The rest of this chapter reviews the generic concepts and policies related to tumor marker evaluation. Specific marker evaluation for a given disease are reviewed in the relevant chapter pertaining to that malignancy.

Critical Elements of a Clinically Useful Tumor Marker

The first and most obvious element of evaluating a tumor marker is to determine its stated use. Tumor markers can be valuable for risk assessment, screening, diagnosis, prognosis, prediction of benefit from therapy, and monitoring disease course (Table 7.2). The most commonly accepted uses are for prognosis and prediction, as well as monitoring. The first two of these require more detailed understanding.

What Is the Question: Prognosis Versus Prediction?

Estimating a patient’s prognosis requires a complicated set of evaluations, which includes the propensity of a malignancy to expand in volume (proliferative capacity), its ability to escape its natural site of origin and establish growth in a foreign tissue (metastatic potential), and its relative sensitiv-

TABLE 7.1. American Society of Clinical Oncology clinical practice guidelines for use of tumor markers in breast and colon cancer (tissue factors only).

<i>Disease</i>	<i>Factor</i>	<i>Use</i>	<i>Guideline</i>
Breast cancer	Estrogen and progesterone receptors	Predictive factors for endocrine therapy	Measure on every primary breast cancer and on metastatic lesions if results influence treatment planning
	DNA flow cytometrically derived parameters	Prognosis or prediction	Data are insufficient to recommend obtaining results
	c-erbB-2 (HER-2/neu)	Prognosis Prediction for: trastuzumab CMF-like regimens doxorubicin taxanes endocrine Rx	Data are insufficient to recommend obtaining results for this use c-erbB-2 should be evaluated on every primary breast cancer at time of diagnosis or at time of recurrence for use as predictive factor for trastuzumab; Committee could not make definitive recommendations regarding CMF-like regimens; c-erbB-2 may identify patients who particularly benefit from anthracycline-based therapy but should not be used to exclude anthracycline; treatment c-erbB-2 should not be used to prescribe taxane-based therapy or endocrine therapy
Colorectal cancer	P53	Prognosis or prediction	Data are insufficient to recommend use of p53
	Cathepsin-D	Prognosis	Data are insufficient to recommend use of cathepsin-D
	Circulating carcinoembryonic antigen	Screening	Not recommended
	Lipid-associated sialic acid CA19-9	Preoperative	Recommended to guide surgical planning
		Postoperative	Recommended to monitor for early, asymptomatic, and resectable metastases
	DNA ploidy and flow cytometry	Metastatic setting	Recommended to monitor benefit from therapy
		Monitoring	Not recommended for screening, diagnosis, staging, or monitoring
P53	Prognosis	Data are insufficient to recommend use of DNA ploidy or flow cytometry	
Ras	Prognosis	Data are insufficient to recommend use of p53 Data are insufficient to recommend use of ras

ity or resistance to therapy. Therapies for most solid tumors include surgery, radiation, and systemic therapies such as hormone therapies or chemotherapies. In this regard, the terms “prognostic” and “predictive” have taken on separate meanings.^{5,6} The prognostic factor designation is usually reserved for those markers that specifically provide an estimate of the odds of the recurrence of a given cancer after local therapy only. It is usually a measure of both proliferation and metastatic potential, and it usually implies the odds of systemic recurrence and/or death in a patient who does not receive systemic therapy. If the factor is associated with a poor prognosis, patients who are “positive” for the prognostic factor have a worse outcome than those who are “negative” in the absence of systemic therapy. Therapy may be

effective, but it is equally so (in relative terms) for both factor-positive and factor-negative patients. The best examples of prognostic factors for most solid tumors are the TNM staging systems.

A predictive factor helps select therapies most likely to work against that patient’s tumor. A predictive factor may be the precise target of the therapy, an associated molecule or pathway that modifies the effectiveness of the therapy, or simply an alteration that is an epiphenomenon linked to the target or pathway of the therapy (such as coamplification of a neighboring gene). If the factor is a pure predictive factor, prognosis in the absence of therapy is the same for factor-negative and -positive patients (it has no prognostic effects). However, assuming it predicts *for* benefit from therapy, factor-positive patients have a much better prognosis than factor-negative patients in the presence of the therapy for which the factor is predictive. For example, it is now clearly established that the level of estrogen receptor (ER) content in breast cancer tissue is positively related to the odds of response and benefit from antiestrogen hormonal therapy, such as ovarian ablation, tamoxifen, or aromatase inhibitors, because the ER plays a fundamental role in estrogen-dependent tumor growth and biology.⁷ In contrast, *p*-glycoprotein content is a negative predictive factor for resistance to certain drugs, because this protein modulates multidrug resistance by increasing efflux of the antineoplastic agent from the cancer cell.⁸

TABLE 7.2. Potential uses of tumor markers.

Determination of risk
Screening
Differential diagnosis
Benign vs. malignant
Known malignant: tissue of origin
Prognosis
Prediction
Monitoring disease course
Detect recurrence in patient free of obvious disease
Patient with established recurrence

Many, in fact most, factors may be both prognostic and predictive. For example, in addition to serving as a predictive factor, ER is also a favorable prognostic factor. Breast cancers with high ER content have generally slower growth potentials, and patients with ER-“positive” tumors have a better prognosis, even if they receive no treatment.^{9,10}

To further complicate this discussion, some markers may be associated with a *poor* prognosis independent of therapy, but they may predict for an *improved* outcome related to specific treatment modalities. For example, in breast cancer, amplification and/or overexpression of HER-2 is a marker of poor prognosis in the absence of any systemic therapy.¹¹⁻¹⁴ However, HER-2 serves as the target for a humanized monoclonal antibody, trastuzumab (herceptin), and response and benefit from trastuzumab are tightly linked to HER-2 amplification and/or overexpression.^{15,16} Thus, untreated HER-2-positive patients have a worse prognosis than HER-2-negative patients if they do not receive trastuzumab, but they may actually have a more favorable prognosis if they do.

These considerations are often ignored in many “prognostic factor” studies. Often, a population of patients is studied with a new, putative prognostic factor simply because the samples to be assayed happen to be available and the outcome for the patients is known. Indeed, a prognostic factor can only be evaluated in the absence of systemic therapy, or at least in the absence of any therapy with which it interacts. A predictive factor can only be evaluated in the context of an untreated control group, preferably one that is prospectively identified and followed, as in prospective randomized trials. It is not surprising that studies of a marker that might have both prognostic and predictive capabilities, especially if these effects are in opposition (as may be the case with HER-2), will provide relatively random and conflicting results if not carefully planned with appropriate consideration of treatment effects control groups and satisfactory control groups.

What Is the Strength of the Marker?

A marker is only helpful if it separates an entire population into two different groups whose outcome is likely to be so different that one group might be treated differently from another. Again using breast cancer as an example, both ER and HER2 are good examples of strong predictive markers that are clinically useful. Patients with ER-negative tumors appear very unlikely to benefit from hormone therapy,¹⁷ and, likewise, it appears that patients with HER2-low or -negative cancers are very unlikely to benefit from trastuzumab.^{4,18} It is important to recognize that clinical utility of a marker is not justified simply because a tumor marker may separate two populations of patients whose outcomes differ with statistical significance. A *P* value less than 0.05 simply implies it is likely that those two populations are different (see following). Rather, for a marker to be clinically useful, it must not only separate the two populations with reliability, the separation must be of sufficient magnitude that one would treat the two groups differently.

How large this magnitude needs to be for a tumor marker to be acceptable for clinical use is an arbitrary decision, and it depends on the perspectives of the patient, the caregiver, and the societal elements that pay for the care. Several studies

have been performed in which patients are queried regarding how much benefit they would require to accept a given level of toxicity.¹⁹⁻²¹ Not surprisingly, results from these studies are heterogeneous, although in general a decreasing proportion of patients is willing to accept therapy as the absolute odds of benefit decrease. However, for a few patients, any benefit is worth the risk of toxicities, and for a few others therapy is never acceptable, even if the odds of benefit are enormous. Sophisticated tools are now available on paper and on the Internet to help patients understand and quantify the relative odds of benefit and toxicities of certain therapies in selected situations, such as for adjuvant therapy of primary breast cancer.²²⁻²⁴ These tools are based on clinical and pathologic prognostic and predictive factors, such as the T, N, and M status, and a few classic markers, such as ER. However, these tools are potentially flexible enough to be modified to permit incorporation of new prognostic factors if the estimate of magnitude between positive and negative subgroups is sufficiently reliable.

Is the Magnitude of Difference Between the Two Groups Reliable?

The hallmark of any scientific observation is, of course, reproducibility. With few exceptions, tumor markers seem to pass through a “life cycle” in which the original report is extraordinarily positive with great acclaim, but subsequent studies fail to live up to the promise. There are several elements regarding both technical variability of the assay and clinical trial design that account for this phenomenon, and these may hinder acceptance of the assay for routine clinical use. There are fundamentally three reasons for this conundrum: (1) technical variability of the assay; (2) variations in the manner in which different assays for the same marker are performed; and (3) inadequate and variable study designs.

The assay must be technically reliable and reproducible.

Assay reproducibility is critical for any clinical test. Reproducibility hinges on several factors, all of which must be standardized and validated. Too often, an assay is developed in an individual investigator’s laboratory based on personal preferences and subjective techniques that are not easily transported to other investigators and laboratories. For an assay to be useful clinically, it must be shown to be accurate throughout a broad dynamic range of values and reproducible at each of these levels as well. Concern must be taken regarding fixatives and other processing of samples, because these can have an enormous impact on the results of an assay from one laboratory to the next, resulting in false positives or negatives.

ANALYSIS AND QUANTITATION OF RESULTS

How the assay is “scored” or “read” is also critical for reproducibility. For example, when immunohistochemistry is performed, does the reader report the results as percent cells that stained, the intensity of staining, or a combination of both? Are the results reported as such, or in an index, such as 0-3+? Furthermore, selection of the cutoff that distinguishes positive from negative populations can give incredibly different results for the same assay. Several means of establishing a cutoff are employed, and there is no consensus regarding the optimal method.²⁵ One method is to arbitrarily select a cutoff,

based on some preconceived reason, such as the mean level of the assay in an affected population or the mean plus two standard deviations (2 SD) of the level in an unaffected population. A second method is to test several potential cutoffs in one population, selecting the one that appears most robust relative to separation of the outcomes of the two groups or to apparent statistical significance. Regardless of the method used, it is essential to validate the results in a separate group of patients.²⁶ Thus, even if the same assay using the same reagents is applied in two different studies, use of different cutoffs will substantially affect the results.

DO TWO STUDIES USE THE SAME ASSAY?

Because of competition among scientists and commercial interests, different assays are often developed to evaluate the same marker. Thus, when reading what appears to be a confirmatory study of a given marker, one must be certain that the same assay was used in both studies. For example, HER2 status can be determined by examination of cancer tissue amplification of the *erbB2* gene using a variety of techniques including Southern blotting, slot-blot quantification, or fluorescence in situ hybridization, and by evaluation of the protein using Western blotting, immunohistochemistry, immunofluorescence, or enzyme-linked immunosorbent assays (ELISA). Moreover, the circulating extracellular domain of HER2 can be quantified in human serum using ELISA.²⁷ Although they are all correlated, each of these assays, which in one way or another provides an indication of overproduction of HER2, appears to differ from the other and to provide different results in regard to prediction of outcome. Furthermore, even if the assay format is the same, use of different reagents or conditions may affect results. For example, it has been clearly shown that different antibodies against HER-2 can provide very different results in immunohistochemical (IHC) assays.²⁸ Thus, it is not surprising that results from study to study are not validated, if the assays that are being compared are not identical.

Was the Study Design Appropriate to Address the Hypothesis?

The results of a tumor marker are most likely to be valid if they are studied in the context of a plausible hypothesis that is prospectively addressed; for example, a study of prognosis in the absence of the therapy being considered or prediction that the specific therapy will be beneficial. Many published studies report results related to hypotheses that are retrospectively derived from the observed data. Although such studies are valuable to generate hypotheses, these observations must be prospectively validated in subsequent, well-designed studies.^{4,25} Unfortunately, most tumor marker studies are performed using archived specimens collected for reasons unrelated to the study under question. Therefore, it is difficult to validate exciting but preliminary observations, which requires time-consuming prospective studies. Nonetheless, failure to do so often leaves the reader unable to draw definitive conclusions and, in the long run, delays acceptance of the marker for clinical use.

How Should Tumor Markers Be Selected for Clinical Use?

To summarize the preceding paragraphs, a good tumor marker study should provide accurate estimate of the magnitude of difference in outcomes between subgroups of patients who are positive or negative for the marker, using a reliable, accurate, and reproducible assay. Do prognostic and predictive factors exist that permit such elegant selection of patients for treatment? Sadly, in most solid tumors, the answer is no. For patients with newly diagnosed solid malignancies, there is no example of a prognostic factor that predicts subsequent recurrence and death with absolute certainty. Therefore, when these markers are applied in the clinic, both physician and patient must accept some margin of error. These decisions involve both the tumor marker results, as already discussed, and also a careful assessment of the magnitude of effectiveness of therapy for the patient's condition (proportional reduction in risk of events), the degree of toxicity of that therapy, and the patient's willingness (as well as the caregiver's and society's) to either forgo potential benefit to avoid toxicity or to accept toxicity and cost to gain benefit.

Therefore, part of the art, and science, of medicine is to determine which markers are most reliable in separating groups of patients into those that will do well from those that will not, and into those that will benefit from therapy from those that will not. If performed appropriately, tumor marker analysis should permit delivery of therapy as efficiently as possible, providing benefit to the greatest number of patients while avoiding exposure to toxicities as much as possible.

Levels of Evidence (LOE) to evaluate tumor markers have been proposed, again by the American Society of Clinical Oncology Expert Panel on Tumor Markers (Table 7.3).⁴ LOE I data are generated from either a prospective, highly powered study that specifically addresses the issue of tumor marker utility or from an overview or meta-analysis of studies, each of which provides lower levels of evidence. LOE II data are derived from companion studies in which specimens are collected prospectively as part of a therapeutic clinical trial, with preestablished endpoints and statistical evaluation for the marker as well as for the therapeutic intervention.

Ideally, the estimate of the relative strength of a marker for clinical utilities should be determined within the context of LOE I (or at worse II) studies. In these studies, the marker is the primary objective of a well-designed, highly powered, hypothesis-driven prospective clinical trial, or it is the objective of a statistically rigorous overview of LOE II and/or III studies. Furthermore, the strength of new prognostic or predictive factors can only be estimated by multivariate analytical methods, including preexisting accepted factors such as TNM staging and histopathology. It is possible that a marker may be quite prognostic or predictive when considered in a univariate fashion but that it is, in fact, only reflecting information already achieved through other, established methods. In this case, acceptance of the new marker would only occur if it can be performed more easily or reliably or less expensively.

TABLE 7.3. Levels of evidence for grading clinical utility of tumor markers.

Level	Type of Evidence
I	Evidence from a single high-powered prospective study that is specifically designed to test marker or evidence from meta-analysis and/or overview of Level II or III studies. In the former case, the study must be designed so that therapy and follow-up are dictated by protocol. Ideally, the study is a prospective randomized trial in which diagnostic and/or therapeutic clinical decisions in one arm are determined based at least in part on marker results, and diagnostic and/or therapeutic clinical decisions in control arm are made independently of marker results. However, may also include prospective but not randomized trials with marker data and clinical outcome as primary objective.
II	Evidence from study in which marker data are determined in relationship to prospective therapeutic trial that is performed to test therapeutic hypothesis but not specifically designed to test marker utility (i.e., marker study is secondary objective of protocol). However, specimen collection for marker study and statistical analysis are prospectively determined in protocol as secondary objectives.
III	Evidence from large but retrospective studies from which variable numbers of samples are available or selected. Therapeutic aspects and follow-up of patient population may or may not have been prospectively dictated. Statistical analysis for tumor marker was not dictated prospectively at time of therapeutic trial design.
IV	Evidence from small retrospective studies which do not have prospectively dictated therapy, follow-up, specimen selection, or statistical analysis. May be matched case controls, etc.
V	Evidence from small pilot studies designed to determine or estimate distribution of marker levels in sample population. May include "correlation" with other known or investigational markers of outcome, but not designed to determine clinical utility.

Summary

In summary, the field of tumor marker generation is evolving rapidly, with a convergence of molecular biology and technology and understanding of clinical trial design and analysis. Several of the large cooperative trialists' groups have now established separate correlative/biologic committees that are charged with designing hypothesis-driven LOE I and II studies, based on results from pilot studies. The emergence of erbB-2 in breast cancer as a predictive factor, in a manner similar to ER, may serve as a model of directed studies that lead to determination of the relative strength of the marker and determination of whether it should be used clinically. One hopes that careful and thoughtful consideration of study design will considerably shorten the life cycle required to being a tumor marker from the laboratory to the clinic.

Design and Analysis of Oncology Clinical Trials

James J. Dignam, Theodore G. Karrison,
and John Bryant

In this chapter, we discuss the design and analysis of oncology clinical trials. Because analysis follows naturally from design and is specified a priori in any well-planned trial, it is appropriate to discuss these topics together. We review clinical trial designs and associated analytical methods used in the different phases of therapy development. Along the way we identify areas in which the methodology is adapting to new approaches to therapeutic intervention. This chapter provides only a brief sketch of the main concepts and current research areas, and we refer the reader to primary sources and comprehensive texts on clinical trials in oncology for further details. Two excellent recent texts in particular, the *Handbook of Statistics in Clinical Oncology*¹ and *Clinical Trials in Oncology*,² provide the fundamentals of trial design, conduct, and analysis, as well as up-to-date discussion of new challenges and active research in statistical methods for oncology clinical trials.

Some General Statistical Concepts

Although we assume some familiarity with basic statistical concepts and space does not permit a detailed account, we review here some concepts vital to the design and analysis of clinical trials and associated studies. In the classical (e.g., frequentist) statistical hypothesis testing paradigm, a quantity referred to as *type II* or β error equals the probability that a statistical test fails to produce a decision in favor of a treatment effect when in fact the effect is manifest in the population. The complement of this probability ($1 - \beta$) is referred to as *statistical power*, and equals the probability of correctly detecting a treatment effect. Statistical power depends on the other principal parameters in hypothesis testing, specifically, the probability of incorrectly finding in favor of an effect when none exists (discussed in a following section), the sample size, and the size of the treatment effect. It is imperative that clinical trials be designed with adequate statistical power, typically 0.80 or greater for anticipated treatment effects that are both realistic and clinically material, so as not to obtain equivocal findings concerning the potential worth of a new treatment under consideration. Studies with low statistical power can cause delay in development or even abandonment of promising treatments and waste valuable resources, not least of which is the participation and goodwill of patients.³ In contrast, an adequately powered trial that does

not find a new treatment to be superior *is* informative, and resources can then appropriately be directed into other more promising alternatives.

In statistical hypothesis testing, *type I* or α error refers to the probability of incorrectly deciding in favor of a treatment difference when in fact none exists. Typically, the α probability is fixed at some small value, such as 0.05 or 0.01. When hypothesis tests are repeated, the probability increases that at least one test result will be erroneous. A particular complication arising in clinical trials is the need to periodically evaluate the primary hypothesis as information accumulates. These *interim analyses* are conducted to ensure that if definitive evidence of benefit or harm emerges before the anticipated end of the trial, then actions can be taken for the protection and benefit of trial participants. Appropriate statistical methodology to accommodate multiple serial analyses is discussed later.

Types of Trials and the Evolution of Treatment

In this section we review design, conduct, and analysis of the three phases of therapy development. We also follow one clinical trial statistician's recommendation that more descriptive names be used that reflect the goals of each study phase.⁴

Phase I or Dose Evaluation Trials

Objectives

The primary objective of a Phase I oncology trial is to determine the maximum tolerated dose (MTD) of a new experimental regimen. The general assumption is that as dose is increased, greater efficacy will be achieved; hence, the search for the highest dose level compatible with an acceptable toxicity profile. This assumption is certainly reasonable, particularly for cytotoxic drugs, although it need not always be the case. For example, the maximum beneficial effect of immunomodulating agents may occur at intermediate dosages, or the degree of efficacy may plateau so that little is gained by increasing the dose beyond a certain level. These situations create further design and analytical challenges that are probably best addressed in a randomized comparative

setting. For the remainder of this section, we assume that the primary aim of a Phase I trial is to determine the MTD, under the assumption that the highest dose will produce the greatest beneficial effects. Secondary objectives may be to conduct pharmacokinetic studies in individual patients or detect evidence of antitumor activity. More recently, a better knowledge of drug metabolic pathways and pharmacogenomics is beginning to be incorporated into some trial designs, with the goal being to evaluate the relationship between toxicity and genotype.⁵

Clinical Issues

Key clinical issues to be addressed when designing a Phase I trial include patient selection, the starting and subsequent dose levels to be evaluated, and the specification of dose-limiting toxicities. The obvious ethical requirement when selecting patients for a Phase I trial is that no other effective treatment is available, although for a given patient there may be more than one experimental trial for which he/she is eligible. Most Phase I studies are conducted in adults with solid tumors; patients with leukemia and children are usually excluded or studied separately.^{6,7} Because assessment of activity is not the main objective of the trial, patients need not have measurable disease and multiple tumor types may be included. Life expectancy should be at least 3 months, the interval from any prior treatment should be sufficient to ensure that toxicities occurring over the course of the trial are due to the new agent and not prior therapy, and patients should generally have normal organ function and biochemical profiles.

The manner in which a starting dose and subsequent dose levels are chosen, and the historical development behind the various recommendations for doing so, have been described.¹⁻⁸ We simply note here that the starting dose is generally chosen to be low enough that there is a very small likelihood of severe toxicity. With regard to dose escalation, the increments are typically rapid initially, followed by smaller increases as one presumably approaches the toxic range. For example, the highly cited *modified Fibonacci* scheme begins by doubling the first dose, then increasing by factors of 1.67, 1.5, 1.4, and 1.33.

The determination of the MTD is based on the toxicities (adverse events) observed in individual patients and is greatly facilitated by the U.S. National Cancer Institute's Common Toxicity Criteria (CTC) system. In the CTC, adverse events (AEs) are grouped into various organ/symptom categories, with each AE graded as 0 (none), 1 (mild), 2 (moderate), 3 (serious/severe), 4 (life threatening), or 5 (fatal). Typically, any grade 3 or higher AE is deemed a "dose-limiting toxicity" (DLT) (although certain grade 3 AEs may be excluded). A second grading scale may be used to indicate whether, in the physician's judgment, the AE is likely to have been related to the investigational treatment, and only those AEs scored to be at least "possibly" related to the agent are regarded as DLTs. Note that while common toxicities can be detected in Phase I trials, the sample sizes are far too small to detect less-frequent adverse events.

The criteria for a DLT should be clearly specified in the protocol, along with the time interval over which each patient will be observed for the occurrence of a DLT (typically one therapy cycle). With appropriately defined criteria, each

patient's outcome can be regarded as a binary random variable Y taking the value 0 if the patient did not have a DLT and 1 if the patient had a DLT within the specified time frame.

Trial Design Types

The first issue to clarify is what, specifically, is meant by the MTD, for as Storer⁹ points out, "a strict quantitative definition of the MTD is rarely acknowledged in clinical protocols." As discussed previously, a dose given to an individual patient is deemed "tolerable" in that patient if he/she does not experience a DLT, but in statistical terms the MTD must be defined with reference to the patient population. By virtue of the traditional and still frequently used "3 + 3" design, described below, the MTD is usually defined as the highest dose level for which the incidence of DLT is less than 33%. Thus, when employing this design, we are saying that we want to determine the dose that will be tolerable in at least 2/3 of the patients, and therefore are accepting that serious toxicity will be produced in up to 1/3 of the patients. Given that most cancers carry an appreciable risk of mortality, this seems an appropriate percentile to target, but it should not be used unthinkingly. There may be some patient populations, for example, in whom a lower percentile would be more appropriate; conversely, patients at a *very* high risk of mortality or morbidity may be willing to accept a greater chance of serious side effects for potential therapeutic benefits.

"3 + 3"

In the traditional "3 + 3" design¹¹ (Table 8.1), groups of three patients are treated. If none experiences a DLT, the dose is escalated, whereas if two or more experience a DLT, dose escalation is terminated and the previous dose level is provisionally defined as the MTD. If one of three has a DLT, three more patients are added at the same dose level, and if none of these has dose-limiting toxicity, dose escalation continues; otherwise, the previous dose level is considered the MTD. Once a presumed MTD is reached, however, if only three patients have been studied at that dose, three more are added and if two or more of these patients experience a DLT (yielding greater than one of six), further dose reduction occurs. Thus, it is intuitive that this design is targeting a dose that is close to but less than the 33rd percentile. Simulations conducted by Storer⁹ and others indicate that it is nearer to the 25th percentile.

ACCELERATED TITRATION

One criticism of the traditional design, particularly when accompanied by a conservative starting dose, is that too many patients are treated at subtherapeutic levels. Simon et al.¹² have therefore proposed a variant of the "3 + 3" algorithm, known as the *accelerated titration design*, to overcome this problem. Essentially, only one patient is treated at each dose level, and the dose is doubled for each subsequent patient until either a DLT is observed or two patients experience grade 2 or higher toxicity. At this point the design reverts to the traditional "3 + 3" with subsequent dose increments of 40%. *Inpatient* dose escalation is also permitted if the patient had no worse than grade 1 toxicity at the previous

TABLE 8.1. Design features for three “classic” statistical designs for Phase I trials.

Design	Description	Pros	Cons
“3 + 3”	1) Begin at lowest dose, treating 3 patients. If DLT rate is —0/3, escalate (to next pre-specified dose level) —1/3, add 3 more: then if 1/6, escalate $\geq 2/6$, go to step 2) — $\geq 2/3$, go to step 2) 2) If 6 patients studied at the previous dose level (1/6 AEs), declare —that dose to be the MTD; otherwise, add 3 more: Then if — $< 1/6$, declare MTD — $\geq 2/6$, decrease dose and continue	Easy to implement Conservative dose levels	Many patients may be treated at subtherapeutic Targeted percentile not explicit
Accelerated titration	1) Begin at lowest dose. Treat one patient at a time and double 2) the dose until DLT observed or two patients have experienced 3) grade 2 or higher AE; then go to step 2) 4) Revert to “3 + 3” design with dose increments of 40% (inpatient) 5) Dose escalation permitted in if no worse than grade 1 AE)	Easy to implement Moves quickly to therapeutic dose levels	More high-grade toxicities will occur Targeted percentile not explicit
Storer’s BD design (up and down)	1) (Stage B) Begin at lowest dose. Treat one patient at a time and 2) escalate until DLT, then deescalate until first nontoxic response; 3) go to step 2 4) (Stage D). If DLT rate is —0/3, escalate (to next prespecified dose level) —1/3, add 3 more at same dose — $\geq 2/3$, deescalate Sampling continues until fixed number, n_D , patients treated at stage D	Easy to implement Moves quickly to therapeutic dose levels Targeted percentile is explicit (33 rd percentile)	More high-grade toxicities will occur

treatment course. As would be expected, this design reduces the number of patients in the trial who are undertreated, at the expense of a slightly higher percentage experiencing grade 3 or higher toxicity. The authors also describe a statistical model for estimating the MTD that takes into account not just whether or not a patient has experienced a DLT but the full range of toxicity data from all treatment courses. Legedza and Ibrahim describe a related longitudinal model that incorporates the effects of current dose, cumulative dose, and clearance rate on cumulative toxicity.¹³ In this design, dose administration within a patient is tailored over successive treatment courses in an attempt to treat all patients at more-efficacious dose levels.

UP AND DOWN

To provide a more solid inferential basis for estimating the MTD, Storer^{9,14} proposed and evaluated the properties of a number of “up-and-down” designs, including two-stage versions to allow more rapid dose escalation, as in the accelerated titration design. His BD design, for example, explicitly targets the 33rd percentile of the tolerance distribution. Initially (stage B), a single patient is treated at each dose level, escalating sequentially from the starting dose until a DLT is observed. Deescalation then occurs until the first nontoxic response, at which point the second stage (stage D) begins and cohorts of three patients are enrolled. Then, if none of the three has a DLT, the dose is escalated; if two or more have a DLT, the dose is deescalated; and if one of three has a DLT, the next cohort is treated at the same dose level. Sampling continues in this manner until a fixed number of second stage patients (for example, $n_D = 24$) are treated. The total number of patients, $n = n_B + n_D$, is therefore variable, depending upon when the second stage is reached. After the trial is completed, a logistic regression model

$$p(x) = \Pr(Y = 1|x) = \frac{\exp(\alpha + \beta x)}{1 + \exp(\alpha + \beta x)} \quad (1)$$

is fit to the n pairs of points $(x_1, y_1), (x_2, y_2), \dots, (x_n, y_n)$ where x_i is the dose and y_i the response (0 or 1) of the i^{th} patient. The method provides not only a point estimate of the MTD, but a means to derive confidence intervals as well. However, for the small sample sizes typically used in Phase I trials, computationally demanding “exact” methods may be required to obtain these confidence intervals. The method is easily modified to estimate other percentiles of the tolerance distribution (i.e., the 25th percentile). Korn et al.¹⁵ found stage B too aggressive and recommended treating two patients at a time, increasing dose levels until the first DLT is observed. Other useful variations of up-and-down designs are discussed by Ivanova et al.¹⁶

CONTINUAL REASSESSMENT METHOD (CRM)

An alternative to the classic designs is the Bayesian approach developed by O’Quigley et al.,¹⁷ who called it the “continual reassessment method” or CRM (Table 8.2). This method is based on a one-parameter model for the dose—toxicity curve, for example, the logistic model (Eq. 1) with the α parameter fixed at a suitably chosen constant a_0 . Within the Bayesian framework, a *prior* probability distribution is assigned to the parameter β , data are collected, and knowledge about this parameter is updated by constructing the *posterior* probability distribution for β . Thus, in the CRM, a prior distribution for β is specified and the first patient is assigned to the dose level whose probability of toxicity as given by Eq. 1 is closest to the 33rd (or other desired) percentile. After observing the outcome in this patient, the posterior distribution for β is formed, toxicity probabilities updated, and the next patient assigned the dose closest to the desired

percentile. This process is repeated until a fixed number of patients have been studied. The method tends to converge to the correct target level, even if the original model is incorrectly specified.¹⁸

MODIFIED CRM

Although it is clearly an attractive approach, some problems with the CRM were immediately recognized. First, there was discomfort about starting the first patient at too high a dose. Second, escalating more than one dose level at a time was thought to be too risky. Finally, there were concerns that trial durations would be extended unduly because of the need to await the outcome in each individual patient before enrolling the next patient. This concern led to the so-called modified CRM^{10,19} whereby the trial starts at the lowest dose level, the dose is increased no more than one level at a time, and the cohort size is increased to three patients. Results of a simulation study comparing the modified CRM to the original CRM and the traditional “3 + 3” design showed that the “3 + 3” design generally placed more patients at dose levels below the MTD; consequently, the CRM designs were more likely to assign patients to therapeutic dose levels and to arrive at the correct estimate of the MTD, although there were exceptions.¹⁰

A method that maintains the simplicity of the classic design, but, as in the CRM, makes better use of the cumulative data, has recently been proposed.²⁰ The method capitalizes on the assumption that toxicity is nondecreasing with dose, using a technique known as isotonic regression to estimate the dose–toxicity curve at each step, essentially pooling and averaging outcomes from adjacent dose levels to maintain a nondecreasing curve. For example, if the current data were 1 toxicity in 6 patients treated at dose level x_1 , 1 in 6 at dose level x_2 , and 0 of 3 at dose level x_3 ($x_1 < x_2 < x_3$), the algorithm would first pool the data at x_2 and x_3 to maintain monotonicity, replacing each estimate with $1/9 = (1 + 0)/(6 + 3)$. As $1/9$ also is less than $1/6$ from the first dose, the data would be pooled again, and all three estimates would be changed to $2/15 = (1 + 1)/(6 + 9)$. Additional patients are added at the current, higher, or lower dose level depending on the current DLT rate in relation to a specified target. The trial is terminated when the same dose level is indicated in three consecutive cohorts, or when some prespecified number of patients have been evaluated. A simulation study comparing the method with the traditional “3 + 3,” modified CRM, and up-and-down designs found similar performance to the modified CRM and fewer patients underdosed compared to the “3 + 3” design, but on average more patients were required and were treated above the true MTD.²⁰

TABLE 8.2. Design features for three Bayesian statistical designs for Phase I trials.

Design	Description	Pros	Cons
Continual reassessment method (CRM)	<ol style="list-style-type: none"> 1) Choose prior distribution for β parameter of logistic family 2) Assign first patient to dose level for which prior probability of DLT is closest to the desired percentile 3) Observe outcome and update posterior distribution Assign next patient to dose level with probability of DLT closest to desired percentile; go to step 3) Sampling continues until fixed number N patients are treated	More patients treated at therapeutic dose levels Utilizes all information available to choose next dose level Targeted percentile is explicit	Requires software to implement First patient could be assigned any dose and dose escalation can jump more than one level leading to higher observed toxicity rates
Modified CRM	<ol style="list-style-type: none"> 1) Choose prior distribution for β parameter of logistic family 2) Begin at lowest dose. Enroll 3 patients, observe outcomes and update posterior distribution 3) Determine dose level with probability of DLT closest to desired percentile, but <i>escalate no more than one level</i>; go to step 3) Sampling continues until fixed number N patients are treated	Less aggressive escalation than CRM Utilizes all available information to choose next dose level Targeted percentile is explicit	Requires software to implement
TITE-CRM	<ol style="list-style-type: none"> 1) Choose prior distribution for β parameter of logistic family 2) Choose T, duration of time over which toxicity will be monitored for each patient and t_{int}, interval between dose cohorts (e.g., half-month) 3) Begin at lowest dose. Enroll 3 patients, follow for t_{int} and observe outcomes 4) For <i>all</i> patients enrolled thus far, calculate $g(x, u)$ (see text); then update posterior distribution Determine dose level with probability of DLT closest to desired percentile, but <i>escalate no more than one level</i> ; go to step 4) Sampling continues until fixed number N of patients are treated	Incorporates late toxicities Reduces trial duration Utilizes all information available to choose next dose level Targeted percentile is explicit	Requires software to implement More toxicities will be observed, particularly if they occur toward end of monitoring period T

TITE-CRM

All the previously mentioned designs require that the toxicity outcome in each patient, or cohort of patients, be observed before more patients are entered. However, in certain situations such as radiotherapy or chemoprevention studies, interest may focus on late-onset toxicities as well as short-term effects, and the current designs would require an inordinate period of time to complete the study. Cheung and Chappell²¹ have therefore proposed an extension of the CRM that incorporates the time to toxicity in each patient, which they termed TITE-CRM. The main idea is as follows. Suppose toxic events occurring anywhere up to T time units from administration of therapy are of interest. Rather than waiting for each cohort of patients to be followed for this length of time ($T = 6$ months in their example), one could enter new patients at, say, half-month intervals. As in the CRM, the first patient is assigned to a dose level based on prior information or, as in the modified CRM, to the lowest candidate dose. The single-parameter logistic model or other suitable dose-response model is assumed, with $p(x)$ corresponding to the probability that an individual receiving dose x will experience a DLT by time T . Then, if an individual has been followed for u less than T time units, the probability of a toxic event is simply taken to be $g(x, u) = u/T \cdot p(x)$. At the time the next patient(s) is (are) to be enrolled, the observed toxicities and follow-up times of patients already entered are used to form the posterior estimate of β , and the dose level for the next patient(s) is selected according to the usual CRM or modified CRM criteria. Simulation studies showed that TITE-CRM produced results comparable to its CRM counterpart, while significantly reducing the average trial duration.²¹ The only downside was that TITE-CRM tended to generate slightly more AEs. As might be expected, differences were greatest for situations in which AEs tend to occur near the end of the observation period, because escalation may occur before any such events are observed.

Phase II or Pilot Efficacy and Safety Evaluation Trials

Objectives and Clinical Issues

Phase II clinical trials are conducted to determine whether a new agent or regimen has sufficient antitumor activity, usually measured in terms of reduction in tumor size, to warrant further study. Secondary objectives are to collect additional safety and toxicity data, and correlative studies to evaluate the effects of treatment on specific biomarkers or other intermediate endpoints may be included. It is assumed that the drug dose and administration schedule will have been determined from prior Phase I trials.

Unlike Phase I studies, Phase II trials should be performed in a single, well-defined tumor type and patient population. The extent of disease, patient performance status, and the amount of prior therapy are usually highly prognostic, and therefore, it is important to weigh the eligibility criteria carefully, as these parameters will define the population for which findings may pertain. This is particularly important, as in most phase II trials the observed level of activity will be compared not to a concurrent control group, but rather to a

historical probability of response to standard treatment for patients presumed to be comparable in terms of stage of disease, performance status, and other characteristics.

Trial Design

ENDPOINTS

For most Phase II trials, drug activity is defined in terms of reduction in tumor burden. The most recent criteria for measuring activity, known as the Response Evaluation Criteria in Solid Tumors or RECIST,²² are based on unidimensional measurements. The criteria require the identification of target lesions and nontarget lesions at baseline. A complete response (CR) is the disappearance of all target and nontarget lesions, provided no new lesions have developed. A partial response (PR) is a 30% or greater decrease in the sum of the longest diameter (LD) of all target lesions, provided no nontarget lesions have progressed and no new lesions have developed. Progressive disease (PD) is defined as a 20% or greater increase in the sum of the LD of target lesions, progression of nontarget lesions, or the occurrence of new lesions. If there has been neither sufficient shrinkage to qualify for PR nor sufficient increase to qualify for PD, the patient is classified as having stable disease (SD). A patient who achieves either a CR or PR is defined as an objective responder, and the proportion of patients responding, that is, the *response rate*, has become the primary endpoint of interest in the design and analysis of phase II cancer clinical trials. While it is conceptually straightforward and can be assessed within a shorter time frame, there has been concern that the response rate is an inadequate substitute for more clinically relevant endpoints such as extension of survival. Some studies have shown that less than 25% of agents that show positive tumor response are eventually found to extend survival in comparative trials,²³ whereas other studies suggest that tumor response is a reasonable surrogate for survival extension.²⁴ Moertel²⁵ and others have raised additional problems with the use of response rates in Phase II trials, such as subjectivity and lack of reproducibility in assessment. Other possible choices for endpoints are discussed later in this section.

SAMPLE SIZE

In a typical Phase II study, the objective is to compare the observed response rate for the new agent to some level, p_0 which is usually set equal to or slightly below the response rate achievable with standard therapy in the target patient population. The value for p_0 must be chosen carefully, using information from previously reported trials and investigator knowledge, because the main objective will be to determine whether there is sufficient evidence to conclude that the response rate for the new regimen is greater than p_0 . In formal terms, if we let p denote the probability of response, the problem can be formulated as a test of the null hypothesis $H_0: p = p_0$, against the alternative hypothesis $H_A: p = p_A$ where p_A is a response rate that, if true, would be clinically material. The value of p_A , along with the sample size, will determine the power of the study and therefore, two points should be noted. First, to detect a small improvement (say, 10% or less) requires a large sample size. For example, to detect an improvement from 20% to 30% with 85% power, more than

100 subjects are required, which may be undesirable for a Phase II trial, where there are limited efficacy data thus far. Second, the value for p_A must be realistic; it is of little value to design and carry out a study to detect an effect size $p_A - p_0$ that is unlikely to be realized, simply because it is compatible with the number of patients that can be recruited in a reasonable time period. Most Phase II clinical trials aim for a response rate improvement of 15% to 20%.

For a specified significance level and power, it is straightforward to determine the number of patients needed for the trial (see Fleming,²⁶ for example) and to test H_0 . It should be noted that, in the context of Phase II trials, hypothesis tests are *one-sided* in the sense that we are only interested if the new treatment improves the response rate and not in establishing whether it could be worse. Statistical power should be high (85% or 90%), because if the drug is rejected as inactive it may never undergo further study. It is not uncommon to relax the α level from the usual 5% to 10%, because if the drug is falsely declared active, its lack of efficacy would likely be uncovered in subsequent trials.

Trial Design Types

MULTISTAGE DESIGNS

Because it is ethically undesirable to expose patients unnecessarily to an ineffective agent, Phase II studies are usually designed to allow early stopping in the event that the drug appears inactive. This idea goes back to Gehan,²⁷ and one of the most popular designs incorporating early stopping is Simon's optimal two-stage design.²⁸ For a specified p_0 , p_A , α , and β , this design calls for enrollment of n_1 patients in the first stage. If r_1 or fewer responses are observed, the trial is terminated due to lack of activity. Otherwise, an additional n_2 patients are entered for a total $n = n_1 + n_2$. Then, if r or fewer total responders among the n patients are observed, the regimen is rejected, whereas if more than r responses are observed, the regimen is declared sufficiently active to warrant further study. The optimal design is the one that minimizes the expected sample size under the null hypothesis. For example, if $p_0 = 0.10$, $p_A = 0.25$ and $\alpha = \beta = 0.10$ (90% power), then 21 patients would be enrolled in the first stage and if 2 or fewer responses were observed, the trial would be terminated. Otherwise, an additional 29 patients would be accrued for a total of 50, and if 7 or fewer responses were observed, the drug would be rejected, whereas 8 or more responses (an observed response rate of 16% or more) would be sufficient to deem it worthy of further investigation. The probability of stopping at the first stage if, in fact, the true response rate is only 10%, is fairly high, 0.65; hence, the attraction of the two-stage design.

Simon also provides tables for a *minimax* design, which is that having the smallest total sample size that satisfies the design constraints, although it often requires a relatively large sample size in the first stage. Jung et al.²⁹ note that there are typically many designs that satisfy the design constraints, and present graphical software that allows one to easily search for a trial design that is a good compromise between different options. Green et al.,² on the other hand, prefer a more flexible two-stage approach in which an approximately equal number of patients are recruited in each stage and the power is set to 90%. In a typical example, if, after the first stage the

alternative hypothesis (e.g., that a response of some specified size exists) is rejected at significance level $\alpha = 0.02$, the trial is discontinued for lack of activity. Otherwise, the study proceeds through the second stage where the null hypothesis is tested at $\alpha = 0.055$. Roughly, this design will stop early if the observed response rate after the first stage is less than p_0 and will declare the agent sufficiently active to warrant further study if, after the second stage, the observed response rate exceeds $(p_0 + p_A)/2$. Three-stage designs have also been proposed.^{30,31} The logistic difficulties of suspending recruitment between stages, as well as the increase in study duration that this entails, lead most investigators to opt for two-stage designs. However, in situations in which it is highly desirable to minimize the number of patients exposed to an inactive therapy, a three-stage design may be attractive. Some have argued that complete and partial responses should not necessarily be combined, because complete responses are far rarer and are much more likely to confer a survival advantage.^{32,33} They propose two-stage designs that distinguish complete from partial responses, giving more weight to the former.

As mentioned previously, a secondary objective of Phase II trials is the collection and reporting of toxicity data. Usually, toxicity analyses are carried out separately from the analysis of response rates, but designs have been proposed that incorporate toxicity and response simultaneously. Conaway and Petroni³⁴ and Bryant and Day,³⁵ for example, consider trials to establish whether a new drug is "sufficiently promising" in the sense that it has both a response rate that is greater *and* a toxicity rate that is no worse than standard treatment. If we let p_R denote the true response rate of the new treatment and p_T the true rate of DLT, the null and alternative hypotheses can be written:

$$\begin{aligned} H_0: p_R \leq p_{R_0} \quad \text{or} \quad p_T > p_{T_0} \\ H_A: p_R > p_{R_0} \quad \text{and} \quad p_T \leq p_{T_0} \end{aligned}$$

where p_{R_0} and p_{T_0} are the response and toxicity rates associated with standard therapy. Thus, the null hypothesis is rejected only if the response rate is sufficiently high and the toxicity rate is not unacceptably high. One must model the association between response and toxicity by introducing another parameter, θ , corresponding to the odds ratio for toxicity among responders relative to nonresponders. Fortunately, however, the design characteristics are fairly insensitive to the assumed value for θ . Finally, as one might be willing to accept greater toxicity with higher response rates and vice versa, Conaway and Petroni³⁶ propose a related design that incorporates such trade-offs.

BAYESIAN TRIAL DESIGNS

The previously mentioned designs are frequentist in nature, in that power and significance probabilities refer to the probability of events under given hypotheses about the parameters of interest. A Bayesian approach offers an alternative inferential framework, for which proponents argue is particularly suited to situations involving accumulating data.³⁷ For example, Thall and Simon³⁸ present a Bayesian design for Phase II trials in which a "moderately informative" prior distribution is assigned to p_S , the response rate associated with standard therapy. A flat or "weakly informative" prior is assigned to p_E , the response rate for the experimental treat-

ment, to reflect the limited knowledge available for p_E before the study is begun. A maximum sample size for the trial, n_{\max} , is specified, patients are enrolled, and the trial is continued until the new drug is shown with high posterior probability to be either promising or not promising or until n_{\max} is reached, in which case the study is deemed inconclusive. Thus, if X_n denotes the number of responders observed among the first n patients enrolled, $n = 1, 2, \dots, n_{\max}$, the posterior probability that p_E exceeds p_S by some minimally interesting amount, δ , is computed. If this probability is very high (say, greater than 0.95) or very low (say, less than 0.05), the trial is terminated and the drug is declared promising or not promising, respectively. Otherwise, the study is continued provided n_{\max} has not been reached.

Thall and Simon³⁸ evaluate the frequentist operating characteristics of this design under continuous monitoring and a maximum sample size of $n_{\max} = 65$. They also suggest setting a minimum sample size, n_{\min} , of 10 patients so that, in effect, monitoring does not begin until the 10th patient is enrolled. Results show, for example, that under a fairly informative prior for p_S centered, say, at 0.20, a weak prior for p_E , and a minimally interesting difference of $\delta = 0.15$, that if $p_E = p_S$ there is a 7.1% chance that the outcome would erroneously lead to a conclusion that the experimental drug is promising, an 83.5% chance that it will correctly be declared non-promising, and a 9.4% chance that the results will be inclusive. If the true effect is positive ($p_E = 0.40$), there is an 87.5% chance that the drug will be declared promising, a 7.7% chance that it will be declared nonpromising, and a 4.8% chance that the trial would be inconclusive. Subsequent work describes a Bayesian sequential design for more complicated situations involving multiple outcomes, such as response and toxicity.³⁹

Another proponent of the Bayesian approach is Heitjan,⁴⁰ who points out that in multistage, frequentist designs, the evidence required for terminating the trial is not the same at all analysis times, and that a drug can be rejected as inactive even though there is no strong evidence that the response rate is any less than that of the standard. He describes a Bayesian approach designed either to convince a *skeptic* that the drug is beneficial or to convince an *enthusiast* that it is not. This is accomplished by using different prior probabilities corresponding to these two states of belief and, after outcomes have been observed, calculating the posterior probability that

(a) the new drug is better than the standard given the skeptic's prior (the "persuade-the-pessimist probability") and (b) the standard is better than the new drug given the enthusiast's prior (the "persuade-the-optimist probability"). Thus, this method requires that the evidence be sufficient "to choose between hypotheses [favorable or unfavorable] to the satisfaction of all interested parties" and, if not, the results are regarded as inconclusive.⁴⁰

RANDOMIZED PHASE II TRIAL

When there are multiple candidate agents to consider advancing to further development, randomized Phase II trials, sometimes called selection designs, provide a means to select agents for further study.⁴¹⁻⁴³ These trials, which allocate patients to different treatments under consideration by random assignment and compare outcomes between groups, have several advantages with respect to patient selection and other biases present in studies without parallel comparison groups (discussed in detail in the next section). However, as a means to determine efficacy in any absolute sense, these trials lack statistical power and α error control at the sample sizes typically envisaged for Phase II trials. Nonetheless, the initial intended use of randomized Phase II trials as "selection designs" has been broadened to encompass small-scale randomized trials with a standard therapy comparison group. Although this approach has some advantages, positive results emerging from these trials cannot be deemed sufficiently conclusive as to preclude Phase III investigation (see Liu in Reference 1 for discussion). Table 8.3 illustrates advantages and disadvantages of one-arm and randomized comparative Phase II trials.

RECENT DESIGN CONCEPTS

For cytostatic agents, where frank tumor shrinkage is not anticipated, there may be a need for alternative Phase II designs based on endpoints other than response rates. For trials enrolling patients who have failed prior therapy, Mick et al.⁴⁴ propose a method that uses each patient as his/her own control, comparing the time to progression under the new agent with the time to progression under prior therapy. Rosner et al.⁴⁵ propose a *randomized discontinuation* design, in which all patients are initially treated with the experimental agent. After a specified interval, responders remain on

TABLE 8.3. Advantages and disadvantages of single-arm versus randomized Phase II trials.

	<i>Single-arm trial</i>	<i>Pilot randomized trial</i>
Advantages	<ul style="list-style-type: none"> • Maximum adverse event information for new agent • Can offer new agent to all participants • Simple endpoint that is rapidly ascertained 	<ul style="list-style-type: none"> • Concurrent control group • Randomization provides for rigorous ancillary studies of tumor response markers • Can use time to event endpoints more readily in this comparative setting
Disadvantages	<ul style="list-style-type: none"> • Historical control group response rate must be used • Tumor response endpoint may be poor surrogate for survival extension • Time to event endpoints may be difficult to define and do not fit into multistage framework 	<ul style="list-style-type: none"> • Low power, high α for feasible sample sizes • Necessity to randomize patients in terminal disease situation • Quantity of adverse event information for experimental agent is reduced • Positive findings may interfere with conduct of appropriately powered Phase III trial

Here, we are considering a randomized phase II trial as a relatively small (100 patients or fewer) study intended to serve as a pilot trial for potential efficacy. Note that the original proposal for use of randomized phase II trials was for selection of potentially superior candidates from among multiple new agents (see Simon et al.⁴¹ and Liu et al.⁴²), and *not* to compare new therapies to existing standards. More recently, Bayesian designs for phase II randomized selection design trials have been proposed (see Esty and Thall⁴³).

treatment and those who progress discontinue, while those patients with stable disease are randomized to either continued treatment with the drug or placebo. The idea behind this design is that the randomized comparison allows one to assess whether the drug is truly slowing the rate of growth of the tumor, as opposed to having simply selected patients for study with slow-growing tumors. Because the patients with stable disease form a more homogeneous subgroup, this design also generally requires a smaller sample size than would a trial that randomized all patients at entry. It is important to bear in mind—and the authors also emphasize this point—that the purpose of this design is mainly to determine whether the drug is active in an explanatory sense. Obviously, it matters a great deal whether the initial percentage of patients exhibiting stable disease is high or low, as in the latter case the total sample size required may be quite large and a demonstration of activity in the randomized component would mean only that there is benefit in a small subset of the population. Korn et al.⁴⁶ point out other caveats with this design. For example, patients may find it unattractive to potentially discontinue a treatment that appears to be working. They describe a number of other approaches, including single-arm trials with time to progression as an endpoint and trials with appropriately validated biologic response markers as surrogates for tumor response.

Phase III or Comparative Efficacy Trials

General Description and Objectives

The term *Phase III trial* is synonymous with a prospective comparison under randomized treatment assignment [alternately called a randomized controlled trial or randomized clinical trial (RCT)] of two or more treatment regimens, conducted for the purpose of establishing which is *superior* or, in some cases, to establish *equivalence* (in the sense that any difference in outcome is smaller than that considered clinically material) between different treatment regimens. Thus, two key features that distinguish RCTs are the inclusion of a concurrent control group and the use of randomization to assign treatment. The main purpose of concurrently evaluating individuals receiving the standard and test treatment(s) is to eliminate temporal trends in diagnosis, characterization of the disease, and ancillary care that would likely be present in any comparison with a historical control group. Concurrent evaluation also provides implicit control over the commonly seen phenomenon of research participation itself having a positive effect on outcomes, regardless of the type of intervention. Randomization, which disassociates treatment assignment from any and all extraneous factors on the part of the patient or the physician, is the fundamental means by which bias is removed from measures of treatment effect.

The obvious alternative to randomization is a nonrandomized comparative trial, but this design is generally insufficient for definitive evaluation of treatments for the purpose of choosing one over another. While differences in characteristics between treatment groups can be addressed to various degrees in other ways, typically by comparing “like with like” through matching, stratification into homogeneous groups, or

statistical modeling or adjustment, only randomization will reliably eliminate bias in treatment comparisons. Furthermore, it is often not the *known* potential confounding factors that we must concern ourselves with, but rather *unknown* or uncollected factors, where these methods are not relevant. Nonetheless, primarily due to ethical concerns, some advocate relying on observational studies with reference to historical experience, coupled with the use of statistical methods to account for potential confounding of treatment effects and other factors, to evaluate new treatments.^{47,48} Numerous problems with the validity of historically controlled comparative studies have been demonstrated specifically in cancer research, including temporal changes in disease definition,^{49,50} data quality issues,⁵¹ diagnostic bias in assessing treatment response,²⁵ and out-of-date historical control comparisons that tend to inflate effects for new therapies.²³ The RCT in and of itself represents a significant medical research advance, and, as the recognized gold standard evaluative tool in therapy development, is integral to the evidence-based medicine paradigm.

Trial Design Issues

ENDPOINTS AND SAMPLE SIZE

Phase III trial design begins with specification of a primary endpoint, which is typically a simple binary event such as survived/died or recurred/remained recurrence free, but usually with one important difference relative to Phase II trials; for each patient the time from randomization until occurrence of this event will be recorded, rather than the event status at some fixed time landmark. These time-to-event endpoints are particularly suited for adjuvant therapy trials, where because the number of patients participating is appreciably larger than in Phase II trials, recruitment takes place over a lengthy interval and each patient will have a different follow-up duration at any given time from trial initiation. Use of follow-up time per patient is more efficient than waiting until all patients have reached some fixed time. The treatment effect measure is usually specified in terms of *hazards*, which can be thought of as failure probabilities or failure rates per unit of time, between two treatment groups. Hypotheses are thus usually formulated in terms of the hazard ratio (HR) as $H_0: \lambda_A/\lambda_B = HR = 1.0$ where λ_A and λ_B are the hazards for treatments A and B, versus alternative $H_A: HR < 1.0$, for some value of the HR that represents a clinically material difference in outcomes. In the case of an equivalence trial, one might test a null hypothesis that the HR does not differ from 1.0 by more than some specified amount such that the two treatments would be considered equivalent (hence, this difference must be small) versus the alternative that a greater difference exists (see References 1, 2 for more on equivalence trials). Under the assumption that this ratio is relatively constant over time, a given HR can be converted to an absolute difference between groups in proportions remaining event free at a given follow-up time. For example, a new/standard HR equal to 0.75, or a 25% reduction in failure rate in the new relative to the standard group, may translate into an absolute difference in the proportion of patients remaining free of the event between groups of 4.6% at 5 years, given that the standard group 5-year survival percentage is 80% (Table 8.4).

TABLE 8.4. Absolute difference in 5-year survival and number of events required for a two-arm Phase III trial.

Reduction in hazard of failure for new treatment	Standard group proportion event free at 5 years						No. of events required
	.50	.60	.70	.80	.90	.95	
20%	.074	.065	.052	.037	.019	.010	630
25%	.095	.082	.065	.046	.024	.012	379
33%	.130	.111	.088	.062	.032	.016	191
40%	.160	.136	.107	.075	.039	.020	128
50%	.207	.175	.137	.094	.049	.025	65

Table entries show the absolute difference (new – standard) in 5-year survival for the hazard reduction due to the new treatment on the left-hand column and the 5-year survival in the standard treatment group (middle columns, top), assuming exponential survival patterns. The right-most column shows the number of events required (Eq. 2) for 80% power at a two-sided $\alpha = 0.05$. The number of patients required for the trial to obtain results in some specified time period will depend on the standard group failure rate and the rate at which patients can be accrued.

From the specification of difference of interest or effect size, the sample size in terms of number of events required to detect this difference with desired statistical power and significance level can be determined. Depending on the anticipated accrual rate and the prognosis (e.g., rapidity of failure events) in the control treatment group, the number of patients required can then be approximated. Typically, the required number of events is based on the normal theory approximation of the natural logarithm of the hazard ratio. For a two-arm trial, the total number of events is

$$D = \frac{(Z_{1-\beta} + Z_{\alpha/2})^2}{[\log_e(HR)]^2 p_A \cdot p_B} \quad (2)$$

where $Z_{1-\beta}$ and $Z_{\alpha/2}$ are the values from the standard normal distribution associated with the power and significance level desired, and p_A and p_B are the proportions of total patients to be allocated to the two arms, respectively (e.g., 0.5 for equal allocation). One can see from this equation that the number of events required depends strongly on the HR, becoming dramatically larger as the HR approaches 1.0 (see Table 8.4). The number of patients required and total duration of the trial depend on the rate of patient accrual and the failure rate in the control group, both of which contribute to the determination of how rapidly the requisite events will be observed. The accrual rate is typically estimated from previous experience and may also involve querying potential investigators to project the accrual rate per unit of time. Similarly, the failure rate for patients under standard therapy is derived from past observations and available literature estimates. The computations are straightforward but generally require computer programs (see Shuster in Reference 1, or commercial programs) or under certain assumptions, tabled values.⁵² Sample size methods have been extended to take into account other factors that will influence power, such as patients withdrawing from the study while it is ongoing (dropout), switching from the assigned treatment to the other group (cross-over), or deviating from protocol treatment (noncompliance).⁵³⁻⁵⁶

Another important design aspect concerns the desire to ensure that factors associated with outcomes, called prognostic factors, are balanced between treatment arms. Although random allocation to treatments naturally provides equal distribution of characteristics, using key prognostic variables as stratification factors, and incorporating these into the randomization process (by randomizing within strata or other means discussed in the next section), imbalances that can arise by chance can essentially be prevented. The number

of stratification factors needs to be limited to a few key factors, because the strata increase multiplicatively with the number of factors and factor levels. For example, the use of four factors [say, age groups (less than 50 years, 50–64 years, 65 years or older), lymph node status (positive, negative), performance status (0–1, more than 1), and surgical procedure (procedure A or B)] produces $3 \times 2 \times 2 \times 2 = 24$ strata in which to balance treatment assignments. As the number of strata becomes large relative to the number of patients to be entered, the efficiency of stratification as a means to balance treatment arms diminishes.⁵⁷

Trial Conduct

RANDOMIZATION

Because randomization is the signifying characteristic of Phase III trials, correct implementation and maintenance of this feature is vital. In the simplest case, a series of treatment assignments are generated from a random mechanism such as a random number table or computer program. Sequential assignments should only be revealed one at a time (to avoid compromising the randomness with respect to the next assignment), and thus it is preferable to have a secure centralized randomization procedure, via telephone or computer contact. To balance the number of patients in each arm, *block randomization*, in which an equal number of assignments on each treatment arm of the trial occurs after each block of patients is enrolled, can be used (for example, assigning ABABBA, AABABB, etc., for randomly ordered strings of assignments brings the number on each arm into balance after each set of six patients; note that the size of the block is not revealed and can also be varied to make the process unpredictable). To incorporate stratification factors to be balanced between treatment arms, blocked randomization can be used within each stratum. When the number of strata is large, and in particular in multicenter trials, this type of assignment scheme can become unwieldy and cannot necessarily assure balance. In this case, some type of *dynamic allocation* scheme can be used whereby the current assignment is generated based on previous assignments. This type of randomization must be centralized, as stratification factor data for all previously enrolled patients must be available when randomizing the current patient. Rather than deterministic assignments to balance the arms, often “biased-coin” randomization is used, in which the assignment probability is weighted toward the arm for which assignments are needed

to achieve balance. The minimization algorithm is frequently used for dynamic balancing taking stratification factors into account.⁵⁸ This allocation scheme balances treatment arms for each stratification factor singly, but not necessarily for every combination of factors, as in fully stratified randomization. However, it is much easier to manage over multicenter studies and performs well for multiple stratification factors.⁵⁷

There are several ways in which the benefits of randomization can be eroded or nullified. Of course, any breach of the random assignment process has an irreparable effect on the validity of the trial. Second, a large number (or differential number per arm) of patients “canceled” or withdrawn from the trial calls into question the validity of the comparison for the remaining participants. Differential follow-up and ascertainment of status per arm can have a similar effect. Third, bias in assessment of outcomes can have a major impact on the estimated treatment effect, and thus, objective outcome measures and blinding of treatment assignment come into play. Treatment assignment blinding is not feasible for many oncology trials (e.g., radiotherapy and most chemotherapy regimens), but has been used with great success in others (e.g., tamoxifen). In either case, and in particular for studies that cannot be blinded (among patients or caregivers), unambiguous, objectively defined endpoints are essential. In cases where determination of the endpoint involves possible observer subjectivity, such as when reading a diagnostic scan to determine disease progression, keeping assessors unaware of treatment assignment may be necessary.

TRIAL MONITORING

As in earlier trials, Phase III trials include provisions for formal oversight of risks and benefits to ensure patient welfare and use resources efficiently. Interim monitoring consists of both continuous oversight of adverse events and periodic interim tests (a predetermined number) of primary study hypotheses. With respect to these interim tests, a large body of statistical developments has addressed how to conduct tests to determine if an early determination of treatment superiority is warranted while at the same time controlling for inflation of α error (e.g., false-positive findings) resulting from repeatedly performing statistical hypothesis tests. Caution is also warranted because early results from time-to-event data tend to be unstable and change as more information accumulates. In essence, these problems are addressed by simply requiring a stricter criterion than the typical P less than 0.05 “significance” for interim analyses, and early approaches to this problem used either a smaller constant significance criterion throughout interim and definitive analyses, chosen such that the significance level for the entire set of sequential tests does not exceed α , or a constant but much more stringent criterion early in interim analyses and a more conventional significance level after the trial has accumulated the requisite information for definitive analysis. Figure 8.1 shows these and some other examples of early stopping boundaries, which when exceeded at any of the interim analyses shown on the x-axis would prompt consideration of early stopping. These boundaries are symmetric with respect to superiority for either the new or standard treatment group, reflecting the fact that two-sided hypothesis tests remain the convention. In reality, it is unlikely that a trial tending

toward a significant difference in favor of the standard treatment would be continued until such a result was realized. Thus, an additional rule that allows for stopping early for “futility” with respect to the new treatment is usually also specified. Alternatively, asymmetric boundaries that more easily allow stopping early for evidence that the new treatment may actually be inferior to the standard (evidence de facto that the new treatment will not ultimately prevail) can be used. More comprehensive treatment of this topic can be found in clinical trials texts^{1,2} or books on group sequential monitoring.⁵⁹ Regardless of the specific approach adopted, an interim analysis plan should be devised during trial design and adhered to throughout trial conduct because failure to account for multiplicity of analyses can result in spurious positive findings. Also, a specified plan may help to avoid diminished influence of a trial even when results are decidedly positive, which can occur if there is a perception by others that the trial had been terminated prematurely due to favorable results at a particular analysis time.⁶⁰

The decision to discontinue the trial (accrual and/or treatment, depending on its current state) and release findings is typically vested in an independent Data and Safety Monitoring Committee (DSMC). However, in addition to evaluating according to the monitoring rule, the DSMC considers a broader body of information regarding the trial as well as external information that bears on treatment for the disease under study. Table 8.5 outlines the membership, aspects of trial conduct over which the DSMC has oversight, and recommendations that might arise from trial review and DSMC

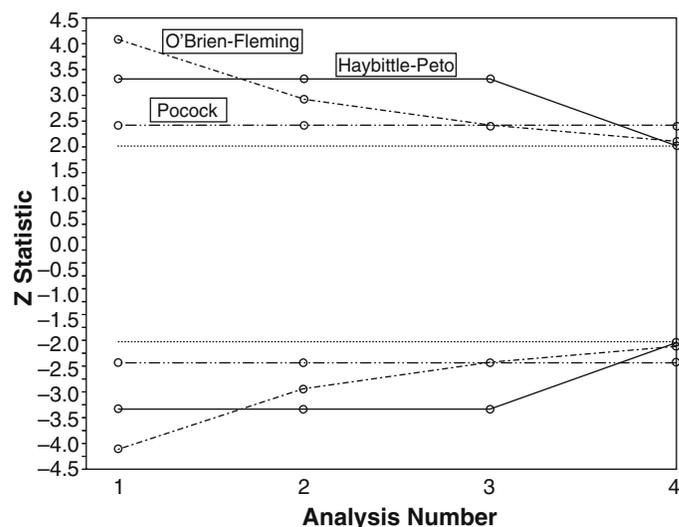

FIGURE 8.1. Different types of stopping boundaries for monitoring a Phase III trial. The upper and lower boundaries represent statistical test values on the vertical axis (on a standard normal scale), which, if exceeded at a given analysis indicated on the horizontal axis, would prompt stopping of the trial (the fourth analysis is the definitive analysis at the predetermined requisite number of events). The horizontal lines at ± 1.96 represent the standard P greater than 0.05 boundary. Note that the Pocock boundary uses a fixed, modestly more extreme value, but the final test result must then also be more extreme than the conventional 0.05 test to be considered significant. The Haybittle-Peto method uses a conventional final test value but is very conservative through the penultimate hypothesis test. The O'Brien-Fleming boundaries begin very conservatively, but change as more information accrues, and also allow that the final test be performed using the conventional significance level.

TABLE 8.5. Prototypical Phase III trial data and safety monitoring committee.

<i>Membership (voting members, external to trial)</i>	<i>Additional attendees</i>
Physicians	Trial statistician
Statisticians	Trial coordinator
Patient advocate	Trial chair ^a
Medical ethicist	Sponsor representatives ^a

Review Scope:

- Patient accrual, reporting delinquency and patient withdrawals, treatment compliance, data quality
- Adverse events
- Treatment efficacy endpoints
- Other relevant materials, including confidential reports provided by other investigators

Decision to stop/alter trial conduct and/or release findings may be based on:

- Evidence of benefit or harm according to monitoring guidelines or adverse events (expected or otherwise) observed in the trial
- Evidence of little likelihood that treatment difference will be realized
- External information that raises concerns regarding the scientific, clinical, or ethical assumptions on which the current trial was based
- Poor likelihood of trial yielding meaningful findings due to problems with accrual, compliance, or patient retention

^aNote that these individuals are typically excluded from discussions of interim efficacy data, although there is currently some debate regarding this issue.

deliberations. The policies and procedures for U.S. National Cancer Institute-sponsored Cooperative Group trials provide a good overview of DSMC structure and function for Phase III trials.⁶¹

Analysis

Definitive analysis commences when either the requisite number of events indicated in the trial design has been observed, or the DSMC has deemed that the trial results should be disclosed due to early stopping conditions being met.

An important aspect of Phase III trial analysis is the definition of the analysis cohort. The concept of analysis by *intention-to-treat* is often discussed, but the definition of this term can sometimes be unclear, so it is best to explicitly describe which patients are included.⁶² In the strictest sense, the intention-to-treat cohort includes all patients randomized, irrespective of eligibility, acceptance of and adherence to assigned treatment, and any and all other postrandomization deviations from protocol. However, it is often the case that patients found ineligible for the trial after randomization due to having been incorrectly staged or for other reasons are excluded from the primary analysis, and this practice (used with caution) is sometimes advocated, as it allows for evaluation of the therapy in the population for which it was intended.² A more controversial and rarely acceptable form of patient exclusion involves removal of patients who did not or could not comply with assigned therapy regimens or received nonprotocol therapy. Such exclusions can easily lead to biased comparisons, and in general, any post hoc analysis of treatment benefit in relation to dose received is fraught with interpretational difficulties and should be avoided in primary analysis.⁶³

For time-to-event data, the principal summaries are the survival distribution (or survival curve) and the estimated

hazard ratio. The survival curve $S(t)$ represents the probability of remaining event free until at least time t , or $S(t) = \Pr(T > t)$. This function is plotted from randomization (e.g., at $t = 0$, $S(t) = 1.0$) to some follow-up time that a remaining fraction of patients has reached. This points to an important feature of time-to-event data, that is, *censoring*, where it is known that a patient is event free as of some follow-up time, but the (potential) failure time is not yet observed. Censoring is a natural consequence of staggered enrollment into the trial, so that at any given time, some patients have less follow-up than others (administrative censoring), but also may occur because patients may withdraw from or be lost to follow-up before experiencing the event of interest. Administrative censoring can be reasonably assumed to be independent of failure risk except in cases where characteristics of participants enrolled changes over time (which is why well-defined entry criteria are necessary). Any censoring associated with propensity for failure (e.g., sicker patients more often withdrawing) that results in different rates of loss per treatment arm can bias treatment comparisons.

In the case in which censoring is assumed independent of probability of failure, then estimating $S(t)$ using available information per patient, including follow-up to censoring, is straightforward. For a set of ordered observed times where one or more patients had an event $t_1 < t_2 < t_3 < \dots < t_j$, define d_j as the number of events at time t_j and Y_j as the number of patients available to possibly fail (all those who have not yet failed and were not censored before t_j ; by convention, those censored exactly at t_j are considered at risk to fail). The Kaplan–Meier (KM) estimator⁶⁴ is the product of the quantities $(1 - d_j/Y_j)$ over the J failure times

$$S(t) = \prod_{j=1}^J \left(1 - \frac{d_j}{Y_j}\right) \quad (3)$$

Although the KM curve is the typical graphical summary, the relative hazard of failure between groups is the principal measure of efficacy. The HR (and associated statistical tests) pertains to the entire span of follow-up, as opposed to a test of difference in the survival curves at a specific time point, in which case the result would depend on which time was chosen. The *log-rank test*, which frequently accompanies the KM curve, in fact compares underlying failure probabilities between groups over the J failure times.⁶⁵ Issues related to this and other tests for comparing survival time distributions are discussed here.

The HR can be estimated by computing the incidence density or *average failure rate* in each treatment group. For two treatment arms with n_A and n_B patients, respectively, the average failure rate for treatment arm A is $I_A = D_A/\bar{T}_A$, where $\bar{T}_A = \sum_{i=1}^{n_A} T_i$, the sum of times to event or censoring for each patient, and D_A is the total number of events in arm A. For I_B similarly computed, $HR = I_A/I_B$. More commonly, the HR is estimated via the Cox proportional hazards model,⁶⁶ which relates the hazard of failure to covariates through the equation

$$\lambda(t, x) = \lambda_0(t) \cdot \exp(\beta_1 \cdot x_1 + \beta_2 \cdot x_2 + \dots + \beta_p \cdot x_p) \quad (4)$$

where $\lambda_0(t)$ is an unspecified “baseline hazard” and the x ’s represent covariates, which may include indicators for treatment group and other factors. For example, for a single covariate, x_1 , representing treatment group with $x_1 = 0$ for the standard

treatment and $x_1 = 1$ for the new treatment, $\lambda_0(t) \exp(\beta_1)/\lambda_0(t) = \exp(\beta_1)$ equals the HR. From this model, a significance test for HR = 1.0 and confidence interval for the HR are obtained. With additional prognostic factors included in the model, $\exp(\beta_1)$ gives the HR *adjusted* or *controlling* for these factors. Prognostic factor analysis using this model or other techniques often follows primary analysis of Phase III trials. The modeling process, which entails deciding which factors to include, determining the correct way to represent a given factor (i.e., in categories, on a continuous scale, and so forth), consideration of interrelationships (e.g., interactions) among factors, and many other issues, can be complex, as can using model results for prediction of individual patient outcomes or classification into prognostic risk classes. A comprehensive review of current modeling methods applied to oncology data is provided by Schumacher et al. in Reference 1.

One important issue concerning the HR and tests used to compare hazards pertains to how failure events occur over time in the groups being compared. The *proportional hazards* condition, whereby the HR is constant over time, is implicit in the previously described model (hence the name). Under this condition, the quantity $\log_e(S^A(t))/\log_e(S^B(t))$, where S^A and S^B are the KM estimates at time t in the two treatment groups, will be approximately the same at different time points on the survival curves. Note, however, that under this condition the absolute difference in proportions event free from the KM curve will not be constant, but in fact the curves will diverge over time. The log-rank test⁶⁵ gives equal weight to failure events across the time span and is the optimal test under proportional hazards. For failure patterns that deviate from proportional hazards, there are a number of alternatives to the log-rank test that are more sensitive to differences between survival curves. The Wilcoxon⁶⁷ test places more weight on failures occurring early, and so is more sensitive to the case where survival curves separate early but may later converge. Other tests also tend to weight earlier failures,^{68,69} and a generalized class of tests exists that encompass the standard log-rank and Wilcoxon test as well as tests with other weighting schemes.⁷⁰ Choice of test should be determined by whether there is specific interest in or expectation that differences will emerge under some pattern other than proportional hazards. In any case, when different tests differ, it is usually the case that the treatment effect is changing over time and thus a single HR may be an inadequate summary, and separate HR estimates for specific time intervals may be more appropriate. One of several formal tests for proportionality can be used when there is empirical evidence of nonproportionality from the KM curve plot. Heuristically, a single HR under strongly nonproportional hazards is akin to the mean of a highly skewed distribution, in that it may be computed but does not serve as a readily interpretable summary of the data. Figure 8.2 illustrates how statistical tests may differ under some different patterns of failure among survival curves being compared.

Another issue with KM survival curve displays relates to the follow-up period shown. Often the curves are plotted until a time point for which very few patients are under observation. This practice can create the misleading illusion of a large expanse between the curves, when in fact variability on the estimated proportion event free when few patients remain is very large, and if a few patients or even one patient were to fail, the estimate would change substantially. It is more

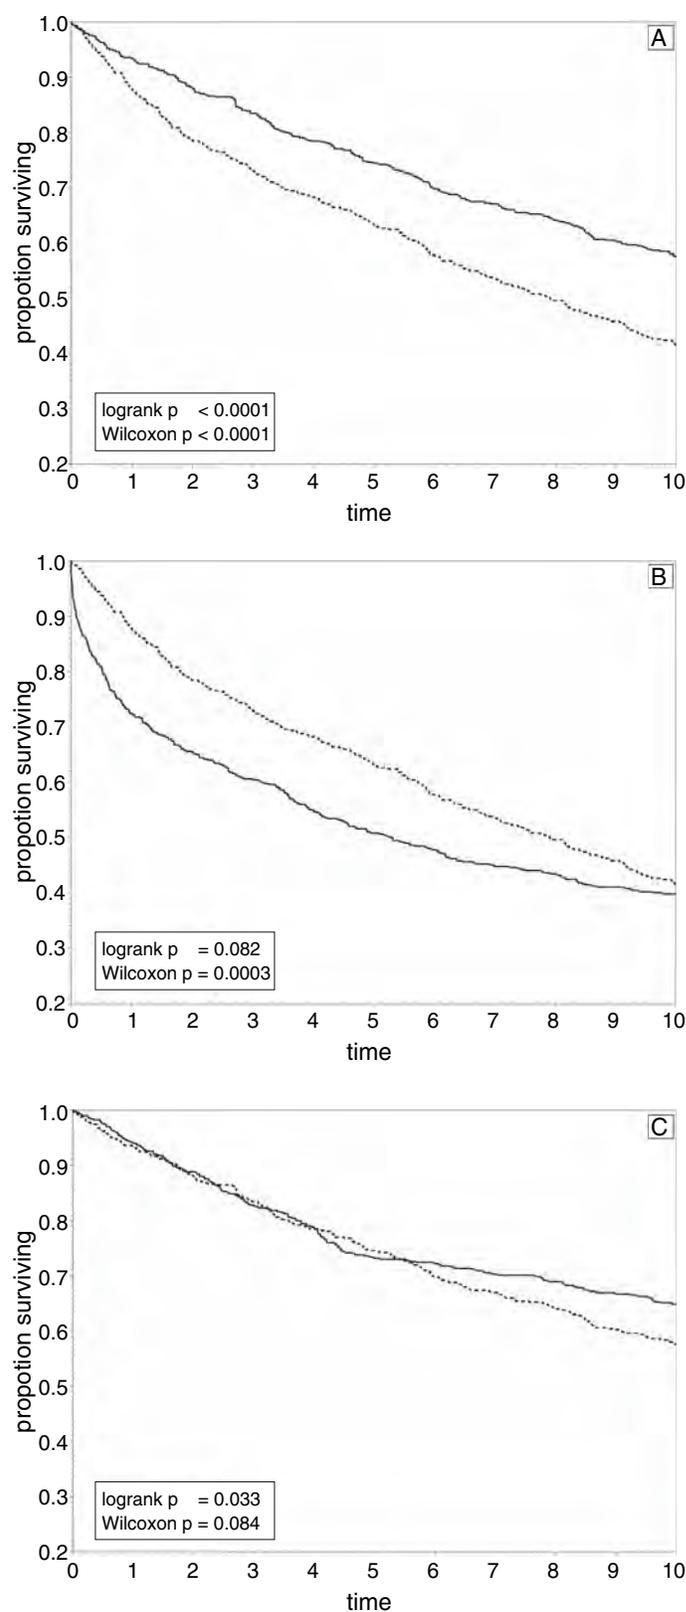

FIGURE 8.2. Examples of survival curves exhibiting different failure patterns. Data are generated from hypothetical data with 500 subjects per group. In comparing curves, the Wilcoxon test gives greater weight to earlier failures, whereas the log-rank test weights failures equally throughout follow-up. (A) Curves follow the proportional hazards pattern. The hazard ratio is constant (HR = 2.0). (B) Curves show a violation of proportional hazards, converging over time as the hazard ratio becomes smaller. (C) These curves also are nonproportional, separating later in follow-up.

appropriate to plot the curves and cite proportions event free only at time landmarks that most of the patients who remain event free have reached.

Some Additional Topics

CONFIRMATORY TRIALS AND META-ANALYSES

Because of the planning, infrastructure, cost, and time required, Phase III trials are carefully designed to avoid equivocal findings, and thus provide definitive evidence for or against changes in therapy standards. Nonetheless, questions regarding the treatments under evaluation will invariably remain unanswered, and thus there is an important role for replicated (referred to as confirmatory) trials and the synthesis of similar trials into a coherent body of evidence. This is particularly important for clinical decision making, where evidence from trials must be weighed in relation to an individual patient's utility for various treatment options. For the small to moderate benefits seen for most cancer treatment advances, these confirmatory trials may in fact be necessary to effect change.^{71,72} Although costly to obtain, such corroborating evidence can contribute greatly to practice changes, as the qualitative value of multiple trials with similar findings cannot be understated. It is also not uncommon that replicated trials fail to obtain similar results, providing an opportunity for closer scrutiny of differences between trials and their potential breadth of applicability.

A more formal quantitative means of combining evidence from trials is by meta-analysis, a widely used analytic tool in many areas of social and medical science. Meta-analysis refers to a process whereby data from independent studies are combined to form a quantitative summary estimate of a given effect. Randomized trials are in fact more suited to meta-analysis than nearly all other research designs, as there is likely to be considerable similarity in disease definitions, study design features, classes of therapeutic agents or procedures, and endpoints, and this information is increasingly well documented in trial reports.⁷³ Meta-analyses were initially carried out by extracting effect estimates from published literature and combining these into a single estimate using statistical techniques, but in medical meta-analysis studies, it is usually considered necessary to obtain patient-level data from each trial, a laborious process that necessarily includes seeking data from unpublished trials to avoid the "publication bias" toward positive findings. Once these data are acquired and standardized for a common endpoint, the individual trial effect measures (i.e., hazard ratios) may be combined using an appropriate statistical model into a summary effect estimate. Results of each trial are also presented, as well as tests for evidence of significant heterogeneity among trials, in which case a single summary measure may be inappropriate and thus omitted. Often, a quality weight measure based on design features is assigned to each trial, providing a natural opportunity to evaluate trial quality.

A principal advantage of meta-analyses is the ability to evaluate consistency among trial findings and possibly uncover small but clinically meaningful treatment effects that were not statistically significant in any one trial (although the meta-analysis is generally not considered the equivalent of an adequately powered RCT). One disadvantage

is that combined trial estimates based on heterogeneous treatment regimens may be able to illustrate only a proof of principle (for example, "multidrug chemotherapy is effective"), which may be of limited use for specific clinical questions, such as which regimen to use. Furthermore, comparisons of different regimens from data aggregated across trials are subject to all attendant limitations and biases of observational studies. Despite these and other limitations and pitfalls,^{74,75} meta-analyses are a valuable complementary research strategy that has been influential in cancer treatment. An excellent example of the methods and data summaries used in meta-analysis in oncology can be found in the reports of the Early Breast Cancer Trialists' Collaborative Group.⁷⁶

BAYESIAN APPROACH

As in the case of Phase I and II trials, Bayesian statistical methodology is increasingly being applied to various aspects of Phase III trials. In study design, a Bayesian approach to formulating the sample size in terms of the questions (1) "what treatment effect might realistically be realized with a new regimen?" and (2) "what magnitude of effect would prompt the current standard to be supplanted?" provides a useful framework that more closely resembles clinical practice.^{77,78} In trial monitoring, the use of "skeptical" and "optimistic" prior distributions introduced earlier, considered in conjunction with accumulating trial results, provides a rational means to determine whether current results are sufficiently convincing to justify early stopping.⁷⁹

Ethics of Clinical Oncology Research

Manish Agrawal, Lindsay A. Hampson,
and Ezekiel J. Emanuel

Ever since the earliest days of cancer research, ethical issues have been integral. In 1891, a French physician, Victor Cornil, reported that to determine whether cancer was contagious, a small section of breast tumor removed from the breast of one woman was implanted in her contralateral noncancerous breast. The surgical resection and implant were conducted when the patient was anesthetized and without the patient's consent. When this research study was initially reported it was condemned "as criminal."¹ In 1892, another cancer surgeon, William Coley, was conducting studies to determine whether "artificial erysipelas" (induced inflammation) would have antineoplastic effects. In describing one patient with a sarcoma, he noted that initially the patient was most reluctant to undergo the treatment. But "after some deliberation he consented, and on the 21st of April 1892 I began inoculations." Since that time, there has been substantial thought about the ethical issues involved in clinical oncology research, producing both more systematic analyses and important empirical data relevant to these issues. We delineate a general framework for analyzing the ethics of clinical research studies and then examine ethical issues involved in individual topics: (1) randomization and clinical equipoise; (2) informed consent; (3) Phase I oncology research; (4) stored biologic samples; (5) genetic testing; and (6) conflict of interest.

General Framework

Clinical oncology research must fulfill eight ethical requirements (Table 9.1).^{2,3} First, research must reflect a collaborative partnership between researchers and the community from which participants are drawn.⁴ Typically, a collaborative partnership is manifest in support from patient advocacy groups and the public for research funding, as well as inclusion of lay or patient representatives in research advisory and oversight boards such as institutional review boards (IRBs). Second, the research must be socially valuable, addressing meaningful gaps in therapy or scientific understanding.⁵ "Me-too" studies confirming well-known findings are unethical. Third, the study must be conducted to generate reliable and valid data so that there is a reasonable chance the data will be able to advance therapy or contribute knowledge. Trivial questions, invalid or biased methods, and poor statistical techniques are unethical because worthless science cannot

justify any risk or inconvenience to research participants. Consequently, there is no conflict between science and ethics. For research to be ethical, it must be good science.

Fourth, subject selection must be fair.^{6,7} The eligibility requirements and recruitment strategies must be defined by the scientific objectives of the research study, not by social vulnerability or status. After scientific objectives, individuals likely to experience lower risks and greater benefits should be considered for recruitment and enrollment. It is not permissible to enroll privileged individuals preferentially in studies that are perceived to be especially promising. It is unreasonable to recruit individuals of a certain group into a study for convenience alone, when the conduct or results of that study would not benefit that group. Fortunately, unfair subject selection is rarely a problem in cancer research, where recruitment is necessarily tied to the disease under study. Fifth, the research must have a favorable risk-to-benefit ratio. Although risks can rarely be eliminated, they should be minimized. Similarly, the potential benefits to the participants and to future patients should be enhanced. When the benefits to individual participants are minimal, the risks are justified by the benefits of advancing knowledge for society. Sixth, research must also undergo independent review by a committee of peers and laypersons, such as an institutional review board (IRB). Such review is intended to provide unbiased evaluation of the scientific and ethical aspects of research as well as institutional and public accountability for that research.

Seventh, subjects must offer their informed consent to participate in research.^{8,9} Informed consent has four requirements: (1) competence of the research participant to make decisions; (2) disclosure of relevant information by the researcher; (3) understanding of the information by the participant; and (4) voluntary consent by the participant to enroll. When participants lack competence, such as in pediatric research, permission from a surrogate is generally required. Finally, respect for persons does not end with informed consent. Researchers must respect the participants' rights to privacy and to relevant new findings and recognize the continued voluntary nature of participation in the study. Most importantly, researchers must monitor the health and well-being of research participants and intervene when it is threatened.

Each of these eight requirements must be satisfied; that is, all are necessary, although in particular circumstances,

TABLE 9.1. What makes oncology research ethical?

<i>Requirement</i>	<i>Underlying ethical values</i>	<i>Explanation</i>	<i>Benchmarks for fulfillment</i>
Collaborative partnership	Nonexploitation and respect for community's self-determination	Inclusion of the patients, representatives of advocacy groups, and other community members in determining research funding, research priorities, ethical oversight, and strategies for studies.	<ol style="list-style-type: none"> 1) Ensure appropriate representation of researchers, health policymakers, and the community. 2) Involve researchers, health policymakers, and the community to share responsibilities for determining the importance of health problem, assessing the value of the research, planning, conducting, and overseeing the research, and integrating the research into the healthcare system. 3) Respect the community's values, culture, traditions, and social practices. 4) Contribute to developing the capacity for researchers, health policymakers, and the community to become full and equal partners in the research enterprise. 5) Ensure recruited participants and communities receive benefits from the conduct and results of research. 6) Share fairly the financial and other rewards of the research.
Social or scientific value	Scarce resources and nonexploitation	Evaluation of a treatment, intervention, or hypothesis with the aim of improving health and well-being or increasing knowledge.	<ol style="list-style-type: none"> 1) Specify the beneficiaries of the research. 2) Assess the importance of the health problems being investigated and the prospect of value of the research for each of the beneficiaries. 3) Enhance the value of the research for each of the beneficiaries through dissemination of knowledge, product development, long-term research collaboration, and/or health system improvements. 4) Prevent supplanting the extant health system infrastructure and services.
Scientific validity	Scarce resources and nonexploitation	Use of accepted scientific principles and methods, including statistical techniques, to produce reliable and valid data.	<ol style="list-style-type: none"> 1) Ensure the scientific design of the research realizes social value for the primary beneficiaries of the research. 2) Ensure the scientific design realizes the scientific objectives while guaranteeing research participants the healthcare interventions they are entitled to. 3) Ensure the research study is feasible given the social, political, and cultural environment and with sustainable improvements in the local healthcare and physical infrastructure.

Fair subject selection	Distributive justice	Selection of research participants so that stigmatized and vulnerable individuals are not targeted for risky research and favored or privileged individuals not preferentially enrolled in potentially beneficial research.	<ol style="list-style-type: none"> 1) Select the study population to ensure scientific validity of the research. 2) Select the study population to minimize the risks of the research and enhance other principles, especially collaborative partnership and social value. 3) Identify and protect vulnerable populations. <ol style="list-style-type: none"> 1) Assess the potential risks and benefits of the research to the study population in the context of its health risks. 2) Assess the risk–benefit ratio by comparing the net risks of the research project with the potential benefits derived from collaborative partnership, social value, and respect for study populations.
Favorable risk–benefit ratio	Nonmaleficence, beneficence, and nonexploitation	Minimization of risks; enhancement of potential benefits. Risks to the individual participants are proportionate to the benefits to the individual participants and to society.	<ol style="list-style-type: none"> 1) Ensure public accountability through reviews mandated by laws and regulations. 2) Ensure public accountability through transparency and reviews by other international and nongovernmental bodies. 3) Ensure independence and competence of the reviews. <ol style="list-style-type: none"> 1) Involve the community in establishing recruitment procedures and incentives. 2) Disclose information in culturally and linguistically appropriate formats. 3) Implement supplementary community and familial consent procedures where culturally appropriate. 4) Obtain consent in culturally and linguistically appropriate formats. 5) Prevent penalization for withdrawal from the research. <ol style="list-style-type: none"> 1) Develop and implement procedures to protect the confidentiality of recruited and enrolled participants. 2) Ensure participants know they can withdraw without penalty. 3) Provide enrolled participants with information that arises in the course of the research study 4) Monitor and develop interventions for medical conditions, including research related injuries, of enrolled participants that are at least as good as existing local norms. 5) Inform participants and the study community of the results of the research.
Independent review	Public accountability, minimizing influence of potential conflicts of interest	Review of the design of the research trial, its proposed subject population, and risk-to-benefit ratio by individuals unaffiliated with the research.	
Informed consent	Respect for persons, autonomy	Provision of information to participants about purpose of the research, its procedures, potential risks, benefits, and alternatives so that the individual understands this information and can make a voluntary decision whether to enroll and continue to participate.	
Respect for potential and enrolled subjects	Respect for persons, autonomy, and welfare	<ol style="list-style-type: none"> 1. Permitting withdrawal from the research 2. Protecting privacy through confidentiality 3. Informing of newly discovered risks or benefits 4. Informing about results of clinical research 5. Monitoring of the health and well-being of participants and providing treatments for adverse reactions from the research. 	

such as mental incompetence or emergency research, the consent of the individual research participant can be waived. Furthermore, these principles are universal; they apply to research in all countries, although precisely how they are fulfilled may vary depending on the particular economic, social, and cultural circumstances. For instance, in cultures in which signatures are not the common form of consenting, other mechanisms may be used.¹⁰ Finally, in designing any particular research study, tensions between the principles may arise. Different principles may have to be balanced against other principles; for some studies, lowering risk may have to be balanced against scientific validity or social value. Such balancing is inevitable. It means that there can be several different ethically acceptable ways to conduct a research study.

Randomization and Clinical Equipoise

Randomized controlled trials (RCTs) permit the comparison of standard care with one or more new interventions. RCTs are the gold standard of clinical research. Controls and some form of randomization have been used for about 100 years,¹¹ although the first modern randomized, placebo-controlled trial was conducted only in 1948 to evaluate streptomycin for pulmonary tuberculosis.¹² There are many concerns about the ethics of randomization, including the need for researchers to suspend their suspicions about what treatment is superior and to follow a protocol rather than provide individualized care.¹³ In addition, randomization is probably the aspect of informed consent most commonly misunderstood by research participants.

Controlling for factors that are unknown but might influence outcomes is the scientific justification for randomization. Clinical equipoise is the dominant ethical justification for randomization.^{14–16} Originally, the concept of *theoretical equipoise* was articulated as a justification for RCTs.¹⁷ Theoretical equipoise held that it was ethical to conduct a randomized research study when there was exactly balanced evidence for the various interventions being tested. Theoretical equipoise has many problems. Rarely is the evidence exactly balanced. It is “overwhelmingly fragile . . . balanced on a knife’s edge [because] it is disturbed by a slight accretion of evidence” for one intervention or the other.¹⁴ Furthermore, it relies on the personal views of individual physicians; it requires each physician who enrolls a patient to be in a state of uncertainty about which intervention is better—a situation that rarely occurs.

In 1987, as an alternative, Freedman proposed *clinical equipoise*.¹⁴ It is based on the recognition that the purpose of a clinical trial is *social*, to change standards of medical practice within the community. Consequently, clinical equipoise exists when there is uncertainty or disagreement among *the expert medical community* about which intervention is better. An RCT is conducted to resolve this uncertainty within the medical community. Clinical equipoise is the ethical manifestation of the statistical dictum that an RCT must begin with an honest null hypothesis.¹⁴ More importantly, “clinical equipoise is consistent with a decided treatment preference on the part of the investigators. [Physicians] must simply recognize that their less-favored treatment is

preferred by colleagues whom they consider to be responsible and competent.”¹⁴ Thus, it is the absence of consensus among the medical experts about the best intervention that ethically justifies the research study.

One virtue of clinical equipoise is that it rejects special ethical significance for any individual physician’s hunch or intuitions about what is best. It relies on data, not on emotions. This approach can help convince patients that a trial is just as good an option as any alternative. Indeed, when there is clinical equipoise, then, at the start of the trial, whatever arm the patient is randomized to, should be as good as any other arm; all arms could be said to be in the patients’ best interest. The recent experience with the trial of bone marrow transplantation for breast cancer should emphasize to the oncology community the dangers—ethical, scientific, as well as for individual patients—of relying on feelings rather than data from RCTs to choose what treatment to receive.

One important empirical question is whether clinical research does adhere to clinical equipoise. If it did, we should find that in many trials there is no difference between the new intervention and standard care, and that the numbers of trials demonstrating that the intervention arm is superior to standard care should be comparable with the number of trials demonstrating the superiority of standard care. The few meta-analyses that exist suggest that intervention arms are shown to be superior more frequently than standard care arms (Table 9.2).^{18,19} Indeed, at least some data suggest that there is an equal balance between studies that show superiority of the intervention arm and those showing superiority of standard therapy when research is sponsored by government agencies. However, when sponsored by commercial organizations, the innovative interventions were significantly more likely to be proven superior. These data suggest that at least when commercially sponsored, there may be too high a threshold for testing a new intervention in an RCT; that is, researchers initiate a new RCT when there is more than sufficient evidence favoring the new intervention’s effectiveness. This choice may be explained by the fact that launching an RCT is costly both in terms of effort and resources. Because of the costs, the research community may hesitate to initiate RCTs except when there is substantial evidence supporting the new intervention.²⁰

Although clinical equipoise seems to solve many ethical problems with randomized control trials, some residual problems remain. For instance, why is a *P* value of 0.05 the level at which the community of medical experts is convinced that one intervention is better than another? Similarly, when the trial is nearing full accrual, clinical equipoise may not hold as data may suggest one arm is better than another. In such circumstances, there may be questions about the ethics of enrolling additional participants, even if the *P* value is not 0.05.

Informed Consent

Informed consent is an important element of ethical clinical research and is the most extensively empirically studied aspect of research ethics.^{21–27} As noted earlier, to have valid informed consent requires fulfilling four elements: (1) competence, (2) disclosure, (3) understanding, and (4) voluntari-

TABLE 9.2. Data on adherence to clinical equipoise in randomized controlled trials.

Author	Year published	Disease(s)	Studies	% favoring innovative therapy	% showing equality between innovation and standard therapy	% favoring standard therapy	Comments
Djulbegovic et al. ¹⁸	2000	Multiple Myeloma	136 reported between 1996 and 1998	29%	59%	12%	Commercially sponsored trials were significantly more likely to favor new innovative therapy arms (74% vs. 26%; $P = 0.004$). Studies funded by nonprofit organizations showed no difference (53% vs. 47%; $P = 0.61$)
Joffe et al. ¹⁹	2004	Adult cancers	103 from two U.S. cooperative cancer groups between 1981 and 1995	29%	68%	3%	Mean effect size = 1.19 (95% CI, 1.12–1.27), favoring innovative therapy arm.

ness.² The published studies have predominantly focused on understanding, by evaluating what research participants understand and what are their motivations (Table 9.3).^{26,28} Disclosure of information and voluntariness are less well studied.^{27,29–31}

Limitations of the Empirical Data on Informed Consent

Despite the emphasis placed on informed consent and the numerous empirical studies, the reliability of conclusions is limited by five serious methodologic problems. First, there are no standard instruments to measure the domains of informed consent. Thus, there are varying and inconsistent methods and outcome measures, and the questions asked vary considerably from study to study. Although there are some proposed measures, none are widely accepted, such as the SF-36 for measuring quality of life.^{32,33} This limits the comparability and generalizability of the available data. Second, there is confusion as to what should be measured. Studies claiming to assess understanding are often measuring motivations, recall, or voluntariness, none of which are understanding. For example, questions asking about the purpose of a study do not distinguish between the investigator's purpose for conducting the study from the purpose a particular individual may have for participating in the study. Third, the studies tend to be small; they usually involve fewer than 100 participants and are from single institutions.

Fourth, there is important variability in the timing of the assessment of understanding. Measuring understanding on the day a research participant decides to enroll in a study assesses understanding at the ethically key moment of decision making. Conversely, measurements made a week or more after signing consent assesses memory or recall rather than understanding. Such assessments may result in differences that could be completely due to the delay in assessment and have nothing to do with the quality of the informed consent process. Finally, insufficient attention has been given to the diversity of study contexts. Issues pertinent for informed consent in a randomized control trial for cancer differ from those for a Phase I cancer trial, or an epidemiologic study, yet these differences are rarely addressed.²⁸

For example, asking a person their understanding of the chances they might benefit by enrolling in a randomized control trial of adjuvant therapy for breast cancer is not comparable to asking a person enrolling in a Phase II study of a single agent for metastatic breast cancer. In the adjuvant situation, the goal is cure, whereas in the metastatic setting the goal is palliation. Thus, a single study attempting to evaluate understanding in patients in these different research contexts is difficult to interpret.

Data on Informed Consent

Despite these limitations, three consistent results emerge from the published studies on informed consent. First, some problems exist with the informed consent process as it is currently practiced.^{23,34} In some cases, disclosure seems to be inadequate. Several studies have suggested that although regulations are being followed, informed consent documents have become increasingly unreadable, lengthy, and uninformative.^{22,35,36} These studies have found the forms written at the level of scientific journals rather than at an acceptable 8th-grade reading level.^{35,36} Another study evaluating disclosure by asking European investigators their practice of obtaining consent found that 12% failed to inform their patients about the trial before randomization, 38% reported not always telling patients that they had been assigned their treatment randomly, and 5% never sought consent.³⁷ However, in the Phase I setting the available data suggest disclosure may be better. The only study evaluating the substantive content of Phase I oncology consent forms found that 99% of 272 forms explicitly stated the study was research and that in 86% this statement was prominent.³⁸ Furthermore, 92% indicated safety testing was the research goal. Overall, the mean length of the risks section was 35 lines in contrast with 4 lines as the average length of the benefit section; and 67% of the forms mentioned death as a potential consequence of participation in the study, whereas only 5% mentioned cure as a possible benefit. Only 1 consent form indicated that any benefits were expected. In a different study, evaluating disclosure during the physician-patient discussion in the Phase I setting, Tomamichel et al. reported that the lack of known treatments and the investigational nature of the Phase I

TABLE 9.3. Studies evaluating the quality of informed consent in Phase I oncology trials.

Author	Year	Sample size	Methods of evaluation	Reasons for participating	Awareness of study purpose and design	Confidence in benefit from enrolling in study	Satisfied with informed consent process	Would participate again
Rodenhuis et al. ⁴⁰	1984	10	Interview 1 week after treatment begun	50% hope for improvement of their diseases; 30% pressure of family	60%–80% recalled, "experimental," "so far only animal studies," "effect uncertain"	—	—	—
Itoh et al. ^{41,65}	1996	32	Questionnaire after enrollment but before drug administration	19% treatment benefit; 63% no benefit but participate anyway	43% knew goal is to determine recommended dose	63% did not expect to benefit	81% said understood almost all information given to them	—
Yoder et al. ⁴⁴	1997	37	Quantitative and qualitative interviews at entry and exit of study	70% to get best medical care; 85% decreased tumor size	—	—	—	100%
Hutchison et al. ⁴⁵	1998	28	Interviews 2–4 weeks after consenting to participate	Majority hope for benefit	—	"Most important reason . . . was hope it might help them"	89%	—
Daugherty et al. ⁹	2000	144 ^a	Interviews within 1 week of receiving drug	73% seeking anticancer response	31% knew purpose	73% thought there may be psychologic benefit	96%	—
Tomamichel et al. ³⁹	1995	31	Quantitative and qualitative analysis of taped interviews	59% possibility of medical benefit	—	—	96%	—
Moore et al. ⁷⁵	2001	15	Pre- and posttreatment questionnaire and structured interviews	Three themes: 1) need to try everything 2) maintaining hope 3) help others Hope for therapeutic benefit	—	Described "living with the reality of incurable disease whilst still hoping for a miracle cure"	—	—
Schutta et al. ^{75a}	2000	8	Quantitative and qualitative analysis of taped focus group	Hope for therapeutic benefit	—	—	—	—
Joffe et al. ²⁸	2001	50 ^b	Mail survey 1–2 weeks after consent	75% knew trials done to improve treatment of future patients; 71% knew may be no medical benefit to themselves	75% knew trials done to improve treatment of future patients; 71% knew may be no medical benefit to themselves	71% knew may not be direct medical benefit to them from participating	90%	77%
Meropol et al. ⁴⁸	2003	328 ^c	Questionnaire after enrollment	60% expect to benefit	—	64% "unsure" or "maybe"	—	—

^aThe initial publication by Daugherty et al.⁹ of 27 patients is included in the 144 patients.

^bSurvey of patients participating in phase I, II, and III studies. Total number of patients was 207 of which 50 were enrolled in phase I studies. Unfortunately, the analysis of the responses failed to stratify according to phase.

^cThe initial publication by Cheng et al. of 30 patients, included in the 328 patients.

oncology study were verbally stated by physicians to cancer patients in more than 90% of consultations and the lack of sufficient knowledge of toxicity of the drug in more than 80%.³⁹ Two other studies report similar findings.^{40,41}

Several studies have focused on evaluating understanding by the research participant and found that the participants did not understand various aspects of the study.^{28,42} For example, a study by Penman et al. of 144 cancer patients participating in trials at academic cancer centers found that participants did not fully understand toxicity;⁴² participants recalled an average of 3 risks when the consent forms mentioned an average of 11 risks. More importantly, participants tended to recall the minor toxicities, such as hair loss, rather than major potential toxicities.

Studies evaluating understanding have consistently found that participants most frequently fail to understand details of research design. In a study of 299 Finnish patients with breast cancer enrolled in a randomized control trial of hormonal treatment, 51% thought the doctor had chosen the therapy.⁴³ More recently, Joffe et al. reported on 207 patients enrolled in Phase I, II, and III oncology studies surveyed 3 to 14 days after consent.¹⁹ Overall, 75% of participants knew that the main reason cancer trials are done is to improve the treatment of future cancer patients, while 71% reported that they may not experience direct medical benefit from participating in the clinical trial, yet 48% thought the treatments and procedures were standard for their type of cancer. The understanding aspect of informed consent in Phase I oncology trials has been the most extensively studied area of Phase I ethics research. Most participants in Phase I oncology studies are motivated to participate by hopes for stabilization, improvement, or even cure of their cancer (see Table 9.3).⁴⁴⁻⁴⁸ This observation has been widely interpreted to suggest patients have deficient understanding of the objectives, benefits, and risks of Phase I research. However, the data also show that patient decisions to participate may reflect a motivation to maintain hope in a difficult situation rather than misunderstanding of the information.⁴⁴ For example, although Daugherty et al. found that 85% of patients were motivated to participate for possible therapeutic benefit, 78% were either unwilling or unable to state whether they believed they personally would receive benefit from participating in a Phase I trial.⁴⁹ Similarly, Itoh et al. found 63% of the participants did not expect any benefit but wished to participate anyway.⁴¹ The largest study evaluating understanding by Meropol et al., which asked Phase I participants how confident they were being among those who would benefit, found only 27% thought they would definitely benefit from participating in research.⁴⁸

Second, several intervention studies have been conducted in an attempt to improve the informed consent process. Three broad types of interventions have been tried: (1) modifying the consent form, (2) augmenting the discussion between research participants and investigators, and (3) using a multimedia or computer-based intervention.^{22,50} Regardless of the approach, the majority of the studies have not shown meaningful improvements in the understanding of research participants. The major exception is by Aaronson et al., finding that using a telephone-based nursing intervention could improve participants' understanding.⁵⁰ About 15% to 20% of participants in the intervention group showed improvements in the level of their understanding of side effects, trial objectives,

and randomization. It should be noted that although studies using consent forms have failed to show a consistent and substantial improvement in understanding, they may still be important to research participants. Joffe et al. found that 84% read the consent carefully and 86% found it easy to understand.²⁸

Finally, despite deficiencies, virtually all the studies report that research participants are generally satisfied with the informed consent process.^{23,42,51-53} Hietanen et al. reported that of 299 breast cancer patients, 68% thought they had enough time for decision making and 87% were happy with their decision to participate.⁴³ Similarly, Verheggen et al. evaluated 198 research participants in 26 clinical trials, finding that the majority of participants were "quite satisfied with the oral and written information disclosure."⁵¹ Daugherty et al., Tomamichel et al., and others report more than 95% satisfaction in the informed consent process by research participants of Phase I oncology trials.^{28,39,49}

Future Directions in Research on Informed Consent

That a discrepancy seems to exist between what patients understand and their satisfaction with the informed consent process poses several research issues. First, what individuals should understand when they decide to participate in research needs to be clearly delineated and justified. As there is not agreement of what constitutes good informed consent, it is difficult to judge the current informed consent process. Some argue understanding of purpose, methods, risks, benefits, and alternatives to the research are essential components of valid informed consent. Others lessen the importance of understanding and argue good faith effort at disclosure in nontechnical language is all that is required for valid informed consent even if patients ultimately do not fully understand. Furthermore, the standards of valid informed consent need to be defined in different research contexts, because what is required for patients to understand may be different depending on the context of the particular study. For example, in a natural history trial studying factors leading to health disparities, good disclosure may be all that is required. Conversely, in a study involving bone marrow transplant with high-dose chemotherapy, total-body irradiation, and a high chance for peritransplant mortality with a potential for prolonged and numerous hospital admissions, a more complete understanding may be more important. Second, what information matters to individuals when making decisions about participating in research needs to be further studied. One reason research participants may not understand certain aspects covered in informed consent is that the details are not that important to or salient for them. If research design is unimportant to research participants' decision making, then it may be difficult, and even unnecessary, to improve their understanding of it.

Besides those discussed previously, in the Phase I context, two issues are particularly important for further research. Studies that delineate between issues of understanding and those of motivation are needed. More importantly, research that evaluates the role hope plays in patients' decisions to participate and whether this hope should be fostered or damped is needed.

Phase I Oncology Studies

Phase I oncology studies are critical to the development of drugs that fight cancer because they are the primary process by which basic research is translated into clinical applications that could potentially lead to larger clinical trials and effective cancer therapies. There are two fundamental ethical concerns about Phase I cancer research: the risk–benefit ratio and quality of informed consent.^{30,31,42,54–56} Data regarding the risk–benefit ratio are reviewed here, whereas the data on informed consent in Phase I studies were discussed earlier under the section on informed consent.

Risks and Benefits of Phase I Oncology Studies

The risks and benefits of Phase I oncology studies have been primarily derived from meta-analyses looking at response rates and mortality.^{57,58} The two largest published meta-analyses of Phase I studies report on trials conducted between 1970 and 1987; they reveal response rates of approximately 5% and mortality of 0.5% (Table 9.4).^{57,58} Although there have been a few other meta-analyses, they are limited by including only single-institution studies, evaluating only a few trials, and not evaluating trials published in the past decade (Table 9.4).^{59–63} Consequently, neither the newer compounds currently being evaluated, such as antibodies, vaccines, immunotoxins, and antiangiogenesis factors, nor improved supportive care measures are reflected in the commonly cited response rate of 5%. More recent data suggest that the response rates may be higher. A recent meta-analysis of 477 Phase I studies sponsored by the Cancer Therapy Evaluation Program (CTEP) at the National Cancer Institute between 1991 and 2002, including 10,867 participants, reported a response rate of 4% for trials with one investigational agent but an overall response rate of 12.2% for all types of Phase I trials, including those escalating doses of proven therapies.⁶⁴ In addition, another meta-analysis looking at all studies published in 2002, reports an overall response rate of 18%.⁶⁵ With the exception of a few agents such as cis-platinum for testicular cancer and imatinib mesylate for chronic myeloid leukemia,

which produced a complete hematologic response rate of 98%, of which 96% lasted beyond 1 year, there are few data on the impact of Phase I oncology studies on other clinical parameters of benefit such as overall survival or symptom control.^{66–68}

In regard to risks, the published meta-analyses report a mortality of 0.5% and the more recent meta-analyses report a slightly higher mortality of 0.7% to 1.3%.^{57,58,64,65} Besides traditional risks such as mortality, toxicity, and survival, non-medical risks are raised as risks that should be factored in the risk–benefit ratio; these include frequent blood draws, radiologic evaluations, physician visits, and biopsies, all of which require a substantial commitment of time and resources from the patients and their families. However, it is unknown whether such factors adversely affect outcomes and quality of life of Phase I research participants. Similarly, there is a concern that nausea, vomiting, and other debilitating side effects are common; however, their overall frequency, severity, and impact on quality of life have been poorly documented. The few data that do exist on the quality of life effect suggest that despite the time commitment and side effects, participating in Phase I oncology studies may actually improve patients' quality of life compared with the alternative of receiving supportive care.^{69–74}

This result seems paradoxical. The improvement in quality of life of cancer patients in Phase I trials may be due to receiving psychologic benefit from participating in Phase I studies.⁴⁹ For some participants, the routine and regular physician contacts reduce psychologic distress during a time of great uncertainty. For others, it may allow them to exercise their willpower in a situation they did not choose.^{45,75} In addition, some also receive comfort from knowing they are helping future patients with cancer.^{28,75,76} More clinical data besides response rates and mortality are needed to fully characterize the risks and benefits of participating in Phase I oncology studies.

Besides obtaining a more complete picture of the risk–benefit ratio of Phase I oncology trials, there are several other research challenges. What criteria should we use to define a favorable risk–benefit ratio for Phase I oncology

TABLE 9.4. Response rates and death rates of Phase I oncology trials.

Author	Trial years	Total no. of research agents evaluated	Total no. of trials evaluated	No. of patients evaluated	Total response rate	Toxic death rate	Other
Decoster et al. ⁵⁷	1972–1987	87	211	6,639	4.5%	0.5%	No
Estey et al. ⁵⁸	1974–1982	54	187	6,447	4.2%		No
Smith et al. ^{58a}	1984–1992	NR	23	610	3%	1%	Single institution
Von Hoff et al. ⁵⁹	1970–1983	113	228	7,960	6.3%	NR	No
Itoh et al. ⁶⁰	1981–1991	38	56	2,200	4%	NR	Japanese studies only
Sekine et al. ⁶³	1976–1993		399	12,076	4.1%		Single-agent studies only
Bachelot et al. ⁶²	1986–1993		9	154	6%	0.6%	
Han et al. ⁶¹	1991–2000	16	16	420	15%		UK studies only
Horstman et al. ⁶⁴	1991–2002		477	10,687	12.2%	0.68%	
Agrawal et al. ⁶⁶	2002		125	2,830	18%	1.3%	

studies? Who should decide what criteria to use to define a favorable risk–benefit ratio?

To determine when a risk–benefit ratio is favorable or unfavorable requires a standard of evaluation, and one appropriate for patients with advanced cancer whose health will most likely deteriorate and who will die, yet no standard has been explicitly articulated. Indeed, determining risk–benefit ratios is one of the most important, but least developed, areas of determining the ethics of research trials.^{2,77–79} One approach could be to elucidate a standard based on socially accepted determinations of risk–benefit ratios already used for cancer treatments, such as in FDA approval of cancer agents. For example, high-dose interleukin 2 (IL-2) is the only FDA-approved treatment for metastatic renal cell carcinoma. This IL-2 regimen has a response rate of 14% (5% complete responses, 9% partial responses), with a median response duration of 20 months.⁸⁰ The possible toxicities of IL-2 are substantial, including a sepsis-like syndrome, requiring judicious use of fluids and vasopressor support to maintain blood pressure while avoiding pulmonary edema from capillary leak. Other chemotherapy treatments, such as gemcitabine, are the FDA-approved treatment of choice for metastatic pancreatic cancer, despite a 5.4% response rate, because of demonstrated quality of life benefits.⁸¹ Thus, an explicit standard, or at least a reasonable approach by which to judge a risk–benefit ratio of Phase I studies, is needed to meaningfully discuss whether a particular risk–benefit ratio is favorable or unfavorable.

Research with Stored Biologic Samples

As information about activation of genes and expression of proteins in cancer tissues becomes more central to oncology, use of stored biologic samples has become an ever more important aspect of clinical oncology research. Over the past decade or so there has been great controversy about when and under what conditions it is ethical to conduct research with stored biologic samples. In 1995, the ELSI-DOE Working Group suggested that all research with stored biologic samples be reviewed by an IRB and that, to show respect for persons, consent should be obtained to use the sample even if not strictly required by the federal research regulations.⁸² Subsequently, other groups have advanced other positions. The American Society of Human Genetics argues recontact for consent is unnecessary for research using previously stored samples, provided the risks are minimal.⁸³

In addition to the disagreements about whether consent should be obtained at all, there are disagreements about what individuals should have to consent to. The National Action Plan on Breast Cancer recommends asking individuals to consent to future research on the disease being studied and separately to consent to research on other diseases.⁸⁴ The National Bioethics Advisory Commission (NBAC) argues that individuals should be offered six choices, including allowing individuals to authorize future research on the same disease, but requiring recontact for consent for research on other diseases.⁸⁵

This disagreement has produced uncertainty about what the ethical requirements are and worries that research is being stymied. Regarding samples to be prospectively collected, the ethical principle of respect for persons suggests

that consent should be obtained. However, there is a further question of what the person should consent to. Respect for persons alone does not determine *how many* or *which* choices individuals should be asked to consent to. For these issues, we need empirical data revealing which choices individuals find as expressions of respect. Similarly, for previously collected samples that lack consent, the question is, what procedures demonstrate respect for persons. Given these questions, empirical research is essential to determining when and how to obtain consent for research with stored samples.

Although the available data are limited, they indicate that research participants are willing to have their biologic samples used for all kinds of research (Table 9.5).^{86–89} Indeed, these data suggest multiple questions on the consent form are unnecessary. Based on these data, it has been suggested that it is sufficient to prospectively ask research subjects to consent to any type of research with their stored biologic sample.⁸⁶ It has also been suggested that previously collected clinical samples can be used in research when anonymized, based on presumed consent with an opt-out when feasible.

Genetic Testing

Rapid advances in molecular biology resulting from new analytical techniques combined with detailed knowledge of the human genome, offer the opportunity of discovering the genetic basis of many cancers.⁹⁰ As basic research into the genetic basis of cancer progresses, the clinical testing of cancer genes is becoming more common.⁹¹ Two ethical issues with genetics testing research are particularly relevant: confidentiality and informed consent.

A fundamental aspect of respect for human persons is protecting confidentiality. The available research suggests that maintaining confidentiality is a real concern of potential research participants. For example, in a study in which Hadley et al. offered genetic testing to 111 eligible first-degree relatives of patients with hereditary nonpolyposis colon cancer (HNPCC), 51% chose to participate.⁹² Fears of discrimination and concerns about psychologic issues were major barriers to testing. A study by Armstrong et al. of BRCA1/2 testing found similar concerns about job and insurance discrimination.⁹³ Worries about job and insurance discrimination are concerns for family members, and safeguards should be in place to protect confidentiality. Research on how valid these concerns are and how frequent breaches of confidentiality involving genetic tests in research occur would be helpful. If they are uncommon, dissemination of such information might increase enrollment into genetic testing research studies, and if they are common, it would help develop safeguards to protect confidentiality.

A second important issue surrounds informed consent and genetics testing. In the context of genetics testing research, it is particularly important for research participants to understand the implications about genetic testing because of its potential psychologic impact on individuals.⁹⁴ Indeed, the data suggest individuals with depressive symptoms are less likely to participate in genetic testing. A study by Lerman et al. of 208 members of four extended (HNPCC) families reported that those with symptoms of depression were four

TABLE 9.5. Data on attitudes toward conducting research with stored biologic samples.

Author	Year	Population	Data source	Percent permitting research with their research-derived stored biologic samples	Comment
Wendler and Emanuel ⁸⁶	2002	504 Americans; 246 enrolled in Alzheimer's research and 258 Medicare beneficiaries	Survey of attitudes	87.9% (for anonymized samples collected as part of research)	27.3% would require consent for research on clinically derived samples that are
Stegmayr and Asplund ⁸⁷	2002	1,311 people 11 years after blood sample collection in the MONICA project	Permission for genetic research	93.0%	22.3% wanted information about each use of their sample
Malone et al. ⁸⁸	2002	5,411 individuals in ECOG cancer studies 2,154 individuals in ECOG cancer studies	Permission as part of informed consent Permission as part of informed consent; more detailed form based on National Action Plan for Breast Cancer model requiring three questions	89.4% 93.7% (cancer) 86.9% (other, noncancer kinds of research)	
Chen et al. ⁸⁹	2004	1,060 individuals enrolled in NIH studies	Permission as part of informed consent	87.1%	6.7% refused future research with stored samples

times less likely to obtain testing.⁹⁵ Biasecker et al. reported similar findings in a study of psychosocial factors effecting genetics testing decisions among BRCA1/BRCA2 families.⁹⁴ Furthermore, informed consent is also exceptionally important in genetics testing research because there is no real option of *going back* once the results of the test are known. Thus, individuals who do not really understand the potential impact of knowing they are carriers of a gene that predisposes them to cancer could potentially suffer long-term consequences. However, with the current emphasis on genetic counseling and the importance placed on it, valid informed consent may already be in place.

Data on risks and benefits of genetic testing would be helpful in genetics testing research. For example, there is a perception of a potential tremendous psychologic burden from knowing the results of genetic tests, but there are few long-term data on how such knowledge affects quality of life, the impact of increased interaction with physicians, and potentially more testing and follow-up. Data on the effects on other family members and family dynamics would also be helpful.

Conflict of Interest

After the Gelsinger case at the University of Pennsylvania and multiple cases at Fred Hutchinson Cancer Center, much attention has been focused on the financial conflicts of interest of clinical researchers in general and of oncology researchers in particular.^{96,97} This controversy raises five fundamental questions: What is a conflict of interest? How frequently do researchers have a financial interest in their own clinical research? Do financial interests distort the design, conduct, or dissemination of research data or compromise patient safety and well-being? How should they be regulated? How well do the safeguards work?

What is a conflict of interest? All professionals have primary interests that define and orient their professional

activities. Teachers' primary interest is to educate their students. Judges' primary interest is to ensure justice is served for plaintiffs and defendants. Physicians' primary interests are to promote patient well-being and to teach medical students. The primary interests of clinical researchers are to produce and disseminate generalizable knowledge that will improve health care for future patients and to ensure the health and well-being of their research participants. In addition to these primary interests, professionals also have secondary interests. For a researcher, these could include publishing, gaining recognition and fame, spending time with his or her family, and obtaining a good income. These secondary interests are not in themselves illegitimate or nefarious; in fact, secondary interests can often be praiseworthy. What makes them problematic is their ability to unduly influence decisions about an individual's primary interest.⁹⁸

A conflict of interest occurs when a secondary interest distorts or appears to distort a judgment related to a primary interest. In other words, a conflict of interest occurs when a reasonable person could "believe that professional judgment has been improperly influenced, whether or not it has."⁹⁸ Mere suspicion by a reasonable person that a professional judgment is biased or unduly influenced is sufficient reason for a conflict of interest to exist, regardless of whether an undue influence has actually occurred. Conflict of interest rules are meant both to ensure objectivity in professional judgments by minimizing the likelihood such judgments will be compromised and to minimize any harms that might result from the bias if it does exist. Thus, the aim of conflict of interest regulations is not to prevent secondary interests altogether, but to prevent the secondary interest from influencing or appearing to influence judgments concerning the primary interest.⁹⁸

How frequently do researchers have financial interest in their own clinical research? With the passage of the Bayh-Dole Act in 1980, which granted universities and medical schools the exclusive licensing rights to intellectual

property developed through federally funded research conducted at their institutions, industry support of research grew significantly.⁹⁹ In 1986, 46% of all biotechnology firms supported research at universities; by 1996, the proportion had doubled to 92%. As a result, universities' share of new gene patents increased from 53% to 73% between 1990 and 1999, and at least 2,900 companies have been formed around an innovation licensed from researchers at an academic institution since 1980.^{100,101} Consequently, from 1991 to 2000, the income to universities from licensing grew from \$121 million to \$997 million per year.⁹⁹ Similarly, the fraction of clinical research supported by industry grew from 32% in 1980 to approximately 62% in 2000 while the federal government's share fell.¹⁰² This expansion by industry has many positive effects for research and researchers, including providing access to industrial facilities and databases, increased financial support for research, and use of industrial expertise.¹⁰³ However, this increase in industry support and involvement in research has also resulted in further opportunities for financial conflicts of interest in clinical research.

Financial relationships between industry and researchers are common; studies suggest that between 23% and 28% of academic investigators in biomedical research receive funding from industry.^{104,105} Probably the most well documented rates of researcher-industry relations are those of the UCSF faculty, which consists of 900 PIs (principal investigators) in an institution with \$374 million in National Institutes of Health (NIH) grants, placing it in the top five institutions receiving NIH funding.¹⁰⁶ In 1999, 7.6% of the faculty reported having personal financial ties to their research sponsors.¹⁰⁶ Of these, 34% had occasional speaking engagements, 33% had paid consultancy arrangements, 32% served on boards of directors or scientific advisory boards, and 14% had equity in a company, with the mean value of the equity being \$100,000. Thus, although the prevalence of faculty with financial ties to industry was relatively low, those with financial interests often had multiple ties, some of which involved substantial sums.

Do financial interests distort the design, conduct, or dissemination of research data or compromise patient safety and well-being? In one bone marrow protocol at the Fred Hutchinson Cancer Center, 80 of 82 enrolled research subjects died and the study investigators had \$294 million of holdings in a drug company sponsoring part of the research.⁹⁷ Importantly, this does not prove that the patients' well-being was compromised by the potential conflict of interest, but it does raise questions. In fact, the researchers were cleared of conflict of interest allegations in a lawsuit that was brought against them and Fred Hutchinson Cancer Research Center by the patient's families.^{107,108} Unfortunately, there are no data substantiating whether the financial interests of investigators compromise the safety of research subjects. This conjecture is difficult to establish, especially as there are no data on the overall safety of clinical research.

Regarding the link between financial interests and research design, the data indicate that industry-sponsored research is certainly no worse methodologically than clinical research sponsored by nonprofit organizations, such as the NIH.^{109–112} Indeed, the data indicate that industry-sponsored research studies may well be more methodologically rigorous.^{18,113} In one study, industry-sponsored trials were more likely to be double blind than trials with other sources of

funding.¹¹⁴ In another study that used a 100-point scale to evaluate five criteria for methodological rigor—randomization, outcome, inclusion/exclusion criteria, statistical analysis, and report of the interventions—industry-sponsored trials scored 73.1 while nonindustry-sponsored studies averaged 53.4 ($P < 0.0001$).¹¹⁵ Recently, Lexchin et al. comprehensively reviewed studies that assessed sponsorship, design, and conduct of research.¹¹⁶ They found that “none of the 13 [assessments in the literatures] reported that industry funded studies had poorer methodological quality . . . Of nine [out of 13 assessments] that provided statistical analyses, four found that drug company sponsored research had better quality scores.” Thus, it appears that financial interests do not compromise research design.

Financial interests may, however, adversely affect data collection and interpretation. Many studies have reported that research funded by industry is more likely to be favorable to the industry's experimental interventions than if the research was funded by a nonindustry source. Of 11 meta-analyses, 9 reported that industry-sponsored trials were significantly more likely to give pro-industry results.¹⁰² Indeed, when all studies were aggregated, having industry sponsorship was associated with an odds ratio of 3.60 (95% CI, 2.63–4.91) for having a pro-industry conclusion. For instance, Als-Nielsen et al. reported that among studies funded by for-profit entities, 51% reported results favorable to industry, whereas only 16% of studies funded by nonprofits generated results favorable to industry.¹¹⁷ Furthermore, one report summarizing a number of randomized studies conducted in multiple myeloma, found that 74% of industry-sponsored trials produced results favorable to the industry's new treatment, whereas only 53% of trials funded by nonprofit entities generated results favorable to the experimental treatments.¹⁸ Specifically regarding oncology studies, Friedberg et al. reported that drug company-sponsored studies were much less likely to report unfavorable qualitative outcomes than studies funded by nonprofit sources (5% versus 38%).¹¹⁸

Importantly, such data do not necessarily demonstrate bias or compromised studies. The fact that industry-sponsored studies generate pro-industry results may reflect a “pipeline” issue; that is, because conducting large research trials is very expensive, industry tends to only undertake drug trial studies when it is reasonably sure the results will be positive. Experimental interventions that are more uncertain or may not generate huge profits may be terminated before large randomized studies because of industry's caution about expending resources. This decision may ultimately deprive society of important new interventions, but it does not constitute a financial conflict of interest that might compromise the integrity of the research design or the data collection and interpretation. However, none of the reported studies links industry funding to biased scientific judgments, which, in turn, produce too many study outcomes favorable to the funding industry. Just showing that industry-sponsored studies generate pro-industry conclusions is insufficient to demonstrate that financial conflicts of interest actually bias the conduct of studies.

Nevertheless, there are data suggesting that industry financial support does distort the judgment of researchers. Stelfox and colleagues analyzed all published studies in 1995–1996 regarding the safety of calcium channel blockers

TABLE 9.6. Support of calcium channel antagonists and financial interest.¹¹⁹

	Support Ca blockers	Neutral	Critical of Ca blockers	P value
No. of respondents	24 (69%)	15 (83%)	30 (91%)	0.02
Financial interest in Ca blocker manufacturer	23 (96%)	9 (60%)	11 (37%)	<0.001
Financial interest in any manufacturer	24 (100%)	10 (67%)	13 (43%)	<0.001
Honorarium from any pharmaceutical manufacturer	75%	40%	17%	<0.001
Research funding from any pharmaceutical manufacturer	87%	40%	20%	<0.001
Employment or consultation for any pharmaceutical manufacturer	25%	33%	17%	0.45

in postmyocardial infarction patients.¹¹⁹ They found 70 publications: 5 original research papers, 32 reviews, and 33 letters to the editor. As Table 9.6 shows, researchers with a financial interest in a manufacturer of calcium channel antagonist, or even those with a financial interest in *any* manufacturer, were significantly more likely to support the safety of calcium channel blockers than researchers without a financial interest. Indeed, this trend held true for researchers with any type of financial interest in any pharmaceutical manufacturer, including receiving honoraria and research funding. The only time there was no association between having a financial interest in any pharmaceutical manufacturer and supporting the safety of calcium channel blockers, was when the researchers' financial interest was to have been employed by or served as a consultant to manufacturers.

Finally, there are data showing that financial interests do alter dissemination of research results. A study of 42 placebo-controlled trials of selective serotonin reuptake inhibitors (SSRI) submitted to Swedish regulators found that, of the 21 studies showing positive effects of the drug over placebo, 19 were published, with the results frequently appearing in more than 1 article. Conversely, of the 21 studies that showed no difference between the experimental SSRI drug and placebo, only 6 were published.¹²⁰ Whether this is a result of the publication bias against negative studies at major journals or the result of industry withholding negative data was not determined. However, a 1993 survey of 2,167 life science faculty from the 50 universities receiving the most NIH funding found that one-fifth of the faculty had delayed publication for more than 6 months during the past 3 years to allow for patent application or negotiation, to resolve intellectual property rights disputes, to protect their scientific lead over competitors, or to slow the distribution of undesired results. Delays in publication were associated with participation in a research relationship with industry [odds ratio (OR) = 1.34] and with commercialization of one's own research results (OR = 3.15).^{104,121} More importantly, there have been a number of high-profile cases in which industry has actively and explicitly tried to prevent the dissemination of negative findings about drugs. In the Olivieri case in Toronto, Apotex, the company that funded Dr. Olivieri's research on their drug, tried to prevent her from publishing findings suggesting that the drug was not only *not beneficial* for patients with iron overload, but may actually be *harmful* to them.¹²² Similarly, the manufacturers of Synthroid brand thyroid replacement, Boots Co., funded a study to compare Synthroid with generic thyroid replacement drugs.¹²³ The results showed no difference in patient outcomes. Boots then tried to prevent the

UCSF researchers who conducted the study from publishing the data.

These data suggest that financial interests probably do not have an adverse effect on the *conduct* of clinical research and may actually be beneficial in terms of study design. Conversely, in terms of data interpretation and dissemination, the data suggest that "money does talk."

How can we protect against this distorting influence of conflicts of interest? In general, there are three types of safeguards for conflicts of interest. First, and most commonly, is for researchers to disclose their financial interest. In addition, the financial interest is managed by instituting data safety and monitoring boards (DSMBs) or independent consent monitors. Finally, when financial interests are too extensive, prohibitions can be implemented.

Disclosure of researchers' financial interests in journal articles is becoming routine and more comprehensive. However, the data about intrainstitutional disclosure and the communication of the disclosed information to the various research oversight groups and committees indicates a flawed system. A recent General Accounting Office (GAO) study of five major research institutions found that the rules regarding disclosure and prohibitions of financial interests varied widely.¹²⁴ Furthermore, the disclosed information was not well recorded by the institutions and was not readily available to the institutions' IRBs when they considered protocols. Of the 111 cases in which researchers had substantial financial interests, the GAO found that in only 3 did the researchers divest and in no cases were they told to do so by their universities.

There are other data indicating that disclosure may not be an adequate safeguard even if institutions do have conflict of interest (COI) disclosure policies in place, researchers frequently lack knowledge about such policies. For instance, at UCSF and Stanford, 58% of researchers surveyed could not accurately describe the COI policy of their institution.¹²⁵ In addition, COI policies lack specificity and there are inconsistent standards for disclosure across institutions.¹²⁶⁻¹²⁸

Importantly, while there have been vociferous calls for disclosure of financial interests to research subjects, there have been almost no data on whether patients can understand these data and how they might react.¹²⁹ Indeed, some highly regarded commentators have worried that disclosure to patients would only reveal the problem without providing them any mechanism to address it, thereby increasing anxiety but not solving the underlying conflict of interest.¹³⁰

To address problems about conflict of interest, the Board of Directors of American Society of Clinical Oncology (ASCO) voted to revise its conflict of interest policy in 2002.

The new policy requires disclosure of all financial payments or interests from entities "having an investment, licensing, or other commercial interest in the subject matter under consideration," including (1) executive or leadership positions, (2) ownership of stock or equity in companies, (3) consultancy or service on an advisory board, (4) honoraria for speeches, (5) royalty payments on a patent, (6) nonresearch-related travel or gifts, and (7) expert testimony.¹³¹ The policy does not view research-related funding, funding to attend investigators' meetings, or funding as part of a grant to present research results at a widely attended open meeting (such as the ASCO annual meeting) as a conflict of interest; therefore, ASCO does not require disclosure of this type of information.

In addition to disclosure, ASCO has also implemented restrictions on researchers' "finder's fees," payments for recruiting goals or recruiting speed, and payments for certain data results. Similarly, ASCO believes that because principal investigators or individuals on the executive committees of large multicenter studies as well as those on data safety and monitoring boards have such extensive decision-making authority over the conduct, analysis, and dissemination of study results, these individuals should have none of the listed financial interests in a commercial sponsor.

There are two important exceptions to these restrictions. Because of the extensive oversight provided through study sections, DSMBs, and other independent review mechanisms, these restrictions do not apply to NIH-supported research studies that might "involve products of specific commercial interests." Furthermore, recognizing the importance of translational research and the reality that the developer of a new technology is probably the best person to conduct the initial research studies, the ASCO policy recognizes that when there is limited worldwide expertise and when "an inventor of a unique technology or treatment being evaluated in a trial," these restrictions might be relaxed. In these cases, there must be a data safety and monitoring board in place to ensure the safety of the research participants.

Ethics is a key area of oncology research, and current ongoing empirical research on many ethical issues—such as how to improve informed consent, the role hope plays in patients' decisions to participate in Phase I studies, and patients' perceptions of COI—may well change the answers to these ethical questions.

Informatics Infrastructure for Evidence-Based Cancer Medicine

Jeffrey P. Bond and Scott D. Luria

*A*n old man, and pale: anemia. Also thin: first thought, cancer. Second thought, tuberculosis, alcoholism, some other chronic process . . . the computer provided him with a differential, complete with probabilities of diagnosis. From *The Andromeda Strain* (1969),¹ by Michael Crichton

How is cancer information exchanged among laypersons, clinical professionals, and medical researchers? High hopes for the role of computers in medical information exchange have been reflected in science fiction for decades. After at least two information technology paradigm shifts (personal computers and the Internet) and countless successful implementations of, for example, shared electronic records, knowledge bases, decision support systems, speech-to-text tools, natural language processing tools, or remote monitoring devices in a variety of medical and nonmedical settings, we are in the process of realizing these high hopes. An important component of cancer information exchange infrastructure is support for the *use of knowledge derived from medical research in combination with patient data to guide cancer-related decisions, that is, support for evidence-based cancer medicine*, the central focus of this chapter.

We focus on three classes of scenarios that require informatics support: a healthcare professional making a cancer-related decision about a patient, someone (referred to here as a layperson) making a cancer-related decision without medical training and without consulting a healthcare professional, and a researcher making a decision regarding a cancer-related experiment. Each such decision involves a collection of potential actions, information that describes the context of the action, and knowledge derived from scientific experiments that constitutes evidence bearing the merit of the potential actions given the context (Figure 10.1).

The purpose of this chapter is to describe how clinicians, patients, and researchers can find information related to cancer prevention, diagnosis, treatment, and research on the World Wide Web. (Although WWW resources will not necessarily behave as they did at the time this chapter was written, we think it is important to include numerous specific examples.) Here *infrastructure*, then, refers to standards, software,

and digital information rather than hardware. We emphasize digital media but do not intend to imply that other media (such as printed textbooks, classroom lectures, handwritten notes, pamphlets, posters in subways, radio/television spots, or phone support lines) cannot be preferable to computer-related infrastructure for accomplishing particular goals. Currently the support for integration of knowledge bases and context data available to most clinicians is poor; in nearly all examples below, this integration is manual.

We do not attempt comprehensive coverage of medical informatics (for example, electronic medical records,² HIPAA,³ or telemedicine,⁴), which includes cancer informatics. Readers interested in resources describing broader aspects of bioinformatics or medical informatics might consult one of the more comprehensive resources listed in Table 10.1. Readers interested in a variety of online bioinformatics databases and software might consider one of the URLs given in Table 10.2.

We focus on two structures that facilitate information exchange: indexes and graphs, analogous to the index and table of contents of a book or the index accessed using a search box and the directory of a Web resource. Given a set of objects, *indexes* associate words or phrases with subsets, which can be combined using set algebra. For example, one can search for clinical trials at <http://clinicaltrials.gov> with a query such as `disease="breast cancer"`, `experimental treatment="surgery"`, and `state="Vermont"`. *Graphs* consist of *nodes* and relationships between nodes. In the cases described here, the nodes are Web pages and the relationships are represented by links or buttons. An example of such a graph is a collection of Web pages including directory pages that support browsing. Graphs need not be hierarchical like a physical filing system because there may be multiple paths between Web pages.

One of the primary difficulties in developing informatics support for cancer-related decisions results from the level of detail we expect. Informatics support for book purchases necessarily includes rudimentary support for cancer informatics in that it serves to identify books on cancer. Searches based on author, title, or keywords from a simple vocabulary (for

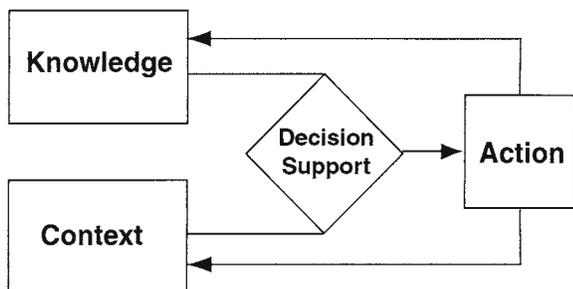

FIGURE 10.1. Schematic describing how potential actions are based on and inform knowledge derived from scientific experiments and the information that describes the context of the action.

example, *breast cancer*) often serve to identify sets of book records that can either be browsed manually or productively ranked (for example, the number of times a book has been purchased is evidence related to the quality of the book). We expect cancer informatics support to do better than simply finding books that will answer questions, we expect to identify chapters or paragraphs that answer our questions. Ideally, informatics resources should answer questions directly.

Such fine granularity requires, relative to the task of simply identifying of books on cancer, a complex vocabulary and a query syntax that supports context data. In this chapter, we focus on four components of such a solution: vocabulary resources that support intelligent indexing, manually created graphs for browsing, manual indexing of documents based on their generality and usefulness, and integration of the search with patient data.

Laypersons' Decisions

A variety of cancer information portals and sources of information exist on the World Wide Web for laypersons (Table 10.3). We focus on two comprehensive resources: Cancer.gov,

which is maintained by the U.S. National Cancer Institute (NCI), and Cancer.org, which is maintained by the American Cancer Society (ACS).

Cancer.gov Features

Cancer.gov is a source of general cancer information as well as information on NCI research programs, NCI research funding, cancer statistics, and clinical trials. The cancer information section, <http://cancer.gov/cancerinfo>, includes a variety of information that is intended for laypersons seeking information about cancer etiology, diagnosis, and treatment. Below we highlight certain features of Cancer.gov.

“What You Need to Know About Cancer” (WYNTK) documents. <http://cancer.gov/cancerinfo/wyntk> provides a starting point for obtaining information about cancer in general and more than 20 specific cancers. Each such document includes information about symptoms, diagnosis, and treatment. An overview document provides a general and readable introduction to cancer with pointers to other NCI resources.

Dictionary. <http://cancer.gov/dictionary/> provides *non-technical* definitions of cancer-related terms. There are currently more than 4,000 terms, with approximately 40 terms added each month. For example:

metastasis (meh-TAS-ta-sis) The spread of cancer from one part of the body to another. A tumor formed by cells that have spread is called a *metastatic tumor* or a *metastasis*. The metastatic tumor contains cells that are like those in the original (primary) tumor. The plural form of metastasis is metastases (meh-TAS-ta-seez).

Physician Data Query (PDQ). <http://cancer.gov/cancerinfo/pdq> is “NCI’s comprehensive cancer database, containing peer-reviewed summaries on cancer treatment, screening, prevention, genetics, and supportive care” and also provides information on clinical trials and directories. Although most of this information is directed at healthcare professionals, many of the topics have links to pages written specifically for patients and linked to dictionary entries. Compared to the WYNTK documents, “PDQ patient” documents are more specific; for example, there is a single WYNTK document on

TABLE 10.1. General biomedical informatics resources.

<i>Resource</i>	<i>Scope</i>
Bioinformatics: A Practical Guide to the Analysis of Genes and Proteins ⁵³	Sequences, structures, genomes, alignments, phylogenetic trees
Bioinformatics Sequence and Genome Analysis ⁵⁴	Sequences, structures, genomes, alignments, phylogenetic trees
NCBI Handbook ²³	NCBI databases (sequence, structure, journal publication, gene expression, textbook, and taxonomy databases) as well as BLAST and genome browsing tools
Nucleic Acids Research Database Issues ⁵⁵	Peer-reviewed set of articles about biological databases
Nucleic Acids Research Software Issue ⁵⁶	Peer-reviewed set of articles about computational biology software
Cancer Informatics ⁵⁷	Cancer informatics
Medical Informatics ⁶	Medical informatics
Public Health Informatics and Information Systems ⁵⁸	Public Health Informatics
Informatics in Primary Care ⁵⁹	Includes chapters on electronic medical, records, clinical decision support, and knowledge bases

leukemia while there are seven PDQ documents for patients on leukemia, each focused on a different leukemia.

Search box. A search box allows users to identify pages relevant to a set of keywords. The search may return both “Best Bets,” NCI pages that Cancer.gov staff have judged most likely to provide the desired information based on the query, as well as a list of pages matching the set of keywords. An advanced search page allows users to restrict the scope of the search based on NCI organization (e.g., to the Division of Cancer Control and Population Sciences), to a database of clinical trials, to subsets of the PubMed publication database, to specific cancer topics (for example, tobacco), or to a database of genetics services.

Browsing support. A directory allows the same documents to be browsed from different points of view, for example, by type of cancer, by treatment, or by etiology.

Examples. Certainly laypersons are encouraged to consult health professionals on cancer-related questions, but laypersons should have many more questions than their physicians have time to answer. We describe how to obtain information related to typical questions by browsing or using the search box.

Example 1. Should I limit use of my cell phone to reduce my risk of cancer?

By browsing:

- Go to <http://cancer.gov/cancerinfo>
- Follow the link to “Prevention, Genetics, Causes”
- Follow the link to “Cancer Causes and Risk Factors”
- Follow the link to “Cellular Telephone Use and Cancer”

By searching:

- Enter “cell phone” in the search box.
- Follow the link to, for example, “Cellular Telephone Use and Cancer”

Example 2. One of my moles looks a little different than it did 5 years ago. Should I make an appointment to see my doctor?

- Enter “mole” in the search box
- Follow the link to “What You Need To Know About Moles and Dysplastic Nevi”
- Follow the link to “Pictures of Melanoma”

Cancer.org Features

Cancer.org is a source of general cancer information for a variety of interest groups: patients, families or friends of patients, survivors, health care information seekers, health-care professionals, and supporters. Below we highlight certain features of Cancer.org.

Context data and private data management. Users can create accounts and set preferences that include interest groups, type of cancer, location, and language. Users can also manage a “Planner,” which includes a calendar, to-do list, e-mail groups, and bookmarks.

Cancer-related information based on context data. The cancer.org home page points to directories for each of the interest groups listed above. For example, the “health information seeker” category points to information about risk, prevention, detection, myths, and statistics. The “patients, family, and friends” directory points to treatment decision support as well as information useful in preparation for or during treatment. The “survivor” directory includes information about healthy lifestyles as well as tapping into the cancer survivor community. If a user selects an interest group, then by default they are directed to the appropriate directory.

“In My Community” boxes present regional information based on the specified zip code. “Getting Specific” boxes

TABLE 10.3. WWW Cancer information resources for laypersons.

<i>Source</i>	<i>URL</i>
Open Directory Project	dmoz.org/Health/Conditions_and_Diseases/Cancer
Yahoo	dir.yahoo.com/Health/Diseases_and_Conditions/Cancers

American Cancer Society	www.cancer.org
American Society of Clinical Oncology	www.plwc.org
University of Pennsylvania	www.oncolink.upenn.edu

present information specific to the specified type of cancer. For example, if a user specifies “health information seeker” as their interest group and “colon and rectal cancer” as the type of cancer of interest, selecting the “Who is at Risk?” link will return a page with general information about cancer risk (for example, “Tobacco and Cancer”) as well as a box that includes information on risk factors for colon and rectal cancer.

Interactive decision support tools. Cancer.org links to NexCura decision support tools, which are designed to be used by laypersons to help them work more effectively with clinicians to make better decisions, and to National Comprehensive Cancer Network⁵ treatment guidelines.

News. An “ACS News Center” box on the home page provides indexed news updates and inspirational stories.

Example. My father had cancer in his sixties and I am 35. What family history information should I collect before an appointment with my doctor?

- Go to cancer.org
- Follow the link to “Cancer Information Seekers”
- Follow the link to “Who is at Risk?”
- If “colon and rectal cancer has been specified in the users preferences, then a link to “What are the Risk Factors for Colon and Rectal Cancer?” will appear. Otherwise, the user can manually choose this type of cancer.

Locating Support Resources, Clinical Trials, or Oncologists

After diagnosis, most cancer patients require more emotional support than a doctor can realistically provide. Although most such emotional support is beyond the capabilities of computer infrastructure, digital infrastructure can help patients find and communicate with other cancer patients. At the NCI site, <http://cancer.gov/cancerinfo/support/> points to information about support, support organizations, finding an oncologist, finances, insurance, and hospice care. For example, the “Taking Time” document includes “Cancer will change your life,” “Your feelings: learning you have cancer,” and “Living each day” sections.

At the ACS site, the “survivors” interest group also includes a variety of support resources for survivors and patients. ClinicalTrials.gov provides a database of federally and privately supported clinical research as well as background information. The American Society of Clinical Oncology Web resources include “People Living With Cancer,” <http://www.peoplelivingwithcancer.org/>, which has resources for finding clinical trials and oncologists.

Clinician Decisions

The importance of evidence-based decision support at the point of service is firmly established,⁶ and many commercial medical informatics support products are available (Table 10.4). Many of these currently offer free limited term trials and support handheld devices. Below we describe some of the information resources that are components of a typical clinical knowledge base.

Technical summaries. In addition to summary text, technical summaries include links to other knowledge resources

TABLE 10.4. Commercial clinical information products.

Product	URL
UpToDate	uptodate.com
First Consult	firstconsult.com
MD Consult	mdconsult.com
InfoPOEMs	info poems.com
WebMD	webmd.com

(including other technical summaries, guidelines, primary literature, and drug information). Such summaries may include information about authors, document status, and the last modification date. Free technical summaries can be found in the PDQ section of Cancer.gov (<http://cancer.gov/pdq>). Technical summaries related to cancer genetics can be found in the Online Mendelian Inheritance in Man (<http://www.ncbi.nlm.nih.gov/OMIM>). Appending “AND review[Publication Type]” to a PubMed query restricts the search to review articles.

Guidelines. Computer interpretable guidelines^{7–11} can provide formal and compact support for evidence-based decision making. Freely available cancer diagnosis and treatment guidelines are available at NGC¹² and NCCN.⁵

Directory. Users unfamiliar with the model of data in a clinical knowledge base benefit from manually curated sets of links to information resources. For example, the Physician Data Query (PDQ)^{13,14} home page points to cancer information summary classes (adult treatment, pediatric treatment, supportive care, prevention, genetics, etc.) and clinical trials resources (search page, user’s guide, or support for clinical trials submission) as well as help documentation that includes an annotated directory (which has extensive text along with headings).

Index. Most cancer information knowledge bases include a search box. After users enter a text string in a search box, a formal query is constructed, the formal query is compared against the documents in the database, and the matches are ordered. Formal queries may be constructed by interpreting “and” or “or” as Boolean operators rather than keywords, by default addition of Boolean operators, by stemming¹⁵ words (so that, for example, “neoplasms” will match “neoplasm”), identifying approximate matches that catch spelling errors (for example, “endometril cancer” will match “endometrial cancer”), considering the semantic role of the words (for example, interpreting “Li” as an author name or as an element), expanding queries based on synonyms (so that, for example, “tumor” will match “neoplasm”), or expanding queries based on generalization/specialization relationships among vocabulary words (so that, for example, “surgery” in a query will match “mastectomy” in a document). Some resources allow subsequent queries to be applied only to the current results.

Drug information. Knowledge bases should include information on dosage, drug-drug interactions, and side effects. The U.S. Food and Drug Administration maintains a database of approved cancer drugs¹⁶ that includes generic drug name, trade name, sponsor, pointers to study details, and dosage. Some PDQ entries are indexed by drugs; for example, entering “tamoxifen” in the search box returns a variety of relevant documents.

Clinical trials. It is important to access clinical trials databases to identify trials for which a patient is eligible and evidence bearing on treatment (evidence that may be preliminary from an ongoing study or final). <http://clinicaltrials.gov> supports identification of ongoing clinical trials based on facility, location, disease, and age group. Appending “AND clinical trials[Publication Type]” to a PubMed query restricts the scope of the search to reports on clinical trials.

Documents for laypersons. Although several knowledge bases for laypersons are described previously, a clinician’s knowledge base should provide direct links from pages aimed at specialists to documents directed at laypersons.

Researchers’ Decisions

Cancer researchers may act based on a collection of information that includes, for example, clinical trials, population data, scientific publications, nucleic acid or protein sequences, genes, genomes, human genetic variation, protein structures, protein domains, gene expression data, or taxonomy. Cancer information also includes relationships between these objects. For example, a gene may be related to a DNA sequence, a protein sequence, a somatic mutation database, publications describing the gene, and summary information about cancers related to genetic variation. Supporting navigation of such a heterogeneous collection of objects based on relationships between them is a difficult problem.

NCBI

The U.S. National Center for Biotechnology Information,¹⁷ or NCBI, was created by the U.S. Congress in 1988 as a division of the National Library of Medicine of the National Institutes of Health. The presence of the architects of the NCBI and its resources is illustrated by the fact that NCBI resources, including GenBank,¹⁸ PubMed,¹⁹ and BLAST,^{18,20–22} are perhaps the most widely known informatics tools for biologists and are used effectively by a wide variety of scientists and educators. Information relating the biologic objects listed above can be accessed through an intuitive search engine, Entrez, that allows users to identify subsets of entries matching search criteria. NCBI developed a programmer’s toolkit and tools for remote data access before the emergence of the World Wide Web. NCBI declared its data model and described data using a formal exchange syntax (ASN.1) before the development of XML.

We do not have the space to cover NCBI tools comprehensively, so instead focus on a few key tools and an example that integrates use of several tools. Comprehensive and regularly updated documentation about NCBI resources is available online in the NCBI Handbook.²³

Keyword-based searches. Entrez provides a consistent interface for querying a wide variety of NCBI databases, including publications, sequences, structures, genomes, genes, inherited disorders, and protein domains. The search box supports an unusually intelligent parser based on a controlled vocabulary (Medical Subject Heading, or MeSH²⁴). For example, a naive query string such as “gene expression tumor treatment fibroblast 2004” is interpreted as (((“gene expression”[MeSH Terms] OR gene expression[Text Word]) AND (tumor[Text Word] OR tumour[Text Word]) OR “neo-

plasms”[MeSH Terms])) AND ((“therapy”[MeSH Subheading] OR “therapeutics”[MeSH Terms] OR treatment[Text Word]) AND (“fibroblasts”[MeSH Terms] OR fibroblast[Text Word]) AND 2004.²⁵). The resulting query is sufficiently precise to retrieve a small number of publications, including, for example, a paper²⁶ on the use of microarrays for predicting the clinical course of several common carcinomas. Selecting the “Details” button shows explicitly how the query is interpreted. A “Preview/Index” button provides support for construction of precise Boolean queries based on the NCBI data model and controlled vocabularies. Additional “Links” provide additional features, including the addition of hyper-text links from words or phrases in PubMed abstracts to related textbook entries.

Sequence-based searches. The BLAST family of tools^{20–22,27} allows certain types of objects, nucleotide sequences (including genomes), protein sequences, and position-specific models of protein or protein domains, to be searched based on sequence features in addition to annotation. The BLAST tools have proven useful because of their ease of use, speed, and reliable statistics. These tools return not only matches to the query, but expectation values that provide an estimate of the number of matches of similar or greater similarity that would have been obtained under a null hypothesis (no related sequences are in the database). Thus, users need not rely on expert knowledge to judge the relevance of a match and can rely on common knowledge from probability and statistics.

Example. What is Li Fraumeni syndrome?

- Select the **OMIM** link from the menu bar <http://www.ncbi.nlm.nih.gov>. OMIM refers to the Online Mendelian Inheritance in Man,²⁸ a manually curated catalog of genes and genetic disorders. Enter “Li Fraumeni in the search box and execute the search.
- Follow the link to “Li Fraumeni syndrome LFS”. This page includes a wide variety of text description of Li Fraumeni syndrome; for example, it indicates that LFS is a familial cancer syndrome of diverse tumors caused by certain mutations in the TP53 gene.
- Follow the link to the “TP53 gene,” which indicates, among other useful information, that the p53 protein binds to and activates the expression of genes that inhibit growth or invasion.
- Following the “Allelic variants” link indicates that an Arg 248 to Trp mutation causes Li Fraumeni syndrome.
- Follow the link to “Cho et al”²⁹ to find an abstract of the paper describing the solution of the p53 structure. Selecting “Links/Books” adds hyperlinks from terms in the abstract to textbook entries describing the linked terms.
- Select “Links/Structure” and follow the link to 1TSR. If you have a structure viewer installed then selecting “View 3D structure” allows you to see that interactions of Arg 248 with the DNA binding site would be disrupted by an Arg248 to Trp mutation.

In this example, NCBI resources took us from the name of a syndrome to an atomic level hypothesis about the cause of the syndrome with a very small number of operations. The infrastructure developed by NCBI provides outstanding capacity for browsing sets of publications, sequences, structures, genes, and syndromes by traversing relationships between them.

European Bioinformatics Institute

Similar to the NCBI, the European Bioinformatics Institute,^{30,31} part of the European Molecular Biology Laboratory, provides support for a wide variety of databases that include sequence, structure, protein family, mutations, and literature databases. Notable features include a uniform interface to germline and somatic locus-specific mutation databases, including APC, CDKN2a, RB1, and TP53 database, support for private management of queries and results, and the Universal Protein Knowledge Base.^{15,32,33}

caBIG

The National Cancer Institute of the U.S. National Institutes of Health has undertaken construction of comprehensive cancer informatics infrastructure, the cancer Biomedical Informatics Grid (caBIG). caBIG includes data, vocabulary, standards, software infrastructure, and applications. Although the initial focus of this effort is on cancer, much of the infrastructure is generally useful in the biomedical sciences.

caBIG data currently include the Gene Expression Data Portal (GEDP³⁴), Cancer Gene Anatomy Project (CGAP³⁵⁻³⁸), the Cancer Molecular Anatomy Project (CMAP³⁹), and the cancer Model Organisms Databases (caMOD⁴⁰). These resources integrate data describing the molecular anatomic changes that accompany transformation of a cell from normal to cancerous. Users can approach these data from the perspective of microarray experiments, genes, tissues, pathways, chromosomes, cancer targets, targeted agents, trials, or cancer models.

The NCI Enterprise Vocabulary Service (EVS⁴¹) provides cancer-specific vocabulary in the context of mature vocabulary resources such as National Library of Medicine's Unified Medical Language System (UMLS⁴²⁻⁴⁶). EVS includes the NCI Thesaurus⁴⁷ and the NCI Metathesaurus.⁴⁸ The NCI Thesaurus provides a graph that can be browsed to find NCI Thesaurus concepts. Concept pages contain technical definitions, synonyms, more general concepts that include the current concept, and relationships to other concepts. For example, browsing from the top level to "Gene," to "DNA Repair Gene," and finally to "OGG1" yields the OGG1 concept entry. Browsing the entry reveals that OGG1 is a gene that encodes a protein that incises DNA at 8-oxoguanine residues, that it is also known as "8-Oxoguanine DNA Glycosylase," that it is included within the concept "DNA Repair Gene," and that it exhibits the "Gene_Found_In_Organism" relationship with the concept "Human." The power of such a vocabulary is not in such manual browsing, however, but in computer inference. A cancer researcher might be interested in finding human genes involved in DNA repair. The NCI Thesaurus would allow a computer to infer, for example, that something pertaining to OGG1, such as a gene expression level, also pertains to "DNA Repair Enzymes," or to include "OGG1" in a response to the question "Which DNA repair genes are found in humans?"

SEER-Medicare

Presumably standards for sharing electronic medical records will eventually allow virtual clinical trials, for example,

researchers will identify patients satisfying specified characteristics based on shared medical records and compare the outcomes by treatment regimen. The Surveillance, Epidemiology and End Results (SEER) program of the NCI collects and distributes cancer incidence and survival data from cancer registries (representing about 14% of the U.S. population at the time of writing). Medicare records provide information about treatment claims for health care services. By linking these two datasets into the SEER-Medicare Linked Database,^{49,50} investigators can evaluate diagnosis and treatment methods without having to recruit patients. More than 100 publications have made use of the SEER-Medicare database. For example, Potosky et al.⁵¹ used the SEER-Medicare-linked database to assess reasons for a dramatic rise in prostate cancer incidence.

Summary

There is currently a wide variety of detailed cancer information available on the World Wide Web. We look forward to the integration of these resources into point-of-service support that integrates with patient data and will further reduce cancer-related pain and suffering (see Figure 10.1).

Acts are chosen based on data describing the context of the decision and evidence/knowledge bearing on the relative merit of acts based on the given context. Figure 10.1 is very general in that many acts that are not cancer related are based on evidence and context data (it is similar to a model of an agent,⁵² a basic entity in the study of artificial intelligence). For example, e-business transactions include product information, evidence about purchasing patterns, context data that include a consumer's transaction history as well as highly sensitive (e.g., credit card) information, alerts, and sophisticated decision support tools that suggest transactions. Below, we provide examples of three classes of decisions that require informatics support: clinicians' decisions, laypersons' decisions, and researchers' decisions.

Clinicians' Decisions. Clinicians act based on patient information and medical knowledge. Rectangles in Box 1 represent classes of information, not individual information sources. For example, "Context Data" for a clinician decision include patient medical information in electronic medical records, handwritten notes, a patient's observations communicated verbally to the clinician, and unrecorded observations based on a physical exam. Scientific evidence comes from training, experience and medical literature. "Scientific evidence" is used here to include a broad range of evidence-based information that includes, for example, the seven warning signs of cancer and DNA mutation databases.

- How will estrogen therapy affect a particular patient's cancer risk?
- Does a patient's family history of cancer warrant genetic testing?
- A patient being seen for an aneurysm is otherwise healthy but has a spot on a chest X-ray. Should I refer for a biopsy, refer to take out a lobe of the lung, or follow noninvasively?

Laypersons' Decisions. Like clinicians, laypersons act based on their medical history and medical knowledge, but in practice these decisions are very different. Clinicians' and

laypersons' acts may be of different types; for example, a clinician's act may be an order for a laboratory test, an act that is unavailable to laypersons. In practice, important acts of laypersons include finding an oncologist, finding a clinical trial, making an appointment with a clinician, identifying a question or observation to present to a clinician, gathering information before a visit to a clinician, a change in lifestyle, and worrying.

Even when clinicians and laypersons are evaluating the same actions, however, clinicians' and laypersons' decisions are, in practice, made with very different informatics support. Clinicians make decisions based on formal medical records, years of professional training and experience, and peer-reviewed medical literature. Laypersons make decisions without such detailed and reliable support, because they may act based on an incomplete understanding of their medical history, limited medical knowledge, hearsay, and information they find on the World Wide Web that is not peer reviewed.

- Should I reduce my cell phone use to reduce my cancer risk?
- I have an unusual mole; do I have skin cancer?
- I have been diagnosed with cancer. How do I find an oncologist, clinical trial, or support group?

Researchers' Decisions. Researchers' acts include the design of experiments, including identification of hypotheses, and inference based on experimental results. For researchers the context data include their experimental data. Scientific evidence includes primary databases (for example, DNA sequence and clinical trials databases), primary literature, and technical synopses.

- Why did prostate cancer incidence increase dramatically in the late 1980s?
- What is the molecular cause of Li Fraumeni syndrome?
- Given gene expression data from a tumor, what is the course of a particular carcinoma?

Economics of Cancer Care

James Khatcheressian and Thomas J. Smith

The Standard Principles of Economics and Oncology

Several major issues emerge when combining the “dismal science” of economics¹ with the science of oncology. With rising healthcare costs yet limited resources, it becomes important to know how to factor economic considerations into the medical decision-making process. This task is made more difficult by the paucity of comparative studies of costs and outcomes (under the general term of cost-effectiveness) and quality of life; as a result, clinicians are left on their own to decide “who does what to whom, at what cost, and with whose money.”

The Cost of Care Is Increasing Rapidly at an Unsustainable Rate

Cancer care is second only to cardiovascular disease in terms of yearly cost to the healthcare system; expenditures for diagnosis, supportive care, and treatment are rising and pose an increasingly severe economic burden on society. Estimates from 2001 reveal that the United States spends \$56 billion yearly on cancer treatment; additionally, \$16 billion yearly is attributed to indirect morbidity costs and \$85 billion for indirect mortality costs. To put this into perspective, medical care costs now are 15% and education now less than 5% of U.S. Gross National Product (GNP) (*New York Times*, January 9, 2004), whereas 30 years ago both medical care and education had 6% of the GNP²; additionally, these costs have risen over the past several years at an annual rate of 10% or higher. Medicare cancer drug costs *tripled* from \$1.2 billion in 1998 to \$3.8 billion in 2002 (Association of Community Cancer Centers Website, accessed August 20, 2003). Precise figures for private insurance, Medicaid, and direct patient costs are not available, but practice patterns are similar. Furthermore, as the baby boomer generation begins to reach retirement age, a time when they are most likely to develop cancer, the economic burden of cancer care and treatment will continue to rise.

How to Factor Economics into Medical Decision Making

With the increasing demand for expanded services, new technologies, and a growing elderly population, conflicts must arise between payers, clinicians, and patients regarding what

services to provide, to whom, and on what basis. Our health economist colleague, Dr. Bruce Hillner, calls this the “What to do to whom, with whose money, at what cost?” question. There are several ways to factor economic costs and treatment effectiveness into decision making. The most informative types of analyses are cost-minimization, cost-effectiveness, and cost-utility; the methods are listed in Table 11.1. We briefly discuss each with regard to its advantages, liabilities, and possible application to clinical practice.

A significant problem is the reluctance of some clinicians and patients to accept limitation of resources or rationing by cost-effectiveness or any other method.³ Although a full discussion of the thorny ethical, legal, and economic issues is beyond the scope of this chapter, some overriding factors based on our experience are listed in Table 11.2. Ethicists,^{4,5} and now clinicians,⁶ have argued that the least ethical way to allocate resources is to continue in the usual unexamined mode and that ignoring the economic issues is not morally defensible. Until there is general consensus in society on “what to do to whom, with whose money, at what cost,” these issues will continue under debate. Concurrently, all payers have limited budgets, so they are doing some form of implicit or explicit rationing now.

Cost or Effectiveness Alone

Clinical Outcomes Alone

This type of study is concerned solely with clinical efficacy such as improved response rates, survival, and symptom management; it ignores treatment costs entirely. This is the easiest method by which to make decisions for treatments that are clearly superior to any others available. A good example of a medication that fits into this category is imatinib mesylate (gleevec) in the treatment of chronic myelogenous leukemia (CML). It clearly has better response rates, time to disease progression, and toxicity profile than the traditional treatment of interferon and cytarabine and has become the standard of care as first-line treatment for CML.⁷ The decision to use imatinib mesylate is quite easy for physicians given the lack of any other similarly effective agents. But at \$24,000/year (www.drugstore.com), an obvious economic consequence of this method is that some patients will not be able obtain a medication due to prohibitive costs, for instance, a 20% co-payment or lack of insurance.

TABLE 11.1. Types of studies and application to oncology.

Type of study	Advantages and disadvantages	Application to oncology
Clinical outcomes alone	Easy to perform. Ignores costs.	Traditional way to make decisions, e.g., imitinab mesylate (gleevec) works for chronic myelogenous leukemia (CML). Use it. Pay what the manufacturer demands.
Cost only	Ignores clinical outcomes.	Often used by insurers as first reaction to “sticker shock” of new drugs, e.g., zevalin at \$22,000–\$28,000/dose.
Costs and clinical outcomes together Cost minimization: assumes two strategies are equal; lowest cost strategy is preferred.	Easy to do if there are direct comparisons.	For instance, if darbopoietin is equivalent to epoietin for chemotherapy-associated anemia, choose the least expensive drug.
Cost-effectiveness: Compares two strategies; assigns \$ per additional year of life (LY) saved by strategy.	Requires a trial that directly compares strategies, and economic analysis alongside that trial. “Only accept treatments that gain a year of life for under \$100,000/life year.”	There are very few direct comparisons of drugs and strategies. The trials typically must be large to detect small differences, are unexciting compared to new drug trials, and have no willing sponsor.
Cost-utility: assigns \$ per additional year of life (LY) saved by strategy, then estimates the quality of that benefit in \$/quality adjusted (QALY).	Compares two strategies, with their quality of life comparisons converted to utility, or the value placed on time in a health state, e.g., time spent on chemo = 0.7 compared to a healthy individual whose utility = 1.0.	There are few interventions that make a large difference in utility. Also, there is rarely one simple yardstick of utility that covers all health states.
Cost-benefit: Compares two strategies but converts the clinical benefits to money, e.g., a year of life is worth \$100,000.	Possible but rarely done due to difficulty in assigning \$ value to human life.	Would almost certainly be unfavorable to most palliative interventions, as patients rarely work or generate income.

The standard cost-effectiveness equation is $\Delta C/\Delta E = (C_2 - C_1)/(E_2 - E_1)$ where C = costs and E = effectiveness of treatment measured in time. For intervention 2, as its cost decreases or effectiveness improves, its CE ratio improves, i.e., decreased cost per year of life gained. When utility, or (life year gained) \times (utility factor), is calculated, the equation becomes $\Delta C/\Delta U$ where $\Delta U = U_2 - U_1$. For example, a therapy that does not improve survival but decreases utility factor to 10% will decrease U by (1 year) \times (0.10) = 0.1 year. If this treatment costs an additional \$10,000/year, then the cost-utility ratio is $\Delta C = C_2 - C_1 = \$10,000 = \$100,000/\text{QALY}$ (the intervention is “less effective” because it adversely affects morbidity).

TABLE 11.2. Difficulties in application of cost-effectiveness analysis or rationing by any method.

Factor	Pros, cons, and comment
We should not ration health care at all.	Avoids the issues—for those able to afford unlimited care. Unsustainable, and not morally defensible in the current high-cost environment. ⁶ Rationing goes on all the time now, based on ability to pay.
There are no accepted guidelines to use.	This is one of the most daunting tasks: to have a uniform standard. For many years, an unwritten rule has been that technologies that cost \$50,000/LY or less were acceptable, based on the incremental cost of dialysis vs. no dialysis. ³ The great majority of published studies referenced that standard. ⁴⁵ Laupacis and colleagues in Canada proposed that therapies under \$20,000/LY (\$ Canadian, 1992) be automatically accepted, that therapies \$20,000–\$100,000 be considered, and that therapies over \$100,000 be rejected. ⁴⁶
The cost-effectiveness ratio of \$50,000/LY is too low.	Recently, Ubel and colleagues have proposed that one of the main reasons cost-effectiveness is not more widely used is that \$50,000 is too low, and that with inflation and the affluence of the United States, a benchmark of \$100,000–\$200,000 is more appropriate. ⁴⁵
There are no unbiased studies.	Initial evidence was that industry-sponsored studies were more likely to be published if positive for their product ⁴⁷ and that industry sponsored more cost-minimization studies, to show that their product was as cost-effective as the competition, but not to address the issue of whether the therapy was a good buy for society. ⁴⁸ A comprehensive review suggests that quality control in most studies was low regardless of funding source and that industry-sponsored trials have improved. ⁴⁹
Clinicians should not ration at the bedside.	Clinicians have no training in this aspect of care, no framework for decisions, and were not able to adequately judge the appropriateness of their patient for care versus others. ⁵⁰ Others argue that the healthcare budget should not be balanced by denying services to vulnerable groups such as the elderly. ^{51,52} Although clinicians may elect to not do these tasks, a more reasonable view is that clinicians should at least be involved, because someone must do it, and the decisions should be best informed. ⁵
The individual always comes first.	Hadorn gave the name “the rule of rescue” to the compelling need of one visible patient (in this case, a 7-year-old with relapsed acute leukemia who might have a small chance of cure with a matched unrelated stem cell transplant) to the less-visible needs of many others who might also need those same healthcare dollars. ⁵³ This rule nearly collapsed the Oregon expansion of Medicaid services to the uninsured; a mechanism for appeals of individual decisions is always necessary, but some services cannot be provided.

Cost Only

This type of study ignores clinical outcomes and relies exclusively upon the expense of a treatment or strategy. Many newer and more expensive agents improve quality and quantity of life (cetuximab, bevacizumab, irinotecan, or oxaliplatin in metastatic colon cancer; all at \$2,000–\$4,000 per treatment).⁶ This type of method is often used by insurers as a rationale to not cover particular medications that may be efficacious but do not have enough supporting data to become a requisite standard of care. Ibritumomab tiuxetan (zevalin), an yttrium-90 antibody to CD20, is an active agent against non-Hodgkins lymphoma (NHL), but may register acute “sticker-shock” effect with many payers at \$22,000–\$28,000 per dose. And although it appears to have definite activity in NHL, it has not yet evolved into a definitive treatment choice in the algorithm of salvage therapy, at least in part because payers may not reimburse for its use. Unfortunately, cost alone does not help clinicians choose among a variety of therapeutic strategies, unless out-of-pocket expenses for patients make treatment unattainable.

Combining Cost and Effectiveness

Cost Minimization

Simply put, with cost minimization two equally effective strategies are compared in terms of cost, and the less-expensive strategy is chosen. Oftentimes, an assumption of equivalent efficacy of the two interventions must be made based on indirect evidence, that is, drug A and B are shown to have similar response rates, but in separate Phase II trials rather than head-to-head studies. Manufacturers are reluctant to design direct comparative studies for fear of losing market share should their product appear inferior.⁸ For example, darbepoietin and erythropoietin have not been directly compared in a large randomized trial until now, but available data indicate they are likely equivalent in the treatment of anemia; therefore, by the cost-minimization method, the less-expensive drug is preferable. This method is most useful when trying to choose between drugs in the same class, such as the hematopoietic growth factors just mentioned. However, assuming equivalent efficacy of drugs from different classes based on noncomparative studies would be fraught with bias.

Cost-Effectiveness

This method compares two known but not equally efficacious strategies and assigns a cost per additional year of life (LY) saved by the best (“dominant”) strategy. Treatment A, which gains 1 month of survival at a cost of \$2,000, has a cost-effectiveness ratio of \$24,000/LY. This cost per unit of effectiveness fosters a reasonable basis of comparison and can be put into a “League Table” (like team standings) so that decision makers can compare alternative uses of the same money. The gold standard way to get this information is to append a concurrent economic analysis to the trial, but such trials can also be done retrospectively after the trial has closed, so long as the assumptions and conclusions are justifiable (“robust”).

For this type of study to be clinically applicable, a limit must be set on the cost that society will pay for the additional year of life saved; otherwise, there is no reason to do the study or impetus for making the strategy more efficient. For example, a typical limit often used is in the range of \$50,000 to \$100,000 per additional year of life saved. By setting this limit, one can then reanalyze the intervention to determine how to improve the cost-effectiveness ratio. There are only two ways to improve the ratio: increase effectiveness or lower costs. Most studies use only the published cost of a drug or intervention. Health economists would argue that the cost of an intervention, including drug price, hospital cost, and physician fees, should always be on the bargaining table. A therapy that costs \$4,000 to save a month of life looks a lot more attractive to payers if the drug cost is reduced to \$1,000 to save that same month! Clinicians should note that the current gold standard for studies is that 1 month of added survival for 12 people is as important as 12 months for 1 person or a chance at cure for a small percentage of people.

Cost Utility

Cost-effectiveness looks only at survival: quantity rather than quality of life gained. Morbidity associated with diagnosis, treatment, or complications is not factored into the calculation for effectiveness. In cost utility, the quality of life in a given state of disease or treatment is converted to a utility ratio where 1.0 equals perfect health and 0 equals death. For example, a patient without evidence of disease after breast-conserving surgery may have a utility range of 0.90 to 1.00, whereas a patient with progressive metastatic breast cancer may have a utility range of 0.40 to 0.60. The utility ratio converts “cost-effectiveness” into cost per quality-adjusted life-year (QALY). For example, an intervention that costs \$10,000 per year of life gained would be converted to \$20,000 per QALY if the treatment’s toxicity lowered the patient’s utility from 1.0 to 0.5 so that only half of a quality-adjusted year was gained. Because utility can be assigned to any disease state, it can be used to compare different strategies across a variety of clinical conditions; survival and quality of life (which may be affected by the treatment, disease state, or both) are combined to arrive at a more realistic cost per year of life gained or, more specifically, cost per QALY.

One difficulty with this method is assigning proper utility ratios. Quality of life assessments are, by nature, subjective and lack a single, standard reference as a guide. Attributes tested usually include, but are not limited to, variables such as emotion, mobility, cognition, and pain. Controversy exists as to the most appropriate source for such testing, whether patients, healthcare workers, or the general population (society) due to differences in perspective. Patients and clinicians view the medical process differently and consequently place greater emphasis on the issues (such as life, morbidity, expense) that matter most to them. For example, patients are more likely than clinicians expect, to accept toxic treatments in exchange for minor clinical benefits,^{9–15} although there is variability,¹⁶ whereas a clinician may place more emphasis on functional status than a patient would. The most objective source and that least prone to personal bias is probably lay people (jurors) as recommended by national consensus panels.¹⁷ The difficulty in this lies in properly educating the jurors in all aspects of a patient’s experience: emotional

TABLE 11.3. Examples of utility ranges.

<i>Disease state</i>	<i>Utility range: 0 = dead 1 = perfect health</i>
Last month of life with acute leukemia	0.00
Metastatic breast cancer, last month of life	0.16–0.54
Extensive small cell lung cancer (SCLC), progressive disease	0.31
Metastatic prostate, depending on symptoms	0.42–0.58
Advanced ovarian cancer, responding to chemotherapy	0.71
Anxiety/discomfort from thoracoscopy	0.88
Induction interferon for stage II/III melanoma	0.94
Extensive SCLC, complete remission	0.99
Hydroxyurea for CML	1.00

turmoil, treatment toxicity, inconvenience, and other physical and psychosocial stressors. Quality of life scores can also be converted to utility values¹⁸ using validated methods, but oftentimes quality of life scores are so high that there is little discrimination between treatments. We have listed some representative utility values for time spent in various cancer states in Table 11.3.

Cost Benefit

This method compares two interventions but assigns the clinical benefit a monetary value; for example, a year of life is worth \$100,000. The figure is usually based on factors related to the overall economic productivity of an individual. Therefore, a treatment that costs \$10,000 to prolong life 1 year might be valued if the person generates \$100,000/year of value to society but not valued if the person is not productive. This kind of analysis, although common in the areas of business, insurance adjustment, and economics, is rarely used in clinical studies because of the difficulties in assigning a monetary value to a human life, especially if that value is tied

into an individual's socioeconomic status. Additionally, this method would almost certainly have a negative impact on most palliative care interventions because these patients rarely generate income.

We have listed a summary of cost-utility studies in Table 11.4 for comparison. Although many of these studies were performed over a number of years with disparate means of analysis and ranges of utility values factored into their equation, they are more likely to be accurate than no data at all and can form the basis of discussion.

How to Apply Cost-Effectiveness Data

The question of how to apply cost and effectiveness data to clinical practice is difficult to answer, as there is no one standard that is universally accepted. A Canadian schema has been widely accepted as one reasonable approach, but it is not used in the United States.¹⁹ Some benchmarks, and representative cost-effectiveness analyses, are listed in Table 11.5. The difficulty in developing a single accepted standard of what is explicit "healthcare rationing" lies in the varied and conflicting motives, points of view, and concerns of the three P's of the healthcare system: patients, physicians, and payers. The perspectives of each are listed in Table 11.6.

The perspective of cancer *patients* is different from that of well people; they are more willing to accept toxic treatments, for perceived minor benefits, than most would imagine. Generally, from studies available, these patients are willing to undergo toxic chemotherapy for a less than 10% chance of cure, 3 months of life prolongation, or greater than 10% chance of symptom relief,^{9–12} although there is variation among patients.¹⁶ Furthermore, there is no reason for a patient to be concerned with treatment costs until their out-of-pockets expenses become prohibitive; until they reach this limiting threshold, they may feel entitled to treatment regardless of the cost.

Physicians may find themselves trapped in the uncomfortable middle ground between their patients' desire for all possible treatment alternatives and societal, or payer, demand to limit treatment costs. For most physicians there is no

TABLE 11.4. Cost-effectiveness of representative cancer treatments.

<i>Intervention</i>	<i>Cost/year of life added</i>
Immunoglobulin for chronic lymphocytic leukemia	\$7,900,000
Autologous bone marrow transplant (ABMT) for all relapsed Hodgkins disease	\$421,000
Antiemesis with ondansetron vs. metoclopramide in cisplatin regimens	\$190,000–\$460,000
IDDS vs. CMM, "as randomized"	\$239,000–\$297,000
First-line fluorouracil (5-FU)-based chemotherapy vs. best supportive care, pancreas/biliary cancer	\$120,000
Pamidronate to reduce skeletal complications in breast cancer	\$119,000
Breast cancer screening, elderly	\$70,000–\$140,000
Adjuvant CMF, 75-year-old woman	\$58,000
5-FU-based treatment for GI cancers	\$31,000
Adjuvant tamoxifen + CMF, ER + women	\$14,000–\$33,000
Breast conservation vs. mastectomy	\$21,000
Biopsy versus no biopsy for 50-year-old man with elevated prostate-specific antigen (PSA) levels	Less than \$0

TABLE 11.5. Barriers to use of cost and cost-effectiveness data.

<i>Group</i>	<i>Barrier</i>
Patients	<ul style="list-style-type: none"> — Patients are more willing to receive toxic treatments for small benefits than well people — Patients may feel entitled to treatment regardless of cost — Cost may not become an issue for patients until out-of-pocket expenses are prohibitive — Strict effectiveness data may not reflect improved quality of life seen with palliative treatments
Physicians	<ul style="list-style-type: none"> — Physicians may be trapped between patient demands for all possible treatment and societal demand to limit care — For most physicians, there are no rewards to limiting care — For many oncologists, the supportive care drugs with high incremental cost-effectiveness ratios may be the most lucrative to the practice
Payers/government	<ul style="list-style-type: none"> — Payers may not want to antagonize their secondary constituents, consumers, by not covering some desired services based on cost-effectiveness data — The lawsuits about high-dose chemotherapy with stem cell transplant for metastatic breast cancer make some payers leery of confrontation

incentive to limit a patient's access to care; in fact, for many oncologists the supportive care drugs such as erythropoietin, filgrastim, and bisphosphonates help support their practice. Physicians may also be hesitant to set limits on cancer care of their own accord outside of widely accepted professional standards; this is both uncomfortable for the physician and probably inappropriate bedside medical rationing that may not be based on sound evidence. For example, a physician may decide that palliative radiation therapy for painful bone metastases should be replaced by opioid medication alone because costs of radiotherapy are assumed to be very high. In fact, studies tell us that radiotherapy in such settings is indeed cost-effective and falls

well within accepted ratio standards.²⁰ In the interest of balancing the appropriate delivery of care with responsible financial prudence, clinical guidelines addressing these issues should continue to be examined by appropriate consensus groups.²¹

Payers often need to balance their need to cut costs by limiting coverage for certain diagnostic or therapeutic interventions with the image they must present to the public, their secondary constituents, and consumers: that of an organization that is primarily concerned with the medical well-being of their clients, rather than their own fiscal health. The federal government, in the form of Medicare and Medicaid, shares the same concerns of private payers.¹⁹

TABLE 11.6. A framework on how to apply cost-effectiveness data.

<i>Category</i>	<i>Consideration</i>	<i>Comment</i>
Treatment A is more effective and saves money compared with treatment B	Use treatment A	Hypofractionated (single-dose) radiation for bone metastases vs. multiple dose schemes ³² PET scans before thoracotomy prevent 21% of futile thoracotomies ²⁶
Incremental cost-effectiveness of treatment A \$0–\$50,000	Use treatment A, as likely appropriate use of societal resources	Several widely used interventions fall here: — Guideline-based pain management vs. oncology-based care ⁵⁵ — Adjuvant therapy for breast cancer — Adjuvant therapy for colon cancer — Stem cell transplantation vs. melphalan and prednisone for myeloma patients under 65 ⁵⁶
Incremental cost-effectiveness of treatment A \$50,000–\$100,000	Consider treatment A	Routine preoperative head CT (vs. none) for resectable lung cancer with no evidence of CNS disease ⁵⁷ Breast cancer screening (vs. none) in women older than 75 ⁵⁸
Incremental cost-effectiveness of treatment A more than \$100,000	Do not use treatment A	Several widely used interventions fall here: — Bisphosphonates for breast and myeloma cancer ⁵⁹ — Selective 5-HT ₃ antagonists for antiemesis (reviewed by Earle et al. ⁵⁴) — Radiotherapy boost to whole breast radiation as part of primary therapy ⁶⁰ — Trastuzumab for metastatic breast cancer ⁶¹

The Lack of Studies

There are a small number of recent studies looking at the issue of cost-effectiveness and cost utility. Barriers to performing such studies include, but are not limited to (1) lack of sponsorship; (2) cooperative group efforts to accrue large enough sample sizes to detect the small differences seen; and (3) the lack of glamour associated with studies that seek to limit resource utilization and possibly come to uncomfortable conclusions regarding how to ration health care.

These studies generate little enthusiasm as they require large patient populations to detect relatively small differences in cost-effectiveness, and there are rarely additional funds to support them. Cooperative groups are more interested in spending money on trials of new therapies than showing cost-effectiveness (partly because there is no ready market for the results), and sponsors are not willing to spend money that puts their product at risk. Several pharmacoeconomic trials that made perfect sense to perform in the cooperative group setting, based on preliminary data, generated no support. The first suggested trial tested 2 µg/kg filgrastim instead of 5 µg/kg filgrastim for prevention of neutropenia, based on a small randomized trial that showed equivalence.^{22,23} The second trial would have used bisphosphonates to prevent skeletal complications from metastatic breast cancer every 3 months rather than monthly, as monthly pamidronate had a cost-effectiveness ratio outside the usually accepted bounds.²⁴ Both trials were turned down by the cooperative group for similar reasons: the job of the cooperative group is to cure cancer, not to save money; someone else should concentrate on saving money; and there are more important questions to answer from the same budget. Drug or device companies may not have much reason to do this, either: the only aspect of a large randomized clinical trial in cancer pain management²⁴ that was not funded by the company was the cost-effective analysis.

Comfort levels of this type of healthcare rationing may also depend on where a clinician practices. In general, Americans spend more on heroic end-of-life intervention than their European counterparts, who are more likely to divert healthcare dollars into preventive strategies. In the United States, more than 20% of all medical expenditures are spent on the last year of a patient's life.²⁵

Studies That Have Changed—or Could Change—Practice

There are a number of studies that would seem appropriate for economic evaluation because of high costs, small benefit, large societal impact, or some combination of these (Table 11.7). Cost or cost-minimization analysis showed that positron emission tomography (PET) scans prevented 21% of futile thoracotomies for resectable small cell lung cancer²⁶; one could argue that PET scans would be used anyway, but they appear to lower costs overall by preventing more expensive surgery. The nonplatinum combination of gemcitabine-paclitaxel was no better or less toxic than other regimens in a large randomized trial and cost 25% more.²⁷ Our own analysis of inpatient palliative care units showed

a 60% cost savings in a matched case-control set and prospective clinical-financial analysis.²⁸ Many other studies were done, but in general, they would not be expected to have either a clinical or economic impact, so are not included.

Cost-effectiveness studies showed that some commonly used treatments were within the range of accepted cost-effectiveness ratios but some were not. Postmastectomy radiation in premenopausal women improved survival at a cost of \$24,900/LY. Capecitabine/docetaxel in metastatic breast cancer, compared to docetaxel alone, improved survival by 3 months²⁹ at a cost-effectiveness ratio³⁰ of approximately \$3,700/LY (Canadian), well within accepted standards of treatment. In this study, utility was not included but the magnitude of survival benefit would likely offset the negative effects of toxicity associated with capecitabine. Of note, the alternative strategies of sequential therapies were not tested, so no conclusion can be drawn. A more expensive initial strategy, autologous stem cell transplant for myeloma instead of melphalan and prednisone, had longer survival that offset the cost, so the incremental cost-effectiveness was acceptable. One recent study³¹ looked at cost-effectiveness through a spreadsheet-based model comparing three strategies for treating pain caused by cancer: guideline-based care, oncology-based care, and usual care. Treatment strategies included medications and procedure-based interventions. The effectiveness unit used was "additional patient relieved of cancer pain," rather than the typical additional year of life gained. Guideline-based care (GBC) was more effective at relieving cancer pain compared to oncology-based care (OBC) or usual care (UC): 80% versus 55% and 30%, respectively. The incremental cost-effectiveness for GBC compared to OBC was \$452 per additional patient relieved of cancer pain, whereas the cost-effectiveness of OBC compared to UC was \$601 per additional patient relieved of cancer pain.

Several cost-utility studies produced noteworthy results. Single fraction radiation for painful bone metastases instead of the usual six treatments was as effective and cost substantially less.³² Gordois and colleagues analyzed the impact of imatinib mesylate (gleevec) in the treatment of accelerated-phase CML and blast crisis CML compared to conventional chemotherapy and palliative care in hospital or at home.³³ Imatinib mesylate improved QALYs in accelerated-phase CML of 2.09 years at \$45,000/QALY and in blast crisis CML of approximately 0.58 months at \$63,000/QALY. An analysis of imatinib mesylate in chronic-phase CML, a much more common and costly treatment, compared with interferon and cytarabine, or bone marrow transplantation, has not yet been published in the English literature. Testing for HER-2 positivity by various methods, and treatment with trastuzumab if HER-2 positive, gave better survival by a few months; however, the cost was always over \$100,000/LY.³⁴ The more common and economically important question, at what cost does trastuzumab gain a year of life, especially in second- or third-line treatment, was not addressed.

Many important advances of the past years have not been studied, including the cost-effectiveness of adjuvant therapy for non-small cell lung cancer, dose-dense therapy of breast cancer, and the effectiveness and cost-effectiveness of most palliative chemotherapy regimens.

TABLE 11.7. Evidence-based new data.

<i>Trial</i>	<i>Reference</i>	<i>Year</i>	<i>No. of patients</i>	<i>Randomized</i>	<i>Stage</i>	<i>Intervention</i>	<i>Median follow-up</i>	<i>Outcome of interest</i>	<i>Conclusion</i>
Cost or cost minimization									
PET scan in resectable NSCLC	Verboun ²⁶	2002	188	Y	I-IV	Conventional workup vs. PET scan preop	1 year after surgery	21% of futile thoracotomies vs. 41% with CWU; avoided 1 in 5, cost saving OS similar; no differences except P + G, cost 2.5% more	PET scan improves preop screening, lowers costs
Cisplatin-paclitaxel, P-gemcitabine, vs. PG	Smit ²⁷	2003	480	Y	IIIB-IV	C + P vs. C + G vs. P + G	1 year		No advantage, higher cost for nonplatinum combinations
Palliative care inpatient units	Smith ²⁸	2003	180	N	End of life	High-volume expert providers, standardized care, algorithms	NA	60% reduction in cost of care compared to usual care, health outcomes similar	Inpatient palliative care units may improve care at less cost
Cost-effectiveness									
Post-mastectomy radiation therapy in premenopausal women	Lee ⁶¹	2002	DA	Y	I-III	Postmastectomy radiation therapy in premenopausal women vs. none	15 years	Relative risk of death reduced to 0.69; adds 0.29 LY at \$24,900/LY	Cost-effectiveness ratio acceptable
Capecitabine + docetaxol vs. docetaxol alone	Verma ^{29,30}	2003		Y	IV	Capecitabine + docetaxol vs. docetaxol alone	NS	Combination gives additional 3 months at cost of \$3,700/LY (Canadian)	Cost-effectiveness ratio acceptable; with improved survival, utility not likely to be important; trial did not have Capecitabine-alone arm for comparison, or test sequential therapy
Autologous stem cell transplant vs. chemotherapy in myeloma	Kourouk ³⁶	2003	36 ASCT, 16 M & P	N	Advanced	ASCT vs. M & P patients < 65, single center		Increased OS by 19.3 months, cost-effectiveness \$13,000-\$64,000/LY (Can)	Cost-effectiveness acceptable under best and worst case scenarios
Pain control	Abernathy ³¹	2003	DA using published data	Some		Pain control with guidelines (G), oncology (O), usual care (U)		Pain control achieved at 1 month in 80%, 55%, and 30%, respectively ICE for guideline-based care \$452/patient.	Acceptable cost per outcome using guidelines to improve pain control
Cost-utility									
Single vs. 6 fractions radiation for painful bone metastases	Van den Hout ³²	2003	Y						
Testing for HER-2 positivity		2004	DA using published data			Testing strategies of immunotesting first, with FISH after, or FISH		All dominant strategies over \$100,000/LY	Authors suggest if society willing to pay for trastuzumab, should be willing to pay for optimal testing; avoids question of whether trastuzumab cost-effectiveness is acceptable

CWU, conventional workup; NSCLC, non small cell lung cancer; P, paclitaxel; G, gemcitabine; NA, not available; NS, not stated; DA, decision analysis; FISH, fluorescence in situ hybridization; ICE, ifosfamide (Ifex®), carboplatin (Paraplatin®), and etoposide (VP-16, VePesid®).

The 2004 Clinical and Research Challenges in Economics and How the Principles and Practice of Oncology May Be Changing

Continued increases in patient demands coupled with escalating costs, without subsequent raises in insurance premiums, will ensure some means of rationing in the future. Cost and effectiveness analyses offer some way to set a level playing field for old and new technologies and competing interests.

Cost-effectiveness analyses can be done successfully either alongside a clinical trial, when economic interests are especially prominent,³⁵ or retrospectively, after a therapy is shown to be effective, but the cost is high. Cooperative groups, industry groups, or individual researchers can do such trials. There is always a potential for publication bias, or industry supporting only those trials that are likely to show their product is within the fundable range of cost-effectiveness ratios, as with clinical trials. Funding for these trials will remain problematic as long as these trials are competing for the same funds as regular clinical or quality of life trials.

The impact of cost-effectiveness studies has been hard to gauge. Reflecting over the past years, we can think of only several examples of the importance of cost-effectiveness studies. When adjuvant chemotherapy for women with node-negative breast cancer was first endorsed, a major objection was the cost, estimated at \$300 million or more yearly in the United States.³⁶ Subsequent studies showed that adjuvant treatments had similar cost-effectiveness ratios to the treatment of hypertension, and were clearly acceptable.^{37,38} Similar objections were raised to the use of chemotherapy for advanced non-small cell lung cancer, with only a few months of time gained compared to best supportive care, but subsequent analyses showed that chemotherapy could actually be cost saving³⁹ or have very acceptable cost-effectiveness ratios.⁴⁰ Chemotherapy with mitoxantrone in advanced prostate cancer showed no survival benefit⁴¹ but actual cost savings due to avoided radiation and hospitalizations.⁴² Royle and Waugh showed that a relatively simple strategy of searching Medline and similar databases is sufficient for finding cost-effectiveness studies,⁴³ so the process of updates should not be difficult. It is important to factor in the cost of the intervention, if a change in prescribing practices is sought, as some interventions may cost more than the cost savings generated, especially with low-cost drugs; this is not likely to be the case in cancer treatment.⁴⁴

Summary

In the United States, the cost of health care is now equal to 15% of the Gross National Product, the highest ever, and is growing at more than 10% annually. Costs rise in response to increased demand for new therapeutic and diagnostic technologies, and as the population ages. Given the limited resources of payers, an evidence-based and practical method is needed to mesh our desire for expanded treatment choices with the reality of limited healthcare dollars. Cost-effectiveness, defined as the amount of money spent to gain an additional year of life (LY) by treatment A compared to treatment B, is one accepted method of analysis and alloca-

tion of resources. Cost-utility assessments, which generate quality-adjusted life-years (QALY), adjust cost-effectiveness to account for the morbidity associated with treatment and illness. We review recent data supporting evidence-based decision making, some high-profile studies that have changed clinical practice, and the economic implication of such changes.

Few studies have integrated cost-effectiveness into their design for a variety of economic and logistic reasons, but such studies are needed if we are to make treatment decisions that are both clinically sound and economically prudent. Once the data are published, clinicians need commonly agreed-upon standards to make treatment decisions that account for cost and effectiveness, such as "Use therapies that cost \$100,000/LY or less and do not use therapies that cost \$200,000/LY and more." If the cost-effectiveness ratio is too high, then the cost of the therapy could be lowered, such as by convincing pharmaceutical manufacturers to lower the cost of a drug.

There are examples of cost-minimization and cost-effectiveness analysis helping in the decision to allocate resources. Hospital-based palliative care consultation teams and inpatient units provide equal or better care and can save as much as 60% per day compared to standard hospital care, and such programs are growing rapidly. PET scanning, although very expensive, reduces futile thoracotomies of potentially resectable non-small cell lung cancer for one of five patients and can be cost saving; however, it would still be used even if it cost additional money. Chemotherapy for metastatic prostate cancer improves symptoms but has limited impact on survival; surprisingly, to many, the cost of chemotherapy is more than offset by avoided complications, such that the cost-effectiveness is acceptable. Imatinib mesylate for CML, bisphosphonates used to prevent skeletal complication in breast cancer and multiple myeloma, trastuzumab for breast cancer, and expensive antiemetics, such as serotonin antagonists, have a cost-effectiveness ratio of more than \$100,000/LY, well outside the \$50,000/LY parameters normally accepted as appropriate for cost-effectiveness. However, the treatments are widely used and accepted as the standard of care. Other effective strategies that use costly interventions such as dose-dense chemotherapy in the adjuvant setting for breast cancer, supported by filgrastim at \$1,000 to \$2,000/cycle, clearly have benefit but have not even been studied.

Cost-effectiveness studies offer an objective method by which to base resource allocation decisions, rather than solely relying on the response rate or survival benefit of a particular strategy. Few new cost-effectiveness or cost-utility studies have changed practice, and many expensive accepted strategies have been adopted without any consideration of cost. The rapid growth of new and expensive strategies with rapid cost escalation increases the need for unbiased cost-effectiveness studies and generally accepted guidelines with which to apply the results.

Principles of Screening for Cancer

Russell Harris and Linda S. Kinsinger

*S*creening is defined as testing for a condition when the person has no recognized signs or symptoms of that condition. The purpose of screening is not to merely detect a condition, but rather to help people live better or longer. This is an important distinction: the detection of earlier disease by itself is insufficient to justify a screening program. The program must additionally demonstrate that people live longer or better because of the earlier detection.

A positive screening test result does not indicate that a person has the condition, but rather that he or she has a higher probability of having the condition. People with positive screening tests usually undergo diagnostic testing to determine whether the condition is present. For example, a woman with a positive mammogram result does not necessarily have breast cancer, but she may undergo a needle localization biopsy to determine whether she has breast cancer.

Screening is not a single test, but rather a cascade of events that can lead to either benefits or harms (see The Cascade of Screening, later in this chapter). Potential benefits include living better or living longer and are usually experienced some years after screening. Potential harms include the effects of false-positive or false-negative screening tests and problems that result from overdiagnosis and overtreatment. Harms are usually suffered soon after screening.

Because screening programs may lead to either net benefit or net harm, decision makers must carefully evaluate proposed programs. Eight criteria distinguish effective programs:

1. Disease: The disease should cause a sufficient burden of suffering to warrant attention and should have a detectable preclinical phase of sufficient length to allow early detection (see The Critical Point in Cancer Treatment, later in this chapter).

2. Test: The screening test should be sufficiently sensitive to detect those cancers that could benefit from earlier treatment. Note that the test does not need to be maximally sensitive but rather “sensitive enough” to detect those cancers that it is important to detect. Cancers that are important to detect are those which are treatable when detected by screening but not when detected clinically.

3. Test: There are usually many more false-positive test results than true-positive results. The screening test should be specific enough to minimize the number of false-positive test results so as to minimize their negative consequences.

4. Availability and acceptability: The screening test, workup, and resultant treatment should be available to all

and acceptable both to clinicians and to the people being screened.

5. Treatment: There must be a treatment for the disease that is more effective when applied to screening-detected cancers than clinically detected cancers. By “more effective,” we mean that people will live longer or better as a result of this earlier treatment.

6. Harms of overtreatment: Often earlier detection includes detection of people with intermediate lesions that would never progress to invasive cancer. Screening may lead many people with these lesions to be subjected to treatment that they do not need and which causes harm. To minimize harms, people with lesions that will not progress to clinically important disease should rarely be subjected to potentially harmful and unnecessary treatment.

7. Benefits and harms: Overall benefits (in terms of people living longer or better) must outweigh overall harms (including harms from the screening test, harms from the workup, the adverse effects of earlier treatment and overtreatment, the psychologic effects of labeling, and the downstream effects of surveillance).

8. Costs: The net health benefits must come at a reasonable cost.

Screening for cancer is a popular idea, but this popularity may be based more on intuition than on understanding. Studies show that the great majority of Americans are convinced that being screened is part of being a responsible citizen.¹ What is less certain is how well the public comprehends the magnitude of the potential benefits of cancer screening; even less certain is whether the public appreciates the magnitude of the potential harms. Further, one could wonder whether the public has a reasonable grasp of the gaps in our knowledge of the effects of screening.

One might argue that whether the public understands these issues is irrelevant. The fact is that the public has decided that cancer screening is a good that it desires. We suggest that there are several important reasons for the public to better understand screening. The first is that screening consumes resources, such as money and the time of medical personnel. In a system strapped for resources to appropriately care for all our people, expending resources on services that offer little benefit and risk greater harm reduces the contribution medical care can make to the health of the public. The second reason is that if widespread screening fails to reduce the rate at which people die of cancer, ultimately the public will ask why it does not. If the medical care system has not

informed the public of the limitations of cancer screening as a strategy to reduce cancer mortality, its credibility will be damaged. Finally, if the public pins all its hopes for cancer control on screening, this attitude may inhibit creative new ideas and research that could develop alternative strategies for cancer control.

The public needs to have a clear idea of both sides of the cancer screening coin: benefits and harms. Clinicians must play a large role in this educational effort. This chapter attempts to help clinicians better understand these issues so that they can appropriately advise the public.

The Idea of Cancer and the Idea of Screening

The public's understanding of how cancer works is central to its understanding of how screening works and thus to its strong interest in screening. Especially relevant is the public's perception of the development and progression of cancer and of the degree of homogeneity of cancers with the same name (e.g., breast cancer) in their malignant potential.

Although the process of cancer development is not completely understood, it is clear that a normal cell does not become cancer suddenly, all at once. Rather, cells undergo a number of assaults over time, with various results.² Some of these assaulted cells develop various abnormal forms, or "intermediate lesions," such as cervical intraepithelial neoplasia (CIN), colonic polyps, or ductal carcinoma in situ of the breast (DCIS). Although not cancer themselves, these intermediate lesions do at times develop into cancer.

As screening frequently detects intermediate lesions, their natural history is important. If nearly all intermediate lesions progress to malignant cancer, then early detection and treatment would appear to be an effective strategy for cancer control. The detection of intermediate lesions would be a triumph. By interdicting the developing cancer at this early point (i.e., even before it can be called a *cancer*), treatment could eradicate a lesion that would have caused major health problems in the years to come.

With many intermediate lesions, however, the majority (most often, the great majority) never progress to invasive cancer. Thus, screening often results in detecting and treating intermediate lesions that do not need to be detected or treated. If there are any harms to this early detection and treatment, the magnitude of these harms must be counted against the magnitude of the benefit. It is doubtful if many people understand this result of screening, or at least the frequency with which it occurs.

After cancer develops, a critical issue is the extent to which it uniformly progresses in a linear and inevitable manner to cause symptoms and death. If cancer is always an inexorably progressive condition, it is intuitively appealing to think that early detection is an effective strategy for cancer control. The experiences of people who have cancer with the same name (e.g., breast cancer) would vary little; all would be destined for a difficult death because the cancer had progressed too far for effective treatment. Again, the facts are otherwise.

Cancers, even cancers with the same name (e.g., breast cancer), vary widely in their growth rate and malignant potential. Studies have found that cancers that vary with respect to certain cell markers have different prognoses.³ Gene

expression profiling using DNA microarrays^{4,5} has shown the genetic heterogeneity of individual breast cancers. There is not one type of breast (or colorectal or prostate) cancer, but a number of types, each with a different natural history. Together with the probable but largely unknown ways in which individual susceptibility varies, these cancer types produce great variation in the ways a particular cancer is expressed. Some cancers in certain individuals grow rapidly and are lethal within a short time, regardless of our best treatments. Screening is unlikely to make a difference for people with such cancers, which may metastasize from the first cell.

Other cancers with the same name grow more slowly, or not at all. People with some of these latter cancers may be greatly helped by early detection and treatment; others have cancers that do not need to be detected and treated at all. In some cases, lesions that clearly meet histologic criteria for cancer do not cause important clinical problems. Experts have termed this last group *pseudodisease*, lesions that appear to be cancer but do not progress to clinically important disease. It is the existence of this type of cancer, less malignant and less requiring of treatment, that gives pause to the push for screening. Here are cancers that do not need to be found early; some of them do not need to be found at all.

Much of the public has another conception of how cancer works. The word *cancer* usually means a condition that universally and inevitably progresses, a condition that is potentially fatal in every case. The fact that some people have long-term survival after cancer diagnosis is attributed to some exceptional characteristic of the individual or to effective treatment. Intermediate lesions are called *pre-malignant*; the popular conception is that they too inexorably progress to cause major clinical problems. This incorrect view of the nature of cancer is an important underlying reason for the popularity of cancer screening. As people have commented to the authors, cancer screening "simply makes sense." Given this view of cancer, one can understand their thinking.

The Critical Importance of Treatment Effectiveness in Determining the Benefits of Screening

The purpose of screening is not simply to detect disease earlier, but rather to help people live better or longer (i.e., improve health outcomes) because of early detection. Thus, the question we need to ask ourselves in considering a screening situation is not how many early cancers we find but how many people avoid poor health outcomes.

Although many people and their clinicians view the potential benefits of screening as primarily a function of the accuracy (especially the sensitivity) of a screening test, in fact, the factor that most commonly limits the benefit from screening is the treatment. For a screening program to improve health outcomes, it must include a treatment that is not only effective but which is more effective if applied earlier than if applied later. That is, the critical issue with screening is the *timing* of treatment. If the treatment is not effective at any time, obviously screening is not useful. If treatment is excellent and just as effective for clinically detected cancer as screening-detected cancer, then again early detection by screening is not helpful. Screening is only useful in improving health outcomes when the treatment is effec-

tive for screening-detected cancer but not clinically detected cancer.

This treatment criterion for a screening program is often misunderstood. The important question is this: where in the natural history of this cancer is the critical point (see following discussion) at which a particular treatment becomes ineffective? Theoretically, at least, many treatments may be effective when a potentially fatal cancer is only a few cells in size. As this cancer grows, however, there comes a point at which treatment is no longer effective in altering its natural history and helping the person to live better or longer. It is the location of this *critical point*, and especially its relationship with the point of detection by the screening test, that determines the effectiveness of the screening-and-early-treatment program. If the critical point is earlier than the point at which the cancer can be detected by screening, then screening cannot be helpful. If the critical point is during the “lead time” produced by the screening test, then screening will be helpful. If the treatment is very effective and the critical point is after the point at which regular, competent medical care would detect the cancer, then screening is not useful because treatment after usual clinical detection is as effective as treatment after screening detection.

When treatment is particularly effective, the critical point for some potentially fatal cancers may be at a far-advanced stage. Even very effective treatments may become ineffective for far-advanced stage cancers. Far advanced stage cancers at diagnosis may occur in several situations: in people who neglect their health; in people without access to regular, competent medical care; or in people without understanding that early signs or symptoms should be evaluated. In the past, for example, some women presented with breast tumors that were the size of a lemon or even an orange. It would be difficult to deny that many such cancers could have been treated more successfully had they been evaluated at an earlier stage. Few women present with such advanced tumors now, at least partly, because most women in this country recognize that breast lumps of any size should be examined by a physician.

The treatment requirement for a screening program is that the treatment must be more effective after detection by screening than after usual clinical detection. It does not require that the treatment be effective for far-advanced stage cancers. One does not need to implement a screening program to prevent the development of far-advanced cancers by helping people understand that new symptoms and signs should be reported to one’s physician. This educational effort is different from screening.

The issue of the effectiveness of treatment at different points in the natural history of cancer is made more complex by the marked variation in cancers and individuals, as just discussed. It is not surprising, for example, that early detection and treatment rarely reduce mortality by 100%. For example, in the overviews of the randomized controlled trials of breast cancer screening, mortality is reduced by less than 20%.⁶ This finding would imply that about 20% of women destined to die of breast cancer have a type of cancer that is better treated earlier than later. The other 80% of women destined to die of breast cancer have a type of cancer for which earlier treatment is not useful. These women may have a particularly malignant form of cancer in which metastasis occurs at an early stage, too early to be detected by screening.

Many other women are detected by breast cancer screening, of course, but these may be women not destined to die of breast cancer. They may have either a less-malignant form of the disease for which later treatment is as effective as earlier treatment or a benign form of cancer that would never have caused major adverse health outcomes even without treatment.

The Critical Point in Cancer Treatment

As shown in Figure 12.1, cancer begins as a small number of cells. If it were possible to detect every cancer at this point, and accurately distinguish the potentially fatal ones from the nonfatal, then our treatments would have a high rate of success. As the cancer grows, however (moving to the right in the figure), the potentially fatal cancers reach a point at which they are less effectively treated. This critical point varies between cancers and within cancers with the same name. It also varies between treatments. An important advance in treatment may mean that cancers can be effectively treated at a later stage in their development (i.e., farther toward the right of the figure).

The relationship of the critical point to the point at which a screening test can detect a cancer helps determine the potential benefits of screening. If the critical point is between points A and B in the figure (i.e., before the screening test can detect the cancer), then screening with the present test will not reduce the burden of suffering of the cancer. If the critical point is between points B and C (i.e., within the detectable preclinical phase of the cancer), then screening may well be helpful in reducing mortality and/or morbidity. If the critical point is to the right of point C in the figure, then the treatment is effective for even advanced cancers, and earlier detection is not needed.

Sensitivity of the Screening Test: A Less Important Criterion

In contrast to effective treatment, the sensitivity of the screening test, that is, its ability to detect early cancer, may or may not be an important factor in determining the benefit from a screening program. If a screening test is made more sensitive (for example, by reducing the cut-point for defining “abnormal”), it is likely that the test will detect more cancers. However, if these additional cancers are either more

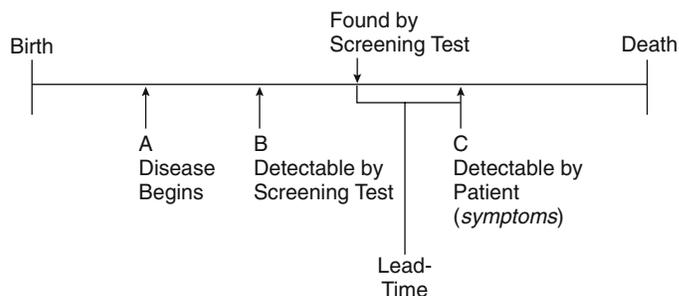

FIGURE 12.1. Natural history of cancer. *Critical Point*, point at which treatment becomes less effective; could be between A and B, between B and C, or after C.

benign (and would never cause problems) or more malignant (and thus have already metastasized), then the extra sensitivity would not have made a contribution to improving health outcomes. The operative question is not how many more cancers are found by a more sensitive test but rather whether screening has moved detection for at least some potentially fatal cancers back to a more treatable stage. If this has not occurred, then the more sensitive test has not been a useful addition to the screening program. This rationale includes such strategies as screening more frequently (i.e., reducing the screening interval), which may increase sensitivity but may or may not improve health outcomes.

For this reason, the sensitivity of a screening test may not be related to its ability to improve health outcomes. For example, screening for cervical cancer with the Pap smear probably has a fairly low sensitivity,^{7,8} yet screening every 3 years apparently reduces cervical cancer mortality by more than 80%.⁹ Developments in the technology of screening tests that seek to improve screening programs by increasing the sensitivity of the screening test may increase sensitivity without improving health outcomes. Such approaches may increase the cost of screening without providing additional health benefit.

Potential Harms of Screening: False-Positive Results and Overtreatment

It is difficult to understand how finding cancer earlier could cause harm. In the popular paradigm of cancer being an inexorably progressive disease, the idea of harms from screening makes little sense. It is not difficult to understand why people report having little concern about being harmed by a screening test. But in a real world in which not every cancer is an enemy, most of the intermediate lesions never progress to invasive cancer, workups and diagnostic tests have side effects, and cancer treatments can cause suffering of their own, the possibility of doing harm with screening is easier to understand.

The Cascade of Screening

Screening is not a single test, but rather a cascade of events that can result in either benefit or harm (Figure 12.2). The first step is the screening test itself. Although some diagnostic tests can have useful intermediate results, with a screening test the result is either positive or negative. If a recommendation for anything other than continued routine screening comes from the screening test, it is a positive test. The patient is notified that all is not well and that further evaluation of some kind is needed.

Typically, with cancer screening, many more people have a negative screening test than a positive. After a positive test, further workup is required to determine whether the screening test is a true positive or a false positive. The workup may vary depending on the degree of positivity of the screening test or other circumstances. Some people with false-positive tests have ongoing anxiety related to the experience of screening whereas others do not.

People with a true-positive test do not all benefit from earlier detection of their cancer. These people fall into four categories. Category 1 includes people with fast-growing,

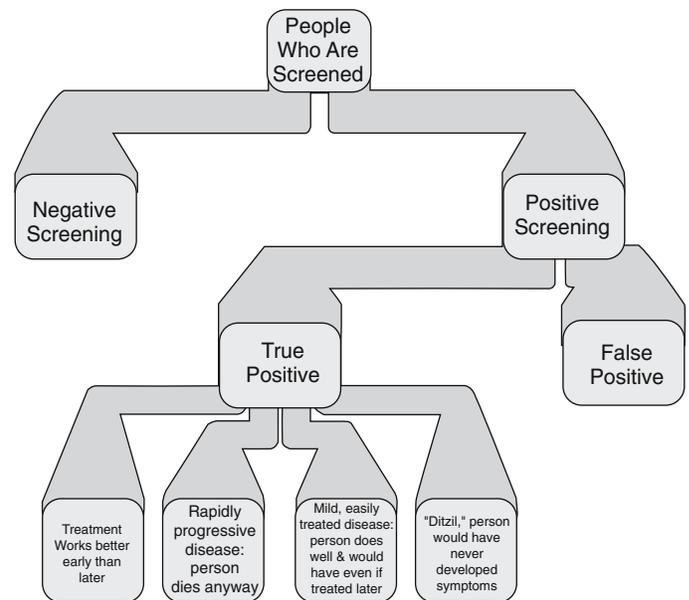

FIGURE 12.2. Cascade of screening.

malignant disease for which treatment is ineffective. These people do not benefit from earlier detection. Category 2 includes people whose cancer is easily treated regardless of when it is detected. These people also do not benefit from earlier detection. Category 3 includes people whose cancer would never have caused important clinical problems and does not need to be treated. These people have “pseudodisease” and do not benefit from earlier detection. Category 4 includes people whose cancer is more effectively treated earlier, after screening detection, than later, after clinical detection. These are the people who benefit from earlier detection. Treatment of people from category 3 is overtreatment; any adverse effects from treatment of this group must be counted as among the harms of screening. This situation happens frequently because category 3 cancers cannot always be accurately distinguished from other categories.

We next consider two categories of potential harms from screening: false-positive screening tests and overtreatment. Although false-negative tests could also theoretically cause harm by false reassurance, we know of little evidence to substantiate this potential harm.

False-Positive Test Results

False-positive screening test results can cause harm both psychologically and by adverse effects from unnecessary workups. Although a positive screening test does not mean that one has the disease in question, it does mean a person has been placed into a higher risk group than previously. That is, the risk of having breast cancer is higher among women with a positive mammogram than among women who have not yet had a mammogram. The individual may experience the uncertainty of not knowing whether she has breast cancer. This occurrence usually causes stress to the individual involved; any delay in the diagnostic workup adds to the person’s concern.

The psychologic trauma from a false-positive screening test can be increased by incomplete resolution of the situa-

tion. For example, women with an abnormal mammogram are sometimes asked to return for follow-up mammograms every 6 months (rather than annually). Similarly, some men with a high prostate-specific antigen (PSA) value and a negative prostate biopsy are asked to return in 3 to 6 months for a second set of biopsies because the cancer may have been missed in the first set. People who have had benign colonic polyps removed are sometimes asked to have repeat colonoscopy at more frequent intervals. Some of these people may suffer psychologic stress as a result of prolonging the experience of uncertainty.

Some people who have had seemingly complete resolution of the false-positive screening test (e.g., a woman with an abnormal mammogram who had a negative biopsy and was told she does not have cancer) still have lasting concerns. A study of women after having a false-positive mammogram found that many still had lingering doubts that interfered with sleep or function 6 months after a negative biopsy.¹⁰ A recent study found a similar result among men with a high PSA screening test and a negative biopsy for prostate cancer.¹¹

Because false-positive tests lead to workups without clinical benefit, any complication from the workup of a false-positive screening test (e.g., colonic perforation from a false-positive fecal occult blood test) is also a harm from screening. Most workups for positive screening tests will be negative.

Although these psychologic effects and complications from workups may seem of little consequence when compared with the potential for extending life by screening, the weighing of these effects on a population level must take into account that the actual number of false-positive screening tests is far larger than the number of true-positive tests, and larger still than the number of true-positive tests that lead to extended life.

The rate at which a screening test yields false positives is determined by its specificity. Many screening tests have specificities above 90%. Although this sounds very high, specificity in the 90% range guarantees a large number of false-positive tests. This is because specificity is the percentage of all people without the cancer who are classified correctly as having a negative test; 1-specificity is the percentage of people without disease who are incorrectly classified as having cancer (i.e., false positive). In a screening program, however, the number of people without cancer is very large; thus, even 10% (or even 5%) of a large number is still a large number.

In most cases, the number of false-positive screening tests outnumbers true-positive tests by a factor of from 4:1 (e.g., prostate cancer) to 10:1 (e.g., breast cancer) or higher. If we consider the proportion of people who have at least one false-positive screening test over a period of years of repeated screening, the ratio of false-positive to true-positive tests is even larger. In one study, nearly 50% of women had at least one abnormal mammogram over 10 years of annual screening.¹²

Because the prevalence of cancer in a screening population is low, the number of true-positive tests is usually low. If, as noted previously (see Figure 12.2), only a fraction of the true-positive tests lead to extended life, then the number of people who could, over a period of years, potentially suffer the harms of a false positive screening test so far outnumbers

the people who may reap the benefits that weighing benefit and harm overall is not straightforward.

As noted previously, improving the sensitivity of a screening test may or may not lead to increased benefits from screening. However, improving the specificity of a screening test often leads to less harm because there are fewer false-positive tests. A smaller number of false-positive tests gives less opportunity for adverse psychologic effects of screening and for adverse effects of negative workups. Thus, improving the specificity of screening tests should often be a priority.

For most tests, whether screening or diagnostic, sensitivity and specificity are inversely related. Thus, increasing the specificity of a screening test may well reduce the sensitivity. The optimal screening test, then, may be neither the most sensitive nor the most specific test, but rather the test (or test cut-point) that gives the optimal trade-off between benefits and harms.

Overdiagnosis and Overtreatment

In addition to false-positive tests, harms may also follow from true-positive tests. Not all people with true-positive screening tests benefit from the earlier detection of cancer. One can think of people with true-positive tests as having cancers in one of four categories.

Category 1: People with an aggressive, malignant cancer may not benefit from screening because the cancer has already metastasized before it can be detected. We are learning, in fact, that some cancers may metastasize within the first few cell divisions, too early to be the target of screening.

Category 2: Other people with slower-growing cancers may be highly treatable even after clinical detection. Testicular cancer may be such a tumor; our treatments are highly effective without the need of early detection. People with such cancers do not benefit from screening.

Category 3: Some people may have pseudodisease, cancers that do not need treatment at all. These people either have intermediate lesions that would not progress but are still considered positive tests (e.g., small colonic adenomas) or have cancer that would not cause clinically important problems for the person in his/her lifetime. These are lesions that appear to be cancer but do not act as we think cancer usually acts. These people cannot benefit from early detection of their "cancer."

Category 4: These are people who can benefit from earlier detection. These people have cancers that are potentially lethal but which can be treated more effectively because they were found earlier. In this case, the criterion is met that the treatment must be more effective if applied after screening detection than later, after clinical detection. Usually, this group of true-positive cancers is a minority of all true positives. The randomized controlled trials of breast cancer screening, for example, tell us that less than 20% of potentially lethal breast cancers (categories 1 and 4) belong to group 4.

A problem with this formulation, however, is that many cancers can only be placed in their proper category retrospectively. That is, the people in category 3, who do not need to be detected or treated, are often initially difficult to distinguish from the other groups. Thus, people in this category are still treated. An example is men with prostate cancer

detected by screening. The majority of men with screening-detected prostate cancer have tumors that are moderately differentiated. Some cancers of this type are potentially lethal whereas others will never cause clinical problems. Because it is impossible to distinguish these cancers with high confidence at the time of diagnosis, virtually all men with this type of cancer are treated. This constitutes overdiagnosis, as we are diagnosing some men with cancer who do not need to be diagnosed, and overtreatment, as we are treating some men who do not need treatment.

The fact of overtreatment is undeniable and likely occurs with many cancers. The most important question is how often it occurs. Determining the number of people in category 3 (the primary group that is affected by overtreatment), however, is not simple. One can consider the issue in either of two ways: pathologically or epidemiologically. These different approaches explain much of the debate about the frequency of "clinically important" prostate cancers.

The pathologic approach to determining the frequency of cancers that do not need treatment uses grade and other cellular prognostic characteristics to determine prognosis at the time of diagnosis. People who are at risk of overtreatment have cancers with more benign characteristics. The problem with this approach is that none of the known prognostic characteristics is able to separate benign from malignant cancers with a high degree of accuracy. For example, one population-based study found that from 40% to 70% of men (depending upon age) with localized Gleason score 7 prostate cancer died of prostate cancer within 15 years of diagnosis.¹³ This finding also means that 30% to 60% of men with this type of cancer did not die of prostate cancer in that time. As these men were diagnosed before widespread PSA screening, it is likely that these survival figures would be higher today, independent of any changes in the effectiveness of treatment. Thus, the Gleason score and extent of tumor only give partial information about prognosis, and we are uncertain about whether an individual man will die of prostate cancer.

Another approach is based on the epidemiology of the cancer. This approach examines such issues as the difference between incidence and mortality; trends over time; changes in the effectiveness of treatment; and the lead time produced by the screening test. Using these assumptions with statistical modeling, investigators can calculate an approximation of the proportion of cancers that would not have caused problems during the person's lifetime. The problem with this approach is that it is based on a number of assumptions, at least some of which may be incorrect.

The best way to calculate the percentage of cancers that would never become clinically apparent is an analysis of results from a randomized controlled trial (RCT) of screening, comparing invited and control groups. If the trial screens people in the invited group for several years and then stops screening, the initial increase in incidence usually seen in the invited group compared with the control group should gradually decrease after the end of screening, as the cancers in the control group are detected at a later time. If the cumulative incidence of cancer in the control group never catches up with the invited group, this is evidence of detection by screening (in the invited group) of cancers that would never become clinically apparent. This approach may theoretically underestimate the true frequency of overdiagnosis, however, as it does not count cancers that produce only

minimal symptoms (but symptoms sufficient to be diagnosed) in the overdiagnosis category. Although such cancers do cause some symptoms, they may grow so slowly that they would never progress to important clinical problems within the lifetime of the individual. The extent to which such cancers exist is unknown, but they do not need to be diagnosed early.

Overtreatment causes harm in a number of ways. First, the individual has been labeled as a "cancer patient," with likely important consequences for the person's life. Second, most cancer treatments have some side effects, some of which may be long lasting. Thus, in attempting to gain additional life in the future, people must undergo immediate harm from treatment. Finally, the large number of people being treated leads to an exaggerated view by professionals and the public of the true frequency of the cancer and the effectiveness of treatment.¹⁴ Further, *5-year survival* statistics, which improve as more benign cancers are detected and treated, provide an erroneous overestimate of the efficacy of treatment (15) (see following discussion), and many "cancer survivors" are actually people who had either benign-type cancers (category 2) or pseudodisease (category 3) (see Cancer Survivors, later in this chapter).

The Fallacy of 5-Year Survival in Indicating the Effectiveness of a Screening Program

The 5-year survival rate is frequently cited as evidence for the effectiveness of screening in reducing cancer mortality. Nearly every cancer has a longer 5-year survival for early-stage disease than late-stage disease. It should then follow that finding the cancer at an earlier stage leads to improved outcomes and lower mortality.

Factors other than the effectiveness of screening, however, are important determinants of the 5-year survival rate.¹⁵ As survival is defined as the time from diagnosis to death, it is heavily influenced by early detection, even if death is not postponed. Thus, improved 5-year survival for early-stage cancers could simply reflect the stage at which the cancer is found, with no effect of screening on the natural history of the cancer.

A second problem with the 5-year survival rate as a measure of the effectiveness of screening is related to the heterogeneity of cancers with the same name. Cancers diagnosed at an early stage may be pathologically different from cancers diagnosed at a later stage. Screening may have little to do with the higher 5-year survival rate for early-stage cancers: they would have lower malignant potential regardless of how (or when) they were detected.

Biases in Cancer Screening

Several biases may lead one to believe that screening is effective even in situations where it is not. The first of these is "lead time bias" (Figure 12.3). As shown in the figure, lead time is the time by which earlier detection advances diagnosis. If treatment is ineffective, however ("situation 2" in Figure 12.3), then the patient will die at the same time he/she would have without earlier detection ("situation 1"). The patient's "survival," measured from diagnosis, has been prolonged but the patient has not benefited. Thus, studies that compare survival between people whose cancers were

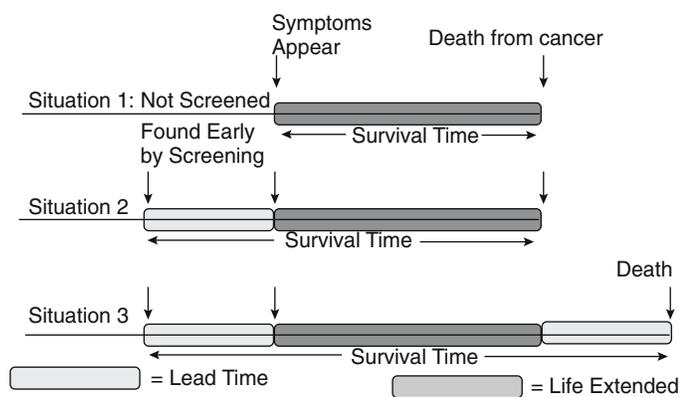

FIGURE 12.3. Lead time bias.

detected by screening with those whose cancer was detected clinically are flawed. The important issue with screening is whether there is a “situation 3,” in which people’s lives have actually been extended. The best study design to avoid this bias is the randomized controlled trial.

A second bias also may cause people to conclude that screening is useful when it is not. This bias, termed “length-biased sampling” (or “length-time bias”), is associated with the heterogeneity of cancer growth rates and malignant potential (Figure 12.4). Patients 1 and 4 in the figure have rapidly progressive tumors that spend relatively little time in the “detectable preclinical phase” area. As a result, these cancers are often missed by screening tests. Patients 2 and 3, however, have slower-growing, less-malignant cancers that are less likely to be fatal. These cancers spend a longer time in the detectable preclinical phase area and thus are more likely to be detected by screening. Thus, length-biased sampling makes us believe that screening is effective because people with screening-detected cancers do better than people with clinically detected cancers. Slower-growing and less-malignant cancers are preferentially detected by screening programs.

Interestingly, patient 4, whose cancer was detected at a later age, does not die of his or her cancer, even though the cancer is faster growing and malignant, because of competing risks: he or she is more likely to die of another cause at this older age. Patient 4 is not helped by screening.

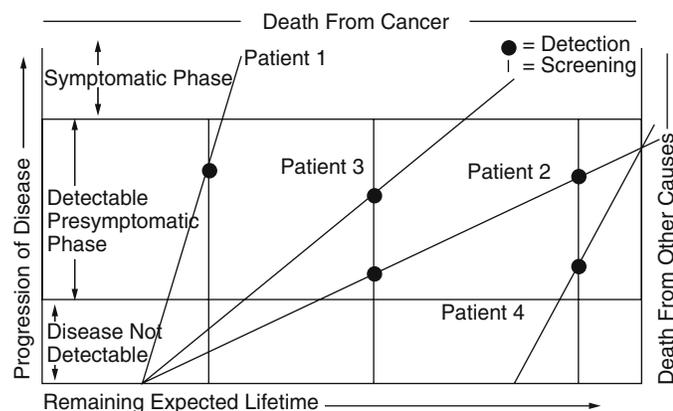

FIGURE 12.4. Length-biased sampling.

Cancer Survivors

The prominence of cancer survivors is a factor in the public’s strong interest in cancer screening. A number of people who appear to have been cured of cancer attribute their well-being to detection of their cancer by screening and resultant early treatment. Their testimony to the power of screening contributes to the public’s perception that cancer screening is a responsibility. However, at least some of these people likely had either an easily treated benign-type cancer (category 2) or pseudodisease (category 3). Neither of these cancers requires earlier detection. Easily treated cancers are slower growing and can be treated as well after clinical detection as after screening detection. Pseudodisease cancers would never have caused important problems and thus do not need treatment at all. Because it is often difficult to distinguish these cancers at diagnosis from more malignant forms, people who do well after treatment tend to attribute their well-being to screening and early detection. Because many of these people choose to have high public visibility, this creates a bias in favor of the public’s view that screening is highly effective in reducing mortality from cancer.

Weighing Benefits and Harms: Decision Making About Screening

Weighing the benefits and harms of screening programs is difficult. First, one must determine the presence and magnitude of the benefits and harms. Benefits seem intuitive, but closer inspection shows that they are easy to overestimate. Evidence about the accuracy or yield of screening tests by itself is inadequate, as is evidence about the effectiveness of treatment in people detected clinically. Etiologic data about trends in mortality over time are open to multiple interpretations. To avoid the strong biases involved, the ideal study design is a randomized controlled trial (RCT) of screening. Even this design, however, is open to criticism, as has been shown by the controversy over the breast cancer screening trials.^{16,17} In the end, the determination of the benefits of screening depends on examining evidence from many sources with different designs, and then considering the relevance of the studies to the community setting.¹⁸ One should consider not only whether there are benefits, but how many people benefit and by how much. Judgment is involved in this complex process.

The same process is involved in determining the harms of screening. This part of the equation is often forgotten: a screening program is justified if, and only if, the benefits outweigh the harms of the program. Even RCTs of screening often do not report on the adverse effects caused by screening.

After determining the magnitude of benefits and harms, decision makers need to consider whether one outweighs the other. A problem is that the benefits and harms are usually in different metrics. Benefits should be stated in terms of the estimated number of lives extended in 1,000 people screened over a given time period. Some have claimed reassurance from negative screening tests as a benefit, but careful examination shows that such reassurance is based on questionable assumptions. The actual reduction in the probability of cancer after a negative cancer screening test is very small. Harms should include the number of people in 1,000 screened with false-positive tests, people who are referred for workups

and may suffer psychologic distress. Ideally, one should also estimate the number of people who were overtreated and the consequences of overtreatment.

Weighing the (usually) small number of lives extended against the larger number of people with various types of harms requires a value judgment. What value is placed on the experience of the people suffering harms and what value is placed on the people whose lives are extended? Currently, our culture seems to have decided that even a small number of lives extended by cancer screening outweighs a larger number of people having problems with false positives and overtreatment. It is not clear whether this concept will change as the public becomes more aware of the magnitude of the benefits and harms from cancer screening.

For many cancer screening decisions, some have suggested that the people undergoing the screening should be informed of the potential harms as well as the potential benefits and should be involved in the decision.¹⁹ This approach is called shared decision making (SDM). Research is currently exploring ways of making SDM more feasible and effective in the clinical setting, using decision aids and other decision support resources.

The benefits and harms of cancer screening usually vary by age. The incidence and mortality of most cancers usually associated with screening increase with age. If screening leads to a constant relative reduction in mortality risk, then the absolute reduction in risk (i.e., mortality benefit) increases with age. Thus, younger people with a low probability of having cancer may receive few benefits and expose themselves to important harms by having screening. For example, women in their forties probably receive some benefit from mammography screening for breast cancer, but the magnitude of benefit is small. These women do, however, have a higher probability of having a false-positive mammogram. Given this information, some women will choose to have mammography in their forties and some will not. The age at which the benefits of screening overcome the harms depends on personal values. In general, however, screening is not offered to people at a younger age who have a very low probability of having cancer.

In considering an upper age limit for screening, it is important to remember that any life extension from screening does not occur immediately after screening but rather some years in the future. Thus, to realize the benefit from screening one must live a certain period into the future. As people age, however, the risk of dying of a cause other than cancer increases. Some older people, then, do not live long enough to benefit from screening. Clearly, people with a limited life expectancy have little to gain from screening.

The harms of screening may or may not vary by age. In some cases (e.g., mammography), the screening test may yield fewer false positives in older people, thus decreasing the harms of this finding. In other cases (e.g., PSA for prostate cancer), the screening test may yield more false positives and thus potentially increase the probability of harms. Harms should be carefully considered in every screening decision; the weight they are given by the patient may vary by age. Interventions to reduce psychologic harms by educating people about false positives before screening may be useful but need more research.

An important decision for people who have decided to be screened is the frequency of repeat screening. It is unusual to

have RCT evidence about the relative benefits and harms of various screening intervals. More commonly, we reason about this issue with indirect evidence, including our understanding of the natural history of the cancer and measurements of cancer incidence in people who have waited different times to be rescreened.

In general, cancer detection is greatest with the first screening round, the so-called prevalence screen, because there are more asymptomatic cancers to be detected initially than on later screening rounds. Cancers detected in a previous round of screening have been removed from the pool of remaining asymptomatic cancers. Thus, a short screening interval will likely find fewer cancers than a longer interval. The longer the interval, the closer cancer detection will revert to the initial round.

The balance of benefits and harms from various screening intervals is more complex. A shorter screening interval usually means increased sensitivity, but specificity may be reduced. In deciding the most appropriate screening interval, one must consider the trade-offs between finding all appropriate cancers (i.e., increased sensitivity) and increasing the rate of harms related to false positives.

The value of cancer screening after previously negative screening tests is uncertain and needs further study. It is possible that various results from previous screening tests (e.g., men with very low PSA values or women with benign types of parenchymal findings on a mammogram) may be markers of people at decreased risk of developing cancer. These markers may help us define a group of people who do not need further screening, thus allowing us to target screening to people who have the greatest possibility of benefit. If by defining a low-risk population (rather than a high-risk population) we could reduce the number of people requiring screening (thus reducing costs and potential false positives and overtreatment), the balance between the benefits and harms of screening could be improved.

The Costs and Cost-Effectiveness of Screening

Even after gathering the evidence about the benefits and harms of screening, policy makers must still ask the question of whether the net benefits are worth the costs and resource utilization. It may be, for example, that annual abdominal computed tomography (CT) scans detect unsuspected cancers of several types and even sometimes extend a life. But the costs of such a strategy (leaving aside the likely harms for the large number of false positives) may be prohibitive. In other words, the benefits may not be worth the cost.

Opportunity costs are also important. That is, if clinicians spend large amounts of time discussing cancer screening that has little probability of benefit, this may take away from time that could be used, for example, to counsel people about stopping tobacco use, or spending more time on SDM for potentially beneficial cancer screening.

Cancer Screening Examples

To illustrate these principles, we have included examples of screening from four different cancers (cervical, prostate, breast, and colorectal) among those most commonly consid-

ered for screening. In each case, there is the clear potential for benefits and harms. In each case, the benefits are not large in an absolute sense, whereas the harms are not inconsequential. Rational people may decide to have or not to have screening for these cancers based on the same understanding of the evidence. It is important for the public to come to a better understanding of the potential benefits and harms of cancer screening.

Example of Cervical Cancer Screening

INCIDENCE AND MORTALITY

In 2004, an estimated 10,520 new cases of and 3,900 deaths from invasive cervical cancer were expected.²⁰ In 2000, the age-adjusted incidence rate in nine Surveillance, Epidemiology, and End Results Program (SEER) registries was 8 per 100,000 women; the age-adjusted mortality rate was 3 per 100,000.²¹ From 1950 to 1970, the incidence and mortality rates of invasive cervical cancer fell impressively by more than 70%. From 1970 to 2000, the rates continued to decrease by more than 40%.²² This trend has been attributed largely to screening with the Papanicolaou (Pap) test.

SCREENING TESTS

The Pap test, the standard screening test for cervical cancer, has never been studied in an RCT. A large body of consistent observational data, however, supports its effectiveness in reducing mortality from cervical cancer. Both incidence and mortality from cervical cancer have sharply decreased in a number of large populations following the introduction of well-run screening programs.^{23–26} Reductions in cervical cancer incidence and mortality were proportional to the intensity of screening.^{22,27}

Case-control studies have found that the risk of developing invasive cervical cancer is 3 to 10 times greater in women who have not been screened.^{28–32} Risk also increases with longer duration following the last normal Pap test, or similarly, with decreasing frequency of screening.^{33,34} Screening every 2 to 3 years, however, has not been found to increase significantly the risk of finding invasive cervical cancer above the risk expected with annual screening.^{34,35}

The precise sensitivity and specificity of Pap tests has been difficult to determine because of the methodological limitations of studies.³⁶ Studies that compare the Pap test with repeat Pap testing have found that the sensitivity of any abnormality on a single test for detecting high-grade lesions is 55% to 80%.^{7,8} Because of the usual slow-growing nature of cervical cancer, the sensitivity of a program of regular Pap testing is likely higher.

Specificity of the Pap test is probably above 90%; it seldom categorizes a woman without any degree of cervical intraepithelial neoplasia (CIN) as having anything more than a mild cytologic abnormality. Specificity is lower, however, for women with mild, clinically unimportant degrees of dysplasia, who are often categorized as having cytologic abnormalities that require further testing and even treatment. Women with such cytologic findings as atypical squamous cells of undetermined significance (ASCUS) are often shown on further evaluation to have neither severe dysplasia nor invasive cancer. If these women are counted

as false positives, then specificity will be calculated as lower.⁷

Newer techniques that employ liquid-based cytology (e.g., ThinPrep) have been developed to improve the sensitivity of screening. As with the Pap test, the optimal studies to determine the sensitivity and specificity of these technologies have not been done. Some less than optimal studies show that sensitivity is modestly higher for detecting any degree of CIN, with modestly lower specificity.^{37,38} One careful study, however, showed that conventional Pap testing was slightly more sensitive and specific than liquid-based cytology.³⁹

The evidence is also mixed about whether liquid-based techniques improve rates of test adequacy.^{37,38} One advantage of liquid-based cytology is that human papillomavirus (HPV) testing can be done on the same preparation; one disadvantage is that liquid-based approaches are more expensive than conventional Pap testing. No study has examined whether liquid-based cytology actually reduces the number of women dying of cervical cancer compared with conventional Pap testing.

RATIONALE FOR SCREENING

Invasive squamous carcinoma of the cervix results from the progression of preinvasive precursor lesions called cervical intraepithelial neoplasia (CIN), or dysplasia. Not all these lesions progress to invasive cancer; many mild and moderate lesions regress. The rate at which invasive cancer develops from CIN is usually slow, measured in years and perhaps decades.⁴⁰ This long natural history provides the opportunity for screening to effectively detect this process during the preinvasive phase, thus allowing early treatment and cure. Because many of these preinvasive lesions (especially low-grade lesions) would have never progressed to invasive cancer,^{41–43} screening also runs the risk of leading to treatment of women who do not need to be treated. This approach leads to harms of screening by overtreatment.

The leading etiologic factor in the development of preinvasive and invasive cervical cancer is infection with specific types of HPV transmitted by sexual contact. Thus, women who are not sexually active rarely develop cervical cancer, whereas sexual activity at an early age with multiple sexual partners is a strong risk factor. About 95% of women with invasive cervical cancer have evidence of HPV infection.^{44–47} Many women with HPV infection, however, never develop cervical cancer; thus, this infection is necessary but not sufficient for the development of cancer.⁴⁸

HARMS OF SCREENING

The major potential harm of screening for cervical cancer lies in the detection of many lesions [such as most cases of low-grade squamous intraepithelial lesions (LSIL)] that would never progress to cervical cancer. Women with abnormal LSIL or high-grade squamous intraepithelial lesions (HSIL) on Pap testing are usually referred for colposcopy and treated with cryotherapy or loop electrosurgical excision procedure (LEEP), which permanently alters the cervix and has unknown fertility and pregnancy consequences. As younger women have the highest incidence of acquisition of HPV and LSIL, they are disproportionately at risk of receiving intervention for a condition that often spontaneously resolves.

The cost of newer screening methods is also problematic. A cost-effectiveness analysis found little effect on life expectancy with the new technologies when used for annual screening.⁴⁹ They may be more cost-effective when used on a less frequent (e.g., every 3 years) basis.

BALANCE OF BENEFITS AND HARMS

Based on an analysis of screening records from nearly 350,000 women in Bristol, England, investigators projected that 1,000 women would need to be screened for cervical cancer for 35 years to prevent 1 death from the disease.⁵⁰ For each death prevented, the authors estimated that more than 150 women have an abnormal result, more than 80 are referred for investigation, and more than 50 receive treatment.

Annually in the United States, 50 million women undergo screening; about 3.5 million (7%) will be referred for further evaluation. Of these, more than 2 million will be referred for further evaluation of atypical squamous cells of undetermined significance (ASCUS).⁵¹ Fewer than 11,000 cases of invasive cervical cancer were expected in 2004. Thus, Pap test screening results in a large number of colposcopies for benign conditions. Strategies to improve the specificity of the cervical cytopathology test are being evaluated by the ASCUS/LSIL Triage Study (ALTS).⁵² Improved specificity, even at the cost of sensitivity, will likely improve the balance between benefits and harms, given the large burden of false positives, abnormalities that do not represent risk for invasive cancer or death.

Improved cervical cancer screening practices may also favor a more positive benefit-to-harm balance. Such practices include not screening women who have had hysterectomies (with removal of the cervix) for benign disease. More than one-third of U.S. women have had hysterectomies by age 65, more than 90% of which are done for noncancer indications.⁵³ These women rarely have important abnormalities on Pap testing.^{54,55} In addition, continued Pap test screening for women over age 65 who previously have had regular cervical cancer screening with normal test results provides little benefit. The risk of cervical cancer and yield of screening decline steadily through middle age.⁵⁶ The majority of older women who are found to have invasive cervical cancer have not been screened recently, if at all.⁵³ Thus, the focus of cervical cancer screening practices should be on finding and screening women at increased risk because of inadequate past screening rather than continuing to screen women at low risk.

Example of Prostate Cancer Screening

INCIDENCE AND MORTALITY

The American Cancer Society estimated that, in 2004, 230,110 men would be diagnosed with prostate cancer; 29,900 men would die of this disease.²⁰ The age-adjusted prostate cancer incidence in nine Surveillance, Epidemiology, and End Results (SEER) registries between 1996 and 2000 was about 173 per 100,000 men.²¹ The mortality during that period was about 33 per 100,000 men. The probability at birth of being diagnosed with prostate cancer by age 80 is about 14%; the probability at birth of dying of this disease by age 80 is about 1.26%.²² The difference between prostate cancer incidence

and mortality is one of largest for any cancer; this difference increased greatly after PSA screening became widespread. This is a strong indication that at least some prostate cancers now detected by screening would never become clinically important.

The incidence of prostate cancer increased dramatically after the beginning of PSA screening in the late 1980s and then stabilized in the later 1990s. Mortality from prostate cancer decreased after about 1992, a total reduction of about 20% by 2000. Screening is one of several possible interpretations of this reduction in mortality.⁵⁷

SCREENING TESTS

The two most common screening tests for prostate cancer are prostate-specific antigen (PSA) and digital rectal exam (DRE). No well-conducted RCT of prostate cancer screening has been completed; two large studies are under way.

Because of the uncertainty about which prostate cancers are clinically important, the sensitivity and specificity of screening is difficult to determine. DRE detects fewer cancers than PSA. Various approaches have been suggested for increasing the sensitivity and specificity of screening, but whether these approaches improve detection of clinically important cancers and reduce detection of unimportant cancers is unknown.⁵⁸

RATIONALE FOR SCREENING

Because of the absence of clear evidence that screening reduces mortality from prostate cancer, the rationale for screening is not established. However, many men are still being screened.⁵⁹ Many believe that the ecologic evidence (showing a reduction in mortality after the start of PSA screening) justifies screening; others find that screening has a strong intuitive appeal.

A single well-conducted RCT compared radical prostatectomy and watchful waiting in men with clinically detected prostate cancer.⁶⁰ After 8 years, fewer men in the prostatectomy group had died of prostate cancer [13.6% versus 7.1%; absolute difference, 6.6% (2.1%–11.1%)]. The groups did not differ in all-cause mortality. As the cancers in this study were more advanced than those usually detected by screening PSA, this study does not provide adequate evidence about the effectiveness of screening.

HARMS OF SCREENING

Two major sources of the harms of prostate cancer screening are false positives and overdiagnosis and overtreatment. False-positive tests are common. On the initial screening round, from 5% to 27% of men (depending on age) have a PSA greater than 4.0 (the traditional cut-point); about 30% of these men will have prostate cancer diagnosed by biopsy.⁵⁷ A problem for men with a negative biopsy is that biopsies often miss some prostate cancers; thus, even a negative biopsy does not assure a man that he does not have cancer,⁶¹ and this uncertainty could increase anxiety.

The frequency of overdiagnosis and overtreatment of prostate cancer caused by screening is uncertain. Surveillance data show a large increase in the number of new cases of prostate cancer, with only a small absolute reduction in mortality, after the introduction of PSA screening in the late 1980s.

If, as seems likely, most of the new cases detected would never have been fatal, then more than half of screening-detected prostate cancers do not require major treatment.

Although a small percentage of prostate cancers have histologic characteristics that reliably predict either a very small or a very large malignant potential, most prostate cancers have intermediate histology, leaving us uncertain about the likely prognosis. Because of the inability to determine prognosis from clinical and histologic data, most men under age 70 years receive aggressive treatment: either radical prostatectomy or radiation therapy. These treatments have important adverse effects, including impotence and incontinence, for some 50% of men being treated.⁵⁷ Thus, if there are a substantial number of men who do not need treatment but receive it, many of them will be harmed unnecessarily. The exact magnitude of this problem is uncertain, but it may be quite large.

BALANCE OF BENEFITS AND HARMS

For screening for prostate cancer, the benefits are not clear whereas the harms are very clear. Thus, the net balance between the two is currently impossible to determine. Given this information, some men will choose to have screening while others will choose not to be screened. Several professional associations and expert groups recommend shared decision making (SDM), informing men of the pros and cons of screening and encouraging them to participate in the decision about whether to be screened.⁶²⁻⁶⁷

Example of Breast Cancer Screening

INCIDENCE AND MORTALITY

The American Cancer Society estimated that, in 2004, 215,990 women would be newly diagnosed with breast cancer; 40,110 would die of this disease.²⁰ About 59,390 women will be diagnosed with carcinoma in situ of the breast, primarily by mammography.²⁰ From 1996 to 2000, the age-adjusted incidence in nine Surveillance, Epidemiology, and End Results (SEER) registries was about 137 per 100,000 women; the age-adjusted mortality during this period was about 28 per 100,000.²¹ The probability at birth of being diagnosed with breast cancer in 80 years of life is about 11%; the probability at birth of dying of breast cancer by age 80 is about 2%.²¹ Breast cancer incidence for all women increased from 1980 to 2000, although the increase slowed considerably in the late 1990s. Between 1990 and 2000, breast cancer mortality for all women decreased by about 2.3% per year.^{22,68} The reasons for this decrease are not clear and may be due to a combination of screening and improved treatment.⁶⁹

SCREENING TESTS

Three primary tests are currently in use for breast cancer screening. Although still controversial, the overall evidence shows that mammography results in a reduction in breast cancer mortality by less than 20%.⁶ Indirect evidence suggests that clinical breast examination (CBE), when well conducted, may also lead to a small reduction in mortality, but uncertainty about this remains.^{70,71} Breast self-examination (BSE) has been shown in a large RCT to be ineffective in reducing mortality.⁷²

The accuracy of mammography depends on a number of factors. One large prospective cohort study of 329,495 women of ages 40 to 89 years from seven population-based mammography registries found sensitivity ranged from 62.9% in women with dense breasts to 87% in women with fatty breasts. Specificity ranged from 89.1% in women with dense breasts to 96.9% in women with fatty breasts.⁷³

The accuracy of mammography varies among radiologists and among countries.⁷⁴⁻⁷⁸ In general, North American radiologists tend to interpret a higher percentage of mammograms as positive than radiologists in other countries, without evident additional benefit. In one study of community radiologists in New England, false-positive rates ranged from 2.6% to 15.9%.⁷⁶ The accuracy of CBE also varies widely among clinicians.⁷⁹

Newer approaches to breast cancer screening are being studied, targeted especially to increasing sensitivity.⁸⁰ Interestingly, although earlier mammography from the 1970s and 1980s was certainly less sensitive than present-day mammography, the Health Insurance Project (HIP) study from this era found a similar reduction in breast cancer mortality as more recent studies.^{81,82} Thus, it is not clear whether increasing sensitivity will provide additional reduction in breast cancer mortality.

RATIONALE FOR SCREENING

The primary rationale for screening comes from the RCTs of screening that have been conducted over the past 30 years.^{17,83} Although the overall evidence suggests that breast cancer mortality is reduced by mammographic screening, the reduction is less than 20%⁶; this means that 80% of the women who have potentially fatal cancers are not helped by screening and earlier treatment. Clearly, some breast cancers are aggressive and metastasize before they can be detected by mammography. Some, however, respond better to earlier treatment than to later, thus reducing mortality.

Given the relatively low reduction in mortality from breast cancer from screening, the absolute number of women whose lives would be extended is small. From one to two women in their forties and from two to six women in their fifties and sixties would have their lives extended by screening annually for 10 years.⁸⁴

HARMS OF SCREENING

The two major potential harms of screening for breast cancer are false-positive tests and overtreatment of ductal carcinoma in situ (DCIS). One study estimated that 49% of women would have at least one false-positive mammogram after 10 rounds of screening; almost 19% would undergo a biopsy as a result of the false positive.¹² False-positive mammograms sometimes lead to a recommendation of a short-interval follow-up (e.g., 6 months rather than a year), despite the evidence that such a policy rarely leads to increased cancer detection.⁸⁵ False-positive mammograms do lead to increased anxiety, both in the short run and after 6 to 12 months, for some women.^{10,86}

Ductal carcinoma in situ (DCIS) is a heterogeneous intermediate lesion with an uncertain prognosis. This lesion was rare before screening mammography but has increased dramatically as the number of women undergoing mammograms has increased. About 1 in 1300 mammograms detects DCIS;

from 16% to 28% of all breast “cancers” are DCIS.⁸⁷ Probably less than 50% of untreated women with DCIS ever develop invasive breast cancer.⁸⁸⁻⁹⁰ Treatment is often surgical; some women have mastectomy whereas others have breast conservation surgery. Few women treated for DCIS eventually die of breast cancer.⁹¹

Because DCIS is so common (an estimated 59,000 cases in 2004)¹ and because its prognosis is so uncertain, many women undergo unnecessary surgery because of its diagnosis. This is an important area of overtreatment. One modeling study found that detection of DCIS plays a minor role in the reduction in breast cancer mortality from screening.⁹²

BALANCE OF BENEFITS AND HARMS

Screening for breast cancer is an important example of the trade-offs involved in the decision to be screened. On the one hand, screening likely does extend some women's lives. On the other hand, screening also leads to many women having workups for false-positive screening tests, and other women having treatment for DCIS, a lesion that would never develop into invasive breast cancer for many women. It is important for women to understand these trade-offs; women should be offered the opportunity to participate in the decision about screening.

Improving screening programs should seek not only to improve sensitivity. Improved sensitivity may or may not further reduce mortality. Improved specificity should also be a priority. If the number of women with false-positive tests can be reduced, potential harms could be decreased, thus improving the balance between benefits and harms.

Another way of improving breast cancer screening programs would involve finding ways of determining which women with DCIS are truly at risk of invasive cancer, allowing some women to avoid unnecessary surgery.

Example of Colorectal Cancer Screening

INCIDENCE AND MORTALITY

In 2004, an estimated 146,940 new cases of and 56,730 deaths from colon and rectal cancers were expected.²⁰ Colorectal cancer (CRC) is the third leading cause of new cancer cases (11% of all new cases) and cancer deaths (10% of all cancer deaths) in both men and women.²⁰ In 2000, the age-adjusted incidence rate in nine Surveillance, Epidemiology, and End Results Program (SEER) registries was 55 per 100,000; the age-adjusted mortality rate was 21 per 100,000.²¹ The lifetime risk from birth of being diagnosed with CRC is about 6%; the lifetime risk of dying from CRC is about 2%. Thus, about 1 in 3 people who develop CRC die of this disease. Between 1992 and 2001, mortality from CRC declined by 1.8% per year⁹³ and incidence declined by 0.8% annually in the United States.⁹⁴ The early detection and removal of precancerous colorectal polyps may have contributed to the decline in CRC incidence and mortality.⁹⁵

SCREENING TESTS

The major screening tests currently available for CRC screening are the fecal occult blood test, sigmoidoscopy, colonoscopy, and double-contrast barium enema. These tests are used to identify precancerous or cancerous lesions in the colon and rectum. No one screening strategy has been shown

to be superior to the others, although they differ in regard to accuracy, effectiveness, and potential harms.

Fecal occult blood testing (FOBT) has been examined in three RCTs involving more than 250,000 people followed for up to 18 years.^{96,97} All three trials found a reduction in CRC mortality from 15% to 33%, with an absolute risk reduction for CRC deaths ranging from 0.8 per 1000 with biennial screening in the United Kingdom over 8 years of follow-up⁹⁸ to 4.6 per 1000 with annual screening in Minnesota during 18 years of follow-up.⁹⁹ The Minnesota study also noted a 17% to 20% decrease in incidence of CRC.⁹⁹ The sensitivity of a single test is approximately 30% to 50%, with a specificity of 90% to 98%, depending on how the test is done. Fecal occult blood tests find about 25% to 50% of patients with colorectal cancer, but only 2% of patients with a positive test had cancer in the Minnesota trial.

The effectiveness of sigmoidoscopy to reduce CRC deaths has been examined in three well-designed case-control studies.¹⁰⁰⁻¹⁰² These studies showed a mortality reduction of 60% to 80%.⁹⁷ In a small, randomized trial of sigmoidoscopy, in which persons with polyps were followed up with colonoscopy, the incidence of colorectal cancer was decreased by 80% but no decrease in mortality was found.¹⁰³ Using full examination of the colon as the “gold standard,” sigmoidoscopy has been found to identify 70% to 80% of patients with advanced adenomas or cancer.^{104,105} The sensitivity and specificity of sigmoidoscopy are difficult to determine, because all visible polyps are typically removed, many of which may have little to no malignant potential.

The ability of screening colonoscopy to reduce colorectal cancer morbidity or mortality has not been directly studied to date. Data from studies of other modalities have been extrapolated to support the effectiveness of colonoscopy. Because it is often used as the gold standard, determining its sensitivity and specificity has been difficult. A recent study by Pickhardt et al., comparing optical colonoscopy with CT virtual colonoscopy,¹⁰⁶ in which 1,233 patients underwent both procedures, found the sensitivity of optical colonoscopy for adenomatous polyps to be 88% to 92%, depending on the size of the polyps. As with sigmoidoscopy, the natural history of many polyps found on colonoscopic examination is not known; thus, the potential for identifying false positives must be considered.

No screening studies of double-contrast barium enema with a mortality outcome have been published; thus, the accuracy and effectiveness of this procedure are unknown.⁹⁶ Its sensitivity is likely lower than that of endoscopic procedures, but if it misses primarily polyps that are small and not likely to progress to invasive cancer, its effectiveness for screening may be adequate.

RATIONALE FOR SCREENING

A variety of different types of polyps occur in the colon and rectum. Hyperplastic polyps are the most common of those that have little potential for becoming malignant. They cannot be distinguished visually from adenomatous polyps, so biopsy is required for diagnosis. Whether the presence of distal hyperplastic polyps increases the risk of proximal neoplastic polyps is uncertain.¹⁰⁷ A systematic review of 18 studies¹⁰⁸ estimated a 21% to 25% risk for any proximal neoplasia in patients with a distal hyperplastic polyp, includ-

ing a 4% to 5% risk of an advanced neoplasm (cancer or polyp with severe dysplasia or villous histology). In 4 of the studies in which colonoscopy was performed regardless of distal findings, however, the relative risk of finding any proximal neoplasia was 1.3 (95% confidence interval, 0.9–1.8).

Two-thirds of all colonic polyps are adenomatous, which are defined as dysplastic and thus have malignant potential. Most colorectal cancers arise from adenomatous polyps. Some proportion of these grow from small (less than 5 mm) to large (greater than 1.0 cm) to cancer, generally over a period of 10 years or longer. The proportion that makes this transition is thought to be small; adenomatous polyps occur in 30% to 40% of adults over the age of 50, but the risk of developing colorectal cancer is only about 6%.¹⁰⁷ However, removal of adenomatous polyps is associated with a reduced risk of colorectal cancer incidence and mortality.

HARMS OF SCREENING

The harms of screening for colorectal cancer include the risk of the screening tests themselves, the risks of the subsequent workup from positive screening tests, the potential for false-negative screening results, and the potential for overdiagnosis and treatment of lesions that would not have become malignant over the person's lifetime. No direct adverse effects of FOBT exist (other than the inconvenience and some patients' distaste for performing the test). Both sigmoidoscopy and colonoscopy are associated with low risks for major complications, including bleeding and perforation of the colon during the examination. A large population-based study of Medicare beneficiaries aged 65 and older found perforation rates of nearly 1 per 1,000 for sigmoidoscopy and 2 per 1,000 for colonoscopy.¹⁰⁹ The risk of death following colonic perforation was 52 to 65 per 1,000 perforations.

Fecal occult blood tests may miss small adenomas, as these lesions frequently do not bleed. Whether that represents a true negative or a false negative is uncertain, as these small adenomas may not be likely to develop into neoplastic lesions. Even though some consider colonoscopy to be the optimal examination of the colon and rectum for detection of precancerous and cancerous lesions, studies have shown that significant lesions (i.e., those larger than 1 cm) may be missed. The Pickhardt study comparing virtual with optical colonoscopy found that virtual colonoscopy missed 5 of 59 advanced neoplasms (defined as adenomatous polyps 10 mm or more in diameter or demonstrating high-grade dysplasia, villous changes, or cancer) and optical colonoscopy missed 7 of the 59 lesions.¹⁰⁶

The risk of overdiagnosis and treatment of lesions that do not have long-term malignant potential (false-positive lesions) is more difficult to quantify. Most adenomas (60%–75%) are smaller than 1 cm on endoscopic examination.¹⁰⁷ The risk for high-grade dysplasia increases from 1% in small adenomas (less than 5 mm) to 6% for medium-sized adenomas (5–10 mm) to 21% for large adenomas (greater than 1 cm).¹⁰⁷

BALANCE OF BENEFITS AND HARMS

In a recent study of a screening colonoscopy program at a work site,¹¹⁰ the authors created a clinical index to stratify risk for advanced proximal neoplasia (defined as an adenoma 1 cm or larger or one with villous histology, severe dysplasia,

or cancer) and to identify a subgroup at low risk for whom screening sigmoidoscopy alone might be sufficient. Scores were based on age, sex, and distal findings. In the validation arm of the study, the 47% of the cohort determined to be in the low-risk subgroup had a risk for advanced proximal neoplasia of 0.4%. Use of the index in this population identified 92% of persons with advanced proximal neoplasia. The number needed to screen (NNS) to detect advanced proximal neoplasia among patients with any distal polyp was 16 and, among everyone, the NNS was 36. The NNS to extend one life from colorectal cancer mortality was not calculated and would be higher.

Colorectal cancer screening reduces death from colorectal cancer and decreases the incidence of invasive cancer by finding and removing adenomatous polyps. These benefits of screening, however, are tempered somewhat by the effort involved, the harms of the screening procedures themselves, and the possibility of overdiagnosis and overtreatment of small lesions with low malignant potential. As tests with greater sensitivity are developed, the risk of overdiagnosis increases.

Patient Decision Making

Peter A. Ubel

- A 73-year-old man requests a prostate-specific antigen (PSA) test from his primary care physician, but the physician does not believe the test is in the patient's best interest.
- A woman with metastatic colon cancer has continued to progress on standard therapy. She asks her oncologist whether she should enter a Phase I trial or, instead, enter a hospice program.
- A woman with a strong family history of breast cancer, and a BRCA-1 mutation, asks her genetic counselor to explain the pros and cons of a prophylactic mastectomy.
- A 55-year-old man with myelodysplasia comes to a cancer referral center to see whether they think a bone marrow transplant is feasible in someone his age.

Patients interact with a wide range of clinicians, seeking help in deciding how to prevent, detect, or treat cancer. Many of these decisions are difficult—sometimes because there is not great evidence about the risks and benefits of specific healthcare interventions, such as the role of PSA testing in preventing mortality and morbidity from prostate cancer; sometimes because the evidence, although solid, is so complex that it is difficult for patients to process the information in the time they have to make a decision; and oftentimes, because the decisions involve difficult value judgments, in which there is no right or wrong decision for all patients, because the best choice varies depending on patient preferences.

How should clinicians handle these difficult situations? When should they make clinical recommendations and when should they let patients decide what is best? How can they explain uncertainty to patients in ways that they can understand? Or should they even bother to do so?

A Paradigm Shift: Involving Patients in Healthcare Decisions

A generation ago, clinicians did not struggle with these questions, because patients played a limited role in their healthcare decisions. For example, a 1961 survey revealed that the majority of patients undergoing cancer treatments did not know that they had cancer; their oncologists withheld such information because of fear that patients could not emotionally handle it.¹ Many physicians did not discuss treatment alternatives with patients, because they, the physicians, would be making the decisions. For example, it was not

uncommon for a woman to wake up from a breast biopsy procedure to learn not only that she had breast cancer but that the surgeon had gone ahead and performed a mastectomy.²

A paradigm shift has occurred over the past several decades. Most physicians now recognize that patients deserve information about their health, and few think it is appropriate to withhold cancer diagnosis from patients, except in the most extreme circumstances.¹ This shift was spurred on in part by the legal community, who encouraged patients to sue physicians for not informing them about their treatment alternatives; by the growth of the bioethics movement and its emphasis on patient autonomy; and by larger societal changes, with consumer groups and community organizations becoming more involved in decision making that was previously left to experts.

Accompanying this shift has been a change in clinicians' attitudes. Many clinicians now recognize that healthcare decisions often involve trade-offs that require value judgments. For example, oncology trials used to measure survival rates while paying little attention to quality of life issues. As the science of quality of life measurement matured, however, such measures have been incorporated into the vast majority of trials, thereby providing important information to guide oncologic decision making. But at the same time, quality of life information has made these decisions more complex. In the past, a study might simply have shown that the median survival for chemotherapy A was 3 months greater than chemotherapy B, making the decision about which chemotherapy to choose relatively straightforward. Now, however, a trial might show that chemotherapy A, although leading to longer survival, also leads to a lower quality of life. Now, the *best* choice depends on patients' preferences for longevity versus quality of life.³

Many clinical decisions are not purely scientific matters, but also involve value judgments that vary from person to person. For example, the right choice, for a patient choosing between surgical and radiation treatment of his prostate cancer, depends on how much he thinks he would be bothered by surgical complications such as impotence or incontinence and on how important he feels it is to have the cancer physically removed from his body. Similarly, whether a woman should begin receiving annual mammography at age 40 or 50 depends on how she feels about the inconvenience and discomfort of mammography, the financial costs of screening, the consequences of false-positive testing, and the benefits of receiving more aggressive screening.

Patients deserve a role in medical decisions, not only because those decisions often hinge on patients' values but also because higher levels of patient involvement in health-care decision making leads to better health outcomes. Patients who are more involved in decisions about their care are more likely to adhere to their treatment regimens, to report higher levels of satisfaction with medical care, and to have better functional and clinical outcomes.⁴⁻⁷ For example, a randomized trial demonstrated that a brief intervention to increase patient involvement in medical decision making among diabetic patients significantly lowered their HgbA1C levels.⁸

Clinicians used to leave patients in the dark about their healthcare decisions. Those days are long gone. Part of the art of medicine now includes knowing how and when to involve patients in healthcare decisions.

How to Involve Patients in Healthcare Decisions

It is one thing to recognize that choices between healthcare interventions often hinge on patients' values and quite another to find a practical and useful way to involve patients in their healthcare decisions. So how can physicians go about doing this?

Clinicians could simply play the role of information providers, giving patients all the information (ideally in a comprehensible manner) that patients need to make their decisions. Genetic counselors often take this approach, seeing their role as educators but not advisors. They help patients understand information, but believe it is beyond their purview to make clinical recommendations. The decision, they believe, is up to the patient. Alternatively, clinicians could give patients information in conjunction with a clinical recommendation, involving patients in decisions by giving them the final say, but guiding them with their recommendations.

More often, physicians reside somewhere between those extremes. Across physicians, then, there is a continuum of decision-making styles, with some physicians leaving decisions completely up to patients, with others sharing decision-making authority with patients, and with yet others taking the decision-making role on themselves by making strong clinical recommendations to their patients. Although the use of some level of participatory decision making has been correlated with higher levels of patient satisfaction and better clinical outcomes, there is little empirical evidence about differences in outcomes across the continuum of participatory decision making.⁹ Many physicians benefit from tailoring their decision-making style to the individual patient and the specific clinical context.

As do physicians, patients vary in their decision-making styles. Some patients prefer to completely defer decisions to their physician. Others see themselves as the primary decision maker and do not want physicians to give them a recommendation. Many patients want to share decision-making roles with their clinicians.¹⁰⁻¹³

Moreover, a given patient's decision-making style varies depending on the clinical situation. When situations are more complex and alternatives do not create value-laden trade-offs, patients often want physicians to play a more significant role

in making decisions.^{14,15} For example, oncology patients being evaluated for possible pulmonary embolisms would rarely feel any need to discuss the relative merits of Doppler testing versus *d*-dimer testing.¹⁶ These kinds of decisions are seen as medical decisions that require a clinician's training to make and which do not lead to the kinds of trade-offs that require patients to be heavily involved in the decision. Other decisions are less clinically complex and involve important trade-offs, such as those described previously between quality of life and quantity of life. In these cases, more patients express an interest in being involved in the decision. For similar reasons, patients express more interest in being involved in decisions for nonacute conditions than emergent ones.

Clinicians should not be expected to know how likely the average patient would be to desire a specific decision-making role in every clinical context they encounter. There would be little reason, in other words, for clinicians to remember that 13% of patients want a physician's recommendation in one specific clinical context whereas 53% want one in another context. As interesting as these statistics are, they are not relevant to the one-on-one decisions that clinicians and patients make. Rather than familiarize themselves with these statistics, clinicians should find out whether *this* patient wants to be involved in *this* decision. And that is best handled by talking with the patient. Such conversations are crucial, because clinicians typically underestimate how involved cancer patients want to be in their decisions.^{17,18}

Although there is significant variance, across patients and across situations, in how involved patients want to be in their healthcare decisions, one desire is almost universal: patients want to be thoroughly informed about their treatment alternatives, even when they want their clinicians to decide what alternative they should take.^{10,19,20} This situation, then, creates another challenge for clinicians, that is, providing their patients with comprehensible information about their healthcare alternatives to help them make good decisions.

Challenges to Helping Patients Make Good Decisions

Emotion

Many physicians fear that patients are so overwhelmed by the emotional content of their situations that they are unable to truly comprehend their medical alternatives. For example, patients often experience strong emotions when they receive cancer diagnoses. Extreme emotions can interfere with good decision making. Patients with terminal metastatic cancers may be so afraid of dying that they grasp at nonexistent straws. Elderly patients with localized prostate cancer may be so distressed at the thought of cancer cells residing in their bodies that they will not even consider watchful waiting.

Clinicians should recognize, however, that emotions are not necessarily antithetical to optimal decision making. For example, neurologists have determined that many patients with frontal lobe injuries have completely intact reasoning abilities; they can process information about risks and benefits normally but make bad decisions about their lives. They make bad decisions because they lack emotional feedback to

guide their decisions.²¹ In some contexts, in fact, intuitive *gut* decision making leads to better outcomes than highly reasoned decision making.^{22,23}

Moreover, even when emotions interfere with optimal decision making, the emotions may still deserve a role in decision making. For example, imagine a patient who is prey to what decision scientists call an *omission bias*; he would rather accept a 10% chance of some terrible outcome from natural causes than a 5% chance of the same outcome resulting as a complication of treatment because he believes he will blame himself for making a choice that leads to a treatment complication.²⁴ Rationally speaking, a 5% chance of something bad happening is better than a 10% chance of the same thing happening. But if this person would truly torture himself if he experienced the complication following treatment, and would not do so if he experienced the outcome naturally, then he should probably not receive treatment.

Similarly, the need to maintain hope and provide accurate information is a central challenge to physician–patient communication in oncology.^{25,26} On one hand, patients report a strong desire to have physicians encourage hope and optimism about their cancer, often in settings where there is little chance of long-term survival.²⁷ On the other hand, overly optimistic communication can lead to a misplaced focus on aggressive treatment and is often regretted by patients when they reach later stages of their illness.²⁸ Furthermore, providing patients with accurate information about a prognosis with and without treatment is necessary for their participation in medical decision making. Concern about how best to balance accuracy and hope can lead many clinicians to avoid participatory decision making.²⁹

Numeracy and Literacy

Patients can also struggle with decisions because they have difficulty processing numerical information. Many people have a difficult time understanding concepts such as percentages or frequencies.^{30,31} They do not know how to interpret imprecise medical information (“the test indicates you have somewhere between a 60% and 80% chance of . . .”). They also have difficulty with medical lingo; even seemingly simple words such as *recurrence* confuse many patients.^{32,33} To make matters worse, physicians are frequently unaware that patients do not understand the information the physicians have communicated to them.^{34,35}

Folklore and Prior Beliefs

Patients’ decisions are often guided by folklore and prior beliefs. A patient who believes that cancer can spread through the air may be reluctant to have a surgical resection of his cancer for fear that the surgery will spread the cancer.³⁶ Culturally based models of disease and illness can clash with biomedical models, hindering participatory decision making.³⁷ These clashes are often evident in patient skepticism about the efficacy of certain biomedical treatments and interest in alternative and complementary approaches.^{38,39} In addition, patients often have false beliefs about their risks of specific cancers. For example, the average woman’s lifetime risk of breast cancer is about 13% and yet the average woman thinks her risk is closer to 40%.⁴⁰ Physicians need to negotiate a common understanding among these divergent beliefs, bring-

ing together respect for the individual cultural background of a patient with the need to help patients understand their true clinical situations.

Distrust

Distrust of the medical profession and other components of the healthcare system may interfere with a patient’s ability to make a good decision. Distrust arises when physicians are no longer seen as committed to acting in their patients’ best interest.⁴¹ This situation may occur when patients are concerned about physician motives, for example, cost-containment, or have had prior experiences of failed expectations.⁴² Largely anecdotal evidence suggests that distrust is most prevalent among minority groups in the United States, in part because of both historical and current examples of racism within the medical system.⁴³ Although some level of skepticism may encourage patients to become involved in their medical decisions, high levels of distrust of the healthcare system may lead patients to discount the potential benefits of medical treatment and avoid medical care. Low levels of trust may also interfere with effective physician–patient relationships, making it more difficult and less rewarding for physicians to devote time and energy to effective participatory decision making.

Desire to Avoid Difficult Decisions

Even in dispassionate moments, people can make irrational decisions—decisions that conflict with their own preferences. For example, imagine the following admittedly hypothetical situation: you were recently diagnosed with colon cancer, and there are two surgical treatments available. Surgery 1 cures 80% of patients without complications, but the remaining 20% die of colon cancer. Surgery 2 also cures patients without complications 80% of the time, but only 16% die of colon cancer. The remaining 4% are cured of their colon cancer, but experience one of four surgical complications: a permanent colostomy, chronic diarrhea, intermittent abdominal pain, or a wound infection that takes 1 year to heal. More than 90% of people say that the four side effects of surgery 2 are preferable to dying of colon cancer. And yet, 50% of people still choose surgery 1 over surgery 2.⁴⁴ It appears that people are so overwhelmed by the sheer number and graphicness of the four complications of surgery 2 that they choose surgery 1. People minimize the survival difference between these two treatments (“the difference is only 4%”) while fixating on the different rate of complications. This seemingly irrational choice does not go away when people are shown, in writing, the inconsistency of their views. Avoiding such decisions probably requires face-to-face conversations.

People do not need to be scared by graphic side effects to shy away from what seem like superior alternatives. For example, in one study, when physicians were presented with a hypothetical patient with severe osteoarthritis, many said they would prescribe a new nonsteroidal antiinflammatory drug (NSAID) for the patient if it were available at the same time that they referred the patient to an orthopedic specialist. But when physicians were told that two new NSAIDs were available, many decided not to prescribe *either* NSAID and simply referred the patient to a specialist without any new medication. Addition of the second NSAID put physi-

cians in a position where they had to make a slightly more difficult choice, and many physicians acted as if they were unwilling to make that choice.⁴⁵ A similar phenomenon likely explains why people are more likely to purchase jams from a grocery store displaying 6 of the jams than one displaying 24; when there is too much to think about, people are averse to making tough choices.⁴⁶

Anecdotal Reasoning

Perhaps one of the most powerful influences on patients' decisions is their anecdotal experiences. It might be hard to interest a patient in chemotherapy whose aunt had a bad experience with chemotherapy. Anecdotal information is very powerful and can draw people's attention away from much more representative evidence. For example, even when informed of the success rates of treatment alternatives, people's choices can be influenced by uninformative anecdotes. A treatment alternative that is described as curing an illness 75% of the time is looked on less favorably if people are exposed to hypothetical anecdotes of patients who did not improve with treatment.⁴⁷

Emotional Mispredictions

Good decisions rely on good predictions. When choosing what television show to watch, what flavor of yogurt to eat, or what house to buy, people try to think about which alternative will best help them reach their goal of being happy or healthy or safe or whatever. And yet, people frequently mispredict how alternatives will make them feel. They spend piles of money on a big new house, expecting it to make them happy, and find out that they miss their cozy, old neighborhood.⁴⁸

Such mispredictions are common in health settings.⁴⁹ For example, patients with inflammatory bowel disease expect that having a colostomy would make them miserable, and yet patients emotionally adapt to colostomies relatively quickly.⁵⁰ People predict that they would be miserable if they had kidney failure, and yet most dialysis patients are happy.⁵¹ Such mispredictions could influence patients' healthcare decisions. If a prostate cancer patient overestimates how much he will be bothered by impotence or incontinence, he may forgo potentially beneficial treatments.

Clinician Resources and Training

Despite the multiple patient factors that hinder effective decision making, clinicians may still be the greatest obstacle to involving patients in their healthcare decisions. Although clinicians rarely withhold cancer diagnoses from patients anymore, they still often fail to give patients enough information to be fully involved in their healthcare decisions. Analyzing audiotapes of visits between clinicians and patients, researchers have found that physicians rarely give patients thorough and comprehensible information about their treatment alternatives.⁵² In addition, clinicians often do a poor job of giving patients an opportunity to express their concerns, interrupting them frequently throughout the visits, and not giving them a chance to ask questions.

Physicians' poor communication results partly from remnants of paternalism. Many physicians still believe that healthcare decisions are primarily theirs to make. Neverthe-

less, even those physicians who reject this view often have difficulty communicating to patients. Most physicians do not receive extensive training on how to communicate effectively with patients.⁵³ Medical school curricula are still dominated by the basic sciences. Also, clinical teaching, although emphasizing the importance of conducting thorough histories and physical examinations, rarely uses the latest advances in the communication sciences. This is unfortunate, because communication skills can be taught, and medical schools that have integrated communication skills into their curricula have found that their medical students are better communicators.⁵⁴

In addition, clinicians face time pressures and fiscal constraints that reduce their incentive to discuss issues at length with their patients. Perhaps more importantly, clinicians recognize that patients are not always emotionally or intellectually prepared to absorb a great deal of information about their healthcare alternatives. Consequently, clinicians may feel that it is a waste of time and money to embark on lengthy discussions of treatment alternatives with their patients.

Helping Patients to Make Better Decisions

It would be easy for clinicians to conclude that, if patients are going to make bad decisions because of emotions, mispredictions, or an inability to make difficult choices, then they should give up on involving patients in their healthcare decisions. But this would be a mistake. It would violate legal and ethical norms, it would reduce patient satisfaction and treatment adherence, and it would leave patients vulnerable to physicians' own biases. Physicians make many of the same mistakes patients make, for example, avoiding difficult decisions and mispredicting the emotional consequences of health problems. In addition, physicians are prone to specialty biases; urologists, for example, have very different attitudes toward radical prostatectomy from radiation oncologists⁵⁵ and different attitudes toward PSA testing from primary care physicians.⁵⁶

For these reasons, we think clinicians should not abandon the idea of involving patients in their healthcare decisions. Instead, we recommend the use of several strategies to facilitate this task.

Being Selective

Patients do not need to be involved in every healthcare decision. When decisions are low stake, and do not involve trade-offs (where patient preferences are important in deciding what is best), clinicians do not need to involve patients in the decisions. For example, patients suffering from chemotherapy-related nausea probably do not want a lengthy discussion of the merits of one class of medication versus another. Instead, they want relief from their nausea.

When deciding how much to involve patients in a decision, clinicians should think about whether reasonable clinicians could disagree about the course of action, not just clinicians from one's own specialty but also those from other specialties. The greater the medical consensus, the less need to talk at great length to patients about inferior alternatives.¹⁶

Clinicians should think about how quickly a decision needs to be made. In emergency situations, it is often diffi-

cult to involve patients in treatment decisions. Furthermore, if emotions are running high, patients are often most likely to rely on clinicians for advice. Patients still need and deserve information about their treatment alternatives, but when patients are too emotional to make decisions, they will often be happy to receive recommendations from their physician. When decisions are not so urgent, however, there is more opportunity to involve patients. Decisions in oncology span the spectrum from the emergent to the elective and clinicians should tailor their decision-making style to this spectrum.

Taking Advantage of Time

Clinicians should remind themselves that strong emotions often dissipate over time. Furthermore, the ability to retain and process information about a cancer diagnosis increases over time. When possible, clinicians should rely on time as a useful clinical intervention. For example, men with new diagnoses of localized prostate cancer often find out about their diagnosis at the same clinic visit that they decide how to treat the cancer. It is doubtful that these patients have had time to absorb all the information in one sitting, especially given their likely shock at receiving a cancer diagnosis. Perhaps a better goal at such a visit is to communicate their diagnosis and prognosis to patients, and let them know that good treatment options are available, which they can decide about over the next few weeks. When delivering bad news to patients, clinicians should expect that many patients will not be able to process much clinical information during the initial visit, and will usually be more capable on subsequent visits of doing so, when the shock has subsided.

Time may also provide an important context for balancing the need for hope and the need for accurate information. The object of a patient's hope should vary as his or her disease progresses. Initially, most patients focus on long-term survival, whereas later patients may be encouraged to move to short-term goals, and finally many terminal patients will shift to hoping for a *good* or peaceful death.^{57,58} Clinicians should understand where a patient is in this timeline and help the patient to reframe his or her object of hope to match their clinical circumstance.⁵⁹ Realistic information can be focused on what is needed to negotiate the decisions at each step.

Using Tools for Providing Information

In helping patients make good decisions, clinicians should give patients written information to help them comprehend their clinical alternatives, when possible, or refer them to appropriate Websites. Providing audiotapes of visits where important decisions are discussed may increase patient satisfaction and retention of information and is nearly universally preferred by patients.⁶⁰⁻⁶² Clinicians should encourage patients to review all materials with loved ones, and arrange for an opportunity to answer any questions that arise. Use of these tools may provide additional benefits by facilitating caregiver support during the decision process.⁶³

Risk communication is an important component of providing information to patients about their medical decisions. Thus, the use of specific strategies for improving risk communication may have substantial benefits for involving patients in their decisions. Presentation of frequencies with specific reference groups (25 of 1,000 people who undergo

chemotherapy will die of the treatment) instead of percentages (0.25%) may reduce confusion and facilitate understanding of small risks.⁶⁴ Furthermore, the use of the same denominator (i.e., 1,000 people) for different risks (e.g., risk of dying of chemotherapy and risk of cancer recurrence) simplifies the comparison of these risks.⁶⁴ Presentation of both negative (25 of 1,000 people who undergo chemotherapy will die of the treatment) and positive framing (975 of 1,000 people who undergo chemotherapy will not die of the treatment) can reduce biases in decision making.^{65,66} Furthermore, when possible, the use of visual aids, such as bar graphs or pie charts, can increase the comprehension and saliency of risk information²⁸ and can even reduce the influence of anecdotal information.⁶⁷

Building Trust

Trust is a critical component of the physician-patient relationship and necessary for patients to participate effectively in their medical decisions. Open communication is one of the key factors that establishes and reinforces trust.⁶⁸ Thus, even relatively basic steps toward participatory decision making, such as providing adequate information to patients and listening to their opinions and concerns, may serve to increase trust in the relationship and further improve decision outcomes. Trust is greatest in relationships where the patient believes that physician values are compatible with their own.⁶⁹ Such perceptions of value congruence are determined in part by the physician's behavior, practice circumstances, and payment structure, but may also be fostered by the physician demonstrating interest in and respect for the patient's life outside of their cancer diagnosis.^{6,70} Trust erodes when physicians fail to meet patients' expectations for communication and competency.⁷¹ Developing systems to minimize errors in either the process or outcomes of care helps to ensure that patients' expectations are met, thereby also increasing trust and facilitating participatory decision making.

Tailoring the Approach to the Individual Patient

Clinicians should remember that one size does not fit all. Some patients depend on your clinical recommendations while others will only want you to lay out their clinical alternatives. Giving recommendations is part of being a good doctor. Recommendations may seem odd in some contexts; if a patient is choosing, for example, between two treatments that yield identical survival rates but different complications, it would seem that the choice entirely depends on the patient's views of the various complications. And yet, may patients expect their doctors to tell them what to do and will be anxious if too much of the decision is laid at their feet.⁷² In such cases, physicians might do best to talk to patients about their various complications, to find out how patients feel about the complications, and then to make recommendations that seem to fit best with patients' values.

Conclusion

Under pressure to see more patients in less time, it is difficult for busy clinicians to always find enough time to involve patients in their healthcare decisions. Fortunately, with the

growth of the Internet, with the increasing use of group visits, and with the expanding use of healthcare teams to take care of oncology patients, there are lots of creative ways clinicians can help patients understand their medical choices. And given the high stakes of so many oncologic decisions, involving patients in their healthcare decisions can be one of the most rewarding aspects of practicing the art of medicine.

Establishing an Interdisciplinary Oncology Team

Nathan Levitan, Meri Armour,
and Afshin Dowlati

In recent decades, cancer treatment has evolved from a purely surgical approach to the complex coordination of sophisticated surgery, radiotherapy, and chemotherapy. The technology associated with pain and nutrition management has improved,¹⁻³ and the importance of psychosocial factors in the treatment of cancer patients has been recognized.⁴ The knowledge base pertaining to cancer treatment has become so vast that many physicians have developed subspecialty expertise in a focused aspect of cancer care. Quality of care analyses have indicated that the improved outcomes of certain cancer treatments occur when they are provided at high-volume facilities.⁵

One response to the challenges inherent in the provision of state-of-the-art cancer care has been the formal coordination of multiple disciplines in the planning and implementation of a treatment program. The American College of Surgeons, which certifies hospital-based cancer programs, requires the interaction of medical oncologists, radiation oncologists, and surgeons at prospective treatment planning conferences.⁶ Patient advocacy organizations such as the R.A. Bloch Cancer Foundation strongly advocate this approach to care as well.⁷

The interaction of multiple disciplines in cancer care has variably been referred to as *multidisciplinary* or *interdisciplinary*. In *The Helper's Journal*, Larson draws a distinction between these two terms. He defines *multidisciplinary care* as that which involves clinicians with multiple different areas of expertise, although not necessarily in a coordinated fashion. In contrast, he defines *interdisciplinary care* as the formal collaboration of these clinicians in each patient's treatment planning, "where the interaction of the team is necessary to produce the final product."⁸ Henceforth, we use the term interdisciplinary with the aforementioned intended meaning.

The purpose of this chapter is to review the scientific basis for and the logistic challenges involved in the delivery of interdisciplinary cancer care. Noting at the outset that currently there is a paucity of data in the medical literature pertaining to the impact of this type of care in comparison to conventional treatment, we explore closely related issues. The following questions are addressed: (1) How has cancer care evolved in recent years, and why is there a need for a

coordinated approach to care? (2) Can cancer care be standardized on the basis of clinical trials outcomes, or must all treatment decisions be individualized? (3) How much variability exists in the delivery of cancer care, and when does this represent a lapse in quality? (4) How can physician behavior be modified to provide patients with the best care? (5) How does the establishment of an interdisciplinary treatment team increase the likelihood that uniform, high-quality, state-of-the-art cancer care will be delivered?

The Historical Evolution of Individual Cancer Treatment Modalities

Surgery

The earliest attempts at surgical treatment for cancer occurred in London in the early 1800s and were described by John Abernethy.⁹ Limited by pain and infection, the outcomes of these operative procedures were poor. With the availability of general anesthesia and antiseptics in the mid-1800s,^{10,11} early procedures for the surgical treatment of breast cancer were developed.¹² In the late 1800s, William Halsted developed an aggressive surgical approach to breast cancer treatment.¹³ The "radical mastectomy" resulted in a fourfold increase in the cure rate for breast cancer.^{13,14} Subsequent advances in opioid pain management and blood banking permitted even more extensive surgical procedures in the 1950s.^{15,16} Breast-sparing surgery became widespread by the 1980s, and axillary sentinel node sampling was developed in the 1990s.^{17,18} By the end of the 20th century, liver transplantation became feasible for selected cases of hepatocellular carcinoma. Additional examples of state-of-the-art cancer surgery include complex reconstruction for hand and neck cancers, bone grafting for resection of pediatric osteosarcomas, nerve-sparing retroperitoneal surgery for prostate and testicular cancer, resection of isolated pulmonary,¹⁹ hepatic,²⁰ or intracranial metastases, minimally invasive abdominal surgery, and video-assisted thoracoscopy.²¹

Radiation Therapy

The origins of radiation therapy for cancer date back to the discovery of the X-ray by Roentgen in 1895.²² The properties of radium were reported by the Curies in 1898.²³ The effectiveness of therapeutic radiation was established in the 1920s,^{24,25} and radiation therapy for cancer treatment became established as a medical specialty within the American Board of Radiology in 1934. Between the 1930s and the 1950s, radiation therapy became a well-established treatment for cancer of the head and neck.²⁶⁻²⁸ By 1950, radiation therapy had also become the treatment of choice for patients with Hodgkin's disease.^{29,30} Brachytherapy became widely used in the 1980s.³¹ By the late 1990s, progress in computer technology facilitated the wide availability of computed tomography (CT) scan-guided computerized treatment planning,³² as well as conformal and intensity-modulated radiation therapy.³³

Chemotherapy

The birth of cancer chemotherapy occurred in the early 1940s, when nitrogen mustard was shown to be effective in the treatment of patients with lymphoid malignancies.³⁴ In 1949, methotrexate was used as curative therapy for patients with metastatic choriocarcinoma.³⁵ Combination chemotherapy became well established in the 1970s, when the effectiveness of the MOPP (nitrogen mustard, oncovin, procarbazine, prednisone) regimen was shown for patients with Hodgkin's disease.³⁶ Widespread use of newer cytotoxic chemotherapeutic agents including anthracyclines, vinca alkaloids, and platinum compounds occurred in the 1980s. The taxanes and the camptothecins were shown to be effective either alone and in combination with other drugs during the 1990s.³⁷⁻⁴⁰ Effective new antiemetic drugs as well as biologic agents for the treatment of neutropenia and anemia have reduced the toxicity associated with cytotoxic chemotherapy and have facilitated the development of high-dose chemotherapy strategies.⁴¹⁻⁴⁵ The newest developments in chemotherapy include monoclonal antibodies directed against lymphoid cell-surface antigens,⁴⁶ drugs that act at the signal transduction pathway to impair cell proliferation,⁴⁷⁻⁴⁹ and antiangiogenesis agents.^{50,51}

Combined Modality Therapy

As surgery, radiotherapy, and chemotherapy treatments for cancer have become individually more sophisticated over time, strategies for combining these modalities have evolved as well. In 1977, the National Surgical Adjuvant Breast and Bowel Protocol Group (NSABP) demonstrated that women who underwent breast-conserving surgery (lumpectomy) followed by radiation achieved rates of long-term survival equivalent to those who underwent mastectomy. Subsequent trials by this and other cooperative groups have proven, in Phase III trials, that postoperative adjuvant chemotherapy can improve long-term survival rates in breast cancer by approximately one-third.^{52,53} Chemotherapy, radiotherapy, and surgery have all been applied in the treatment of locally advanced breast cancer.⁵⁴

Adjuvant therapy for colon cancer patients with nodal involvement can improve 5-year survival rates by approxi-

mately 30%.⁵⁵ Patients with rectal cancer or gastric cancer benefit from postoperative concurrent chemoradiotherapy.⁵⁶ Carefully selected patients with non-Hodgkin's lymphoma or Hodgkin's disease are treated with chemotherapy followed by radiotherapy.⁵⁷ The use of concurrent chemoradiotherapy without surgery for patients with limited-stage small cell lung cancer has been associated with previously unattainable cure rates of more than 20%.⁵⁸ Patients with stage III superior sulcus non-small cell lung cancers benefit from concurrent chemoradiotherapy followed by surgery.⁵⁹

Organ preservation can be achieved with concurrent chemoradiotherapy for patients with cancers of the larynx, hypopharynx, and nasopharynx.^{60,61} Nigro demonstrated that patients with anal cancer can achieve improved cure rates (75% versus 30%) and also avoid surgical resection of the anus when they are treated with this bimodality approach.⁶² In treating pediatric patients with osteosarcoma, the use of initial chemotherapy and radiation followed by limb-sparing surgery for those who respond to induction therapy can reduce the incidence of amputation to 17%.^{63,64}

Controversies in Multimodality Treatment

Phase III clinical trials have demonstrated the superiority of combined modality treatment over surgery, chemotherapy, or radiotherapy alone for several types and stages of cancer. However, the emergence of new data with potential relevance to treatment decisions is a dynamic process. Just as one issue is addressed by clinical research, the next question is asked by investigators involved in the design of future trials. In addition, clinical trials may produce confusing or contradictory data. Accordingly, if one attempts to define "state-of-the-art" multimodality cancer therapy, there may be disagreement among treating physicians in many clinical situations. Several examples are presented next.

Lung cancer is the most common cause of cancer deaths among men and women in the United States. Patients with this disease are common in the practices of medical and radiation oncologists as well as thoracic surgeons. The importance of surgical resection in the treatment of stage I and II non-small cell lung cancer is well established, as is the role of chemotherapy for patients with symptomatic metastatic disease. The efficacy of postoperative adjuvant chemotherapy following lung cancer resection has recently been demonstrated.^{65,66} However, it is unclear which chemotherapy regimen is optimal, and whether patients should be treated if they have a small stage IA cancer, if more than 6 weeks have elapsed since surgery, or if patients are advanced in age. Postoperative radiotherapy has been shown to reduce local recurrence without a clear prolongation of survival for patients with stage II and III disease. The decision to use this treatment in the immediate postoperative period versus at the time of tumor recurrence must be individualized.

There are strong data to indicate that patients with clinical stage III lung cancer should undergo careful mediastinal staging before surgery. If multistation nodal involvement is evident, based on radiographic procedures or surgical nodal evaluation, tumor resection should not be carried out. This practice is not followed by many physicians across the United States. The role of preoperative chemotherapy for patients

with clearly resectable stage IIIA lung cancer is not well defined, nor is the optimal combination of chemotherapy, radiotherapy, and surgery for patients with advanced IIIA disease.

Breast cancer is the second most common cause of cancer death among women in the United States. The efficacy of hormonal and radiation therapy following resection of in situ cancer has been established, although the use of one or both modalities must be considered for each patient.⁶⁷ Adjuvant chemotherapy following resection of node-positive disease for pre- and postmenopausal women is well established, although the optimal combination of chemotherapy drugs and the role of consolidation therapy are unclear.⁶⁸ Radiotherapy to the chest wall following resection of breast cancer with multiple positive nodes can prolong survival. However, the utilization of this treatment is highly variable.⁶⁹

Patients with locally advanced breast cancer are generally treated with induction chemotherapy. The optimal role and sequence of radiation and surgical resection are not clear.^{70,71} Finally, although a multitude of chemotherapy drugs have been shown to be effective in the treatment of metastatic breast cancer, there is disagreement concerning the use of sequential single agents versus combination chemotherapy.⁷²

Esophageal cancer that invades at least into the muscularis propria is often treated with concurrent chemoradiotherapy followed by surgery. If one examines the results of Phase III clinical trials, the efficacy of this combined modality therapy is questionable.^{73,74} In the management of *rectal cancer*, the use of a mesorectal excision has been shown to be superior to conventional resection.⁷⁵ It is not clear how to determine which surgeons are properly trained to perform this procedure.⁷⁶ Induction chemoradiotherapy is used in selected patients in an effort to minimize the extent of resection and, in some cases, to permit a sphincter-sparing approach.

For patients with muscle-invasive *bladder cancer*, chemoradiotherapy can be used selectively to achieve bladder preservation.⁷⁷ However, the application of limited surgery, chemoradiotherapy, and radical cystectomy remains highly variable.⁷⁸ The management of *prostate cancer* is complex, as options often include observation, hormonal therapy, surgery, or radiation (external beam or brachytherapy).⁷⁹ Clinically node-negative nonseminomatous *testicular cancer* can be managed with initial chemotherapy or with observation; treatment varies with the preference of the treating physician and the details of the patient's disease.⁸⁰

Variability in Clinical Practice

The preceding examples highlight the complexity of cancer care, the absence of a single correct approach to the management of many patients, and the need to individualize treatment decisions. However, one could also ask to what extent variability in cancer care is the result of justifiable differences in the interpretation of clinical trials outcomes versus a lack of familiarity on the part of physicians with state-of-the-art medical information. Several investigators have attempted to address this question, largely in reference to nonmalignant conditions.

Ellerbeck demonstrated wide variation in the use of aspirin and beta blockers following myocardial infarction

during 1992–1993 in several states in the United States.⁸¹ This study was conducted at a time when the benefit of these medications was widely recognized. Patients for whom there existed a possible contraindication to these medications were excluded from the study. At the time of hospital discharge, 77% of patients received aspirin and 45% of patients received beta blockers.⁸² Schein showed that the selection of the type of procedure utilized by ophthalmologists for cataract excision varied with their surgical volume and with the number of years in practice.⁸³ Carey studied the use of radiographs in the evaluation of patients with low back pain. He found that chiropractors and orthopedic surgeons in private practice were more likely than those employed by a large institution to order radiographs.⁸⁴ Wennberg reported marked differences in the use of coronary angiography and revascularization in different regions of New England. He demonstrated that the number of stress tests performed in a region correlated with the number of invasive procedures that were subsequently performed.⁸⁵

Guadagnoli showed that Medicare beneficiaries with a strong medical indication for coronary angiography following myocardial infarction were more likely to be referred by their physicians for this procedure if they were enrolled in a fee-for-service rather than a managed care insurance plan (46% versus 37%).⁸⁶ Hemingway showed that among 908 patients in London with a strong medical indication for coronary angioplasty, 34% were not referred for this procedure; and among 908 patients with a strong medical indication for coronary artery bypass graft, 26% were treated medically.⁸⁷ These studies suggest that, although some examples of variability in treatment recommendations reflect the need to individualize patient management, others indicate a lapse in the quality of care.

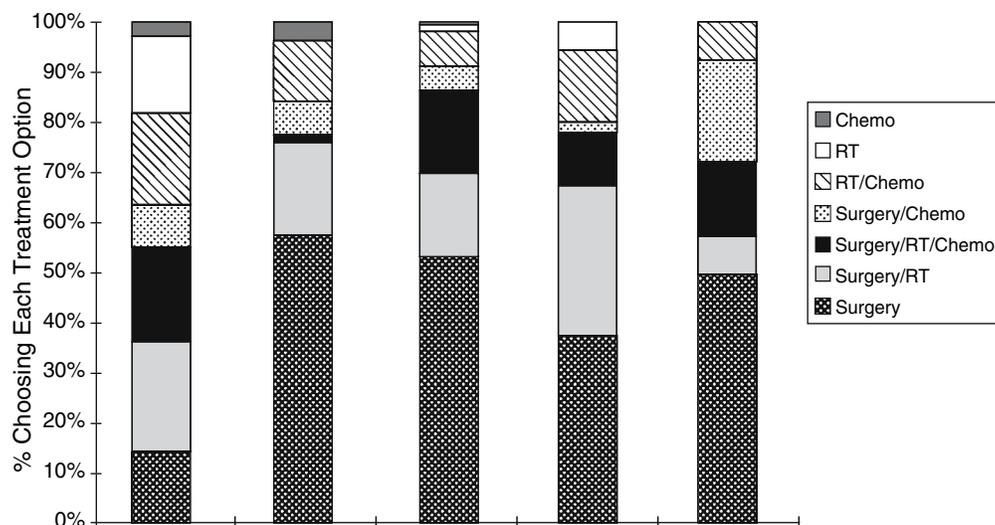

Variability in Cancer Care

If one attempts to assess the variability of cancer care across the United States, or the extent to which physicians adhere to established standards of cancer care, there are few data available.⁸⁸ Perez developed a questionnaire containing five different lung cancer case scenarios.⁸⁹ Primary care physicians, pulmonologists, medical oncologists, radiation oncologists, and thoracic surgeons were asked to complete the survey. Questions pertained to prognosis, recommended treatment, and the expected impact of treatment on outcome. For all stages of lung cancer, the recommended treatments varied greatly among the different specialists. Differences of opinion pertained not only to complex and controversial treatment decisions, but also to issues for which a clear standard of care had been established.

Emanuel and colleagues⁹⁰ used data from the Centers for Medicare and Medicaid Services to retrospectively study the use of chemotherapy in the final months of life for patients over the age of 65 (Figure 14.1). They found that, in the state of Massachusetts, 33%, 23%, and 9% of patients received chemotherapy in the last 6 months, 3 months, and 1 month of life, respectively. These data are among the first large-scale outcomes analyses of the practice of chemotherapy administration in the United States.

An initiative is currently under way to retrospectively analyze the use of adjuvant chemotherapy for patients with

FIGURE 14.1. Percentage of physicians (by specialty) choosing each treatment option for the treatment of stage II non-small cell lung cancer. Specialty by column, from left: primary care physicians (PCPs), pulmonary physicians, oncologists, radiation oncologists, and thoracic surgeons. (From Emanuel et al.,⁹¹ by permission of *Annals of Internal Medicine*.)

colon and lung cancer.⁹¹ This study, jointly sponsored by the Rand Corporation and the American Society of Clinical Oncology, will document the compliance of medical oncologists in the United States with two practice recommendations that are well supported in the medical literature and are considered standard care.

Alteration of Physician Practice Patterns

Thus far, we have described the complexity of many cancer treatment decisions. We have reviewed some of the data pertaining to variability in treatment patterns for multiple medical conditions, including cancer. We have shown that in some situations this variability reflects the absence of a single correct evidence-based approach, whereas in other situations the deviation from an established standard practice constitutes a lapse in quality of care.

In an effort to encourage uniformity of care when a *best practice* does exist, several strategies have been employed. These include the following:⁹²

- Didactic continuing medical education presentations
- Distribution of consensus conference recommendations
- Individualized physician education (academic detailing)
- Active participation in guideline development
- Physician feedback specific to his/her prior treatment decisions
- Reminders encountered by physicians in the course of active patient care

Several studies have shown that neither traditional didactic continuing education programs nor the dissemination of patient care guidelines is effective in altering physician behavior.⁹³⁻⁹⁷ Following the national distribution in Canada of a consensus statement pertaining to the use of cesarean section, physician acceptance was measured.⁹⁸ Surveys demonstrated that only 67% of targeted physicians were aware of the recommendations, and rates of cesarean section declined only slightly. Following the dissemination of the

Joint National Committee VI Hypertension Treatment Guidelines in the state of New York, physician compliance was found to be approximately 52%.⁹⁹ The distribution of guidelines for the management of community-acquired pneumonia to physicians at the Massachusetts General Hospital resulted in a 56% rate of compliance.¹⁰⁰ Poor adherence of surgeons to guidelines concerning breast cancer management has been demonstrated.

Several other interventions have been shown to be more effective. When physicians are used individually to educate colleagues, some change in behavior has been observed.¹⁰¹⁻¹⁰³ Reminders in the chart specific to individual patients have been shown to be more effective than general reminders or lectures.¹⁰⁴⁻¹⁰⁶ Recruitment of local physician opinion leaders to advocate a particular change and/or provision of specific feedback concerning their compliance with guidelines can also alter behavior.¹⁰⁷⁻¹¹¹ Involvement of physicians in the process of local guideline development can be effective as well.¹¹²

Several authors have attempted to explain the difficulties that are encountered in attempting to change physician practice.¹¹³ Smith suggests that the many years of formal education and postgraduate training to which physicians are exposed, as well as their own practice experience, result in the establishment of somewhat rigid practice patterns that are difficult to alter.¹¹⁴ He notes that the multitude of printed materials to which physicians are exposed may actually desensitize them to new educational content.

Grol proposes that the most effective strategy for altering physician practice patterns should include the integration of several techniques (Table 14.1).¹¹⁵ These methods include (a) provision of scientific evidence in the development of guidelines, (b) interactive rather than "top down" physician education, (c) ongoing monitoring of clinical performance and provision of feedback to physicians, and (d) patient empowerment. Greco adds that physician opinion leaders, financial incentives, financial penalties, and administrative rules are influential as well.¹¹⁶

TABLE 14.1. Effects of different strategies to improve patient care.

Strategy	No. of reviews	No. of studies	Conclusions
Educational materials, mailed information	9	3–37	Limited effects
Continuing medical education	4	3–17	Limited effects
Interactive educational meetings	4	2–6	Few studies, mostly effective
Educational outreach visits	8	2–8	Particularly affects prescribing and prevention
Use of opinion leaders	3	3–6	Mixed effects
Feedback on performance	7	16–37	Mixed effects, effect on test ordering
Reminders	5	5–68	Mostly effective
Substitution or delegation of tasks	7	2–14	Pharmacist, effect on prescribing; nurse, no effect
Use of computer (systems)	4	7–21	Computerized decision support, mostly effective
Total quality management and continuous quality improvement	1	55	Limited effects, weak study designs
Patient-oriented interventions	7	2–34	Mixed effects, reminding patients mostly effective in prevention
Combined and multifaceted interventions	16	2–39	Mostly very effective

The Case for Interdisciplinary Treatment Teams in Cancer Treatment Planning

Information presented heretofore in this chapter can be summarized as follows:

The knowledge base necessary to provide state-of-the-art cancer care is extensive.

The cancer treatment literature resides in journals specific to several different medical specialties, and no single physician is likely to be familiar with all aspects of this scientific evidence.

A familiarity with active clinical trials and emerging scientific data for each type of cancer is needed.

Physicians from different cancer-related specialties often have divergent opinions concerning cancer treatment and prognosis.

For most major types of malignancy, some treatment recommendations are established as standard care whereas many others remain controversial.

Although data are not available to quantify the extent to which physicians involved in cancer care adhere to standard treatment recommendations, studies pertaining to several other fields of medicine suggest that compliance may be suboptimal.

When emerging medical knowledge is presented to physicians in a didactic fashion, they are slow to integrate such information into their patterns of practice.

The mere dissemination of treatment guidelines to physicians does not alter their treatment decisions.

To alter physician practice patterns, necessary steps include interactive learning, engagement of physicians in the process of guideline development, involvement of “thought leaders,” and provision of ongoing outcomes data.

If one accepts these conclusions, then the need for a collaborative approach to cancer care is clear. When physicians from multiple cancer-related specialties meet to discuss new cancer patients and to prospectively plan the optimal treatment plan, several important events occur.

1. Specialty-specific knowledge is shared among participating physicians.

2. New information from the medical literature possessed by any member of the group is shared and likely integrated into the treatment planning process.

3. Disagreements among specialists are discussed until a unified opinion is formulated, thus providing the patient with clear and consistent information.

4. Locally applicable treatment guidelines are developed by participating physicians. The fact of their involvement in the process increases the likelihood of adherence.

5. The interdisciplinary team is an ideal forum for the identification of key outcome measures. These same physicians can review the data and modify the process of treatment as needed; this constitutes a *total quality management* cycle.¹¹⁷

6. Medical institutions involved in clinical research can utilize these meetings to determine patient eligibility for clinical trials and to inform the treating physicians accordingly.

Models for the Delivery of Interdisciplinary Care

As noted previously, there is broad support on the part of both medical professional organizations and patient advocacy groups for an interdisciplinary approach to cancer care. It is generally accepted that care labeled as such is characterized by the participation of multiple specialists in the formulation of an individualized treatment plan for each patient. However, beyond this definition, the optimal structure for such a process has not been clearly defined.

Three models for the provision of interdisciplinary gastrointestinal cancer care have been described in a 2002 monograph prepared by The Advisory Board Company.¹¹⁸ The simplest model consists of a prospective treatment planning conference. Next, in order of increasing complexity, is the *virtual clinic*, in which a coordinator facilitates movement of the patient through his/her multiple physician visits and testing procedures. The highest level of integration is achieved by the establishment of a "comprehensive clinic," in which all physicians involved in the care of the patient practice in a single location (Table 14.2). There are no available data to indicate either the number of institutions that are providing interdisciplinary cancer care or the specific model(s) in use at these intuitions.

Beyond Surgery, Radiation Therapy, and Chemotherapy

Thus far, our discussion of integrated care has focused on the coordination of physicians from multiple cancer-related specialties. One can broaden the definition of interdisciplinary treatment to include several other components of care. Ko reviewed the records of 301 cancer patients and 6,745 controls and found that oncology patients frequently had coexistent pulmonary and cardiac conditions, thus requiring the participation of primary care physicians, cardiologists, and pulmonologists in the process of treatment planning and delivery.¹¹⁹ A model of interdisciplinary care for hepatocellular carcinoma published by Van Cleave and colleagues includes (in addition to physicians) nurses, social workers, pharmacists, and a chaplain.¹²⁰

To what extent do psychosocial and/or nutritional services alter outcomes in cancer care? Several clinical trials have tested the hypothesis that psychologic treatment can prolong survival in cancer patients.¹²¹⁻¹²³ The results of these studies

are contradictory, and no firm conclusions can be drawn. More uniform data suggest that this type of intervention can favorably affect quality of life.^{122,124-126} Arguably, relief of distress and enhancement of quality of life may be more appropriate metrics with which to evaluate the efficacy of psychosocial services for cancer patients than prolongation of survival.

Potential nutritional interventions range from oral to parenteral and from cancer prevention to the support of patients with metastatic disease.¹²⁶⁻¹²⁸ Some investigators have found that oral intake of fish oil can reverse cancer anorexia and weight loss while others have observed no benefit.^{129,130} Although the use of parenteral nutrition for patients with end-stage cancer can prolong survival, the associated cost and adverse effect on quality of life add complexity to the decision to undertake this therapy.¹³¹

A detailed review of the data pertaining to psychologic and nutritional intervention in cancer care is beyond the scope of this manuscript (see Chapter 85). However, there exists a broad body of literature pertaining to these treatments with which physician members of the interdisciplinary team are unlikely to be familiar. Mental health professionals and nutritionists can bring this expertise to the interdisciplinary team.

A demonstration project entitled Safe Conduct has been implemented as a component of care for patients with advanced lung cancer at the Ireland Cancer Center at University Hospitals of Cleveland. For participating patients, in addition to physician services from several cancer-related specialties, the interdisciplinary team includes a spiritual counselor, a social worker, and a nurse practitioner. In addition to careful attention to pain and symptom control, this team addresses the spiritual, emotional, and logistic needs of participating patients throughout the continuum of care.

Project Safe Conduct's positive impact on patients and caregivers emerges in several areas, based on preliminary data comparing these patients to lung cancer patients receiving care at ICC 1 year before the introduction of the Safe Conduct Team (SCT) (Figure 14.2):

The number of hospice referrals increased from 13% to 80%.

The hospice length of stay increased from an average of 10 days to 43 days.

The hospital admission rate (number of hospitalizations per patient per year) was 3.20 before Project Safe Conduct and dropped to 1.05 for SCT patients.

Unplanned hospitalizations and emergency room visits dropped from 6.3 per patient to 3.1.

TABLE 14.2. Models of interdisciplinary care.

<i>Model</i>	<i>Interdisciplinary clinic setup</i>	<i>Collaborative treatment planning</i>
Prospective treatment planning conference	Clinic visits not formally coordinated	Interdisciplinary treatment planning conference
Virtual gastrointestinal (GI) clinic	Patients see multiple specialists during separate but coordinated visits	Interdisciplinary treatment planning conference on separate day
Comprehensive GI clinic	Patients meet with multiple specialists during a single clinic visit	GI specialists confer on treatment planning during clinic visit

Source: Courtesy of the Advisory Board Company.

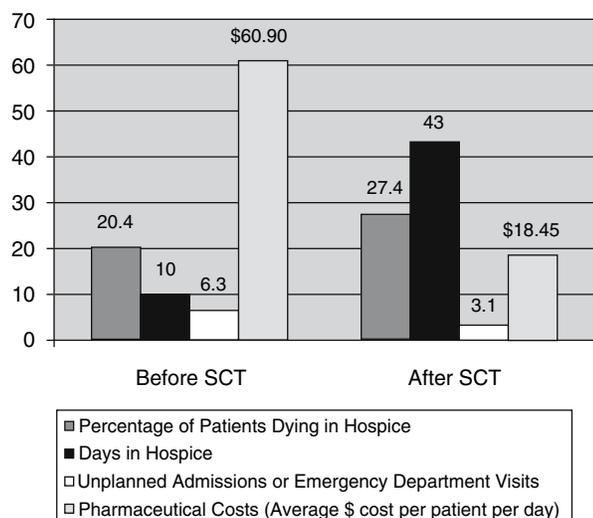

FIGURE 14.2. The positive impact on patients and caregivers of Project Safe Conduct emerges in several areas, based on preliminary data comparing these patients with lung cancer patients receiving care at Ireland Cancer Center (ICC) 1 year before the introduction of the Safe Conduct Team (SCT).

Seventy-five percent of SCT patients died at home, where most patients prefer to be at the end of life.

Average per-day pharmaceutical costs dropped from \$60.90 per patient to \$18.45.

Caregivers of SCT patients reported reduced burdens in interviews conducted after the death of their loved one.

Economic Implications

Quality of care considerations aside, the existing fee-for-service model of medical care in the United States (including the traditional Medicare plan) does not provide a strong economic incentive for the provision of interdisciplinary cancer care. Administrative costs associated with the establishment and support of these teams cannot be passed on to insurers. Although Medicare has developed a modifier that provides reimbursement if a patient is seen by several physicians in the same clinic in 1 day, physicians cannot bill for time spent at treatment planning conferences.

Theoretically, there are economic advantages that could result from an interdisciplinary approach to cancer treatment. In *Market Driven Health Care*, Dr. Regina Helzlinger predicts that consumers are increasingly demanding integrated disease-focused care.¹³² If so, then institutions providing such services may have an advantage in the medical marketplace regardless of the reimbursement model.¹³³ In addition, the interdisciplinary team may contribute to optimal resource utilization and efficient work flow. Data do not exist to facilitate a more rigorous return-on-investment analysis pertaining to interdisciplinary cancer care.

Future Directions

In this chapter, we have shown that there exists in the medical literature strong justification for the establishment of interdisciplinary teams for cancer treatment. Several

potential models with differing levels of complexity have been described, although the optimal structure for the delivery of such care has not been defined. The incremental cost involved in establishing these teams, as well as the impact on reimbursement, resource utilization, clinical trials participation, and patient satisfaction, remain unclear. Most important, the effects of interdisciplinary care on disease-free survival, overall survival, and quality of life have not been measured. Carefully designed outcomes studies are needed to address these issues.

Principles of Complementary and Alternative Medicine for Cancer

Andrew J. Vickers and Barrie Cassileth

Complementary and alternative medicine (CAM) is a general term used to describe techniques as diverse as chiropractic and yoga, iridology and meditation, colonic irrigation and spiritual healing. As such, it resists simple definition. Most published definitions describe CAM simply as practices outside of mainstream care.¹ A more fundamental issue concerns the difference between *complementary* and *alternative* approaches. Alternative therapies are used in place of mainstream care. Conversely, complementary therapies are used as adjuncts to mainstream care for symptom management and to enhance quality of life. This distinction is especially important in oncology, where treatment choices can be literally a matter of life and death.

CAM is widely used by the general public in the United States^{2,3} and in other industrialized countries.⁴⁻⁷ CAM use is markedly prevalent among cancer patients: a systematic review located 26 surveys of cancer patients from 13 countries, including 5 from the United States. The average prevalence across all studies was 31%, with prevalence rates as high as 64% in published reports.⁸ Research published subsequent to the systematic review showed similar or slightly increased rates of CAM use.⁹⁻¹⁵ Particularly popular today among cancer patients is the use of herbs, vitamins, and other dietary supplements. For example, more than one in four prostate cancer patients at a Canadian cancer clinic¹⁶ and at a veterans' affairs medical center¹⁷ used supplements or herbal treatments. A review of several studies reporting CAM product use in breast cancer patients found rates as high as 50% for herbs and 60% for other supplements.¹⁸

Given such widespread use, the first principle of CAM for cancer is that health professionals should ask patients about their use of CAM. This information helps to complete the clinical picture and to alert clinicians to potentially harmful interactions with conventional therapy. Keeping an open dialogue with patients is also likely to reduce the risk that they abandon conventional care to pursue unproven alternative cures.

In this chapter, we review data on alternative cancer treatments, botanical (herbal) anticancer agents, and interactions between CAM therapies and conventional oncologic care. We then review the evidence supporting the use of complementary therapies for symptom control.

Alternative Cancer Therapies

This section reviews *alternative therapies*, anticancer therapies offered outside of mainstream cancer treatment programs. Most of these methods are based on unfounded theories and involve considerable travel or expense; many are also known to incur significant risks of adverse events. It is common for advocates of alternative therapies to promote their treatment instead of conventional care. For example, Nicholas Gonzalez, a private physician in New York who treats cancer with a regimen that involves diet, vitamins, enzymes, and enemas, has stated that "You don't do chemotherapy and [my regimen]. You do one or the other."¹⁹ This feeling raises the possibility that patients may be harmed by postponing care of proven benefit, an especially important consideration given that alternative cancer therapies are shown to be ineffective when subjected to clinical trial.

The related principle is the importance of trying to dissuade patients from using unproven cancer therapies. These therapies are typified by one or more of the following characteristics:

1. Promoted as effective against a wide range of ailments
2. The government or medical profession is said to conspire to suppress the therapy
3. Use of testimonials instead of facts and figures
4. Product is available from only one source
5. Credibility based on having been available for years and on anecdotal reports
6. New laws of nature are used to explain how it works
7. Promoted as "less toxic" than mainstream cancer treatment
8. Recommended for use instead of mainstream cancer treatments

Burzynski and Antineoplastons

An alternative cancer therapy popular for over a decade is that of Stanislaw Burzynski, who treats cancer with what he terms "antineoplastons." These are mixtures of peptides, amino

acids, and other simple organic substances that he claims promote the body's natural defenses against cancer. Although he has published several studies of his own, these are of a rather unclear design.²⁰ A Phase II trial in glioma conducted under the auspices of the National Cancer Institute (NCI) was halted due to poor accrual and a failure of Burzynski to agree with the investigators on possible expansion of the eligibility criteria. Nine patients were accrued, six of whom were evaluable for response. There were no objective responses, and all six patients showed evidence of tumor progression after treatment durations between 16 and 66 days. The mean time to treatment failure (progression or discontinuation due to toxicity) was 29 days. All nine patients died before the study closed, all but one death resulting from tumor progression.²¹ Despite the absence of data in support of Burzynski's regimen, it remains heavily promoted, especially as a treatment for pediatric brain tumors.

High-Dose Vitamin C

High-dose vitamin C was originally popularized as a cancer therapy by Linus Pauling. His claim that vitamin C potentiated the body's ability to fight off cancer garnered intense public interest and prompted two randomized trials in the late 1970s and early 1980s. Both trials found no difference between vitamin C and placebo, with short survival times regardless of allocation.^{22,23} Interest in vitamin C as a cancer therapy recurred as researchers argued that early investigations were based on incomplete understanding of the vitamin C mode of action and that the oral doses used were inadequate.²⁴ Intravenous vitamin C with arsenic is currently under investigation as a treatment for myeloma at Sylvester Cancer Center.²⁵

Laetrile

Laetrile is a substance derived from the pits of apricots and other fruits. It was a popular alternative cancer cure throughout the 1970s until research documented its lack of benefit²⁶ and its sale was banned in the United States. Following a two-decade hiatus, promotional activity resumed. Often termed "vitamin B₁₇" or sold as amygdalin, laetrile currently is available via the Internet and in Tijuana, Mexico.

Metabolic Therapies: Gerson and Gonzalez

Metabolic therapies are based on the belief that cancer is a symptom of the accumulation of toxins. The aim of treatment is therefore "detoxification" using coffee enemas or high colonics, special diets, raw juices, enzymes, and supplements. A retrospective study of melanoma patients treated by Gerson therapy, conducted by physicians working at the clinic where study patients were treated, concluded that 5-year survival of patients receiving Gerson therapy was higher than reported in large cohort studies.²⁷ This analysis was flawed by the use of unadjusted comparisons to nonrandomized controls and the exclusion of 40% of the Gerson therapy patients from analysis. In response to detailed criticisms, the authors accepted that a nonrandomized study such as the one published did not provide strong evidence of a treatment effect.²⁸ A more promising result has been reported from a cohort study of 11 pancreatic cancer patients treated by Nicholas Gonzalez using

a metabolic regimen. Gonzalez reported 81% survival at 1 year and 45% survival at 2 years and claimed such results were far superior to national averages.²⁹ The study was small and obviously prone to several biases: not only is the comparison to national average unadjusted for confounders, but the principal results are based on patient selection; 12 patients who did not comply with treatment were excluded from analysis. Nonetheless, the generally positive results reported by Gonzalez were sufficient to prompt an NIH-funded Phase III trial, which remains under way.

Psychotherapy as a Cancer Cure

The theory that changing mental state can affect the course of cancer has been popularized by authors such as Bernie Siegel and Deepak Chopra. A support group program called Exceptional Cancer Patients (ECaP), developed by Dr. Bernie Siegel, was evaluated in a matched cohort study. Thirty-four women with breast cancer attending the ECaP program were matched 1:3 with comparable patients identified from tumor registries. At 10 years of follow-up, there were no differences in survival between the two groups, with approximately 40% of patients in both groups alive at the end of the study.³⁰

Several other studies, however, appear to show survival advantages in cancer patients receiving psychologic treatment. In the late 1970s, David Spiegel conducted a randomized trial that aimed to examine the effects of a psychosocial support group on quality of life and symptoms in women with metastatic breast cancer. As a post hoc analysis, the investigators looked at survival differences and reported a statistically significant prolongation of survival in the group receiving psychosocial support.³¹ This trial has been extremely widely publicized and extensively cited, despite an unplanned survival analysis and subsequent randomized replications that failed to support Spiegel's results.^{32,33}

Electromagnetic Therapies

Some practitioners claim that cancer and other diseases are caused by disruptions of the body's electromagnetic fields. They believe that disease can be treated using pulsed, high-frequency electromagnetic waves. "BioResonance Therapy" is a relatively new version of the many alternative "energy therapies" that predominated in the 1930s. For example, Royal R. Rife developed an energy machine to destroy the microbes that he believed were the cause of cancer. Electromagnetic therapies today are costly treatments, offered mainly in Tijuana, Mexico, and in some European countries, despite their lack of value.

Oxygen and Ozone Therapies

Oxygen therapy refers to treatments based on the idea that cancer and other disease cannot survive in an oxygen-rich environment. Such therapies purport to kill cancer cells by delivering high levels of oxygen to tissues. Methods include intravenous infusion, ingestion, colonic administration, or dermal application of hydrogen; "ozone autohemotherapy," in which blood is bubbled with ozone and reinjected; and "oxygenated" water, pills, and solutions. Oxygen therapies are popular today despite the absence of supportive data and reports of serious side effects, including death.³⁴⁻³⁶

Botanical (Herbal) Medicines Used Against Cancer

Medicines derived from whole plant extracts, and which therefore contain many different types of molecules, are generally described as herbal medicines. The term botanical is used here to reflect that such agents are obtained from a wide variety of natural products, not just from herbs. Medicinal botanicals are minimally toxic, particularly when compared with plant-derived chemotherapeutic agents, and they are readily available without prescription. Described next are some botanicals commonly used by cancer patients. No botanical product has been proven effective against cancer, despite Internet claims of herbal remedy cures.

A principle of CAM for cancer is therefore that patients should not be advised to pursue anticancer therapy with botanicals.

Essiac. Essiac was popularized by a nurse, Rene Caisse, who claims to have derived the formula from a traditional native healer. This product consists of four herbs: burdock root, Turkey rhubarb, sorrel, and slippery elm. A review in the *Canadian Medical Association Journal* reported no published research on Essiac.³⁷

Mistletoe. Mistletoe extracts, which are more widely known by the trade names Iscador, Helixor, and Eurixor, are popular cancer treatments in Europe and are available in some mainstream European cancer clinics. Unlike many botanical treatments, mistletoe extracts have been subjected to randomized trials in cancer patients. A systematic review of early trials revealed small sample sizes and serious methodologic shortcomings in most studies.³⁸ In subsequent larger studies, no survival benefit was found in patients with malignant melanoma³⁹ or head and neck cancer.⁴⁰ A small trial in glioma reported possible benefit in a subgroup, but there were no overall differences between groups.⁴¹

Noni. This popular botanical product is typical of many unproven therapies: it is a natural product used for “thousands of years” by “traditional Polynesian healers.” The discovery of its use against cancer is colorful, involving the miraculous cure of a pet dog. Claims made for noni are ambiguous and implausible, as it is promoted as a “blood purifier” to “cleanse the body of harmful bacteria.” Its value for cancer is based on a mouse study⁴² that used a polysaccharide fraction of the fruit. There are no published human studies of noni.

Pau d’arco tea. Pau d’arco tea is said to be an old Incan remedy for many illnesses, including cancer. Made from the bark of an indigenous South American evergreen tree, its putative active ingredient, lapachol, has been isolated. In a Phase I trial, the blood levels of lapachol that were achieved without toxicity were far below those predicted to be effective on the basis of cell culture studies.⁴³

PC-SPES. PC-SPES (PC for prostate cancer; spes is Latin for hope), a botanical treatment for prostate cancer, consists of eight herbs, all but two from Traditional Chinese Medicine. Laboratory research supports the activity of PC-SPES against prostate cancer, and antiproliferate and proapoptotic effects on tumor lines *in vitro*⁴⁴ have been demonstrated.^{45,46} In rat models, PC-SPES decreased the incidence of spontaneous tumors and reduced tumor

weight of implanted tumors.⁴⁷ PC-SPES also demonstrated estrogenic activity in a yeast assay and in mice.⁴⁴

Phase II studies with PC-SPES show prostate-specific antigen (PSA) declines and improvements in pain and quality of life.^{48–50} In a single-arm study of PC-SPES involving 70 patients with prostate cancer, no patient progressed objectively or in terms of PSA at median 64-week follow-up. PC-SPES was associated with a number of endocrine side effects⁵¹ and with increased risk of thromboembolic events.^{52–54} A randomized trial comparing PC-SPES to DES in 90 patients with androgen-independent prostate cancer found that 17 of 38 PC-SPES patients, versus 8 of 39 DES patients, achieved a PSA response ($P = 0.023$).⁵⁵

Despite these encouraging results, a survival advantage for PC-SPES has yet to be demonstrated. More importantly, the product is no longer available for clinical use: PC-SPES was found to contain warfarin (and SPES, a more generic version for all cancers, to contain alprazolam) and was withdrawn by the manufacturer in February 2002.

β-Glucans. Many mushrooms used in Oriental botanical medicine contain β-glucans, a class of polysaccharide molecule. These agents have been widely studied for their anticancer effects. Most human Phase III trials of mushroom-derived β-glucans have used the polysaccharide Kureha (PSK), an extract of *Coriolus versicolor*, or an extract from the culture medium of *Schizophyllum commune* Fries known as SPG. Trials typically compared chemotherapy or radiotherapy plus β-glucan versus conventional treatment alone, finding superior survival for PSK compared to controls following colectomy,^{56,57} gastrectomy,^{58,59} and esophagectomy.⁶⁰ In a typical trial, 120 patients with Dukes’ C colorectal cancer undergoing curative resection were randomized to PSK or placebo and followed for up to 10 years. Significant differences between groups for both disease-free and overall survival emerged, with median survival in the PSK group approximately 5 years compared to just over 4 years in controls.⁵⁶ SPG was slightly but not significantly superior to control for gastrectomy, although improved survival was seen in patients with curative resection in a subgroup analysis.^{61,62} Results have been less encouraging in breast cancer^{63,64} and leukemia.⁶⁵ The most promising results for SPG are seen in cervical cancer, with trials demonstrating improvements in survival⁶⁶ and increased rates of tumor response.⁶⁷

In Phase II trials, an extract of Shiitake mushroom given to 61 patients with prostate cancer found that no patient experienced PSA decline, 4 showed some evidence of disease stabilization, and 23 patients progressed.⁶⁸ In a “preference” study, 269 consecutive patients undergoing liver resection for hepatocellular carcinoma were offered active hexose correlated compound (AHCC), an extract of several different fungi. Overall survival in the 113 patients who selected AHCC was superior to that of nonusers (hazard ratio, 0.64; $P < 0.001$).

Green tea. Interest in green tea as an anticancer botanical stemmed originally from epidemiologic research that demonstrated lower rates of various cancers, particularly colorectal cancer, in Chinese and Japanese green tea drinkers.⁶⁹ Typically, tea consumption was compared in cancer patients and matched local controls. Odds ratios for colon and rectal cancer among the highest consumers were 0.6 to 0.8 compared to those who did not consume

tea regularly.⁷⁰ Green tea prevents induced colorectal tumors in animal models^{71,72} and appears to have moderate inhibitory effects on cell growth.^{73,74} Although green tea is under study as a possible chemopreventive agent,⁷⁵ its viability as a cancer treatment has yet to be documented.

Interactions Between CAM and Conventional Oncologic Therapy

Concurrent use of botanicals with conventional treatments raises the risk of interactions,⁷⁶ including herb–drug interactions that reduce the effectiveness of chemotherapy.

The relevant principle of CAM for cancer is that patients should avoid botanical products and other dietary supplements during and for a 2-week washout period before chemotherapy, radiotherapy, or surgery. Botanicals with hormonal effects should not be used concurrently with hormonal therapy.

Metabolic interactions: Many botanicals are known to modify the activity of cytochrome CYP450 3A4, affecting the blood levels of drugs metabolized on this pathway.⁷⁷ St. John's wort, for example, induces CYP450 3A4 *in vitro*,⁷⁷ and in a randomized cross-over study, the plasma concentration of SN-38, irinotecan's active metabolite, was dramatically reduced when patients concurrently used St. John's wort.⁷⁸ Several other popular botanicals, such as *Echinacea* and goldenseal, also were shown to modify CYP450 3A4 activity by an *in vitro* screen.⁷⁷

Antioxidants: Many cytotoxic therapies, notably radiotherapy, depend on producing oxidative damage within the cancer cell. The activity of radiotherapy depends at least in part on the production of free radicals. Many botanicals, such as grape seed extract and ginseng, contain antioxidant constituents. Patients may unwittingly exacerbate the problem by taking additional antioxidants in the form of other dietary supplements. It is widely thought that concurrent administration of antioxidant supplements may, at least in theory, compromise the effectiveness of radiation therapy and some chemotherapeutic agents.⁷⁹ Although some researchers believe that concurrent use of antioxidants and cytotoxic therapy⁸⁰ can produce benefits, suppression of chemotherapy-induced apoptosis by antioxidants has been demonstrated *in vitro*.⁸¹ Moreover, a nonrandomized comparative study recently found poorer survival in patients taking high doses of vitamins, including antioxidants, concurrent with systemic therapy.⁸² At the very least, caution is advised.

Hormonal interactions: Many botanicals, including soy, chasteberry, dong quai, ginseng, and red clover, contain phytoestrogens, or plant-based estrogen-like substances. These compounds may interfere with antiestrogen therapies such as tamoxifen or raloxifene, or promote the growth of estrogen-sensitive tumors.^{83,84} Indeed, genistein, the predominant isoflavone in soy products, reduced the inhibitory effect of tamoxifen in a mouse model of breast cancer.⁸⁵ Similarly, black cohosh increased the proliferation of MCF-7 breast cancer cells *in vitro*.^{86,87} Although some authors claim the opposite effect, that is, that botan-

icals containing phytoestrogens can inhibit breast tumor cell growth or potentiate antiestrogen therapy,⁸⁸ the possibility of harmful interactions will remain a concern until studies are conducted.

Other chemotherapy interactions: CAM products may interact with chemotherapeutic agents through a number of other mechanisms. *In vitro* study has shown that berberine, a component of a number of herbs, upregulates the expression of pgp-170, a multidrug-resistant transporter protein, in a number of cancer cell lines, resulting in decreased paclitaxel cytotoxicity.⁸⁹ Botanicals can also interfere with the conversion of chemotherapy prodrugs to the active form⁹⁰ or with apoptotic pathways.⁸¹

Surgical interactions: Over-the-counter remedies interfere with blood coagulation, posing a risk of bleeding complications in the perioperative period.⁹¹ Garlic and vitamin E are common examples. Psychoactive herbs, such as valerian or kava kava, are reported to potentiate the sedative effects of anesthetics.⁹¹

Complementary Therapies for Symptom Control

Therapies such as acupuncture, massage, relaxation therapy, and hypnosis are widely used for symptom control by the general public. Acupuncture, for example, is widely used in the United States to treat conditions such as back pain, and massage therapy is sought to help treat for anxiety disorders. Similarly, complementary therapies are increasingly used to treat symptoms of cancer or its treatment. A description of the most important complementary therapies is given below, followed by a review of the evidence for their effects against cancer-related symptoms. On the basis of this evidence, the following principles apply to the use of complementary modalities for cancer symptoms:

- Hypnosis or relaxation therapy should be considered for acute or chronic cancer pain, particularly when pain is poorly controlled with medication or when medication causes unacceptable adverse effects.
- Acupuncture is indicated to help control chronic cancer pain that remains severe despite medication or when medication causes unacceptable adverse effects.
- Mild or moderate mood disorders can be alleviated with therapies such as relaxation, imagery, meditation, and massage. Music therapy is available for inpatients at some cancer centers and appears effective for mood disorder in this population.
- Hypnosis or acupuncture is often effective for poorly controlled acute or subacute nausea in cancer patients.
- Botanicals do not relieve hot flashes.

Types of Complementary Therapies

Mind–body medicine. A wide variety of complementary therapies are used to relieve stress and enhance quality of life by producing relaxation. Hypnosis is the induction of a deeply relaxed state during which the therapist works to increase suggestibility and to help patients suspend critical faculties. Once in this state, sometimes called a hypnotic trance, patients are given therapeutic suggestions to

encourage changes in behavior or symptom relief. Visualization and imagery techniques involve the induction of a relaxed state followed by use of a visual image, such as a pastoral scene, that enhances the sense of relaxation. Progressive relaxation involves sequential tensing and relaxing of muscles.

Acupuncture. Acupuncture is the insertion of very fine needles at special points on the body. Although details of practice may differ between individual schools, all traditional Chinese medical theory is based in the Taoist concept of *yin* and *yang* and the flow of *Qi* (energy) along hypothesized channels in the body. Stimulating acupuncture points situated on these channels provides one way of altering the flow of energy. Modern scientific understanding views acupuncture points as corresponding to physiologic and anatomic features such as peripheral nerve junctions.

Massage. Therapeutic massage involves manipulation of the soft tissue of whole or partial body areas to induce general improvements in health, such as relaxation or improved sleep, or specific physical benefits, such as relief of muscular aches and pains.

Music therapy. Music therapy is the controlled use of music to effect clinical change. Music therapists select and play live music according to patient mood and preference. They may involve patients in music making by having them develop lyrics, sing, or play a drum.

Pain

The most commonly used complementary therapies for pain include mind–body techniques, acupuncture, and massage. Both a systematic review⁹² and a National Institutes of Health (NIH) technology assessment panel⁹³ have supported the use of hypnosis for cancer-related pain. There is also randomized trial evidence that relaxation and imagery reduce pain in cancer patients.⁹⁴ There is good evidence that acupuncture is effective for both chronic and acute nonmalignant pain.⁹⁵ Support for its use in oncology comes from a recent randomized trial involving 90 patients with refractory neuropathic cancer pain: pain scores at 60 days fell by more than a third in the acupuncture group compared to little change in patients receiving placebo ($P < 0.001$ for the difference between groups).⁹⁶ Several small randomized trials indicate that massage can reduce pain in cancer patients at varying stages of disease.^{97,98} In the largest study to date, 87 hospitalized cancer patients were randomized to massage or to control on a crossover basis. Pain and anxiety scores fell by approximately 40% during massage compared with little or no change during control sessions.⁹⁹ National Comprehensive Cancer Network (NCCN) guidelines currently recommend consideration of massage and acupuncture for refractory cancer pain.¹⁰⁰

Anxiety and Depression

Many complementary therapies modulate levels of arousal. The most obvious examples are hypnosis and relaxation therapies. A systematic review included 15 randomized trials that assessed the effects of relaxation therapies on acute, treatment-related anxiety and depression in cancer patients. Scores of patients receiving relaxation therapy were approxi-

mately half a standard deviation better than controls, with differences between groups being statistically significant.¹⁰¹ Several randomized trials have explored the effects of relaxation treatments on anxiety and depression in out-patients. In a typical study, 109 cancer patients with varying diagnoses and different stages of disease were randomized to receive seven weekly 90-minute meditation classes and were encouraged to practice meditation at home. Anxiety and depression scores fell by nearly 50% in the meditation group with little change in controls ($P < 0.01$ for difference between groups on reanalysis).¹⁰²

The broad perception that massage is relaxing has now been documented in randomized trials.^{103–106} Several studies examined the effects of massage on psychologic endpoints in cancer patients. In a high-quality trial, 35 patients undergoing autologous bone marrow transplant were randomized to receive up to nine 20-minute massages during inpatient stay or to standard care control. Massage was superior to control for anxiety, fatigue, and general well-being, although differences for depression did not reach statistical significance.¹⁰⁷ A randomized cross-over study of 87 hospitalized cancer patients found that foot massage reduced anxiety scores substantially whereas the control procedure produced little change.⁹⁹

Music therapy has been shown to reduce mood disturbance in patients undergoing autologous bone marrow transplant: 69 patients were randomized either to receive a course of treatments from music therapists during their inpatient stay or to standard care alone. Total mood disturbance scores fell by approximately two-thirds immediately following music therapy compared to only about 15% in controls ($P = 0.0003$ for the difference between groups). When measured over the course of the inpatient stay, anxiety scores were approximately 33% lower in the music therapy group ($P = 0.014$).¹⁰⁸

Nausea and Vomiting

A variety of cognitive behavioral techniques address chemotherapy-related nausea and vomiting; many include hypnosis and relaxation techniques.¹⁰⁹ Most randomized trials show clinically and statistically significant improvements in nausea and vomiting in patients assigned to relaxation or hypnosis compared to controls (Table 15.1).

There is solid evidence that acupuncture reduces postoperative nausea and vomiting. A meta-analysis of 19 studies involving 1,679 patients showed that acupuncture reduced both nausea (relative risk compared to placebo control, 0.4; 95% CI, 0.2–0.7; 5 trials) and vomiting (relative risk compared to placebo control, 0.5; 95% CI, 0.35–0.65; 8 trials) in the immediate postoperative period. These findings were robust to sensitivity analyses of study size and quality.¹¹⁰

The results for chemotherapy-associated nausea are less clear. In one study, women undergoing myeloablative chemotherapy were randomized to acupuncture, placebo acupuncture, or antiemetic medication. The mean number of vomiting episodes in the three groups was 6.3, 10.7, and 13.4, respectively, with highly significant differences between acupuncture and placebo.¹¹¹ The effects of acupuncture on nausea and vomiting, however, do not appear to persist. One estimate is that the effects of treatment do not last more than approximately 8 hours.¹¹² Wristbands that provide continuous electrical or pressure stimulation to an acupuncture point on

TABLE 15.1. Randomized controlled trials (RCTs) of hypnosis or relaxation versus control.

Author	Year	Patients	Intervention	Result
Jacknow ¹²³	1994	20 children with chemotherapy nausea/vomiting	Hypnosis versus standard care control	No difference in nausea/vomiting but fewer antiemetics in hypnosis group; less anticipatory nausea in hypnosis group at follow-up
Zeltzer ¹²⁴	1991	54 children starting chemotherapy	Hypnosis versus relaxation versus standard care control	Hypnosis superior to nonhypnotic relaxation for control of both anticipatory and posttreatment nausea; both treatments superior to control
Vasterling ¹²⁵	1993	60 adults starting chemotherapy	Relaxation versus distraction versus standard care control	Relaxation and distraction equally effective and superior to control for anticipatory nausea
Morrow ¹²⁶	1982	60 patients experiencing anticipatory nausea	Systematic desensitization (including relaxation) versus standard care control	Decreased anticipatory nausea in the treatment group compared to control
Troesch ¹²⁷	1993	28 newly diagnosed patients about to start chemotherapy	Guided imagery and relaxation versus standard care control	Less nausea and vomiting in the treatment group but no statistically significant differences from controls
Cotanch ¹²⁸	1987	60 patients receiving in-patient chemotherapy	Relaxation versus music tapes versus standard care control	Decreased vomiting in relaxation group compared to controls; trend toward decreased nausea
Holli ¹²⁹	1993	67 patients receiving chemotherapy	Relaxation therapy versus standard care control	No differences in vomiting between groups
Syrjala ¹³⁰	1992	45 patients undergoing bone marrow transplant	Hypnosis versus cognitive behavioral training versus "therapist contact" control versus standard care control	Nausea and vomiting did not differ between groups
Syrjala ⁹⁴	1995	94 patients undergoing bone marrow transplant	Hypnosis versus cognitive behavioral training versus "therapist contact" control versus standard care control	Nausea did not differ between groups
Burish ¹³¹	1981	16 patients undergoing chemotherapy	Hypnosis and relaxation training versus standard care control	Lower nausea scores in treated patients; very low levels of vomiting in both groups
Lyles ¹³²	1982	50 patients undergoing chemotherapy	Relaxation therapy and hypnosis versus standard care control	Lower nausea in group receiving relaxation therapy and hypnosis
Zeltzer ¹³³	1984	19 children with chemotherapy nausea/vomiting	Hypnosis versus supportive counseling	Large reductions in symptoms in both groups; no difference between groups
Burish ¹³⁴	1987	24 patients undergoing chemotherapy	Relaxation therapy versus standard care control	Less nausea and vomiting in relaxation therapy group
Lerman ¹³⁵	1990	48 patients undergoing chemotherapy	Relaxation therapy versus standard care control	Relaxation therapy reduced postchemotherapy nausea; effects on anticipatory nausea depended on patient's predominant coping style
Feldman ¹³⁶	1990	60 patients undergoing chemotherapy	Hypnosis versus standard care control	No difference between groups

the wrist are promoted for purported antiemetic effects, but studies do not support their value.¹¹³⁻¹¹⁶ Wristbands may not provide adequately strong stimulation to the acupuncture point.¹¹⁷

Hot Flashes

Botanicals such as soy and black cohosh are promoted to reduce treatment-related hot flashes in cancer patients. However, evidence suggests that they are not effective. Randomized, placebo-controlled trials show no benefit for black cohosh¹¹⁸ or soy^{119,120} in reducing the frequency of hot flashes in breast cancer patients. Vitamin E decreases hot flashes only minimally,¹²¹ but its low cost and lack of toxicity have led at least some authorities to recommend its use.¹²²

Complementary and Alternative Medicine for Cancer: Summary

Current data suggest that many patients use CAM therapies. The use of complementary therapies for symptom control can be encouraged. These therapies are noninvasive, pleasant, and effective. Randomized trials support their value. Conversely, alternative methods, promoted for use instead of conventional oncologic therapy, should be discouraged. These methods are not effective. Moreover, they are invasive, typically biologically active, expensive, and potentially harmful, as patients may delay timely receipt of beneficial care while trying a nonviable "alternative."

The provision of evidence-based complementary therapies along with mainstream cancer treatment is a relatively

recent development. Termed “integrative oncology” to emphasize the integration of complementary and mainstream care, this synthesis seeks to provide optimal overall management of cancer patients. High-quality research, an integral aspect of integrative oncology, is enabled when the expertise available in cancer programs is applied to the study of complementary therapies. Because research supports the value of complementary modalities in the control of symptoms associated with cancer and its treatment, these modalities should increasingly become part of oncologic care.

Fundamental Aspects of the Cell Cycle and Signal Transduction

Jeffrey R. Skaar and James A. DeCaprio

During normal cycles of cell growth and division, cells are exquisitely sensitive to their environment, responding to many stimuli ranging from nutrient availability, growth factors, and cell density with either increased proliferation or growth arrest. The cell's ability to sense and respond to these environmental cues is lost on the progression of cells to a malignant state, rendering cancer cells resistant to growth inhibition by growth factor withdrawal, contact inhibition, or irradiation. These cancerous cells acquire many genetic and epigenetic mutations that can constitutively activate signaling pathways to mimic growth factor signaling, block growth inhibitory signals, and fundamentally alter core components of the cell-cycle machinery, removing key inhibitors or increasing amounts and activity of key activators. Although the genetic alterations of many upstream genes of diverse function have been shown to lead to malignancy, in the end these upstream factors feed into a core network that governs cell-cycle progression.

The Cell Cycle

The cell cycle can be divided into four phases: G_1 , S, G_2 , and M. G_1 refers to the gap between the mitosis (M) of the previous cell division and the DNA synthesis (S) stage of the upcoming cell, and G_2 refers to the gap between DNA synthesis and mitosis. Additionally, quiescent cells, which are nondividing but metabolically active and terminally differentiated, such as muscle cells or neurons, are considered to be in G_0 phase.

The control of cell-cycle progression from G_1 to S to G_2 to M is tightly controlled by the activities of a small number of heterodimeric kinase complexes (Figure 16.1). The regulatory subunit of each dimer is required for kinase function, and the levels of these regulatory proteins oscillate throughout the cell cycle in response to upregulation by transcription factors and downregulation by the ubiquitin proteasome system. Because of the cyclic behavior of these regulatory subunits, they are called cyclins, and the kinases they regulate are called cyclin-dependent kinases (cdks).

In general, expression of G_1 cyclins activates the G_1 -specific cyclin-cdk complex, allowing transcription of genes required for entry into S phase, including the DNA synthesis machinery; S-phase-specific cyclins; and proteins that remove

inhibitors of S-phase cyclin/cdk activity. The increase in S-phase cyclin expression and function causes activation of the DNA synthesis machinery as well as the transcription of genes required for M phase, including cyclins and the mitosis machinery. Finally, M-phase cyclin-cdk complexes activate the mitotic machinery to break down the nuclear envelope, assemble the mitotic spindle to align the chromosomes during metaphase, and divide the cell during anaphase.

Because the cyclins in each phase of the cell cycle are degraded by the ubiquitin proteasome system on phase progression, once a cell enters the cell cycle, it is obligated to attempt complete cell division. Therefore, the primary control of cell-cycle entry occurs in G_0 cells, when cyclins are not expressed. Exposure of G_0 cells to mitogens induces the expression of cyclins and other proteins required for the cell cycle. After a certain period of exposure to mitogens, the cell reaches the restriction point, and it is irrevocably committed to entering the cell cycle. If mitogens are removed before the restriction point, the cell will exit the cell cycle and reenter G_0 .

When G_0 mammalian cells are stimulated with mitogens, receptor tyrosine kinases transduce signals to activate immediate early transcription factors such as c-Fos and c-Jun, causing expression of the D-type cyclins, the E_2F family of transcription factors, and other early genes required for progression through G_1 .¹⁻³ The activities of these early gene products ultimately control the passage of the cell through the restriction point and into the cell cycle. During G_1 , E_2F family transcription factors are bound by the retinoblastoma protein, pRb, which converts E_2F from a transcriptional activator to a transcriptional repressor via its association with histone deacetylase complexes. As cyclin D levels rise through G_1 in response to mitogenic stimuli, the cyclin forms an active cyclin-cdk complex with either of the two related D-type cyclin cdks, Cdk4 or Cdk6; these active kinase complexes drive the cell through the restriction point by phosphorylating pRb, allowing E_2F to activate transcription of cyclin E (Figure 16.2). As the amount of cyclin D-Cdk complex increases, it acts as a sink for the Cip/Kip family of cdk inhibitors.⁴

The Cip/Kip inhibitors, including p21, p27, and p57, act as potent inhibitors of cyclin E/Cdk2 activity. Cyclin D-Cdk complexes contribute to increasing cyclin E/Cdk2 activity through E_2F -mediated transcription as well as the sequestra-

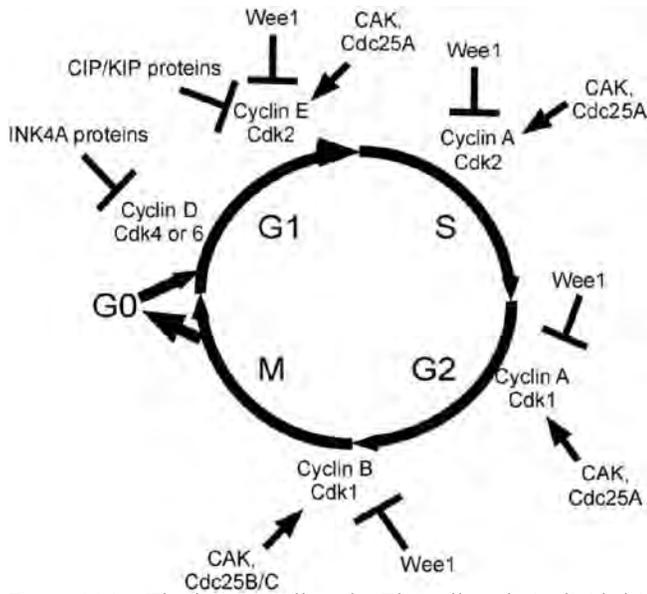

Figure 16.1. The human cell cycle. The cell cycle is divided into four phases: G_1 , S, G_2 , and M. Cyclin D–Cdk4/6 controls early G_1 , cyclin E–Cdk2 controls late G_1 , cyclin A–Cdk2/1 controls S and G_2 , and cyclin B–cdk1 controls G_2 and entry into M phase. Activators and inhibitors of these cyclin–cdk complexes are shown. G_0 is a state defined by quiescent, nondividing cells that have exited the cell cycle.

tion of the Cip/Kip inhibitors. The production of robust cyclin E/Cdk2 activity supplants cyclin D/Cdk4/6 activity as the driving force of progression from G_1 phase to S phase.⁴ At this point, the cell has passed the restriction point, as cyclin D/Cdk4/6 activity is no longer required. Cyclin E/Cdk2 serves to hyperphosphorylate pRb, completely removing its inhibition of E2F, allowing transcription of genes required for S phase, including cyclin A, the S-phase cyclin.

Cyclin A, similar to the D-type cyclins, can bind two distinct cdks, Cdk2 and Cdk1. Currently, any differences in the function between the two cyclin A–Cdk complexes are unknown. The active cyclin A–Cdk2/1 complex has a nuclear localization and is thought to control DNA replication, controlling initiation and restricting replication to once per cell cycle, by phosphorylation of substrates. RPA, Mcm4, and the DNA polymerase α -primase are known cyclin A substrates that are involved in DNA replication.⁵ In addition to a role in regulating DNA replication, cyclin A plays a key role in allowing cell-cycle progression through G_2 phase into M.

During S phase, cyclin B levels begin to increase, and by G_2 phase, two cdk complexes, cyclin A–Cdk1 and cyclin B–Cdk1, are active. The accumulation of active cyclin B/Cdk1 is strictly dependent on cyclin A/Cdk1 activity. During the S and G_2 phases, cyclin A/Cdk1 phosphorylates Cdh1, preventing it from targeting cyclin B to the anaphase-promoting complex (APC) for ubiquitination and degradation.⁵ Active cyclin B/Cdk1 first accumulates in the cytoplasm, where it is thought to prepare structural components of the cell for the upcoming cell division. Cyclin B/cdk1 activity reorganizes the cell's microtubules and microfilaments, and phosphorylates proteins in the nuclear lamina, resulting in this structure's breakdown.⁶ Just before the breakdown of the nuclear membrane, cyclin B/Cdk1 translocates to the nucleus to target further substrates, including those that control the shutdown of RNA polymerase III-mediated

transcription.⁶ Finally, cyclin B and cyclin A are rapidly degraded by the APC before the end of mitosis. The APC also mediates the transition from metaphase to anaphase by degrading securin, the inhibitor of separase. Separase then proceeds to cleave Scc1, a protein found in the cohesin complex of proteins that holds the newly replicated chromosomes together, allowing anaphase to ensue.

In addition to being regulated by their cyclin partners, mammalian cdks are subject to regulation by a number of different inhibitors throughout the cell cycle. These inhibitors can arrest or slow the cell cycle in response to many signals including nutrient depletion, failures in DNA replication, and DNA damage. During the G_1 to S transition, two distinct inhibitor classes function to inhibit Cdk4/6 and Cdk2 activity. The INK4 family of proteins (p16INK4A, p15INK4B, p18INK4C, and p19INK4D) are noncompetitive inhibitors of Cdk4 and Cdk6, binding to these kinases and causing allosteric changes that weaken binding to both cyclin D and adenosine triphosphate (ATP).⁴ With the exception of p19INK4D, the expression of the INK4 family does not appear to be cell-cycle dependent, and p16INK4A, which appears to be the most important of the INK4 proteins, has been shown to increase with age and population doubling. However, the exact mechanism of regulation of this family of proteins remains under investigation.

The Cip/Kip family of cdk inhibitors, which includes p21, p27, and p57, also function at the G_1 to S transition. Cip/Kip inhibitors can inhibit multiple cyclin–cdk complexes with varying efficiencies, but, important for the G_1 to S transition, as already mentioned, they inhibit cyclin E/Cdk2 strongly while inhibiting cyclin D/Cdk4/6 poorly.⁴ When bound to the cyclin E–Cdk2 complex, the Cip/Kip proteins bind the catalytic site of the cdk, blocking ATP from binding. In addition to being inactivated by titration away from cyclin E–Cdk2 complexes by cyclin D/Cdk4/6, p27 is subject to ubiquitin-mediated degradation during S phase. Although the regulation of all the Cip/Kip proteins is not completely understood, the gene for p21, *CDKN1A*, in particular, is subject to upregulation by the p53 tumor suppressor (see following) in response to DNA damage, allowing p53 to block cell-cycle progression.^{3,7–9} p21 is a particularly potent protein for inducing cell-cycle arrests, as it can also inhibit cyclin A/Cdk2 and, indirectly, cyclin A/cyclin B/Cdk1.⁶

During the S, G_2 , and M phases of the cell cycle, cyclin–cdk complexes containing Cdk2 and Cdk1 are also regulated by activating and inhibiting phosphorylations. All the cdks require an activating phosphorylation provided by a Cdk-activating kinase (CAK) composed of cyclin H, Cdk7,

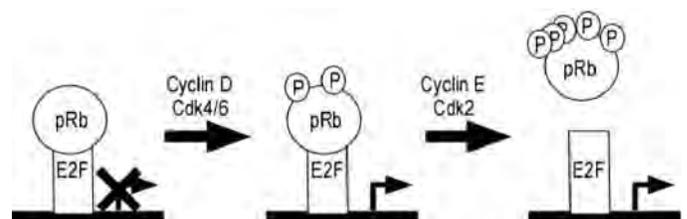

Figure 16.2. Inactivation of pRb by cyclin–Cdk complexes in G_1 . Phosphorylation of pRb by cyclin D/Cdk4/6 in early G_1 partially inactivates pRb, allowing some E2F-mediated transcription. Hyperphosphorylation of pRb by cyclin E–Cdk2 in late G_1 phase completely inactivates pRb, allowing uninhibited E2F-mediated transcription.

and MAT1.^{5,6} Because the cyclin H-Cdk7 complex can be inhibited by the Cip/Kip inhibitor p21, p21 upregulation by DNA damage can induce a G₁ arrest by direct inhibition of cyclin E/Cdk2 and a G₂-M arrest by indirect inhibition of cyclin B/A/Cdk1 via cyclin H/Cdk7 inactivation. However, the most potent control over Cdk2 and Cdk1 activity comes from the inhibitory phosphorylation of two amino-terminal tyrosine residues by the Wee1 kinase.⁶ Phosphorylation of these residues blocks not only the ability of the kinase to transfer phosphate but also the ability to bind ATP. Removal of these inhibitory phosphorylations is accomplished by the actions of a Cdc25 phosphatase member. Cdc25A specifically dephosphorylates Cdk2 and Cdc25B and Cdc25C specifically dephosphorylates Cdk1.^{6,10} The effects of Cdc25B and Cdc25C on Cdk1 are additive, and after activation by Cdc25B, cyclin B/Cdk1 activates Cdc25C by phosphorylation in a positive feedback loop. By regulating the levels and activities of Wee1 kinase activity and Cdc25 phosphatase activity, the cell can stop or promote cell-cycle progression as required. For example, the detection of DNA damage during S phase results in the rapid degradation of Cdc25A and increased expression of Wee1, causing a cell-cycle arrest.¹⁰

Finally, cell-cycle progression can be blocked by other pathways not directly involving cdks and cdk inhibitors. The mitotic spindle checkpoint monitors the proper attachment of chromosomes to the mitotic spindle and the proper alignment of these chromosomes along the metaphase plate. Failures in the mitotic spindle activate a mitotic checkpoint complex (MCC) that includes Mad2, BubR1, and Bub3. Mad2 and BubR1 both can bind and inhibit Cdc20, the subunit of the APC that targets securin, as well as cyclin B, for degradation.¹¹ Inhibition of APC-mediated degradation of securin prevents cleavage of the cohesin complex holding replicated sister chromosomes together, preventing mitosis.

The Cell Cycle and Cancer

With all the growth-promoting and -inhibiting signals that are integrated into the core cell-cycle controllers, it is surprising that the majority of cancers, although arising from mutations in many different genes, result from the improper activation or inactivation of relatively few pathways. Recent research in cell culture systems coupled with genetic analysis has shown that human cells acquire changes to as few as five distinct pathways, mainly controlling protein phosphatase 2A (PP2A) function, telomere maintenance, RAS activation, the pRb pathway, and the p53 pathway.¹ Currently the contribution of PP2A inactivation to cancer is unknown, although it has been suggested that only the inactivation of a particular subtype of PP2A complexes is required for transformation of human cells. However, significantly more is known about telomere maintenance, RAS activation, the pRb pathway, and p53 pathway in human cancer.

Telomerase

Telomeres, the repetitive, structured regions of DNA at the end of chromosomes, are required elements for chromosome integrity. These regions are not synthesized by the normal replicative DNA polymerases, but they are instead added to the end of chromosomal DNA by the telomerase ribonuclear

protein, composed of an RNA template and the telomerase reverse transcriptase (TERT) protein.¹ The telomeres form a unique structure that allows for linear DNA chromosomes to persist without the activation of DNA damage pathways. After expression of telomerase ceases during the differentiation of a cell, subsequent DNA replications cause a progressive shortening of telomeric regions of DNA as a result of the inability of normal replicative DNA polymerases to completely copy the end of chromosomes. Over time, the loss of telomeric DNA to the "end replication problem" results in the activation of a checkpoint similar to DNA damage responses.^{1,12} In normal cells, this telomeric checkpoint activation results in senescence, but mutations in the pRb pathway and the p53 pathway can allow these cells to continue to cycle.^{1,12} Although these cells can escape senescence, the shortening of telomeres continues with each replication, reducing overall telomere length to a critical level. At this crisis point, telomeres fail to protect chromosome ends, activating DNA damage responses that result in chromosome fusion, leading to breakage, genomic instability, and massive amounts of cell death.¹² Rare escape mutants of crisis either reactivate telomerase to maintain telomere length or acquire mutations that activate the alternative lengthening of telomeres (ALT) pathway. For cancer cells to gain infinite replicative capacity, they must maintain telomere length via one of these two methods, most commonly reactivation of telomerase expression.

The pRb Pathway

The ability of a cancerous cell to break through senescence is governed by mutations affecting the pRb pathway, the p53 pathway, and the activation of Ras. As already discussed, pRb acts as the ultimate inhibitor of the G₁ to S transition by binding and converting the E₂F transcription factor into a repressor. Hyperphosphorylation of pRb, initially by cyclin D/Cdk4/6 and then cyclin E/Cdk2, dissociates pRb from E₂F, allowing E₂F-mediated transcription to occur. The importance of pRb in cancer is documented in hereditary retinoblastoma, which originally defined pRb as a tumor suppressor protein. In hereditary retinoblastoma, patients inherit one wild type and one mutant allele of *RB1*. The normal allele of *RB1* is lost in a somatic cell, leading to the development of an *RB1*-/- tumor. This loss of heterozygosity (LOH) defines the classic tumor suppressors.³ Although mutation of *RB1* itself leads mainly to retinoblastoma and some osteosarcomas, the importance of the pRb pathway to all cancers has been confirmed by mutation of pRb or pRb pathway modifiers in other tumors. Nearly all known tumors contain a mutation that activates Cdk4, amplifies cyclin D, or eliminates the Cdk4/6 inhibitor p16INK4A. In particular, a high percentage of breast cancers exhibit overexpression of cyclin D1, whereas p16INK4A is often inactivated in melanomas and pancreatic cancer.⁴ Even more strikingly, known human tumor viruses, such as human papilloma virus, the causative agent of most cervical cancers, and Kaposi's sarcoma-associated herpesvirus, the causative agent of Kaposi's sarcoma, target the pRb pathway specifically through direct pRb inactivation or by expression of a constitutively active D-type viral cyclin, respectively. Finally, mutations in the pRb pathway appear to be mutually exclusive, with tumors containing mutations in only one gene in the pathway. Of

special note, mutations within p16INK4A are especially potent because it shares its second exon, read in a different frame, with the p14ARF (alternate reading frame) tumor suppressor, which functions in the regulation of p53.^{2,13} The two proteins are both considered products of one gene, *CDKN2A*.

The p53 Pathway

Mutations in the p53 pathway allow cancerous cells to avoid senescence by preventing cell-cycle arrest at the G₁ to S and G₂ to M transitions. *TP53* is a canonical tumor suppressor gene and is subject to LOH in tumors. Germ-line mutation of p53 causes Li Fraumeni syndrome, an early-onset cancer syndrome, resulting in a broad spectrum of tumors, including cancers of the brain, breast, and blood.¹⁴ Additionally, Wilms' tumors often have germ-line mutations in *TP53*. Mutations in *TP53* are found in more than 50% of all sporadic tumors, and, in some capacity, p53 appears to be dysregulated in every cancer. p53 functions as a tetrameric transcription factor, promoting the expression of cell-cycle arrest genes and proapoptotic genes in response to signals of DNA damage, aberrant growth signaling, heat shock, and other cellular stresses.⁷ Tumors commonly contain point mutants in the p53 DNA-binding domain, and mutations often result in the abnormal stabilization of p53. Additionally, heterozygous mutations of *TP53* can function as dominant negatives for p53 function because of the tetramerization functions of p53.^{3,9} Finally, p53 is also a target for inactivation by human papilloma virus in cervical cancer, affirming its importance in the development of cancer.

Functional inactivation of p53 is advantageous for tumor formation because it affects two cell-cycle transition points as well as apoptotic pathways. The dual function of p53 allows the cell to stop cycling to attempt to repair damage and to undergo apoptosis if the damage is irreparable. When induced by cellular stress, p53 activates transcription of the gene for the Cip/Kip inhibitor p21 to induce both a G₁ and G₂-M arrest.^{7,9} Additional products of p53 target genes, including GADD45 and 14-3-3 σ , also aid in arresting the cell cycle.⁹ Proapoptotic p53 target genes include the genes for PUMA, Apaf-1, and Bax, a critical inhibitor of the antiapoptotic protein Bcl-2.^{9,15} A negative feedback loop is also initiated by p53-mediated transcription, increasing levels of the p53 ubiquitin ligase Hdm2, potentially allowing resumption of the cell cycle following repair of damage.

Under normal conditions, p53 is extremely unstable, but upon exposure to genotoxic stress, it is stabilized by phosphorylation of serine residue 15 (Figure 16.3). Depending on the genotoxic stress, the kinase responsible for this phosphorylation is either the ataxia telangiectasia-mutated (ATM) kinase or the ataxia telangiectasia and Rad3-related (ATR) kinase.^{3,9} Notably, inherited mutations in *ATM* result in cancer, although not all the ATM cancer-relevant functions involve p53. Phosphorylation of serine 15 interferes with p53 binding to the ubiquitin ligase Hdm2, blocking ubiquitination of p53 and resulting in stabilization of p53. As noted earlier, stabilized p53 induces the expression of genes involved in arresting the cell cycle to allow for DNA repair but also induces proapoptotic genes if the cell cannot repair the damage. Transcriptional activation by p53 is dependent on binding to the transcriptional coactivators p300/CBP that activate p53 by acetylation of C-terminal lysines and func-

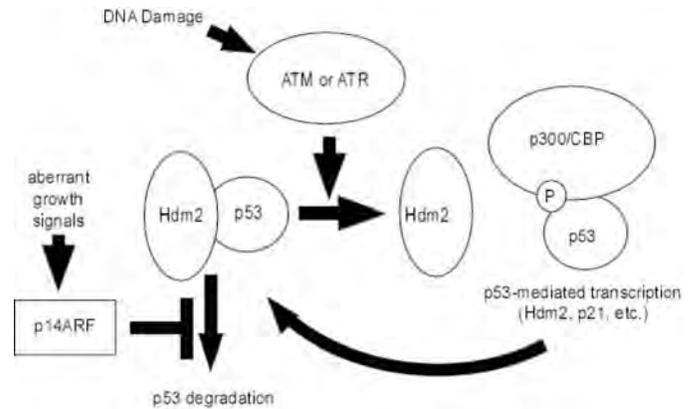

Figure 16.3. Regulation of p53 activity. Phosphorylation of p53 by ataxia telangiectasia-mutated (ATM) or ataxia telangiectasia and Rad3-related (ATR) in response to DNA damage leads to the dissociation of the p53–Hdm2 complex, resulting in p53 stabilization. p14ARF inhibits the ubiquitin ligase activity of Hdm2 toward p53, resulting in p53 stabilization.

tion as a histone acetyltransferase for transcription. p53 can also be activated in response to aberrant growth signals, such as inappropriate inactivation of pRb, through a distinct pathway involving p14ARF.¹³ p14ARF binds to Hdm2 and prevents the polyubiquitination of p53 independent of p53 phosphorylation.² Activation or overexpression of E₂F or c-Myc induces apoptosis through p14ARF-mediated stabilization of p53, creating a link between the pRb and p53 pathways.

Because of their functional significance to the p53 pathway, Hdm2 and p14ARF are often dysregulated in human cancer, and it is thought that the majority of tumors with wild-type p53 overexpress *HDM2* or inactivate *CDKN2A*, the gene encoding p14ARF. In particular, p14ARF mutations are common in melanoma. Although it is not strictly required to inactivate both p53 and pRb through the same mutation event, both Hdm2 and p14ARF can become dysregulated by mechanisms that also inactivate the pRb pathway. Hdm2 is often amplified in human cancers as part of an amplicon with Cdk4, and p14ARF is often lost by deletions that affect p16INK4.^{2,4} The role of other proteins intimately associated with p53 in human cancer, such as p300/CBP, is less clear, although they remain a target of investigation.

Signal Transduction

The mitogenic signals that a cell receives are transmitted through receptor-associated tyrosine kinases (RTKs) to RAS, which in turn activates a multitude of cellular pathways leading to cell growth and proliferation. Therefore, a broad class of oncogenic mutations that occur in signal transduction pathways can generally be considered RAS pathway activators. Oncogenic mutations in the RAS pathway can occur upstream of RAS, downstream of RAS, or in RAS itself. Activated mutants of all three RAS proteins can promote oncogenesis, and, although their functions are not entirely overlapping, a generic RAS signaling pathway is described next (Figure 16.4).¹⁶

The RAS proteins are small, farnesylated GTPases. Farnesylation, the attachment of a 15-carbon lipophilic chain, is required for proper localization of RAS to the cell membrane in close proximity to RTKs.^{16,17} When mitogens bind to an

RTK, the receptor dimerizes and becomes autophosphorylated, allowing the SH₂ domain of an adapter protein known as growth factor receptor-bound protein 2 (GRB2) to bind, which in turn recruits the son of sevenless (SOS) protein to the cell membrane, where RAS is anchored.¹⁷ SOS functions as a guanine nucleotide exchange factor (GEF), facilitating the ability of inactive RAS to become active RAS by exchanging bound guanosine diphosphate (GDP) for guanosine triphosphate (GTP). RAS in the GTP bound state remains active until a GTPase-activating protein (GAP) allows the hydrolysis of GTP to GDP.¹⁷

GTP-bound RAS can activate a multitude of pathways, but two are particularly relevant to our understanding of cancer. First, RAS activates the serine/threonine kinase RAF, which subsequently activates the mitogen-activated protein kinase (MAPK) pathway.¹⁷ The end effect of the activation of this pathway is the activation of c-Fos and c-Jun by phosphorylation, resulting in the upregulation of gene expression required for the G₁ phase of the cell cycle, including the D-type cyclins. A second pathway activated by RAS is the phosphatidylinositol 3-kinase (PI-3) pathway.¹⁷ Activated PI-3 kinase phosphorylates phosphatidylinositol 4,5-bisphosphate to produce the second messenger phosphatidylinositol 3,4,5-triphosphate. This second messenger lipid can activate numerous other proteins including the kinase Akt. Phosphorylation by Akt promotes growth by inactivating many proapoptotic proteins such as Bad and the forkhead family of transcription factors. The PI-3 kinase pathway also affects levels of the Cip/Kip protein p27, most likely through upregulation of the proteins required for p27 degradation. Finally, the functions of the PI-3 kinase pathway are antagonized by the phosphatase and tensin homologue (PTEN) protein that

removes a phosphorylation from the PI-3 kinase-generated secondary messengers.

The RAS pathway and various subpathways are subject to activation at many points in cancer. Activating mutations in the epidermal growth factor receptor (EGFR), platelet-derived growth factor receptor (PDGFR), c-Kit, and FMS-like tyrosine kinase 3 (FLT3). RTKs are common in cancer, as well as simple overexpression of normal proteins.¹⁸⁻²¹ Mutations in RAS that maintain the GTP-bound state are also found in tumors, and the inactivation of RAS GAPs, such as the NF1 tumor suppressor, can lead to RAS activation through decreased rates of hydrolysis of GTP.¹⁶ Additionally, several downstream RAS effectors have links to cancer. BRAF activations have been observed in many patients, and the PTEN tumor suppressor is also subject to inactivation in multiple cancers. Finally, RTKs are not the only RAS activators. Other tyrosine kinases such as the translocation product BCR-Abl can bind GRB2 and activate RAS. *BCR-Abl* is the oncogene found on the Philadelphia chromosome, and activation of RAS by BCR-Abl is required for its oncogenic function.²²

Targeted Therapy

Historically, cancers have been treated with nonspecific genotoxic agents and antimetabolic drugs such as cisplatin and taxol. Such chemotherapeutic agents are successful in killing cancerous cells; however, their lack of specificity can result in increased toxicity for normal cells as well. Knowing the pathways required for the transformation of human cells allows not only the rational design of drugs against specific pathways in cancer, but also the correct application of treatment based on the mutations present in individual tumors. In particular, the pRb pathway and Ras pathway have been examined for potential small molecule drugs that are effective and easily delivered. Both these pathways contain enzymes that catalyze posttranslational modifications required for functional activity, and these enzymes are particularly important for small molecule inhibitor approaches.

CDK Inhibition

Although designing drugs for restoring pRb binding to, and repression of, E₂F would be extremely difficult, the G₁ cyclin-cdk complexes appear to be good candidates for rational drug design. Preventing hyperphosphorylation of pRb should block the cell from breaching the restriction point, preventing cell-cycle progression. The inhibition of the G₁ cyclin-cdk complexes can be targeted in two distinct ways. The most obvious method of inhibition is the direct inhibition of the desired cyclin-cdk complex, but a second method of cyclin/cdk inhibition, analogous to the effect of the Cip/Kip p21 on cyclin B/Cdk1, seeks to inhibit the cyclin/cdk activation by CAK or prevent inhibition by Wee1.²³ Many cdk inhibitors have been developed, with varying degrees of specificity for individual cdks. In general, these inhibitors tend to inhibit other cellular kinases as well as cdks, and the design of absolutely specific cdk inhibitors is not imperative, providing that nonspecific inhibitors are effective treatments. Currently the most promising cdk inhibitors in clinical trials are flavopiridol and UCN-01, both of which are nonspecific cdk inhibitors.

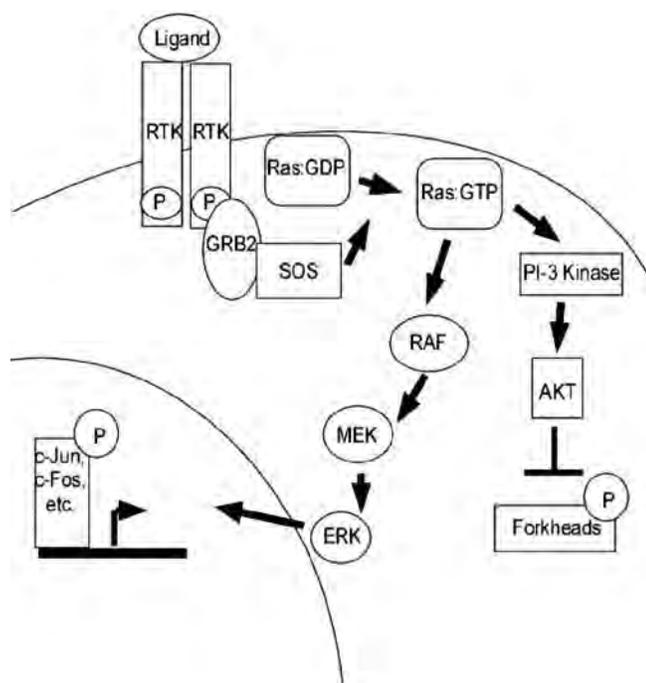

Figure 16.4. The RAS pathway. Mitogenic stimuli from growth factors are transmitted through receptor tyrosine kinases (RTKs) to RAS, which becomes active by exchanging guanosine diphosphate (GDP) for guanosine triphosphate (GTP). GTP-bound RAS can activate many pathways, including the RAF and phosphatidylinositol 3-kinase (PI-3) kinase pathways.

Flavopiridol inhibits a broad spectrum of cdk's by acting as a competitive inhibitor of ATP for the binding pocket of cdk's.²³ Although the inhibitory effect of flavopiridol on most cdk's can be competed away by the addition of excess ATP, the inhibitory effect of flavopiridol on cyclin T/Cdk9 cannot be competed away by the addition of excess ATP, making the exact mechanism of inhibition of cyclin T/Cdk9 unclear. Additionally, flavopiridol appears to be more specific for a subset of cdk's because it is less potent in its inhibition of cdk7 (CAK). Cell-cycle arrests from flavopiridol can result at either the G₁-S transition or the G₂-M transition. As expected, the G₁-S transition results in part from the direct inactivation of Cdk4/6/2, but flavopiridol also reduces *CYCLIN D1* expression and inhibits activation of G1 cdk's by CAK.²³ The inhibition of CAK can also result in the G₂-M arrest.

UCN-01 causes cell-cycle arrest in a different manner from flavopiridol, regulating the activity of cdk's indirectly at low concentrations.²³ Created by rational design from staurosporine, a nonspecific kinase inhibitor, UCN-01 affects several kinase targets, including PKC, cdk's, Wee1, and PDK1.²³ Although UCN-01 only directly inhibits cdk's at high concentrations, it has an antiproliferative effect that functions in part through its inhibition of Wee1. Blocking Wee1 activity leads to increased activation of Cdk1, causing premature entry into mitosis and apoptosis. Recent research also indicates that UCN-01 can inhibit PDK1, which may contribute to the antiproliferative effects. PDK1 activates Akt by phosphorylation, so inhibition of PDK1 would prevent Akt from inactivating the forkhead family of transcription factors. Although UCN-01 affects cdk regulation through Wee1, the drug clearly has off targets, such as PDK1, which may contribute to its success or failure as a chemotherapeutic agent.

Ras Inhibition

The RAS pathway offers many possibilities for the small molecule approach, including the targeting of RAS itself, modifiers of RAS activity, upstream activators, or downstream effectors. Of these approaches to inhibition of RAS activity, targeting of RAS itself has been the least successful. The development of drugs that block GTP binding and do not result in the activation of RAS has been difficult. Because of the high concentrations of GTP in a cell, it is likely that such a drug would have to be used at very high concentrations.²⁴ Instead, most attempts to target RAS pathways have focused on RAS modifiers, downstream effectors, and upstream activators.

The modification of RAS by farnesyltransferase is essential for the proper membrane localization and activation of RAS. Farnesyltransferase adds a 15-carbon chain to a cysteine near the C-terminus of RAS, which is then cleaved by an endopeptidase before the new C-terminus is methylated by a methyltransferase.¹⁷ After these reactions, RAS localizes to the plasma membrane, where K-RAS and N-RAS, but not H-RAS, undergo an additional palmitoylation. Soon after the discovery of this pathway, inhibitors of the farnesyltransferase were developed. These inhibitors are quite successful in inhibiting farnesyltransferase activity *in vitro* and *in vivo*, but they have been ineffective in inhibiting RAS in patients because of the alternative pathways for targeting K-RAS and N-RAS to the membrane.^{24,25} In the presence of farnesyltransferase inhibitor, K-RAS and N-RAS become substrates

for geranylgeranylation, the addition of a 20-carbon group that substitutes for farnesylation. Inhibitors of this process were also generated, but the combination of farnesylation and geranylgeranylation inhibitors results in high levels of cytotoxicity, most likely because of other targets of farnesylation and geranylgeranylation.²⁵ Despite the lack of success of farnesyltransferase inhibitors, the endopeptidase and methyltransferase involved in RAS localization remain possible targets for this approach.

The inhibition of downstream RAS pathways has also been an area of active research for chemotherapeutic agents. The signal transduction machinery of the BRAF and PI-3 kinase pathways appears suitable for the development of small molecule inhibitors. In fact, inhibitors of the BRAF and MEK kinases have been developed and used in clinical trials, and although the compounds are successful in inhibiting their kinases, they generate only partial responses.²⁴ More recent attempts to target downstream pathways are focusing on the PI-3 kinase pathway, but these attempts remain in their infancy.

Receptor Tyrosine Kinase Inhibition

By far the most successful approach to targeting the RAS pathway in cancer has been to develop inhibitors of upstream activators of RAS. The development of inhibitors for specific RTKs limits the utility of these drugs to cancers where that particular RTK is overactive, but given these constraints, this class of drugs seems highly effective. RTKs play prominent roles in many cancers, ranging from non-small cell lung cancer to breast cancer to gastrointestinal stromal tumors, which often feature activation/overexpression of EGFR, ErbB2/HER-2, and c-Kit, respectively.^{22,26} Additionally, the Bcr-Abl oncoprotein, which causes chronic myelogenous leukemia, can mimic RTK signaling. The fusion of Bcr to c-Abl redistributes the normally nuclear c-Abl activity to the cytoplasm, where it can activate RAS.

Drugs using two different mechanisms of action have been used successfully against the upstream activators. First, herceptin, a humanized antibody against the extracellular domain of Erb2, has been used in treating Erb2/HER2/Neu-positive breast cancers. Erb2 is the most highly active EGFR family member, and although there is no known ligand for Erb2, activation of other EGFR family receptors by ligand binding results in their heterodimerization with Erb2 and increased signaling potential.^{21,26} The antibody stops the transmission of signals to RAS before they start by binding Erb2, blocking dimerization and activation, and stimulating internalization and degradation of the receptor.²⁶ Herceptin may also contribute to immune responses against tumors, as demonstrated by the increased effectiveness of herceptin with a complete Fc region of the antibody. Several other humanized antibodies have been approved for use in targeting RTKs; erbitux targets EGFR, whereas avastin targets vascular endothelial growth factor receptor (VEGFR).

The second class of drugs is small molecule inhibitors of the tyrosine kinase activity of receptors such as PDGFR and EGFR, which have been targeted for inhibition successfully with gleevec and iressa.²⁶ Gleevec is the final product of a screen that began looking at modified ATP competitive inhibitors of PKC- α for the inhibition of PDGFR, which is activated in many tumors. Although it was designed as an

inhibitor or PDGFR, it functions against RTKs related to PDGFR, such as c-Kit. Surprisingly, it also was found to be effective against the Bcr-Abl fusion protein. When used in the treatment of cancers resulting specifically from activations of c-Kit and Bcr-Abl, such as gastrointestinal stromal tumors and chronic myelogenous leukemia, respectively, gleevec has been wildly successful.²⁶ Iressa, a small molecule inhibitor of EGFR, has also been a successful treatment in non-small cell lung cancer, and inhibitors of several other RTKs involved in cancer, such as FLT3, are under development.²⁰

Although antibodies and small molecules targeting RTKs are effective, they have limited utility for the treatment of multiple cancers, as the targeted RTK must be activated in a tumor for the drugs to have an effect. For instance, herceptin is only beneficial in breast cancers expressing Erb2, which encompass only 30% of all breast cancers.²⁶ Even further specificity has recently been shown with non-small cell lung cancers and iressa. The target of iressa, EGFR, is expressed in the tumors of multiple patients, but the best response is seen only in a subset of patients who have somatic mutations in the kinase domains of EGFR.^{18,19} This exquisite sensitivity has also been reported for gleevec treatment of tumors containing c-Kit mutations. Taken together, the examples of herceptin, iressa, and gleevec, show that inhibition of RTKs is extremely effective only when the expression pattern and mutations of the receptors in any given tumor are known.

Although much is known about the core cell-cycle machinery and the alterations of the machinery in cancer, many modifiers of these proteins, either upstream or downstream, and their connection to the core cell-cycle machinery remain a mystery. Further research into these areas will present new targets for the rational design of drugs to combat cancer. The continued development of effective cancer treatments is dependent upon a further understanding of the pathways that lead to cancer, the development of drugs that inhibit these pathways, and the ability to determine which drugs to use against specific cancers or even the tumors of specific patients.

Viral Carcinogenesis

Michele Carbone and
Giuseppe Barbanti-Brodano

Important causes of human tumors are biologic and environmental agents, mostly of a chemical and physical nature, that act by genotoxic mechanisms which induce alterations in the cell genome such as chromosomal deletions, rearrangements, and mutations. In the complex multifactorial pathogenesis of cancer, viruses often participate as biologic cofactors that cooperate with chemical and physical agents in both the initiation and progression of tumors. Thus, the detection of a tumor virus in a given tumor does not establish causation. Moreover, the genetic background of an individual and his/her immune status at the time of infection or during viral latency may influence susceptibility to various carcinogens, especially viral carcinogens. Often, it appears that oncogenic viruses act at the beginning of tumor development, inducing in the host cell a number of genetic alterations and immortalizations that can lead to tumor growth. Viruses at other times can be oncogenic only upon infection of cells that already contain genetic alterations. For example, BKV can transform human mesothelial cells that overexpress Notch-1 and which express telomerase activity, whereas in the absence of these alterations, mesothelial cells were not transformed. Oncogenic viruses may act directly, as the combined effects of viral sequences or gene products within the target cell lead to transformation. In other circumstances, the role of viruses may be more subtle, that is, predominantly indirect. Examples of this condition are liver cancer, arising during hepatocyte regeneration that follows hepatitis B and C virus infection, and acquired immunodeficiency syndrome (AIDS)-associated neoplasms, favored by loss of antitumor immune surveillance as a result of human immunodeficiency virus (HIV) infection of the immune system and consequent immunosuppression. HIV-induced immunosuppression allows the emergence of oncogenic viruses such as Epstein-Barr virus (EBV), which causes B-cell lymphomas in AIDS patients. Thus, in AIDS, two viruses cooperate independently to cause human cancer. It is also argued that the regenerative process associated with liver cirrhosis, which is caused by hepatitis B virus (HBV) and hepatitis C virus (HCV) infection, and the release of cytokines by the inflammatory infiltrate in the regenerating liver favor tumor development. In this latter scenario, the role of HBV and HCV in causing hepatocellular carcinoma would be indirect yet critical.

Viruses are important causes of cancer in several animal species, and they are increasingly implicated in human neo-

plasia. Because oncogenic viruses are generally involved in the initial phases of tumor development, control of viral infection should prevent or reduce the incidence of those tumors linked to viral infection. Cancer-associated viruses belong to several families of deoxyriboviruses and riboviruses (Table 17.1). The International Agency for Research on Cancer (IARC) so far has identified six viruses—human papillomavirus (types 16 and 18), Epstein-Barr virus, hepatitis B virus, hepatitis C virus, human T-cell lymphotropic virus type I, and human immunodeficiency virus type 1 (also, KSHV is a likely candidate)—as group 1 carcinogens, that is, agents that have been shown to be carcinogenic in humans. Together, these viruses may cause or contribute to about 15% of human malignancies.¹ However, if other viruses for which the evidence is suggestive but not definitive, and the group 2 carcinogens are included, this value would almost double.¹ Ment in SV-40 as an emerging carcinogenic agent.

The classic Koch's postulates, formulated to demonstrate the etiologic role of microorganisms in infectious diseases, cannot be applied directly to prove the viral etiology of human tumors for various reasons: (1) several tumor-associated viruses are ubiquitous in humans, and (2) they produce a persistent or latent infection in many human tissues, making epidemiologic studies difficult. Viruses are seldom complete carcinogens, and their carcinogenic potential becomes apparent only when studied together with those carcinogens associated with a specific tumor type. For example, skin carcinomas in patients infected with cutaneous human papillomavirus (HPV) develop in sun-exposed areas because of the cocarcinogenicity of UV light; SV-40 infection may carry a higher risk of mesothelioma development in individuals exposed to asbestos, etc. Furthermore, cooperation among different viruses may be required for cocarcinogenesis, such as HIV-1 and EBV in lymphomas that develop in AIDS patients. In this case, HIV causes immunosuppression that facilitates EBV lymphomagenesis. Thus, because Koch's postulates do not address these issues, new rules should be considered to establish the oncogenic role of viruses in humans.²⁻⁴ To address this problem, the National Cancer Institute (NCI) organized (December 11-12, 2003), an international workshop with some of the leading experts in various disciplines. The recommendations of this workshop concerning the identification of human cocarcinogens appeared in an issue of *Seminars in Cancer Biology* in 2004, edited by M. Carbone and M. Wong.

TABLE 17.1. Human tumor viruses.

<i>Virus family</i>	<i>Virus</i>	<i>Genome type</i>	<i>Associated tumors</i>
Herpesviridae	Epstein–Barr virus	DNA	Burkitt's lymphoma B-cell and T-cell lymphomas Nasopharyngeal carcinoma Gastric cancer Leiomyomas and leiomyosarcomas
	Human herpesvirus 8	DNA	Breast cancer (?) Kaposi's sarcoma Primary effusion lymphoma Castleman's disease Multiple myeloma (?)
Papovaviridae	BK virus	DNA	Brain, bone, pancreatic, and urinary tract tumors
	JC virus	DNA	Brain tumors, mainly medulloblastoma, colorectal tumors
	Simian virus 40	DNA	Mesothelioma, brain and bone tumors, lymphomas
	Human papillomavirus	DNA	Skin, anogenital, oral, and laryngeal papillomas and carcinomas
Hepadnaviridae	Hepatitis B virus	DNA	Hepatocellular carcinoma
Flaviviridae	Hepatitis C virus	RNA	Hepatocellular carcinoma Lymphoproliferative diseases (?)
Retroviridae	Human T-cell lymphotropic virus I	RNA	Adult T-cell leukemia and lymphoma
	Human T-cell lymphotropic virus II	RNA	Hairy cell leukemia Kaposi's sarcoma
	Human immunodeficiency virus 1	RNA	B-cell lymphoma Anogenital carcinoma (?) Hepatocellular carcinoma (?)

Oncogenic Deoxyriboviruses

Herpesviruses

EPSTEIN–BARR VIRUS

Epstein–Barr virus (EBV) is a member of the human herpesvirus subfamily Gammaherpesviridae. EBV is an enveloped virus with a double-stranded DNA genome of 172 kilobases (kb) containing more than 100 genes. EBV is a ubiquitous virus that infects and persists in about 90% of the world's human population. EBV selectively infects mature B lymphocytes, the only cells bearing the CD21 receptor for virus attachment, recognized by the viral envelope glycoprotein gp350.⁵ However, natural killer (NK) cells can also be infected with EBV and are associated with unusual malignancies of these cell types. Primary infection with EBV usually occurs in childhood. In most cases, the clinical course is unapparent. In a subset of infected individuals, primary EBV infection can result in infectious mononucleosis, a self-limited lymphoproliferative disease. The syndrome of mononucleosis is more frequent when primary infection is delayed into adolescence. Once infected, individuals become lifelong virus carriers and, when the virus has gained access to the B-cell compartment, it is disseminated to many organs including liver, Bm, and central nervous system (CNS). B cells are eliminated by specific cytotoxic T cells, and T-cell immunosuppression can lead to the development of EBV-

associated malignant lymphomas. However, EBV is also associated with the development of lymphoid and epithelial malignancies in apparently immunocompetent hosts.⁶

After infection, EBV enters a latent state, with or without a minimal production of viral progeny. During latency the viral genome remains in an episomal state, sometimes with rare viral DNA molecules integrated into the cell genome.⁵ Latent infection by EBV causes the immortalization of B lymphocytes, which lose the ability to achieve terminal differentiation. EBV-infected B lymphocytes produce antibodies but never reach the stage of plasma cells.⁵ During latency, EBV expresses only some of its genes: six proteins localized in the nucleus and called Epstein–Barr nuclear antigens (EBNA) 1, -2, -3A, -3B, -3C, and leader protein (LP); three proteins localized in the cytoplasmic membrane, called latent membrane proteins (LMPs) 1, -2A, -2B; two small noncoding RNAs (EBER-1 and EBER-2); and the *BARF1* gene, located in the *BamHI-A* region of the viral genome.⁵ Several of these genes are expressed in EBV-immortalized lymphoblastoid cell lines and in EBV-associated malignancies.^{5,6} These genes have activities that may contribute to the deregulation of normal cell growth and to oncogenesis. EBNA-1 is a DNA-binding protein that is postulated to act as a transcriptional activator of the cellular recombinase-activating genes RAG-1 and RAG-2,⁷ which in turn lead to chromosomal translocations within the host cell. The main function of EBNA-1 is maintenance of the EBV episome during cell division. EBNA-2 (in concert with EBNA-LP) also functions as a transcriptional activator

that induces the expression of *CD21*, which encodes the cellular EBV receptor, and *CD23*, the tyrosine kinase *c-fgr*, *cyclin D2*, and all the other latent EBV genes, including the LMP-1, LMP-2A, and LMP-2B.^{5,6,8} LMP-4 by itself cannot transform human cells. LMP-1 transforms rodent cells and is necessary for transformation of human cells; it has multiple effects, including increased expression of cellular adhesion molecules, upregulation of lymphocyte activation antigens, and stimulation of the transcription factors, such as AP1 and NF- κ B.^{5,6}

The human lymphoid malignancies associated with EBV infection are Burkitt's lymphoma, B-cell lymphomas in immunocompromised individuals, T-cell lymphomas, the X-linked lymphoproliferative disease, and Hodgkin's disease.⁹⁻¹⁵ Lymphocyte immortalization induced by EBV and the acquisition of an indefinite life span may increase the probability of accumulating genetic alterations that can lead to malignancy. In fact, EBV-positive lymphomas typically develop specific chromosomal translocations involving the regulatory sequences of the immunoglobulin genes on chromosome 14q32 (76% of cases), 22q11 (16% of cases), or 2p11 (8% of cases), which are joined to the *c-myc* proto-oncogene on chromosome 8q24.¹⁶ These translocations cause the deregulated activation of *c-myc* expression and are the basis for oncogenicity in BL. *c-myc* activation renders the proliferation of EBV-immortalized cells independent of *LMP1* and *EBNA2* expression.¹⁷ EBV infection may favor, but is not a necessary prerequisite, for the rearrangement of *c-myc* and for lymphoma development, because rare cases of endemic Burkitt's lymphoma (BL) in equatorial Africa are EBV negative.^{18,19} Moreover, only 15% to 20% sporadic BL in the Western world are EBV positive whereas all BL contain the typical *c-myc* translocations.²⁰ EBV-associated B-cell lymphomas occur with notable frequency in patients with acquired immunodeficiency syndrome (AIDS), and 65% to 100% of AIDS lymphomas, especially brain lymphomas, contain EBV DNA. These tumors, in addition to *c-myc* translocations, often contain *c-ras* mutations, p53 inactivation by deletion or point mutation, and *bcl-6* rearrangements.^{21,22} A similar set of molecular alterations was described in EBV-positive lymphoproliferative disorders and lymphomas arising in immunosuppressed transplant patients.²³ I think EBV by itself is able to drive these proliferative conditions. They are initially polyclonal, and through selection become monoclonal and autonomous, that is, no longer responsive to reduction of immunosuppressive drugs. These findings support the notion that multiple genetic alterations are required for the development of the transformed phenotype. EBV, by contributing to some of these genetic changes, increases the risk of these tumors in infected individuals.

The X-linked lymphoproliferative disease (XLP) or Duncan's disease is a hereditary syndrome caused by the alteration of a gene located at chromosome region Xq25.^{24,25} The XLP gene, called SH2D1A, was recently cloned,²⁵ and its product regulates the interaction between B and T lymphocytes. Mutations in the SH2D1A gene, detected in XLP patients, generate a state of immune dysfunction that induces an altered response to viral infections, especially to EBV. XLP patients, when infected with EBV, develop in approximately 65% of cases a severe form of infectious mononucleosis that is fatal in 70% of children less than 10 years of age.²⁵ Most surviving patients develop a lymphoproliferative disorder or a lymphoma, and a few develop aplastic anemia or vasculi-

tis.²⁵ The pathogenesis of the disease is related to an enhanced response to EBV infection.²⁵ Following infection with EBV, normal individuals develop a T-cell response to EBV-infected B cells with elevated serum levels of TH-1 cytokines, such as interferon- γ and IL-2. This response is greatly increased in XLP patients,²⁶ and the dysregulated TH-1 response is considered the most important pathogenetic event that causes fulminant infectious mononucleosis. The malignant lymphomas arising in XLP patients are non-Hodgkin's B-cell lymphomas of the Burkitt's type and diffuse large cell lymphomas.²⁴ The expression of EBV genes has not been studied in detail in XLP lymphomas, and the pathogenic role of EBV in these tumors is under investigation.

In Hodgkin's disease (HD), EBV involvement is supported by the presence of EBV DNA in 26% to 67% of sporadic cases and in 100% of HD arising in AIDS patients.^{13,27} Episomal EBV DNA is detected in the multinucleated Reed-Sternberg cells, the malignant neoplastic giant cells of HD that are required for the histopathologic diagnosis of the disease. The EBV genome is detected also in Hodgkin cells, the mononuclear giant cells that are considered the precursors of Reed-Sternberg cells. In HD, Reed-Sternberg and Hodgkin cells represent clonal expansions of EBV-infected cells. The oncogene EBV LMP-1 is expressed within Reed-Sternberg cells and their precursors, whereas EBNA-2 is not expressed.^{13,27} The function of EBNA-1 is to maintain the EBV episome, from which the various EBV onco-proteins are expressed. LMP-1, the most potent EBV oncogene, seems to play an important role in the pathogenesis of HD.¹³ In addition to the EBV-infected Hodgkin and Reed-Sternberg cells, the pathologic tissue contains macrophages, B and T-lymphocytes that outnumber the malignant cells. In this context, the EBV antigens expressed in HD neoplastic cells may stimulate the reactive cellular component of the disease to secrete cytokines and other biologic mediators that could favor the growth and the expansion of tumor cells.¹³

EBV can also infect nonlymphoid cells, such as epithelial and, in children with AIDS, muscle cells, which are devoid of the CD21 receptor. EBV probably infects these cells by fusion or cell-to-cell contact with EBV-infected lymphocytes.^{5,28} Thus, EBV can contribute to the development of some types of epithelial cancers, such as nasopharyngeal carcinoma (NPC).^{9,14,15} Undifferentiated NPC accounts for up to 80% of all NPC and occurs with high prevalence in certain regions of East Asia, such as Southern China. Clustering of this tumor in these specific geographic areas is probably a result of a combination of genetic predisposition and lifestyle factors.^{14,15} Detection of IgA antibodies against the EBV viral capsid antigen, a rare finding in the normal population, has been successfully employed as a marker of increased tumor risk in screening programs in high-incidence areas.^{14,15} Multiple copies of monoclonal EBV episomes are present in every cell of NPCs,^{14,15} whereas integrated EBV DNA has been detected only in a fraction of NPC.^{28,29} Immunoblotting demonstrates LMP-1 protein in 65% or more NPC, and LMP-1 transcripts are detectable in virtually all cases by polymerase chain reaction (PCR) analysis.^{14,15,30} EBNA-1 is expressed in essentially all NPC cells. Other nonlymphoid malignancies possibly associated with EBV are gastric carcinoma, leiomyoma, and leiomyosarcoma. In gastric carcinoma, the viral DNA is found in approximately 90% of the rare gastric lymphoepithelioma-like carcinomas and in about 10% of the common gastric ade-

nocarcinomas.^{28,31,32} EBV is present in clonal, episomal form in the malignant epithelial cells that express *EBNA1* but not other *EBNA* genes or *LMP1*.^{28,30–32} Recently, it was shown that the EBV *BARF1* gene, which acts as an oncogene,³³ is expressed in EBV-positive gastric adenocarcinomas,^{32,34} suggesting that *BARF1* contributes to gastric cancer. Leiomyomas and leiomyosarcomas are rare smooth muscle cell tumors whose frequency is increased in immunocompromised patients, especially in HIV-positive patients and in organ transplant recipients.^{35,36} Leiomyomas and leiomyosarcomas developing in immunocompromised patients, but not in immunocompetent individuals, are associated with EBV, and the tumor cells harbor episomal monoclonal EBV genomes.³⁵ EBV is the likely cause of oral hairy leukoplakia,²⁸ an EBV cytolytic lesion not known, and is associated with undifferentiated parotid carcinoma.³⁷ The possible association of EBV with some aggressive forms of breast cancer has been suggested by some investigators,³⁸ but presently the weight of evidence does not support a pathogenic role of EBV in breast cancer. The mechanisms of cellular transformation by EBV are reported in Table 17.2. LMP-1 also induces a variety of invasiveness, metastasis, and angiogenic factors including matrix metalloproteinase (MMP)-9, cyclooxygenase (COX)-2, vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF)-2, and HIF1X.

HUMAN HERPESVIRUS 8

Human herpesvirus 8 (HHV-8) is a herpesvirus recently isolated from Kaposi's sarcoma (KS) tissue³⁹ using the technique of representational difference analysis.⁴⁰ HHV-8 is a gamma-herpesvirus, showing sequence homology to EBV and to herpesvirus saimiri, a squirrel monkey virus that induces lymphoproliferative disorders in monkeys and transforms human T cells.⁴¹ HHV-8 is associated with KS, primary effusion lymphoma (PEL), and Castleman's disease. PELs are AIDS-associated lymphomas characterized by malignant lymphocyte effusions in the pleural, pericardial, and peritoneal cavities, usually without significant tumor masses or lymphadenopathy. All PELs contain HHV-8 DNA and most, but not all, are coinfecting by EBV,^{42–44} suggesting that the two viruses may cooperate in neoplastic transformation. Multicentric Castleman's disease (MCD) is a rare polyclonal lymphoproliferative disorder⁴⁵ appearing in both immunocompromised and immunocompetent individuals. HHV-8 is present in nearly 100% of HIV-1-positive patients with MCD. Among MCD immunocompetent patients, HHV-8 is detected in about 40% of cases.⁴⁴

KS occurs in four epidemiologic forms⁴⁶: (1) classic KS, a rare tumor of elderly men, usually of Mediterranean origin, with a mild clinical course; (2) endemic KS, developing in HIV-1-negative individuals in equatorial Africa; (3) iatrogenic KS, occurring in immunosuppressed transplant recipients; and (4) epidemic KS, presently the most common form of KS, developing in patients with AIDS. KS lesions exhibit a complex morphology and contain a variety of cell types, including malignant spindle cells, probably of endothelial origin.^{47–49} KS cells release various lymphokines, including IL-6 genome, interferon- γ (IFN- γ), basic fibroblast growth factor (bFGF), tumor necrosis factor- γ (TNF- γ), and VEGF. KS growth is enhanced by inflammatory cytokines of the Th1 type and by the HIV-1 Tat protein.⁴⁷ These observations suggest that the local dysregulation of cytokines plays an important role in the development of KS lesions. HHV-8 DNA was detected in 89% to 100% of KS biopsies and in only 2% of non-KS biopsies, except for blood (8%–25%), from the same individual,^{43,44} indicating that the viral load is highest in KS lesions. Seroepidemiology demonstrates that HHV-8 antibody prevalence is low (2%–3%) in the United States and in England, and that it is greater and increases steadily with age in Mediterranean Europe and in Africa. HHV-8 seroprevalence reaches 85% in KS patients and 35% in homosexual men. Moreover, in this latter category the prevalence of HHV-8 antibodies rises with the increasing number of homosexual partners in the previous 2 years,⁴⁴ suggesting that HHV-8 could be the sexually transmitted agent previously suggested to be associated with KS.^{48,49} HHV-8 is not present in other vascular tumors, including angiomas, hemangiomas, and angiosarcomas, and is only rarely detected in other forms of skin tumors, such as squamous cell carcinomas and melanomas.⁴⁴ The presence of HHV-8 DNA in peripheral blood cells of HIV-1-positive individuals and HHV-8 reactivation from a latency stage correlates with a greater risk of developing KS.^{44,50,51} PCR in situ hybridization, RNA in situ hybridization, and immunohistochemistry showed HHV-8 in nearly all spindle cells of KS lesions.^{44,51,52}

The oncogenic mechanisms of HHV-8 are not fully understood. Sequence analysis of the viral genome⁵³ yielded clues to the transforming activity of HHV-8.^{44,52,50} Several HHV-8 genes have significant sequence homology to human genes,^{44,50,52,54} suggesting that the virus has captured cellular genes during evolution. The viral homologues are similar to cellular genes involved in apoptosis, growth control, cell-cycle regulation, and chemokine and cytokine signaling. HHV-8 contains a gene homologous to *bcl-2* that inhibits apoptosis.⁵⁵ The viral antiapoptotic activity is supported by

two other cellular homologues: FLIP, which interferes with apoptosis signaled through the FLICE death; and LANA, which binds p53, inhibiting p53-mediated apoptosis.^{44,50,52} HHV-8 also codes for a *cyclin D*-like gene whose protein product participates in pRb phosphorylation.^{56,57} Another HHV-8 protein that is involved in cell proliferation is the G protein-coupled receptor (GPCR), which is constitutively active for downstream signaling in the absence of the chemokine ligands.⁵⁸ GPCR shows a high sequence homology to the cellular IL-8 receptor, transforms NIH3T3 mouse fibroblasts in vitro, and induces VEGF expression.⁵⁹ Transgenic mice expressing HHV-8 GPCR in hematopoietic cells develop angioproliferative KS-like lesions in multiple organs.⁶⁰ The viral MIP-I, MIP-II, and MIP-III proteins exhibit homology to the cellular chemokine MIP-1- α . MIP-I and MIP-II possess strong angiogenic potential and may therefore contribute to the marked vascularization characteristic of KS.⁶¹ The K1 protein of KSHV, the homologue of EBV LMP-1, also induces MMP-9 and VEGF expression (John Pagano, personal communication). Furthermore, the virus encodes a homologue of cellular IL-6, a possible growth factor for KS cells, and up to four proteins related to cellular interferon-regulatory factors (IRF)^{52,54,62} that may confer resistance to the antiproliferative effects of IFN- α . Because KS growth appears to be supported by a variety of cytokines,⁴⁷ it is interesting that HHV-8 codes for homologues of cellular cytokines and cytokine receptors that may function as growth factors for the proliferation of KS cells. HHV-8 has also been linked to the development of multiple myeloma,⁶³ but this association is not established.

Papovaviruses

BK VIRUS, JC VIRUS, AND SIMIAN VIRUS 40

BK virus (BKV), JC virus (JCV), and simian virus 40 (SV-40) belong to the family of Papovaviridae. The three viruses are similar in structural and functional properties.^{64,65} Nucleotide sequence homology of the three viruses is 68% to 72%, and protein sequence homology is 76% to 90% in different regions of the viral genomes.⁶⁴ Primary infection by BKV and JCV occurs in childhood and is usually unapparent. During primary infection, the virus spreads by viremia to several organs and establishes a latent infection in the kidneys. Reactivation from latency can be induced by immunologic impairment. BKV and JCV are ubiquitous in the human population worldwide, and seroprevalence in adults is 80% to 100%. Both viruses are probably transmitted by the respiratory and the orofecal route.^{4,66,67} BKV and JCV cause posttransplantation interstitial nephritis in renal transplant recipients and BKV causes hemorrhagic cystitis in bone marrow transplant patients.^{4,64-66} JCV is the etiologic agent of progressive multifocal leukoencephalopathy, a severe degenerative neurologic disease affecting immunosuppressed individuals.^{64,65} SV-40, which is a monkey virus, was introduced only recently into the human population when polio vaccines, produced in SV-40-contaminated monkey kidney cell cultures, were massively administered to millions of individuals between 1955 and 1963.⁶⁸ Soon it was shown that people vaccinated with SV-40-contaminated polio vaccines shed infectious SV-40 in stools for at least 5 weeks after vaccination.⁶⁹ This observation suggested that SV-40 could be transmitted from recipi-

ents of contaminated polio vaccines to contacts by the orofecal route and could spread in humans by horizontal infection. This hypothesis is supported by some experimental results. First, SV-40 DNA sequences have been detected in normal and neoplastic tissues of persons too young (1 to 30 years) to have been vaccinated with SV-40-contaminated polio vaccines.^{3,70-74} Second, SV-40 sequences have been found in blood specimens of neoplastic and healthy individuals^{72,74,75-79} and SV-40 virions were detected in urine and sewage samples,^{68,80} suggesting that the hematologic and orofecal routes of transmission might be responsible for SV-40 horizontal infection in humans. An alternative or additional hypothesis is that some polio vaccines continued to be contaminated by SV-40 after 1963.⁸¹ Third, infectious SV-40 was rescued by transfection of monkey cells with the DNA of an SV-40-positive human choroid plexus carcinoma in an individual too young to have received a contaminated vaccine.⁸² Finally, antibodies to SV-40 capsid antigens were found in sera of children and of both normal and HIV-1-infected adults.⁸³⁻⁸⁶

The early region of the BKV, JCV, and SV-40 genomes, which is expressed in the initial phase of the replicative cycle, encodes the two viral oncoproteins: the large T antigen (Tag) and the small t antigen (tag). The Tag displays multiple functions that alter the normal physiologic metabolism of cells, ultimately leading to immortalization and neoplastic transformation.^{64,65,87-89} An important property of Tag in relation to transformation and oncogenicity is its ability to bind and block the functions of the tumor suppressors p53 and the pRb family proteins (p105 Rb1, p107, and p130 Rb2).⁸⁸⁻⁹¹ Polyomavirus Tag induces chromosomal damage in human cells characterized by numerical and structural chromosomal aberrations such as DNA gaps, breaks, dicentric and ring chromosomes, deletions, duplications, and translocations.⁹²⁻⁹⁵ The molecular mechanism of the clastogenic effect of Tag may reside in its ability to bind topoisomerase I⁹⁶ and in its helicase activity,⁹⁷ which could induce chromosome damage when Tag promotes the unwinding of the two strands of cellular DNA. Moreover, Tag inhibition of p53-induced apoptosis allows DNA-damaged cells to survive, increasing their probability of becoming transformed and acquiring immortality.⁸⁹ Small tag⁹⁸ cooperates with large Tag in transformation by reducing serum dependence of transformed cells and binds protein phosphatase 2A (PP-2A).⁹⁹ PP-2A is a serine/threonine phosphatase that regulates the phosphorylation signaling activated by protein kinases,¹⁰⁰ and it has recently been shown to function as a tumor suppressor gene involved in some lung, colon, and breast carcinomas and melanoma.^{101,102} In addition, SV-40 small tag is able to enhance transcription of E₂F-activated early growth response genes.¹⁰³

BKV, JCV, and SV-40 transform to neoplastic phenotypes and are highly oncogenic in rodent and human cells.³ The spectrum of experimentally induced tumors is similar but distinct for each of the three viruses.³ BKV, JCV, and SV-40 DNA were detected in human tumors by PCR, and occasionally by Southern hybridization of the whole cell genome, indicating the presence of relatively low amounts of viral sequences. Expression of virus-specific RNA and Tag was often observed in virus-positive tumors. The histotype of the human tumors positive for viral sequences corresponds to that of the tumors induced by the three viruses in experimental animals. BKV has been associated to human brain tumors, tumors of pan-

creatic islets, osteosarcomas, and tumors of the urinary tract.^{3,4,64-66,104} BKV DNA sequences were also detected in primary KS and in KS cell lines.¹⁰⁵ JCV has been associated with human brain tumors, especially astrocytoma and medulloblastoma,^{64,65,106-109} and possibly with colorectal carcinoma.¹⁰⁹⁻¹¹² In colorectal cancers, negative for mutations in the APC gene, JCV Tag activates the Wnt pathway, with consequent constitutive expression of β -catenin,¹¹³ which leads to continuous cell proliferation. SV-40 is associated with human mesothelioma, with brain tumors, and possibly with osteosarcoma and non-Hodgkin's B-cell lymphoma.¹¹⁴⁻¹¹⁷ Human brain tumors can be coinfecting by SV-40 and BKV or by SV-40 and JCV,¹⁰⁷ suggesting a possible interaction between polyomaviruses in oncogenesis. In three human brain tumors, one of the authors (G.B.B.) detected the simultaneous presence of the DNA sequences of BKV, JCV, and SV-40.^{4,66} It remains to be demonstrated whether in these tumors the viruses coexist in the same cells. Some studies, however, did not detect SV-40 in human tumors.¹¹⁸ Three independent panels have reviewed the association of SV-40 with human tumors: one organized by the National Cancer Institute,²⁸ one by the Institute of Medicine,¹¹⁹ and one at an international SV-40 mesothelioma consensus conference held at the University of Chicago.¹²⁰ All three panels concluded that there is compelling evidence that SV-40 is present in some human tumors, especially mesothelioma and brain tumors, and that SV-40 is a potent cocarcinogen.

Because BKV and JCV are ubiquitous in humans,³ their DNA sequences are often detected not only in tumors but also in normal tissues.^{72,74} The viral load in BKV-, JCV-, and SV-40-positive human tumors is usually low (10^{-2} to 10^{-4} genome equivalents per cell), and Tag is expressed only in a fraction of tumor cells.^{3,75} This is a general characteristic of polyomavirus-induced tumors: for example, only a fraction of tumor cells in SV-40 transgenic tumors is Tag positive. However, BKV, JCV, and SV40 induce chromosome aberrations^{92,95} that can affect the functions of genes important in tumorigenesis.¹²¹ Once the genetic damage has been triggered in tumors and chromosomal alterations have reached a threshold, genomic instability ensues^{122,123} as a result of the functional alteration of DNA repair genes, especially in the presence of Tag-mediated inactivation of cellular p53, which prevents DNA repair or apoptosis of damaged cells. These events lead to accumulation of genetic lesions and to tumor progression.^{122,123} A similar course of events may occur in some polyomavirus-positive human tumors, where the clastogenic activity of Tag, similarly to a chemical or physical carcinogen, initiates the tumorigenic process by causing DNA damage, and then becomes dispensable; it may be lost during tumor progression when the accumulation of genetic alterations renders the presence of viral transforming genes unnecessary. Immunoselection may select against persistently polyomavirus-infected cells, whereas genetically mutated cells that have lost the viral genome may have a proliferative advantage and become the prevalent population in the tumor. This "hit-and-run" mechanism has been demonstrated in SV-40-mediated transformation of some rodent cells.^{124,125} In human mesothelial cells, SV-40 Tag activates an autocrine-paracrine loop involving the hepatocyte growth factor (HGF) and its cellular receptor, the oncogene *c-met*,¹²⁶ as well as VEGF and its cellular receptor.^{127,128} It has been suggested that HGF and VEGF, released from SV-40-positive

cells, bind their receptors in neighboring SV-40-negative cells, driving them into proliferation and tumorigenesis.¹²⁶⁻¹²⁹

There is strong evidence in support of a causative association between SV40 and mesothelioma, including (1) the ability of SV-40 Tag to bind and inactivate p53 and Rb family proteins in primary human mesotheliomas^{130,131}; (2) the induction of growth arrest and apoptosis in mesothelioma cell lines transfected with antisense DNA to the SV-40 early region gene¹³²; (3) the presence of SV40 in malignant mesothelioma cells and not in nearby stromal cells microdissected from the same slide¹³³; and (4) the activation, in primary human mesothelial cells, of *Notch-1*, a gene promoting cell-cycle progression and cell proliferation,¹³⁴ considered a general requirement for the maintenance of the neoplastic phenotype in human cells.¹³⁵ Also, (5) human mesothelial cells are resistant to SV-40-induced cell lysis and are particularly susceptible to SV-40-mediated transformation^{126,136} because human mesothelial cells limit SV-40 replication thanks to the endogenous high levels of wild-type p53.^{136,137} Therefore, SV-40 DNA remains episomal, the viral oncogenes are expressed, cell lysis is limited, and the frequency of transformation is high ($1-5 \times 10^{-3}$ transformed foci in human mesothelial cells compared to $1 \times 10^{-7}-1 \times 10^{-8}$ transformed foci in human fibroblasts).^{136,137} (6) Human mesothelial cells are specifically susceptible to SV-40 infection compared to the human polyomavirus JCV, which does not infect mesothelial cells, and BKV, which causes mesothelial cell lysis.¹³⁸ (7) Asbestos, which is the main cause of human mesothelioma, cooperates with SV-40 in transformation of human mesothelial cells,¹³⁶ suggesting that asbestos and SV-40 are cocarcinogens in the pathogenesis of mesothelioma. (8) SV-40 tumor antigens induce telomerase activity in human mesothelial cells,¹³⁸ a requirement for cellular immortalization and tumor growth. (9) SV-40 induces promoter methylation and inactivation of the RASSF1A tumor suppressor gene in both SV-40-positive mesothelioma and in SV-40-transformed human mesothelial cells.¹³⁷ Most of the conflicting arguments concerning the role of SV-40 in human tumors have been extensively discussed in a recent critical review¹³⁹ that points out the unique features of SV-40 infection in humans and emphasizes the limitations of the conventional studies of descriptive epidemiology which cannot reliably distinguish among infected and noninfected cohorts.^{119,139}

HUMAN PAPILLOMAVIRUSES

Papillomaviruses belong to the family Papovaviridae and are small (55 nm), nonenveloped viruses with a double-stranded circular DNA genome of about 8 kb. Papillomaviruses infect several animal species and are highly species specific and epitheliotropic. The human papillomavirus (HPV) species comprises more than 140 different types, but only a few types are prevalent in human neoplasia.^{140,141} HPV is associated with both benign and malignant proliferative epithelial lesions affecting the genital organs and skin.¹⁴² The mucosal HPV types infect the anogenital tract. Low-risk HPVs, with HPV-6 and HPV-11 as classic representatives, induce benign proliferations such as condylomata acuminata and papillomas that often regress and only rarely progress to malignancy. High-risk HPVs are associated to cervical cancer and other anogenital malignancies, such as vulva, vagina, penis, and anal cancer. Six HPV types, HPV-16, -18, -31, -33, -35, and

-39, are associated with more than 90% of cervical carcinomas.^{140,141} The cutaneous HPV types are involved in skin warts and in epidermodysplasia verruciformis (EV), a hereditary autosomal recessive disease associated with a state of immunodeficiency and characterized by a great number of skin warts, often disseminated and confluent. In up to half of the affected patients, the warts of EV progress to skin carcinomas,¹⁴⁰⁻¹⁴³ usually in sun-exposed sites because of the effect of UV irradiation, a clear example of cooperation in human carcinogenesis between a physical agent and viral infection and genetic predisposition. The HPV types most commonly involved in skin warts and EV lesions are HPV-5, -8, -9, -12, -14, -20, -23, -38, -49, and -75, but the squamous cell carcinomas arising from EV lesions contain mostly HPV-5, -8, -20, -23, and -38.¹⁴⁰⁻¹⁴³

The role of HPV in human neoplasia involves complex mechanisms.¹⁴⁰⁻¹⁴⁴ Of great importance in the pathogenesis of both genital and cutaneous HPV-associated tumors is host immunosuppression, especially loss of cell-mediated immunity. Skin warts and cutaneous squamous cell carcinomas are common in immunosuppressed transplant recipients, and the frequency of condylomata acuminata and cervical cancer is enhanced in HIV-1-infected patients.^{140,141} Most of the information about the role of HPV in anogenital tumorigenesis has been obtained from studies of cervical cancer.¹⁴⁴ While the genome of the low-risk HPV-6 and HPV-11 remains episomal in benign genital papillomas, the DNA of high-risk HPV-16, -18, -31, and -33 becomes integrated into the DNA of the tumor cells in cervical cancer.^{144,145} Despite frequent loss of much of the viral genome in cervical cancer cells, the regions encoding the early viral proteins E6 and E7 are always maintained and expressed in HPV-positive cervical cancers.¹⁴⁰⁻¹⁴⁵ Analysis of the high-risk HPV genomes in a variety of in vitro systems and in primary tumors indicated that the E6 and E7 genes are the primary oncogenes of HPV. HPV cannot be grown in vitro, possibly because virus maturation specifically requires differentiated epidermal cells. However, in vitro studies using retrovirus-mediated gene transfer and other transfection techniques demonstrated that HPV-16 or HPV-18 E6 and E7 genes in combination were able to efficiently immortalize and transform primary human foreskin keratinocytes (which resemble the normal in vivo target cells of HPV), whereas E7 alone immortalized genital keratinocytes at a reduced efficiency and E6 alone was ineffective.¹⁴⁶⁻¹⁴⁸ HPV-16- and HPV-18-transformed keratinocytes showed aberrant differentiation patterns that made them almost indistinguishable from cells of low-grade cervical intraepithelial neoplasia, a precursor of cervical cancer.¹⁴⁶⁻¹⁴⁸ Retrovirus constructs encoding low-risk HPV-6 E7 alone or both HPV-6 E6 and E7 failed to immortalize genital keratinocytes.¹⁴⁸

Subsequent molecular analysis of the transforming activities of E6 and E7 oncoproteins has elucidated their role in the pathogenesis of genital cancer. The E6 protein of high-risk HPV types binds the p53 tumor suppressor protein with high affinity and mediates its degradation via the ubiquitin pathway.^{149,150} The E6 protein also activates telomerase¹⁵¹ and binds E6BP or ERC55, a calcium-binding protein^{152,153} that may influence keratinocyte differentiation. Moreover, E6 binds paxillin,¹⁵⁴ which mediates a variety of signals from the cytoplasmic membrane to focal adhesion molecules and the actin cytoskeleton and binds, and possibly inactivates the hDLG protein,^{155,156} the human homologue of the *Drosophila*

large tumor suppressor protein. E6 transactivates TATA containing heterologous promoters through a mechanism unrelated to p53 binding.¹⁵⁷ The observation that although the E6 proteins encoded by several other papillomaviruses, such as bovine papillomavirus, HPV-1, and HPV-8, do not interact with p53 yet show strong transforming activity,¹⁵⁸ emphasizes the biologic relevance of these additional E6 activities.

The E7 oncoprotein binds p105Rb. The affinity of high-risk E7 proteins for pRb is severalfold higher than that of low-risk E7 proteins.^{145,159} pRb plays an important role in cell-cycle control by coordinating entry of cells from G₁ into S phase.^{89,160} Unphosphorylated pRb binds members of the E₂F family of transcription factors^{89,145,161} in early G₁. E₂F proteins transcriptionally activate *c-myb*, *c-myc*, *c-fos*, *c-jun*, *cyclin A*, and *cyclin E* genes and other genes involved in DNA replication and stimulation of cell proliferation.^{89,145} By binding to E₂F, pRb inhibits E₂F-mediated transcriptional activation and thus blocks cell-cycle progression from G₁ to S. In normal cells this block is relieved by phosphorylation of pRb through the action of the cyclin-dependent kinases (CDKs), resulting in the dissociation of the E₂F-pRb complex. Free E₂F is then able to transactivate its cell-cycle-promoting target genes, triggering progression into S phase.^{89,145,160,161} The E7 oncoprotein can disrupt the pRb-mediated control of the cell cycle through at least three different mechanisms, leading to release of E₂F and to unregulated activation of E₂F target genes: (1) the direct binding of E7 to pRb results in a competitive interference with pRb-E₂F complex formation,^{89,145,162} (2) E7-induced degradation of pRb,^{145,163} and (3) E7-mediated interference with regulatory pathways upstream of pRb, such as blocking the activity of the p21^{WAF1} CDK inhibitor.^{164,165} The interaction with pRb is not the only activity through which E7 can contribute to cell transformation, as the transformation potential of mutant E7 proteins does not necessarily correlate with their ability to bind pRb.¹⁶⁶⁻¹⁶⁸ E7 also interacts with the pRb-related proteins p107 and p130,^{89,145} and it has been found in complexes with the cell-cycle regulatory proteins cyclin A, cyclin E, p21^{WAF1}, and p27^{KIP1}.³⁰ E7-induced alterations of the molecular pathways controlled by these cell-cycle regulatory proteins further contribute to the dysregulation of cell growth. E7 interferes with p21^{WAF1}-mediated regulation of DNA methylation³⁰ and with the p21^{WAF1}-induced DNA replication arrest in cells with DNA damage,³⁰ thus favoring the accumulation of DNA damage.¹⁶⁹ E7 has transcriptional modulatory activities and can influence transcription of cellular genes in an E₂F-independent fashion by interacting with proteins of the AP1 family of transcription factors¹⁷⁰ or with general transcription factors, such as the TATA box binding protein (TBP).¹⁷¹

The functional inactivation of the p53 and pRb family gene products by the oncoproteins of high-risk HPV types substitutes for mutations in these tumor suppressor genes. Indeed, it was shown that primary genital tumors and tumor cell lines infected with HPV do not carry mutations in *p53* and *Rb* genes,^{172,173} although mutations may subsequently occur during tumor progression toward an invasive and metastatic phenotype. Conversely, p53 mutations are detected only in the rare HPV-negative cervical cancers.¹⁷⁴ In contrast to high-risk anogenital HPV infections, cutaneous HPV infections may contribute indirectly and in a less complex way to skin squamous cell carcinoma: the presence of HPV may simply protect cells from apoptosis after genetic

damage induced by solar exposure, thus resulting in increased survival of the genetically altered cells.¹⁴¹ Besides their involvement in genital and cutaneous carcinogenesis, HPVs are also linked to head and neck cancers and to esophageal carcinoma.^{141,143,175} Although the transforming functions of HPV E6 and E7 proteins are important pathogenetic factors in human tumorigenesis, they are probably not sufficient to induce malignancy. In animals, human papillomavirus often cooperates with other carcinogens to cause cancer.¹⁴⁴ An outstanding example of the synergism between papillomaviruses and environmental factors is bovine papillomavirus, which induces papillomas and carcinomas of the alimentary tract in cattle in cooperation with dietary carcinogens.¹⁷⁶ Some metabolites of the vaginal microbial flora, alcohol, and smoke are considered relevant risk factors for the development of cervical, oropharyngeal, and laryngeal cancers.^{141,143,175} Sexual hormones may enhance the oncogenic effect of HPV on genital tissues, because the promoter of high-risk HPV types harbors consensus sequences responding to transcriptional activation by estrogens and progesterone.³⁰ Herpes simplex virus infection may cooperate with HPV by promoting DNA mutations in genital tissues.¹⁷⁷ Physical carcinogens also have a cooperative role, as shown by transition to malignancy of the EV lesions exposed to UV light¹⁴⁰⁻¹⁴³ and by the frequent conversion of laryngeal papillomas to carcinomas following X-ray treatment.¹⁴¹

Hepadnaviruses

HEPATITIS B VIRUS

Hepatitis B virus (HBV) is the prototype of a new family of closely related DNA viruses, the Hepadnaviruses. This family comprises the woodchuck hepatitis virus (WHV), the ground squirrel hepatitis virus, and the duck hepatitis B virus as well as several other avian and mammalian strains. As in humans infected with HBV, chronic hepatitis and hepatocellular carcinoma (HCC) are commonly observed in persistently infected woodchucks and less frequently in infected ground squirrels and ducks.¹⁷⁸ All the hepadnaviruses show hepatotropism and similar life cycles in their hosts. They all start the replication cycle by reverse transcription of viral RNA to form DNA within core particles of the virus. The partially double-stranded circular DNA encodes four overlapping open reading frames¹⁷⁹: *S* for the surface or envelope gene, *C* for the core gene, *P* for the polymerase gene, and *X* for the *X* gene. The *S* and *C* genes have upstream regions designated pre-*S* and pre-*C*. The whole virion, or Dane particle, is a 42-nm spherical body that contains the nucleocapsid. The viral envelope, coded by the *S* gene, contains three distinct components (large, middle, and small proteins) that are synthesized by beginning transcription within the pre-*S* or *S* gene, respectively. HBV can produce a large excess of the envelope surface antigen (HBsAg), consisting of both rods and small spheres with an average diameter of 22 nm, that can be found in patients' blood. The hepatitis B core antigen (HBcAg) is the nucleocapsid that encloses the viral DNA. When HbcAg-derived peptides are processed and expressed on the surface of hepatocytes, a T-cell-mediated immune response is induced to kill infected cells and eliminate the virus. The hepatitis B antigen (HbeAg) is a circulating peptide derived from the core gene and secreted by liver cells. Its presence in

serum is a marker of active viral replication. The *X* gene encodes two proteins that have transactivating activity on the HBV enhancer to support viral replication. The *X* proteins can also transactivate cellular genes that may play a role in hepatocellular carcinoma.

Chronic HBV infection and cirrhosis are conditions leading to the development of HCC.¹⁸⁰⁻¹⁸³ This concept emerged from evidence that (1) the greatest incidence of HCC is detected in areas of the world (tropical and equatorial regions) where HBV infection is widespread and (2) most patients affected by HCC bear markers of a long-lasting HBV infection. Based on prospective epidemiologic studies, it is estimated that chronic HBV carriers exhibit a 100-fold-increased risk for HCC development.¹⁸⁴ In sub-Saharan Africa with a high incidence of HCC, endemic infection by HBV cooperates in HCC together with exposure to aflatoxins derived from fungi of the *Aspergillus* genus, which grow on improperly stored foods.^{181,185} The mechanisms of hepatocarcinogenesis by HBV are both direct and indirect. The direct mechanisms are related to integration of the HBV genome into cellular DNA and to potential oncogenic functions expressed by some viral genes (Figure 17.1). The role of HBV integration is most clearly observed in animal models. In more than 50% of HCCs arising in woodchucks, the WHV sequences specifically integrate 5' or 3' to the proto-oncogenes *c-myc* or *n-myc*, inducing a steady-state level overexpression of their mRNA, due to near insertion of the WHV enhancers.¹⁸⁰ In human HCC, the HBV DNA integrates randomly in the cellular genome, and direct effects of insertional mutagenesis on oncogene activation were observed. In one such rare case, HBV DNA was integrated within an exon of the gene of the retinoic acid receptor β ,^{180,186} disrupting the gene sequence. Because retinoic acid is important in inducing terminal cell differentiation, the inappropriate expression of one of its receptors may disturb the normal control of cell growth. In a second HCC, HBV DNA integration occurred in an intron of the *cyclin A* gene,^{180,185,187} leading to its truncation and to the production of a *cyclin A*/HBV fusion gene. The N-terminus of the cyclin A protein, containing the signal for protein degradation, was deleted and replaced by HBV pre-*S* sequences (including the strong pre-*S*₂/*S* promoter). The resulting fusion protein was expressed in a high amount, and it was resistant to degradation.^{180,185,187} Constitutive expression of this chimeric form of cyclin A may lead to cell-cycle deregulation, uncontrolled DNA synthesis, and cell proliferation. In human HCC, deletions, rearrangements, and mutations at several chromosomal loci are frequently observed,^{180,185} inducing overexpression of *c-myc* and *c-fos* oncogenes and reduced expression of the most common tumor suppressor genes, such as p53, pRb, and p16^{INK4}.¹⁸⁵ None of these chromosomal alterations, however, seems to be a direct consequence of HBV DNA integration.

A more relevant direct viral mechanism of human hepatocyte transformation is related to the expression of the HBV *X* gene.¹⁸³ Its products, the *X* protein, transform NIH3T3 and other immortalized mouse cells to the neoplastic phenotype,^{188,189} and transgenic mice expressing the HBV *X* gene from the HBV promoter develop HCC.¹⁹⁰ HBV *X* can transcriptionally activate a broad array of cellular genes, including epidermal growth factor and cellular proto-oncogenes, such as *c-myc*, *c-fos*, and *c-jun*. Because HBV *X* does not bind to DNA, HBV *X*-mediated transcriptional alterations may

Direct mechanisms

Insertional mutagenesis due to integration of HBV DNA into the sequence of cellular genes: *retinoic acid receptor β* and *cyclin A*. Transcriptional alterations due to the HBV X protein, affecting cellular genes *EGF*, *c-myc*, *c-fos*, *c-jun*, *p53* and DNA repair genes.

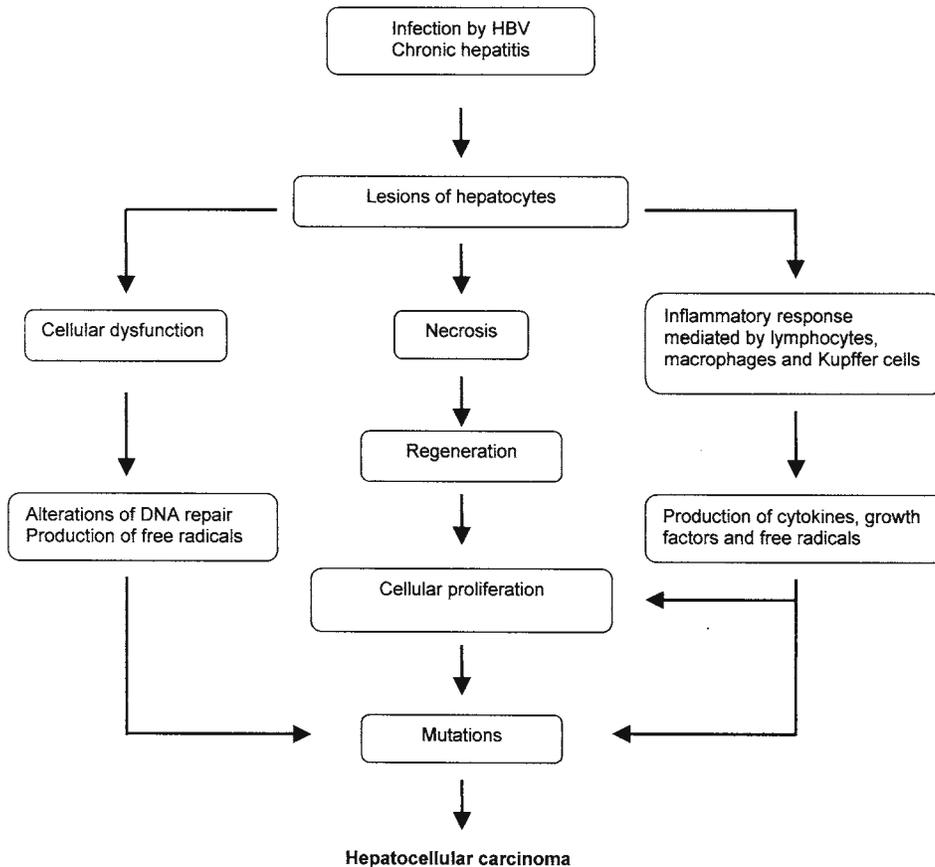

Indirect mechanisms

FIGURE 17.1. Indirect and direct mechanisms and the integration of the HBV genome into cellular DNA.

occur through the interaction with cellular transcription factors in the nucleus, through posttranscriptional modulation of their activities or through affecting signal transduction cascades in the cytoplasm.²⁶ HBV X binds p53,¹⁹¹ inhibiting p53-mediated transcriptional transactivation¹⁹² and apoptosis.¹⁹³ A close correlation has been observed between the HBV X-p53 interaction and the development of HCC in a transgenic mouse model.¹⁹⁴ The mechanism of p53 inhibition by HBV X is unique, because p53 is sequestered by HBV X in the cytoplasm of hepatocytes,¹⁹⁵ thereby blocking entry of p53 into the nuclear compartment. A further mechanism by which the HBV X protein could influence HCC development is through binding to components of DNA repair complexes. For example, the X protein binds to a human homologue of a UV light-damaged DNA-binding protein in monkeys.¹⁹⁶ The X protein also blocks binding of p53 to a transcription factor, ERCC3, involved in DNA repair.¹⁹² The disruption of the fidelity of DNA repair, mediated by the X protein, may contribute to the genetic alterations observed in infected hepatocytes. HBV DNA integration in some HCCs can result in the deletion of the 3'-end of the HBV X and pre-S/S genes. This deletion leads to the synthesis of truncated pre-S/S pro-

teins, which exhibit transactivation potential for a wide range of cellular genes involved in cell proliferation such as PKC, *c-raf*, AP-1, and NF- κ B.¹⁹⁷

HBV may also elicit an indirect promoting effect in liver cancer. This effect is related to the immunopathogenesis of chronic HBV infection. The T-cell-mediated immune response to HBV antigens, mostly derived from HBcAg epitopes located on the surface of hepatocytes, normally kills infected cells in the liver and clears the organ from HBV infection. When this cellular immune response is ineffective, the HBV infection progresses from acute to chronic hepatitis and, in some patients, to liver cirrhosis. During this process, the coexistent inflammation and hepatocyte regeneration increase the risk of HCC development. Liver cell proliferation in the presence of inflammation and of inflammatory mediators favors accumulation of genomic alterations, which can lead to hepatocyte transformation. During the inflammatory response, lymphocytes and macrophages produce cytokines and growth factor that stimulate hepatocyte proliferation. The phagocytic cells release products of the oxidative metabolism such as H₂O₂ and hydroxyl radicals.^{180,183} Oxygen free radicals, produced by activated Kupffer cells, lead to the formation of

8-hydroxyguanosine adducts, which are promutagenic DNA lesions inducing G to T transversion.^{180,183} The role of hepatocyte necrosis and regeneration in hepatocarcinogenesis is best illustrated by Chisari's model of *HbsAg* transgenic mice.^{198,199} These mice overproduce the HBV large envelope polypeptide, accumulate toxic quantities of HBsAg within the hepatocytes, and develop a severe, prolonged hepatocellular injury. This lesion triggers inflammation, regenerative hyperplasia, transcriptional deregulation, and aneuploidy, finally progressing to neoplasia. These results are supported by the evidence that mice transgenic for the *TGF- α* gene, showing continuous mitogenic stimulation of hepatocytes, develop liver cancer.²⁰⁰ In human chronic hepatitis, liver injury may be due to either the immune response during HBV infection or the toxic effects of alcohol.^{30,181,201} In summary, severe prolonged cellular injury and persistent growth stimulation induce a proliferative response, which leads to genetic damage that can lead to tumor development. It should be noted that HBV also replicates in extrahepatic sites, such as bone marrow, lymphoid cells, pancreas, and kidneys.^{202,203} Therefore, clearance of the virus from hepatocytes may not cure the disease, and HBV moving from these extrahepatic locations may reinfect the liver after transplant.²⁰²

Oncogenic Riboviruses

Flaviviruses

HEPATITIS C VIRUS

The hepatitis C virus (HCV) belongs to a genus of the family Flaviviridae. The virion is spherical and enveloped. The genome is a single-stranded linear RNA molecule of about 9.5 kb encoding a single large polyprotein precursor of about 3,000 amino acids from which three structural and seven nonstructural proteins are generated by specific cleavage. The capsid protein or core protein is located at the amino-terminus of the polyprotein precursor. Similarly to HIV-1, HCV shows a great genomic variability, thus representing a quasi-species, that is, a population of closely related, yet heterogeneous, viral genomes.^{204–206} Nevertheless, HCV can be subdivided into six major genotypes. HCV genetic heterogeneity may have important implications because it could influence the immunologic and therapeutic responses as well as represent a major obstacle in the preparation of an effective anti-HCV vaccine.^{30,204–207} Epidemiologic studies have shown that HCC is associated with HCV infection, but the proportion of cases related to HCV varies considerably.²⁰⁸ In countries of southern Europe such as Italy, Spain, and Portugal, as well as in Japan, HCV infection appears to be the most frequent underlying cause of HCC, because from 50% to 70% of patients with HCC show anti-HCV antibodies. In the United States, the proportion of patients with HCC who are seropositive for anti-HCV antibodies is much lower, about 30%,^{208,209} but still very significant.

The process of hepatocarcinogenesis caused by HCV results mainly from indirect mechanisms.¹⁸³ Similar to HBV infection, when the cell-mediated immune response fails to eradicate HCV infection, the acute hepatitis may evolve toward chronic persistent hepatitis, cirrhosis, and HCC. As for HBV infection, the host immune response plays the major

role in causing the hepatocellular damage.^{182,205,206,208,210} During the evolution from acute infection to chronic hepatitis and cirrhosis, the repeated bouts of inflammation, necrosis, and hepatocyte regeneration favor the emergence of a neoplastic liver cell population. Cirrhosis is found in about 90% of HCC patients with HCV markers,^{182,205} although there are patients with HCV-related HCC without liver cirrhosis.²¹¹ This observation suggests a possible direct role of HCV in hepatocarcinogenesis. Various mechanisms appear possible. The HCV nonstructural protein NS3 transforms to the neoplastic phenotype in the NIH3T3 mouse fibroblasts.²¹² Moreover, the HCV core protein suppresses apoptosis^{183,213} and, in cooperation with the human activated *c-H-ras* oncogene, causes malignant transformation of primary rat embryo fibroblasts.²¹⁴ Finally, HCV core gene transgenic mice develop HCC.²¹⁵ The HCV genotype 1b has been associated with more severe and rapidly progressive liver disease and a higher risk of HCC.^{182,208}

HCV infects other tissues besides the liver, and it is associated with several diseases,^{216,217} such as sialadenitis, membranoproliferative glomerulonephritis, and mixed cryoglobulinemia, a disorder characterized by the presence in the serum of a mixture of polyclonal immunoglobulins of various isotypes that reversibly precipitate at temperatures below 37°C. Most of these immunoglobulins are complexes of polyclonal IgG and polyclonal rheumatoid factor that are mainly IgM.^{216,217} Because mixed cryoglobulinemia is considered the expression of a low-grade malignant lymphoproliferative disease, an association was postulated between HCV and lymphoproliferative disorders. Epidemiologic studies showed a significant association between HCV infection and B-cell non-Hodgkin's lymphoma (NHL).²¹⁷ HCV-related markers (HCV RNA and anti-HCV antibodies) were detected in 34% of B-cell NHL, compared to 3% Hodgkin's lymphomas and 1.5% healthy controls.²¹⁷ Comparable values of association between B-cell NHL and HCV infection were confirmed in subsequent studies,^{217,218} although HCV markers were not detected in NHL cells in HCV-infected patients.^{216,219,220} A case-control study demonstrated that HCV infection increases by 50-fold the risk of B-cell NHL involving the liver and the major salivary glands (the most common sites of HCV infection) and by four fold the risk of lymphomas at other sites.²²¹ Although HCV has been widely detected in peripheral blood mononuclear cells of patients with mixed cryoglobulinemia and B-cell NHL with HCV infection, the virus replicates poorly in lymphoid cells.^{216,219} Therefore, the postulated oncogenic role of HCV in lymphoproliferative disorders is presently unclear. According to other models of B-cell lymphomagenesis,¹³ HCV may act as an exogenous prolonged antigenic stimulus inducing a mitogenic effect and proliferation of B lymphocytes in HCV-infected patients.²¹⁹ Treatment with IFN of HCV infection in patients with splenic lymphomas led to strikingly complete responses of the lymphomas, but not in noninfected patients.

Retroviruses

HUMAN T-CELL LEUKEMIA VIRUS TYPES I AND II

Human T-cell leukemia viruses type I (HTLV-I) and type II (HTLV-II) belong to the subfamily Oncovirinae of the family Retroviridae. HTLV-I infection is endemic in Japan, other

regions of Asia such as the Philippines, the Caribbean region, central Africa, and some areas of Australia and New Guinea. In these areas of the world, the seroprevalence rate of antibodies to HTLV-I is 5% to 33% in the normal human population.²⁰⁷ HTLV-I is associated with adult T-cell leukemia and lymphoma (ATL),^{222,223} as well as with its cutaneous variants, mycosis fungoides and Sézary's syndrome. HTLV-I is also the etiologic agent of HTLV-I-associated myelopathy or tropical spastic paraparesis. HTLV-II is associated with an atypical form of hairy cell leukemia.^{30,222,224} Monoclonal integration of HTLV-I proviral DNA was demonstrated in ATL neoplastic cells, and all individuals with ATL have antibodies to HTLV-I.^{225,226} HTLV-I, at variance from the avian and rodent retroviruses, immortalizes T lymphocytes much like the oncogenic deoxyriboviruses, that is, through the product of a viral oncogene, the *tax* gene. The Tax protein has pleiotropic effects because it is able to activate or repress the expression of a wide array of cellular genes.²²⁷ Tax does not bind directly to DNA, but it interacts with cellular transcription factors or modulators of cellular functions. Binding of Tax to NF-KB results in transcriptional activation of *IL-2 α* and *IL-2 β* receptor genes, leading to autocrine stimulation of T-cell proliferation.^{228,229} Interaction of Tax with serum responsive factor (SRF) activates the expression of *c-fos* and of the early growth response genes *egr-1* and *egr-2*.²³⁰ Other cellular genes activated by Tax include the *GM-CSF*, *IL-1*, *IL-3*, *IL-6*, *PDGF*, *TGF- β 1*, *TNF- β* , and *NGF*.²³¹ Conversely, Tax represses transcription of the *DNA polymerase β* gene²³² encoding a cellular enzyme involved in host cell DNA repair. This finding suggests a possible correlation between HTLV-I infection and host cell chromosomal damage, which is often observed in ATL. Tax inhibits the expression of the *lck* gene,²³³ encoding a tyrosine kinase of the *src* family, which plays a major role in the regulation of T-cell activation.²³³ Tax also dysregulates the cell cycle by binding and inactivating p16^{INK4}, a key inhibitor of CDK4 and CDK6.²³⁴ In HTLV-I-infected cells, Tax is responsible for the stabilization and inactivation of p53 protein by phosphorylation at Ser15, which blocks p53 interaction with transcription factors.^{227,235} Tax also targets the mitotic checkpoint protein MAD-1, an important control protein for the formation of the mitotic spindle.^{227,236} The block of p53 and MAD-1 functions may be responsible for the genetic instability, aneuploidy, and chromosomal rearrangements that have been reported in ATL cells,^{226,227} and may affect oncogenes, tumor suppressor and DNA repair genes. Also, Tax expression enhances the mutation frequency in chromosomal DNA after transfection of the *tax* gene into the rat fibroblastic cell line Rat 2.²³⁷ These diverse effects of Tax

suggest a scenario where ATL cells are initially dependent on Tax expression for proliferation. After the appearance of chromosomal aberrations and mutations involving genes crucial in oncogenesis, the neoplastic cells grow independently from Tax and ATL progresses toward a more malignant phenotype.

HUMAN IMMUNODEFICIENCY VIRUS TYPE 1

Human immunodeficiency virus type 1 (HIV-1) belongs to the subfamily Lentivirinae of the family Retroviridae. In the course of HIV-1 infection, an opportunistic neoplastic pathology develops that is mainly due to immunosuppression, leading to decrease of the immune surveillance against tumors and latent viruses. Indeed, most cancers arising during AIDS are associated with oncogenic viruses (Table 17.3), because HIV-1 infection provides the immunologic background on which other viruses can escape immune control and induce tumors.²³⁸ However, a large body of evidence indicates that HIV-1 itself may be oncogenic through the expression of the Tat protein, the product of the early HIV-1 *tat* gene.^{239,240} The Tat protein of HIV-1 is a small polypeptide of 14 to 15 kDa containing 86 to 102 amino acids, depending on the viral strains. Tat is a potent transactivator of the HIV-1 LTR and is also able to activate the expression of many cellular genes, thereby affecting cellular functions and inducing angiogenesis, cell proliferation, inhibition of apoptosis, and oncogenesis.^{239,240} A remarkable property of Tat protein is that it is released from HIV-1-infected cells, circulates in the bloodstream and in extracellular fluids, and is taken up by uninfected cells where it exerts its biologic effects.^{241–243} Tat induces neoangiogenesis in vivo^{240,244} and has a synergic effect with bFGF on the induction of KS-like lesions in nude mice.²⁴⁵ During neoangiogenesis and cell growth, Tat activates the expression of cytokines, chemokines, and growth factors (IL-1 α , IL-1 β , IL-2, IL-6, IL-8, IFN- γ , TNF- α , TNF- β , MCP-1, bFGF, VEGF, GM-CSF, PDGF, SF/HGF, and TGF- β) by KS cells and induces the activity of urokinase and collagenase IV, which allow endothelial cells to invade underlying tissues.²³⁹ The multiple angiogenic and growth-stimulating effects of Tat, together with the profound immunodeficiency associated with AIDS, may be responsible for the more aggressive and invasive behavior of AIDS-KS compared to the other forms of this tumor.^{46,49} When Tat is transfected under the control of the HIV-1 long terminal repeat, it efficiently transforms immortalized keratinocytes to a neoplastic phenotype.²⁴⁶ Moreover, Tat inhibits expression of the manganese-dependent superoxide dismutase (*Mn-SOD*) gene by direct interaction with *Mn-SOD* transcripts,²⁴⁷ thereby contributing to the establishment and maintenance

TABLE 17.3. Tumors with increased incidence in acquired immunodeficiency syndrome (AIDS).

Tumor	Associated virus
Kaposi's sarcoma ^a	Human herpesvirus 8 and HIV-1 Tat

^aTumors whose frequency is significantly increased in AIDS patients.

of oxidative stress. *Mn-SOD* has been shown to control cell proliferation by regulation of the oxidative metabolism²⁴⁸ and is a candidate tumor suppressor gene involved in the pathogenesis of melanoma and other human tumors.²⁴⁹ The oncogenic activity of Tat may be related also to its ability to downregulate p53 expression^{250,251} as well as to upregulate *IL-2*, *bcl-2*, and *IL-6* gene transcription.²⁵²⁻²⁵⁵ The angiogenic and tumorigenic effects of Tat are confirmed and recapitulated in *tat*-transgenic mice.^{256,257} These animals develop angiogenic proliferation in the derma, resembling the early phases of KS. In addition, they develop skin papillomas and carcinomas, adenocarcinomas of subcutaneous glands, lymphoid hyperplasia and lymphomas, liver dysplasia and hepatocarcinomas, polyps of the rectum, and squamous cell hyperplasia of the anal orifice and adjacent perianal skin. Liver dysplasia affects about 40% of *tat*-transgenic mice^{256,257} and represents a pre-neoplastic state, predisposing to liver tumorigenesis induced by chemical carcinogens.^{258,259} In conclusion, the HIV-1 Tat protein is oncogenic and may be a cofactor in AIDS-related malignancies, especially in KS and PELs where Tat may cooperate with HHV-8 in the angiogenic and oncogenic effects.^{46-49,239}

Conclusions and Perspectives

There has been notable progress in recent years in identifying the causative roles of viruses in human tumors and elucidating the molecular mechanisms of virus-induced cellular transformation. Because of the multifactorial and multistep nature of human carcinogenesis, infection with a tumor virus is usually not sufficient for malignant transformation and tumor growth. Human tumor viruses must therefore be studied in the context of the cofactors that cause a specific tumor type susceptibility. Exposure to exogenous and endogenous carcinogens, genetic alterations of the host cells, and the patient's immunologic status determine, among infected individuals, those who will develop a malignancy. Great efforts are under way to set up effective therapeutic and prophylactic interventions against tumor viruses.³⁰ Vaccines against tumor viruses have both prophylactic and therapeutic applications and may protect from viral infection or may control tumor growth by eliciting a cell-mediated immune response against infected tumor cells. Excellent results have been obtained with an anti-HBV prophylactic vaccine, prepared with HBsAg expressed in yeasts. The report of a national HBV vaccination program in children of Taiwan indicates that the incidence of HCC is declining,^{182,260} and a similar trend is observed in other areas of the world with endemic HBV infection, where the anti-HBV vaccine has been administered on a mass scale. This is the first example of prevention of a human cancer by vaccination. Recently, the introduction of a new oral HBV recombinant vaccine constituted by HBsAg produced in transgenic potatoes and production of HbsAg in transgenic tomatoes and bananas is under way.²⁶¹ Oral immunization, because of its simplicity of use, ease of administration, and increased compliance, represents the ideal mode of delivery for implementation of large-scale vaccination programs in poor areas of the world where HBV infection is endemic and the incidence of HCC is high.

Vaccination against HCV faces more difficult problems because of the genetic heterogeneity virus and its great anti-

genic variability. Therefore, an HCV vaccine is not yet available. Vaccines against HPV have been prepared by using the nonstructural proteins E6 and E7 as well as virus-like particles made of the structural proteins L1 and L2 from HPV-16 and HPV-18. Rodents immunized with these proteins become resistant to papillomavirus tumorigenesis.^{30,262,263} These HPV vaccines are currently being tested in clinical trials. A vaccine against EBV was prepared with the major envelope glycoprotein gp350, the main component of the EBV envelope antigen, which functions as a viral receptor for virus attachment to susceptible cells. This vaccine protected cottontop tamarin monkeys from B-cell lymphomas induced by EBV,^{264,265} but it has not been adopted for use. A recombinant vaccinia vector containing a safety-modified SV-40 Tag sequence was constructed.²⁶⁶ Such modified Tag excludes the p53 and Rb protein binding sites as well as the amino-terminal oncogenic CRI and J domains,²⁶⁷ but preserves the immunogenic regions. Tumorigenesis studies carried out in mice indicated that this vector can efficiently prime the immune response to provide effective, antigen-specific prophylactic and therapeutic protection against SV-40 Tag-expressing lethal tumors.²⁶⁶ This vaccine is currently being produced for testing in clinical trials and would be used, as a prophylactic measure, in individuals exposed to asbestos, at risk for mesothelioma. Although truncation of Tag at the carboxyl terminus, where the p53 binding sites are located, produces unstable products,²⁶⁷ such types of vaccines may represent in the future a useful immunoprophylactic and immunotherapeutic intervention against human tumors associated with SV40.²⁶⁸

A vaccine against HIV-1 has long been sought. Several vaccine preparations, based on the two envelope glycoproteins gp120 and gp160 as well as on the core capsid antigen, have been tested, but the results were generally disappointing.²³⁹ The evidence that both the intracellular and the extracellular Tat protein is crucial for HIV-1 replication^{239,240} prompted the preparation of anti-Tat vaccines. These vaccines protected monkeys from a lethal challenge with the SHIV virus,^{269,270} a recombinant virus containing the HIV-1 *tat* gene within the simian immunodeficiency virus (SIV) genome. It seems reasonable, therefore, to include the Tat protein within the polyvalent vaccine that will be used in the future to prevent and cure the HIV-1 infection. As a result of the oncogenic properties of Tat, anti-Tat immunization may also reduce the incidence of Tat-related tumors arising in the course of AIDS.

Environmental Carcinogenesis

T. Sabo-Attwood, M. Ramos-Nino,
and Brooke T. Mossman

Environmental carcinogens are broadly defined as compounds that humans are exposed to through diet, lifestyle, infectious agents, and occupation.¹ They are considered as nongenetic factors that contribute to cancer risk. A subset of *known* and *reasonably anticipated* human carcinogens can be classified as environmental carcinogens and include such compounds as dioxins, metals, components of pesticides, the polyaromatic hydrocarbon (PAH) benzo(a)pyrene (BaP), and mineral fibers such as erionite and asbestos² (Table 18.1). These contaminants are major constituents of indoor and outdoor air pollution, water, soil, and food products.

Criteria for deciding whether a substance is a carcinogen are constantly being modified as technology and our understanding of carcinogenesis evolve. Definitively linking exposure to environmental contaminants and cancer is difficult because parameters such as dose, duration, composition, and routes of exposure are indeterminate. Currently, the U.S. Environmental Protection Agency (EPA) relies on data from human epidemiologic, animal, and mechanistic studies to classify compounds as carcinogens. Individually, these approaches have limitations, and therefore, these assays should complement each other in defining which compounds have the ability to cause cancer in humans.

One of the major hurdles in assessing the ability of environmental contaminants to cause disease is defining the dose of exposure. Contact with suspected compounds is commonly at low levels over long periods of time. In many cases, the latency period can last decades, masking our ability to realize the cancerous potential of compounds until many people are already sick; this is the case for asbestos-related diseases that have latency periods of greater than 20 to 40 years.³ Thus, a causal link between exposure to asbestos and malignancies was not realized until long after thousands of people were exposed.

Another difficulty in assessing the exposure dose of compounds found in the environment is their ability to bioaccumulate in both environmental media and human tissues. Many potential carcinogens have lipophilic properties whereby smaller doses accumulate in human tissues over time.⁴ Biomagnification through the food chain is also another way small doses of chemicals are amplified. For example, there is increasing concern regarding compounds termed hormonally active agents (HAA) that have the ability to act as natural hormones such as estrogen, androgens, and

thyroidal proteins. Although much controversy exists regarding the carcinogenic potential of HAAs, they have been implicated in a variety of reproductive diseases including breast and prostate cancers.^{5,6} Enough scientific data have convinced the EPA to mandate the testing of all active ingredients of pesticides for endocrine disrupting effects through the Food Quality Protection Act (P.L. 104–170, 1996).

It is also difficult to causally link carcinogenesis to a single compound because environmental contaminants are frequently present as complex mixtures. Interactions of a single compound with other chemicals and elements may greatly increase or decrease the carcinogenic potential to human populations.

As exposure to target compounds can vary greatly among individuals, much of the information available today regarding human cancer risk stems from occupational and accidental exposures. In these situations, information regarding the dose, composition, and duration of the exposure is readily available. A classic example is the industrial accident in Seveso, Italy, where in 1976 an explosion at an industrial plant released large quantities of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) into the air.⁷ Populations residing in the vicinity of the plant have been studied to try and elucidate the direct effect of TCDD exposure on human health, specifically the development of cancers. Although controversial, evidence from epidemiologic, animal, and mechanistic studies support the National Toxicology Program (NTP) classification of TCDD as a known human carcinogen.⁸

Mechanisms of Action of Environmental Carcinogens

Cancer is a multistage process that involves tumor initiation, promotion, and progression. Environmental carcinogens can initiate and/or advance this process by altering the expression and activity of genes crucial to biologic processes that maintain cell growth, differentiation, DNA repair, cell-cycle control, and apoptosis, among others.

In many cases, these compounds act through genetic mechanisms, interacting directly with DNA. Some are metabolically activated to reactive molecules that form covalent adducts with DNA, causing mutations in genes important to processes such as cell-cycle regulation and DNA repair.⁹ Polyaromatic hydrocarbons were the first compounds shown

TABLE 18.1. A partial list of known and reasonably anticipated human carcinogens.

Aflatoxins
Arsenic compounds, inorganic
Asbestos
Benzene
Benzo(a)pyrene^a
Cadmium and cadmium compounds
Chromium hexavalent compounds
Coal tars and coal tar pitches
Coke oven emissions
Diethylstilbestrol
Environmental tobacco smoke
Erionite
Ethylene oxide
Nickel compounds
Pesticide components: dichlorodiphenyltrichloroethane (DDT)^a
Radon
Silica, crystalline (respirable size)
Solar radiation
Soots
2,3,7,8-Tetrachlorodibenzo-p-dioxin (TCDD); dioxin
Thiotepa
Wood dust

^aAll compounds that are "reasonably anticipated" human carcinogens. Compounds focused on in this chapter are denoted in boldface type.

Source: Data from the National Institute for Environmental Health Sciences NTP. Tenth Report on Carcinogens, 2002.²

to cause cancer (at least in part) by forming covalent adducts with DNA. The most notorious PAH historically is BaP, a compound that was isolated from coal tar in 1930 and shown to induce tumors in rodent models. It was later discovered that a reactive metabolite of BaP could form covalent adducts with DNA, resulting in altered cell growth and repair.¹⁰

Compounds may also act through epigenetic mechanisms whereby they do not directly alter the genome, but cause mitogenic expansion of initiated cells by modifying the expression of genes that control cell proliferation and death.¹¹ Changes in DNA methylation, growth factor signaling pathways, oxidative stress, and cellular communication are thought to contribute to carcinogenesis.^{12,13}

Certain genes are thought to be major targets of chemical carcinogens. These genes, termed *proto-oncogenes* and *tumor repressor genes*, when mutated, allow cells to grow uncontrollably. Alterations in these types of genes have been discovered in many different types of cancers including breast, colon, and lung cancer.^{9,14}

The proto-oncogenes that have been identified so far, such as *ras* and *myc*, have many different cellular functions including regulation of the cell cycle and apoptosis.¹⁵ Mutations in these genes contribute to dysregulated cell division. The mutant proteins retain their normal functions but are no longer sensitive to the controls that regulate these processes.

ras gene products are involved in kinase signaling pathways that regulate cell growth and differentiation. Mutations in *ras* have been implicated in organochlorine pesticide and polychlorinated biphenyl (PCB)-induced human cancers¹⁶ and in Syrian hamster embryo cells (SHE) exposed to arsenic.¹⁷

One of the most well recognized tumor suppressors is *p53*. In general, tumor suppressors produce products that inhibit cell division under suboptimal conditions for growth such as DNA damage and loss of growth factors. This gene is found to be defective in about half of all tumors, regardless of their type or origin.^{18,19} The mutations that inactivate *p53* may be inherited or acquired sporadically during an individual's life span.²⁰

Mutations in *p53* have been observed in various cell lines exposed to environmental contaminants. For example, an increase in *p53* mutations was discovered in human breast epithelial cells (MCF) exposed to organophosphorous pesticides,²¹ and in human bronchial epithelial cells by PAHs.¹⁴ Whether environmental compounds contribute to the development of these types of cancers in humans by directly mutating *p53* or similar types of genes remains to be elucidated.

The propensity to develop cancer following environmental exposure to compounds can be increased by genetic factors. Gene polymorphisms can render individuals more susceptible to developing cancer in comparison to the average population.²² Many of these mutations arise in metabolizing enzymes that can increase the formation of reactive compounds in the body. One of the best studied populations is cigarette smokers. Mutations in cytochrome P-450 enzymes increase the formation of reactive metabolites of BaP, a major component in cigarettes. Additionally, phase II enzymes that are required for elimination of reactive compounds have also been shown to contain mutations; this leads to DNA damage that contributes to the development of lung cancer.²³ Therefore, individuals with these mutations are at greater risk to develop cancer from cigarette smoke. Studying populations with specific polymorphisms gives us important information regarding the mechanism of action of environmental carcinogens.

Occupational Carcinogens

Occupational carcinogens, a subset of environmental carcinogens that are generally encountered at higher doses due to workplace use, are more easily detected, and exposures can be regulated. As illustrated previously, a person's risk of developing cancer is influenced by a combination of factors including genetics, the presence of certain medical conditions, diet, and personal habits (cigarette smoking and alcohol consumption). Occupational hazards, particularly coal tar fumes, asbestos, and aromatic amines, have been linked historically to cancer development.²² According to the National Institute for Occupational Safety and Health, an estimated 20,000 cancer deaths and 40,000 new cases of cancer each year in the United States are attributable to occupation (less than 8% of all cancers). Many U.S. workers are exposed to substances that have tested as carcinogens in animal studies, but less than 2% of chemicals (of a total of approximately 80,000 chemicals) in commerce have been tested for carcinogenicity.²⁴ When new chemicals are introduced into the U.S. market, the Toxic Substances Control Act (TSCA) requires a manufacturer or distributor to submit a premanufacture notice to the EPA 90 days before marketing. The EPA may order additional testing, including cancer bioassays. In general, chemicals are selected for testing when there is a significant human exposure or evidence suggesting potential carcinogenicity.

Identification of occupational cancers often depends on the observation of a cluster of cases. Following these initial observations, it is necessary to establish a link between the agent and the development of cancers. This phase normally is followed by a cohort study, which compares the incidence of cancers in people exposed to the suspected agent with an unexposed population or a case-controlled epidemiologic study. In the case-control study, populations with cancer are compared to those without it to determine if exposure to the suspect carcinogen occurs more frequently among people with cancers. The strengths and limitations of occupational cancer epidemiology are highlighted by Ward et al.²⁵ As of 1999, the International Agency for Research on Cancer (IARC) classified 38 chemicals with industrial uses as Group 1 (known human carcinogens). In addition, many other industrial chemicals are in IARC Groups 2A and 2B, indicating "probably" or "possibly" carcinogenic to humans. These classifications indicate that there is sufficient evidence for carcinogenicity in animals but less than sufficient evidence from epidemiologic studies. Most insufficient evidence is the result of appropriate cohorts for accurate epidemiologic studies.²⁵

More than 3 million U.S. workers are estimated to have potential occupational exposure to agents classified by IARC as Group 1 or Group 2A or 2B.⁸ Doll and Peto estimated that occupational exposures accounted for 4% of human cancers, and the majority of these cases involved lung cancers and mesotheliomas caused by asbestos exposure.²⁶ Other estimates range as high as 10%.^{27,28} The contribution of occupational carcinogens to human cancers is exceeded only by cigarette smoking and diet.²⁵

In light of the multiplicity of compounds considered environmental or occupational carcinogens, we have chosen to review a few select compounds and information on their carcinogenic potential. Initially, we discuss contaminants to which the general population is exposed in food products, water, and air pollution; these include PAHs, dioxins, pesticides, and arsenic. We then concentrate on naturally occurring durable fibers to which humans are primarily exposed in environmental and occupational settings, namely asbestos.

Polyaromatic Hydrocarbons

Polyaromatic hydrocarbons are a group of more than 100 ubiquitous environmental contaminants that occur naturally in coal, crude oil, and gasoline and are produced mainly from incomplete combustion of fossil fuels. PAHs are found in tobacco smoke, smoke from wood-burning stoves and fireplaces, and motor vehicle exhaust.² Additionally, smoking or charbroiling meat can increase the formation of PAHs.²⁹ Aside from occupational exposure, humans can potentially come into contact with PAHs through contaminated air, food, and water sources.²

One of the major routes of exposure to PAHs is via air pollution. It has been estimated that the daily intake for the general population of total PAHs inhaled is 207 ng/m³.³⁰ PAHs are believed to be present in urban air absorbed to respiratory particles.²³ Once inhaled, these compounds can form covalent adducts with DNA, or are metabolized to quinones by CYP450 enzymes, namely CYP1A1, that initiates the formation of reactive oxygen species (ROS). The formation of ROS can also be stimulated by particle-induced inflammation.³¹

The consequence of these actions is thought to contribute to carcinogenesis via damage to DNA, initiation of cell proliferation, or alterations in cell-cycle control.

The carcinogenic potential of PAHs has been well established for decades, and evidence to date has resulted in many of these compounds being labeled as reasonably carcinogenic.² The most striking data come from animal and in vitro studies of BaP, as well as occupationally exposed populations and cigarette smokers. Epidemiologic data supporting the development of cancer in the general (nonsmoking) population by inhaling these compounds is not as robust, but recent studies in conjunction with previous occupational exposure data suggest that exposure to PAHs in ambient air is a current concern. Presently, increases in markers of genotoxicity such as PAH-DNA adducts, PAH-protein adducts, cytogenetic damage, and urinary metabolites³⁰ have been detected in several populations exposed to air pollution containing PAHs as a major contaminant in comparison to control regions.³¹ Lung tumors have also been detected in animals exposed to PAH-containing diesel exhaust.³² Data from in vitro studies show that *c-myc* expression, adduct formation, and cell-cycle progression are altered in lung epithelial cells exposed to PAHs³³ and particulate matter containing PAH compounds.³⁴ Li et al.³⁵ showed a positive correlation between PAH content of particulate matter and the generation of ROS in rodent macrophages, whereas arsenic caused oxidative stress-induced apoptosis in rat lung epithelial cells.³⁶

PAHs are also found in groundwater, usually as a result of industrial runoff into raw water supplies, and in leachates from coal tar and asphalt linings in water storage tanks and distribution lines. Overall, the levels of PAHs in drinking water supplies have been relatively low and, in general, are more abundant in food than water. A study by Kazerouni et al.²⁹ showed the presence of PAHs in charbroiled meats and vegetables. They suggest that PAHs in plants are directly acquired from contaminated soil and air. Although animals that ingest PAHs in their diet get stomach cancers, future studies are required to determine if human populations are at increased risk for PAH-induced cancer through dietary exposures.²

The genotoxic mechanisms by which PAHs initiate cancer have been extensively explored since the discovery years ago that reactive metabolites of BaP could form DNA adducts. Based on this information, current biomarkers of PAH exposure have been limited to the detection of PAH metabolites and PAH-DNA adducts in blood, urine, and various tissues.^{37,38} Epigenetic mechanisms are not as well defined; however, recent studies indicate PAHs can alter cell signaling cascades that control cell communication, growth, and immune functions, which may lead to additional targets that would be useful as biomarkers of exposure. The expression of key signaling pathways including mitogen-activated protein kinase (MAPK), activator protein 1 (AP-1), nuclear factor kappa beta (NFκβ), and protein kinase C (PKC) have all been shown to be affected by PAHs. More specifically, PAH-induced activation of MAPK, which resulted in altered cellular communication via gap junctions,³⁹ suppressed various PKC isoforms,⁴⁰ suppressed humoral and cell-mediated immunity,⁴¹ and induced AP-1 and NFκβ, which may be involved in tumor-promoting effects.³⁵ Additionally, PAHs have been shown to act through nuclear receptors, including estrogen receptors and the aryl hydrocarbon (Ah) receptor.^{42,43} Deciphering which signaling pathways are involved in PAH-

induced carcinogenesis is a complex task that is a current focus of researchers in the field.

Pesticides

Pesticides are a group of both natural and synthetic compounds that are used to control unwanted insects, plants, fungi, and rodents. All pesticides contain biologically active compounds that are purposely designed to interfere with normal biologic processes in target organisms. The activity of these compounds may target specific plants or animals, or they may be toxic to a wide range of species. Therefore, humans exposed to certain pesticides may be at risk to the toxic effects of these compounds, including the development of certain cancers.

Aside from individuals who come into contact with pesticides through occupational exposures, the general population is exposed to pesticides through the ingestion of food and water, by absorption through the skin, or by inhalation during application. Assessing exposure through these routes is extremely difficult because many of these factors rely on lifestyle and vary tremendously on an individual basis.

The EPA's pesticide program and other national and international bodies have classified approximately 165 pesticide chemicals as known, probable, or possible human carcinogens. Currently, there is a lack of human data to support most pesticides as being definitively carcinogenic to humans (except arsenic and ethylene oxide). However, data from animal and in vitro mechanistic studies suggest many of the main components of pesticides have the potential to cause cancer in humans and are therefore classified as probable carcinogens.²

Many pesticides may cause tumors by disrupting cell proliferation, apoptosis, and cell communication and inducing oxidative stress through nongenotoxic mechanisms.¹² For example, glycolphosphate-based pesticides alter cell-cycle parameters in human lymphocytes.⁴⁴ In another study, different chemical classes of pesticides were shown to alter cellular proliferation by activation of *erbB-2*/MAPK signaling pathways.⁴⁵

1,1,1-Trichloro-2,2-bis(*p*-chlorophenyl)-ethane (DDT) is one of the most well-studied organochlorine pesticides reasonably anticipated to be a human carcinogen.² Despite the banning of DDT in the United State in the early 1970s because of its adverse effects on wildlife, it is still produced in other countries.⁴⁶ DDT is an environmentally persistent compound that has been detected at high levels in air, water, soil, plants, animals, and human tissues. A great deal of controversy surrounds the carcinogenic potential of DDT. There is an abundance of in vitro data to suggest DDT is carcinogenic; however, data from human and animal studies have been inconsistent.

DDT can interfere with normal endocrine pathways and so it is suspected to contribute to the increasing incidence of breast and prostate cancers. There is also evidence of DDT-induced tissue damage through oxidative mechanisms.⁴⁷ More recently, DDT has also been shown to alter cell signaling pathways (MAPK) that regulate growth through the AP-1 transcription factor.⁴⁸ DDT also activated the oncogene *erb-B2* and MAPK phosphorylation in human prostate⁴⁵ and breast epithelial cells,⁴⁹ which correlated with cell proliferation. These results provide evidence of signaling pathways whereby environmental chemicals may alter tumorigenesis.

Arsenic

Inorganic arsenic has been known as a human carcinogen for decades. The first evidence suggesting arsenic could cause cancer occurred in 1977.⁵⁰ During this time, arsenic was being applied directly to the skin as a treatment for psoriasis, which resulted in the development of skin cancers.⁵¹ Arsenic is released into the atmosphere from both natural and anthropogenic sources, the latter being responsible for the majority of emissions released.⁵¹ The production of arsenic in the United States has been banned since 1985; however, it is still imported for use. The current concern lies in being exposed to arsenic through food and drinking water. Additionally, individuals may be exposed to arsenic compounds through air emissions from industrial facilities that manufacture pesticides, glass, and cigarette tobacco, smelting operations, and the burning of fossil fuels.²

Studies from around the world have linked exposure to arsenic with the formation of skin, lung, and bladder cancers. There is also increasing evidence that arsenic increases the risk of developing cancers of the kidney, liver, and colon. The majority of epidemiologic studies have focused on populations with contaminated groundwater/drinking water. Many of these populations have higher incidences of lung cancers in comparison to control populations.^{52,53} More recently, there is concern that ingestion of arsenic through contaminated food sources and ambient air pollution may be additional routes of exposure.

The means by which arsenic causes cancer is not well understood. Multiple mechanisms have been proposed and include both genotoxic and nongenotoxic modes of action.⁵¹ Arsenic does not interact with DNA, but indirectly causes chromosome aberrations, genomic instability, and aberrant DNA methylation in promoter regions of genes. In animal studies, arsenic induces the formation of ROS, which may alter regulation of DNA repair and cell-cycle progression.^{54,55} The generation of ROS by arsenic can have a profound effect on signal transduction pathways. Growth factor receptors [epidermal growth factor receptor (EGFR), platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF)], G proteins (Ras, C-src), kinases [extracellular regulated kinase (ERK), c-Jun NH₂-terminal kinase (JNK), p38], and nuclear transcription factors [NFκβ, AP-1, hypoxia-inducible factor 1 (HIF-1)] have all been suggested as targets of arsenic-induced oxidative damage through mechanisms that are still poorly understood.⁵⁶ Arsenic can also affect these pathways independent of free radical generation by direct interaction with these proteins. Alterations in these signaling pathways can have profound effects on cell proliferation, apoptosis, differentiation, and transformation.⁵⁷

Dioxins

Dioxins are a collective group of structurally related compounds that are by-products of industrial and combustion activities such as smelting, bleaching of paper and pulp, the manufacture of some pesticides, waste incineration, and burning fuels such as wood, coal, or oil. They are also released from natural processes such as volcanic eruptions and forest fires.² Dioxins are found throughout the world in air, soil, water, and food sources. These compounds break down very slowly and therefore tend to bioaccumulate in the environ-

ment. Dioxins also tend to accumulate in the tissues of both mammalian and aquatic species. The major route of exposure is now thought to be via food sources.²

Environmental exposure to dioxins has been a concern for decades. Two of the best publicized accounts of dioxin exposure include the industrial accident in Seveso, Italy, in 1976⁷ and the use of Agent Orange during the Vietnam War in the 1960s and 1970s.⁵⁸ Epidemiologic data from these incidents imply that there is sufficient evidence of an association between dioxins and various cancers including soft tissue sarcomas, lymphomas, leukemias, and Hodgkin disease.

TCDD is the most well-studied dioxin. TCDD is regarded by the NTP as a known human carcinogen (Ninth Report on Carcinogens, 2001) based on sufficient evidence from human epidemiologic and mechanistic studies. Experimental animal studies also support TCDD as a carcinogen because it produces tumors in multiple species including mice, rats, and hamsters. Mutations in the proto-oncogene *H-ras* have also been observed in TCDD-exposed animals.⁵⁹ Despite the decision of the National Institute of Environmental Health Sciences (NIEHS) to add TCDD to the list of known carcinogens, scientists argue that current scientific data suggesting the carcinogenic potential of TCDD in humans are weak and inconsistent.⁶⁰

The best-studied mode of action of TCDD-induced carcinogenesis is via the aryl hydrocarbon (Ah) receptor. The Ah receptor controls the expression of genes containing a xenobiotic response element (XRE) in their promoters. Studies have shown activation of the Ah receptor by TCDD produces a wide spectrum of biologic responses, including altered metabolism, growth, differentiation,⁶¹ stress, DNA repair, and motility,⁶² that may contribute to carcinogenesis.

The effect of TCDD on specific signaling pathways has recently been studied. For example, the MAPK-ERK pathway has been implicated in TCDD-induced carcinogenesis through activation of tumor necrosis factor- α (TNF- α) and epidermal growth factor (EGF).⁶² Whether activation of this pathway by dioxins is independent of the Ah receptor remains to be elucidated. New scientific approaches including gene arrays are currently being employed to gain a better understanding of the mechanisms responsible for dioxin-mediated carcinogenesis. Recently, Martinez et al.⁶³ showed that TCDD alters multiple integrated cell signaling pathways associated with lung cancer in human airway epithelial cells using a gene array approach.

Asbestos: General Aspects of Exposure

Asbestos, a group of naturally occurring, fibrous silicate minerals, include the serpentine mineral, chrysotile, and five amphibole minerals (actinolite, amosite, anthophyllite, crocidolite, and tremolite)⁶⁴ (Table 18.2). Chrysotile, anthophyllite, amosite, and crocidolite are the only forms that have been used commercially.⁶⁵ However, tremolite can be a contaminant in chrysotile and talc deposits, and actinolite is a common contaminant in amosite deposits.² Occupational exposure to chrysotile, amosite, anthophyllite, and mixtures containing crocidolite has resulted in lung carcinomas, and mesothelioma has been observed after occupational exposure to crocidolite, amosite, and, to a lesser extent, chrysotile asbestos.⁶⁶⁻⁶⁸ Due to asbestos-related cancers in occupational settings, consumption of asbestos in the United States has been declining since 1973.²

Asbestos is released into the environment from natural and man-made sources and has been detected in indoor and outdoor air, soil, drinking water, food, and medicines. Significant exposure to any type of asbestos increases the risk of lung cancer, mesothelioma, and nonmalignant lung and pleural disorders, including asbestosis, pleural plaques, pleural thickening, and pleural effusions. This conclusion is based on observations of these diseases in workers with cumulative exposures ranging from about 5 to 1,200 fibers/year/mL, which results from 40 years of occupational exposure to air concentrations of 0.125 to 30 fibers/mL. These conclusions are supported by results from animal and mechanistic studies.⁶⁹

Evidence for asbestos carcinogenicity in humans comes from epidemiologic studies as well as from numerous clinical reports on workers exposed to asbestos in a variety of occupational settings.^{68,70} Most recently, tremolite asbestos exposure has been associated with an increased incidence of disease in vermiculite miners and millers from Libby, Montana. Vermiculite is a clay mineral used in concrete aggregate, fertilizer carriers, insulation, potting soil, and soil conditioners. The Libby mine opened in 1921 and at one point accounted for 80% of the world's vermiculite production. The Libby vermiculite deposit is unique in the sense that it contains an average amphibole asbestos content of 4% to 6%,⁷¹ including tremolite and actinolite.⁶⁹ Miners, millers, and some residents of Libby were exposed to high levels of asbestos-containing dust and developed nonmalignant respi-

TABLE 18.2. Types and physicochemical properties of asbestos fibers (defined as having at least a 3:1 length-to-diameter ratio).

Type	Composition	Morphology	Sources
Chrysotile	$(\text{Mg})_6(\text{OH})_8\text{Si}_4\text{O}_{10} (\pm\text{Fe})$	Curly	95% of asbestos usage historically
Crocidolite	$\text{Na}_2[\text{Fe}^{3+}]_2[\text{Fe}^{2+}]_3(\text{OH})_2\text{Si}_8\text{O}_{22} (\pm\text{Mg})$	Straight/rodlike	Mined in Australia and South Africa
Amosite	$\text{Fe}_7(\text{OH})_2\text{Si}_8\text{O}_{22} (\pm\text{Mg}, \text{Mn})$	Straight/rodlike	Mined in Australia and South Africa
Tremolite	$\text{Ca}_2\text{Mg}_5(\text{OH})_2\text{Si}_8\text{O}_{22} (\pm\text{Fe})$	Straight/rodlike	Contaminant of certain chrysotile deposits
Anthophyllite	$(\text{Mg}, \text{Fe})_7(\text{OH})_2\text{Si}_8\text{O}_{22}$	Straight/rodlike	Mined in northern Europe
Actinolite	$\text{Ca}_2\text{Fe}_3(\text{OH})_2\text{Si}_8\text{O}_{22} (\pm\text{Mg})$	Straight/rodlike	Contaminant of certain chrysotile deposits

Source: Data from Guthrie,⁶⁴ by permission of BookCrafters, Inc., 1993.

ratory diseases, lung cancer, and mesothelioma.⁶⁹ A mortality review that compared asbestos-related deaths in Libby versus Montana versus the United States found that, for the 20-year period examined (1979–1998), mortality from asbestosis was approximately 40 times higher than the rest of Montana and 60 times higher than the rest of the U.S. population. Lung cancer mortality was 1.2 to 1.3 times higher than expected compared to Montana and the United States, and the mesothelioma mortality was also elevated.⁷² The Libby vermiculite mine closed in 1990, but its products are still on the market.⁷¹ In a recent medical testing program to identify and quantify asbestos-related radiographic abnormalities among persons exposed to vermiculite in Libby, cross-sectional interview and medical testing was conducted in 7,307 persons who have lived, worked, or played in Libby for at least 6 months before December 31, 1990. Of these, 6,668 participants received chest radiographs to assess the prevalence of pleural and interstitial abnormalities. The study showed 17.8% of pleural abnormalities and less than 1% interstitial abnormalities.

Tremolite asbestos, a hydrated calcium magnesium silicate [$\text{Ca}_2\text{Mg}_5\text{Si}_8\text{O}_{22}(\text{OH})_2$], is also a known contaminant of chrysotile and fibrous talc.^{73–75} The differences in cancer potential between chrysotile asbestos, a serpentine mineral, and amphibole asbestos have been debated extensively. Many studies show that chrysotile is cleared from the lungs more rapidly than amphiboles.⁷⁶ Due to the clearance and dissolution of chrysotile, it has been suspected that contaminating tremolite might be responsible for mesotheliomas occurring in chrysotile miners and millers.⁷⁵ It also has been suggested that processed chrysotile contains little or no tremolite.⁷⁷ Amosite asbestos was the most common fiber type found in the lungs of asbestos-exposed mesothelioma patients.⁷⁸ In a more recent study by Roggli et al.,⁷⁵ 312 cases of mesothelioma were analyzed for fiber types in lung parenchyma by scanning electron microscopy. Tremolite was identified in 53% of the cases and was increased in 26% of the cases. Fibrous talc was identified in 62% and correlated strongly with the tremolite content ($P = 0.0001$). Chrysotile was only identified in 10% of the cases, and amounts correlated with the proportion of tremolite. In 4.5% of the cases, non-commercial amphibole fibers (tremolite, actinolite, and/or anthophyllite) were the only fiber types found existing above background (control individual) levels. They concluded that tremolite in lung tissue samples from mesothelioma victims were derived from contamination of talc and chrysotile, and that tremolite accounted for a considerable fraction of the excess fiber burden in end-users of asbestos products.

Asbestos-Induced Malignant Disease

BRONCHOGENIC CARCINOMA/LUNG CANCERS

Heavy occupational exposure to asbestos has been associated with developing lung cancer, and a dose–response relationship between asbestos exposure and cancer incidence has been well documented.^{79,80}

Cigarette smoking and asbestos exposure have additive or synergistic interactions in inducing cancer of the lung.^{68,81} Compared to cigarette smokers with no asbestos exposure, there is a substantial increase in mortality rate in cigarette-smoking asbestos workers.^{81,82}

MESOTHELIOMA

Malignant mesothelioma is a rare tumor that is derived from mesothelial cells of the serosal surface of a body cavity. The most important causal factor for the development of human mesothelioma is exposure to asbestos, primarily to amphibole asbestos. After Wagner et al.⁸³ reported 33 cases of pleural mesothelioma in a crocidolite-mining area in South Africa, increasing attention has been given to this disease. Although mesothelioma is a rare disease with an annual incidence in the United States of 2,000 to 3,000 cases, a steady rise in cases has been reported.^{84,85} In Europe, the incidence of malignant pleural mesothelioma has risen for decades and is expected to peak between the years 2010 and 2020.⁸⁶ In a recent study on 1,445 cases of mesothelioma in the United States, it was determined that commercial amphiboles were responsible for most of the mesothelioma cases observed.⁷⁵ Chrysotile asbestos may produce mesothelioma in man, but the number of cases is small, and the required exposures are large.⁸⁷ A recent report suggests that heavy exposures to chrysotile asbestos alone or with negligible amphibole contamination can cause malignant mesothelioma and other lung cancers in man.⁸⁸ However, studies evaluating worker populations that are transient and may be exposed to different types of fibers over a lifetime are difficult to interpret.

Mechanisms of Action of Asbestos Fibers

The potential of asbestos fibers to cause cancer has been linked to their geometry, size, and chemical composition. Long (more than $5\mu\text{m}$), thin (diameter less than $3\mu\text{m}$) fibers are a health concern⁸⁹ and have been found to cause mesothelioma and fibrosis after intrapleural or intraperitoneal administration to rodents.⁹⁰ In addition to size, the chemical composition of fibers plays an important role in determining the durability, biopersistence, and biodegradability of asbestos types. The greater durability of amphiboles compared to chrysotile appears to be one of the principal reasons for their greater carcinogenic potential. Amphibole fibers persist at sites of tumor development and may serve as stimuli for neoplastic growth of cells.^{91,92} The persistence of the amphibole fibers at the site of tumor formation is important to both tumor induction and promotion because the mean latency period between initial exposure to asbestos and the development of mesothelioma is around 30 to 40 years.^{67,93}

An important unresolved issue is whether asbestos fiber carcinogenicity is through direct effects of asbestos on mesothelial cells or through indirect mechanisms involving oxidative stress.^{94,95} A ramification of interaction of long (more than $5\mu\text{m}$) fibers with cells is frustrated phagocytosis and a prolonged oxidative burst.⁹⁶ The increased durability and high iron content of the amphiboles, crocidolite, and amosite also may contribute to their higher carcinogenic potential through oxidants catalyzed by iron and/or surface reactions occurring on the fiber. The cytotoxicity of crocidolite fibers in human lung carcinoma cells is directly linked to iron mobilization and is followed by increased ferritin synthesis, a perpetual feedback system for uptake of iron by cells.^{97,98} Studies on animal models and cell cultures have confirmed that asbestos fibers generate ROS and reactive nitrogen species (RNS).^{67,95,99} These effects may be potentiated by the inflammation associated with fiber exposures.¹⁰⁰

A complex profile of somatic genetic changes has been revealed in human malignant mesotheliomas. These changes implicate a multistep process of tumorigenesis. The occurrence of multiple, recurrent cytogenetic deletions suggests that loss and/or inactivation of tumor suppressor genes are critical to the development and progression of mesothelioma. Deletions of specific regions in the short (p) arms of chromosomes 1, 3, and 9 and long (q) arms of 6, 13, 15, and 22 are repeatedly observed, and loss of a copy of chromosome 22 is the single most consistent numerical change.¹⁰¹

Asbestos fibers in vitro cause the production of DNA damage either via production of ROS or by direct damage to chromosomes after phagocytosis of fibers.^{90,102} The consequences of such DNA damage could be the loss of tumor suppressor genes, activation of proto-oncogenes, or unregulated generation of growth factors through paracrine/autocrine mechanisms.¹⁰³ Asbestos also causes alterations in cell signaling pathways linked to abnormal growth control in pulmonary epithelial cells, mesothelial cells, endothelial cells, and fibroblasts.^{3,104} Asbestos also activates redox-sensitive transcription factors such as NF- κ B¹⁰⁵ and AP-1,¹⁰⁶ which leads to increased cell survival, inflammation, and, paradoxically, the upregulation of antioxidant enzymes such as manganese superoxide dismutase.¹⁰⁰ This enzyme is also overexpressed in asbestos-related mesotheliomas,^{107,108} rendering them highly resistant to oxidative stress in comparison to normal mesothelial cells.

Carcinogenesis was classically thought to be a proliferation-driven process. However, it is now recognized that neoplastic growth is an imbalance between apoptosis and proliferation. In support of this concept, a dynamic balance between apoptosis and cell proliferation is observed in

mesothelial cells exposed to crocidolite asbestos.¹⁰⁹ Studies in vitro indicate that asbestos can induce apoptosis in mesothelial cells through formation of ROS^{110,111} and by mitochondrial pathways.^{94,112}

Studies in our group have found that the EGFR is an important initial target of asbestos fibers at the cell membrane (Figure 18.1). This growth factor is required for proliferation of human mesothelial cells¹¹³ and is produced in an autocrine fashion in mesotheliomas.¹¹⁴ Autophosphorylation of the EGFR occurs in mesothelial cells after in vitro exposures to asbestos. Moreover, aggregation and phosphorylation of the EGFR by long fibers initiates cell signaling cascades linked to asbestos-induced injury and mitogenesis.^{115,116} Increased expression of EGFR in rat pleural mesothelial cells correlates with the carcinogenicity of mineral fibers.¹¹⁷

We have also shown that the EGFR is causally linked to activation of the MAPK cascade and increased expression of the proto-oncogenes *c-fos* and *c-jun* (see Figure 18.1).^{116,118} Expression of both *fos* and *jun* family members (components of the transcription factor AP-1 complex) is required for transition through the G₁ phase and entry into the S phase of the cell cycle.¹¹⁹ Most recently, ERK 1/2-induced activation by asbestos has been linked to the induction of *fra-1*, an important component of the AP-1 complex that is causally related to anchorage-independent growth in mesothelioma.¹⁰⁷ Microarray analyses have shown increased expression of *fra-1* in rat and human mesotheliomas.¹²⁰ Other growth factors and their receptors also are important in malignant mesothelioma including transforming growth factor- α (TGF- α), which binds to the EGFR,¹²¹ insulin growth factor II,¹²² and PDGF.¹²³ Increased levels of hepatocyte growth factor (HGF)

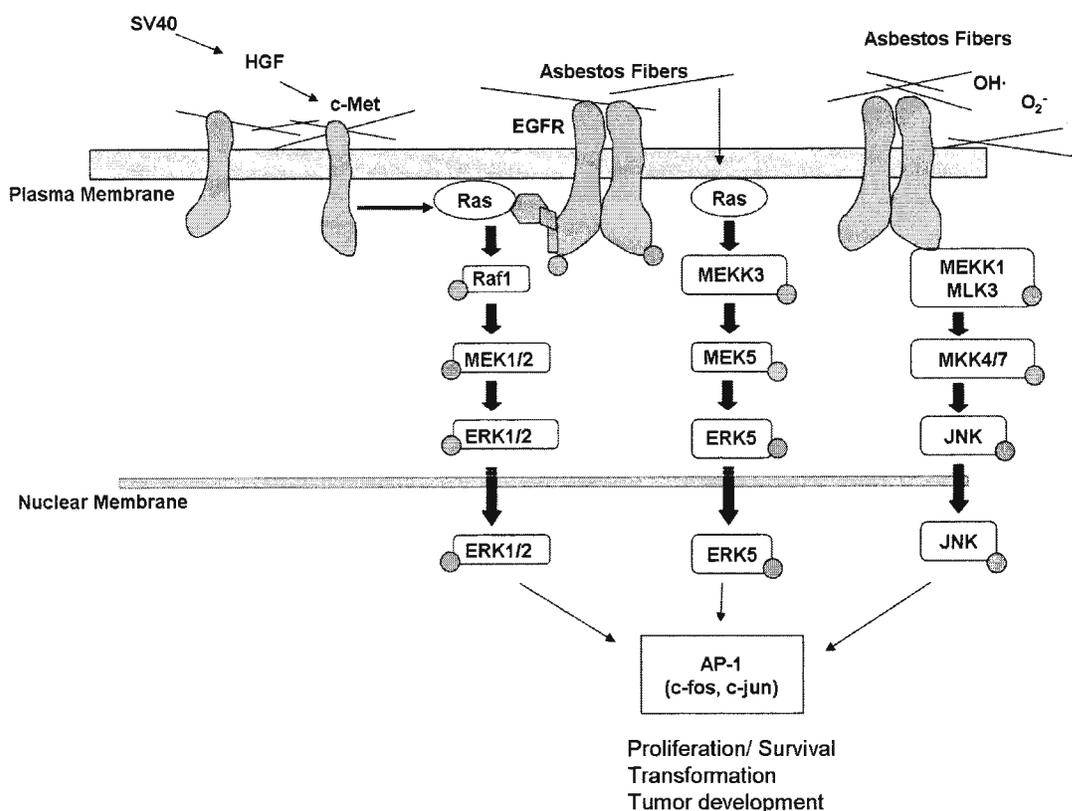

Figure 18.1. Schematic showing some of the major cell signaling events thought to be involved in asbestos-induced carcinogenesis.

TABLE 18.3. Summary of important environmental/occupational carcinogens and their modes of action

	DNA adducts	Elaboration of ROS	Cell-cycle progression	Cell signaling/altered transcription factors	Mutations in proto-oncogenes/tumor suppressors
PAHs (BaP)	X ³³	X ³¹	X ³³	X ³⁹	X ¹⁴
DDT		X ⁴⁷	X ⁴⁹	X ⁴⁸	X ⁴⁵
Arsenic		X ⁵⁵	X ⁵⁵	X ⁵⁶	
TCDD			X ⁶²	X ⁶¹	X ⁵⁹
Asbestos		X ⁹⁵	X ¹¹⁹	X ¹⁰⁶	

Superscript numbers are references to support these mechanisms.

and keratinocyte growth factor (KGF), known growth factors for mesothelial cells, have been detected in pleural lavage fluids in rodents exposed to asbestos.¹²⁴ The HGF receptor, c-Met, a proto-oncogene product whose activation leads to cell growth and altered morphogenesis, is activated in SV-40-positive human mesothelioma cells.¹²⁵ High expression levels of *c-met* have been detected in rat mesothelioma cells and are *fra-1* dependent.¹²⁶

Conclusions

Identification and understanding the mechanisms of cancer induction and/or development induced by environmental carcinogens are critical for both cancer prevention and therapeutic approaches. As emphasized at a recent workshop,¹²⁷ removal or reduction of carcinogens in the environment is the most effective way to reduce future cancer risks. In this regard, clinicians and basic scientists should be advocates in the public health arena.

This chapter illustrates the complexities of action of diverse groups of environmental/occupational carcinogens, but also indicates common modes of action that might be modeled in bioassays using human cells to predict carcinogenicity (Table 18.3); these include assays for DNA damage or repair and carcinogenic adduct formation and assays for activation of key proto-oncogenes or inhibition of tumor suppressor genes. It is important to realize that agents in combination, for example, asbestos and cigarette smoke, may be more carcinogenic than individual agents; thus, modeling and revealing additive or multiplicative risks from mixtures of carcinogens are critical future tasks. Defining gene-environment interactions will also be important in defining genetic predisposition to suspect agents.

A recent volume¹²⁸ presents the challenges of diagnosis and treatment of occupational cancers to the physician, which include the necessity for thorough patient questionnaires emphasizing smoking habits and working histories. The identity of prototypic cancers, such as mesothelioma, may pinpoint asbestos exposures, but these tumors are difficult to diagnose. A multidisciplinary clinical team is advocated to address genetic factors, diagnosis of tumors, treatment options, and follow-up of patients.

Cancer Metastasis

Kevin McDonnell and
Anton Wellstein

Cancer metastasis, the spread of cancer from its primary location to secondary sites, heralds the progression to a fundamentally distinct oncologic disease. Metastatic infiltration often disrupts the integrity and physiologic functioning of the target organ, giving rise to the pain, morbidity, and mortality that make metastatic disease such a devastating illness.¹⁻¹¹

Molecular Origins of the Metastatic Phenotype

The biologic process by which a primary tumor escapes the vicinity of its original environment and colonizes remote destinations is complex, involving a cascade of pathophysiologic events. Such events, it has been suggested, occur through a sequence of stochastic genetic alterations¹² fostered by an inherent genetic instability.¹³⁻¹⁵ These mutations are perpetuated by a mechanism of evolutionary selection, which confers a survival advantage on the metastasizing cell.¹⁶⁻¹⁸ In contrast to the idea of random molecular occurrences spawning the metastatic phenotype, some investigators have proposed that metastasis derives from activation of preexisting genetic scripts, for example, RAS- and/or MYC-mediated mechanisms,^{19,20} that promote metastasis. Alternately, cells may acquire the ability to metastasize via the silencing of metastatic suppressor genes.^{21,22} The first metastatic suppressor was identified as the "non-metastatic clone 23" (NM23) gene,²³ whose suppressive effects are believed to be mediated via influences upon ERK-MAPK signaling.²⁴ Subsequently, additional metastatic suppressor genes have been characterized, including, among others, KAI-1,²⁵ KISS-1,²⁶ tissue inhibitors of metalloproteinases (TIMPs),²⁷ MKK4,^{28,29} BRMS1,³⁰ SSeCKs,³¹ RhoGD12,³² and Drg-1.³³ This collection of metastasis suppressor genes are unified mechanistically insofar as they inhibit the spread of primary tumors via modulation of cellular growth and adhesion properties and cytoskeletal architecture.²⁹ Whether the metastatic phenotype ultimately develops from a series of random mutations, activation of preprogrammed genetic scripts, or inhibition of suppressive mechanisms, further investigations of the molecular origins of this phenotype may yield important insights into the specific targeting and/or control of cancer metastases.

The Tumor Microenvironment

The metastasizing cancer cell is endowed with a constellation of properties that permits it to successfully translocate to secondary tumor sites. Among these properties is the ability to sustain uncontrolled primary growth.¹² Such primary growth takes place by virtue of the cell's own genetic programming, but it also may be abetted by a permissive microenvironment.³⁴⁻³⁸ Microenvironmental biologic status may have a dramatic effect on the capability of the tumor to expand and ultimately metastasize. For example, the microenvironment provides a rich source of tumor growth stimulatory molecules. Microenvironmental expression of these factors permits primary tumor expansion and induces tumor metastasis.³⁹⁻⁴² Other microenvironmental influences are important with regard to tumor growth and metastasis as well. For example, the immunologic status of the microenvironment mirrors the immunologic integrity of the organism as a whole, and this integrity exerts a dramatic influence on tumor growth.⁴³ Immunodeficient states are associated with increases in the incidence of cancer,^{44,45} and ultraviolet irradiation-induced compromise of immune function results in increased malignant growth.⁴⁶⁻⁴⁹ Conversely, there has been demonstrated an inverse relationship between the occurrence of cancer and metastasis and activation of microenvironmental immunity.⁵⁰⁻⁵³

The Tumor Microenvironment: Blood Vessel Formation

Microenvironmental vascular status also exerts a profound impact on the ability of the primary tumor to grow and metastasize. Expression of blood vessel growth-promoting molecules is generally a poor prognostic factor associated with cancer^{54,55} and specifically with breast cancer,⁵⁶⁻⁵⁸ cancer of the central nervous system,⁵⁹⁻⁶¹ gynecologic cancers,⁶²⁻⁶⁴ gastrointestinal cancer,⁶⁵⁻⁶⁷ and prostate cancer.^{68,69} Proclivity for metastasis correlates with the degree of tumor-associated blood vessel formation.⁷⁰⁻⁷⁸ Such tumor-associated blood vessel formation promotes metastasis in two ways: blood vessels function to transport growth-stimulating nutrients to the burgeoning primary tumor and as a conduit by which metastasizing cells travel toward their secondary tumor destinations.

The formation of blood vessels is regulated by the cumulative effects of a variety of molecules; the roles of these mol-

ecules typically are defined during the period of embryonic blood vessel formation and later reprised in the context of pathologic tumor-associated vessel genesis. During embryonic development, blood vessels arise via a number of distinct mechanisms including vasculogenesis, angiogenesis, and vessel intussusception.

Vasculogenesis is the *de novo* construction of the vasculature. During this process, embryonic mesoderm is stimulated to differentiate into precursor hemangioblasts and then endothelial cells. Fibroblast growth factors (FGFs)⁷⁹ and vascular endothelial growth factor (VEGF)⁸⁰ provide key differentiation signals initiating the mesodermal to endothelial transition. VEGF, together with other molecular factors, cue endothelial cells to proliferate further and assemble into linear aggregates that subsequently reorganize to form a tubular vascular reticulum.⁸¹⁻⁸³ Additional molecules play more specialized roles; for example, the integrins induce lumen formation,⁸⁴ and angiopoietin 1 acts to promote the entrenchment and stabilization of the nascent vasculature by modulating endothelial cell adherence to nearby tissue and extracellular components.⁸⁵⁻⁸⁷

Following incipient vasculogenic establishment of the original blood vessel system, the vasculature may continue to expand via ancillary mechanisms including angiogenesis or vessel intussusception. Angiogenesis entails proliferation of the previously established endothelial cell population, permitting collateral expansion from the nascent vascular reticulum. VEGF is a primary molecular promoter of angiogenesis. However, for efficient collateral expansion to occur, angiopoietin 1-mediated fortification of the vasculature must be abrogated. Such reversal is mediated through the antagonistic actions of angiopoietin 2, which inhibits the actions of angiopoietin 1 at the Tie 2 receptor, permitting the disruption of endothelial cell-extracellular matrix stabilizing interactions.⁸⁸ An additional mechanism that may allow expansion of the extant blood vessel system is the process of intussusception in which blood vessels are split by VEGF-stimulated growth and interposition of an endothelial tissue barrier across the lumen of the vessel.⁸⁹⁻⁹²

The pathologic formation of blood vessels during tumor growth and metastasis reactivates many of the mechanisms operating during embryonic blood vessel formation. Reminiscent of embryonic vasculogenesis, endothelial precursor hemangioblastic cells are activated from the bone marrow. These cells incorporate into the newly forming tumor vasculature,⁹³⁻⁹⁶ frequently comprising more than one-third of the blood vessels.⁹⁷ Both FGF and VEGF have been demonstrated to function as molecular mediators of tumor-associated vasculogenesis.⁹⁸⁻¹⁰² Angiogenic sprouting, as well, contributes to pathologic blood vessel formation, and this mechanism is also modulated by FGFs and VEGF¹⁰³ in addition to angiopoietin 2.¹⁰⁴

Tumors may also achieve vascularization via specialized mechanisms. Tumors may “co-opt” existing blood vessels by associating with previously established vasculature and, in so doing, satisfying their own metabolic needs by allowing themselves access to the nutrients and oxygen transported through these vessels. Intriguingly, in a mechanism referred to as “vascular mimicry,” tumor cells may functionally imitate the endothelial cell itself by forming tumor cell-lined channels that accommodate blood flow.^{90,91,105}

The Angiogenic Switch

Generally, blood vessel formation takes place when the stimulatory effects of proangiogenic molecules surpass the inhibitory effects of antiangiogenic molecules. More specifically, the magnitude and actual pattern of the blood vessel formation depends upon the precise timing, distribution, and absolute and relative expression levels of these angiogenic factors. In turn, expression of these factors is initiated by various genetically programmed triggers that have been designated “angiogenic switches.”^{106,107} Within the pathophysiologic context of tumor-associated blood vessel formation, these switches are clinically and phenotypically important insofar as their activation is one hallmark of an aggressive, metastatic phenotype.

Within the tumor microenvironment, an angiogenic switch may be activated in response to an altered physiologic milieu. For example, when a burgeoning tumor outgrows its blood supply and creates a circumstance of tissue hypoxia, there occurs a reactive increased expression of multiple genes including, among others, hypoxia-inducible factor 1 (HIF-1).^{108,109} HIF-1, in turn, modulates an angiogenic cascade involving expression of a multitude of proangiogenic factors including VEGF¹¹⁰⁻¹¹² and FGF.¹¹³ Other physiologic perturbations such as hypoglycemia¹¹⁴ and ischemia¹¹⁵ may also lead to activation of an angiogenic switch.

The angiogenic switch, in addition to the increased levels of VEGF and FGF, may also comprise increased expression of proangiogenic matrix metalloproteinases,^{116,117} the downregulation of antiangiogenic factors,¹¹⁸ activation of oncogenes, or inactivation of tumor suppressor genes.^{114,115,119,120} Activation of angiogenesis may also derive from the cumulative acquisition of proangiogenic genetic elements over time, for example, through the horizontal transfer of DNA among neighboring tumor cells.¹²¹ Ultimately, elucidation of the molecular basis of the angiogenesis activation will yield additional insight into mechanisms of tumor progression and allow for effective targeting of tumor metastasis.¹²²

The Importance and Role of the Lymphatic System During Metastasis

The lymphatic system functions as a key microenvironmental adjunct to the vascular system for the spread of metastasizing cells to their secondary sites.^{123,124} The importance of the lymphatic system as an avenue of metastatic dispersion is underscored by the prognostic value associated with the spread of cancers to regional lymph nodes^{125,126} and the impact of the removal of such lymph nodes on the prevention of metastasis and overall survival.^{127,128}

That peritumoral lymphatics play an integral role in metastatic spread is established^{129,130}; what is more controversial is the role that intratumoral lymphatics play.¹³¹⁻¹³⁴ This controversy has been fueled by the recent discovery of lymphatic-specific molecules such as VEGF C,¹³⁵⁻¹³⁷ VEGF D,^{138,139} and VEGFR-3.^{140,141} An association between tumor expression of these lymphatic-specific factors and metastasis has been established, suggesting that tumor lymphangiogenesis is an important prognostic indicator in the same fashion as is tumor angiogenesis.^{142,143} It is anticipated that the metastatic significance of intratumoral lymphatics

and lymphangiogenesis will be more firmly defined as additional lymphatic-specific molecules are identified and the mechanism of tumor-associated lymphangiogenesis is further examined.

Intravasation

Following proliferation, metastasizing cells exit from the primary tumor site into the bloodstream or the lymphatic circulation via the process of intravasation.⁸ Woodhouse et al. observed that intravasating cells recapitulate the peripatetic cell phenotype characterizing embryonic physiologic processes that are dependent upon migrating, invading cells such as the primordial establishment of the original vascular and nervous systems.^{144,145}

The migratory aspects of intravasation entail specific cellular capabilities. The cell must exhibit the mechanical ability for translocation; the development and advancement of pseudopodia permit such locomotion.¹⁴⁶ A variety of motility factors promote pseudopodia-mediated translocation; these include autocrine molecules, for example, insulin-like growth factor II¹⁴⁷ and autotaxin,¹⁴⁸ paracrine molecules such as insulin-like growth factor I,¹⁴⁹ and the extracellular matrix molecules laminin, fibronectin,¹⁵⁰ and collagen.¹⁵¹

For the metastatic cell to transit successfully beyond its microenvironment, it must traverse the extracellular matrix. Abetting this penetration, metalloproteinases degrade the extracellular matrix,^{152,153} with expression levels of metalloproteinase expression correlating with the proclivity of cells to metastasize.^{154,155}

Tumor-associated blood vessel formation furthers the intravasation process. Extracellular matrix degradation takes place via the degradative effects of endothelial cell-released collagenases and urokinases.¹⁵⁶ As well, VEGF expression accompanies the expansion of the tumor vascular network. VEGF, which is also known as vascular permeability factor,¹⁵⁷ causes the formation of leaky permeable vessels. Such leakiness, important for the expansion of the tumor vasculature,¹⁵⁸ also contributes to the successful intravasation of metastasizing tumor cells.

End-Organ Arrest: Organ-Directed Metastasis

Postintravasation, tumor cells migrate to the sites of metastasis. Clinical and experimental observations suggest that metastatic destinations are selective for specific tissues¹⁵⁹; for example, among others, breast and prostate cancers preferentially metastasize to bone,¹⁶⁰ colorectal cancer to the liver,¹⁶¹ and skin cancer to the lung.¹⁶²

Mechanisms proposed to account for directed metastasis are controversial. The British surgeon Stephen Paget retrospectively investigated the metastatic destinations of a variety of cancers by examining autopsy records and documented organ-specific metastasis patterns.¹⁶³ He attributed this proclivity for organ-specific metastasis to a salutary interaction between the metastasizing cell and the end organ. He likened the metastasizing cell to a seed that thrives in the growth-promoting "soil" of the target organ.

An alternative mechanism explaining directed metastasis was proposed in the early 20th century by another surgeon, James Ewing. Ewing also documented a nonrandom pattern

of metastatic cancer spread; in contrast to Paget, however, Ewing suggested that metastatic patterns could be attributed to an anatomic, circulatory bias¹⁶⁴; that is, metastasizing cells tend to lodge and secondarily proliferate at the first vascular bed distal from the primary tumor site.

Analyses of patterns of metastatic spread provide support for Ewing's hypothesis. Weiss et al., in extensive studies of colon cancer metastasis, observed generalized proximal organ metastasis correlating with the magnitude of target organ flow.¹⁶⁵ Weiss' analyses, however, do not wholly vitiate the "seed and soil" hypothesis of Paget. To the contrary, in these same studies, Weiss observes that patterns of secondary metastasis do not perfectly correlate with the magnitude of blood flow. In some organs, the tendency for metastasis is greater than or less than what would be predicted solely on the basis of the magnitude of blood flow. These findings suggest that some specific interaction between the circulating metastatic cell and the target organ influences the likelihood of that cell metastasizing to that organ. Additional observations corroborate this notion; patients with ovarian cancer frequently develop malignant abdominal ascites, necessitating placement of peritoneovenous shunts. In these circumstances, malignant cells are drained from the abdomen back into the circulation via the jugular vein whence they pass through the capillary bed of the lungs. Ewing would predict that these patients would develop pulmonary metastases, and yet autopsy results reveal an overwhelming absence of such growths.^{166,167}

Hart and Fidler examined the organ biases of B16 melanoma metastases. In the whole animal, B16 cells spontaneously form metastases within the lung and ovaries. The investigators intravenously injected B16 cells into mice bearing syngeneic pulmonary, ovarian, and renal subcutaneous implants.¹⁶⁸ Hart and Fidler found that B16 tumors do not develop randomly; rather, they formed selectively within the implanted lung and ovarian tissue, and not within the kidney tissue. Thus, it would seem that some special interaction between circulating B16 cells and the pulmonary and ovarian tissue dictates the metastatic bias.

A number of recent investigators, including Binacone et al., have sought to elucidate the mechanistic basis of organ-selective metastasis.¹⁶⁹ E-selectins are adhesion molecules expressed on the surface of endothelial cells. Binacone demonstrated that the destination of metastasizing B16 cells could be efficiently directed by controlling cell-surface expression of E-selectin. This demonstration suggested that organ-directed metastasis may be defined, in part, by an interaction between proteins expressed on the surface of the target organ endothelium and those expressed on the surface of metastasizing cells. In support of this hypothesis, the metastatic destination of Chinese hamster ovary cells can be altered by transfecting these cells to express $\alpha_4\beta_1$ integrin on their surface.¹⁷⁰

In agreement with the idea of metastasizing cell-organ endothelium interactions providing a basis for organ-selective metastasis, a number of different lines of evidence have suggested the uniqueness of organ endothelia.¹⁷¹⁻¹⁷³ Ruoslahti and his coworkers have suggested that the uniqueness of the organ endothelia derives from signature endothelial cell-surface proteins that comprise an *address system* and ensure delivery of the metastasizing cell to a designated target tissue.¹⁷⁴⁻¹⁷⁶ For example, specific proteins have been identified that mediate the binding of metastatic breast and prostate

cancer cells to lung tissue¹⁷⁷⁻¹⁷⁹ and colon cancer cells to the liver.¹⁸⁰

Taken as a whole, the evidence supports both a circulatory, anatomic bias, as proposed by Ewing, and unique end-organ properties, as theorized by Paget, underlying the ultimate site of metastasis. Recent investigative initiatives have sought to further define the molecular basis and relative contributions of the circulatory, anatomic, and "seed and soil" mechanisms toward organ-directed metastasis.

Extravasation

Having arrested at their target organ, metastasizing cells must extravasate from the circulation by traversing the endothelium and underlying basement membrane to achieve successful secondary metastatic growth. This success derives to a significant degree from the same locomotive and tissue penetrative capacities that were required to complete intravasation.

Novel insights into the molecular and mechanical aspects of extravasation have been garnered by the development and implementation of innovative experimental and investigative techniques such as *in vivo* video microscopy¹⁸¹⁻¹⁸³ and laser scanning confocal microscopy.¹⁸⁴ The ability of metastasizing cells to translocate beyond the endothelium significantly relies upon the inherent locomotive potential of the metastasizing cell and has been correlated with the expression of, among other molecules, transforming growth factor-beta¹⁸⁵ and activation of promotogenic pathways involving, for example, protein kinase 2/p38¹⁸⁶ and c-erbB-2.¹⁸⁷ To complete its transendothelial migration, the extravasating cell may also require a permeable endothelial cell layer^{188,189} as well as activation of transendothelial migratory mechanisms.¹⁹⁰⁻¹⁹²

Beyond the endothelial layer, the metastasizing cell must penetrate the underlying basement membrane. Mechanistically, this process has been compared with the process of inflammation-associated leukocyte infiltration¹⁹³⁻¹⁹⁸ requiring, reminiscent of intravasation, metalloproteinase expression to degrade the basement membrane.¹⁹⁹⁻²⁰¹ Once the extravasation process is complete, the metastasizing cell faces its final obstacle of secondary proliferation at the metastatic site.

Growth and Expansion of the Tumor at the Secondary Site

Expansion of the tumor at its secondary site represents perhaps the most clinically significant of the metastatic steps, for it is this growth and colonization at the target organ that causes the physical disruption and physiologic derangement of that organ, ultimately giving rise to the morbidity and mortality characterizing metastatic disease.

Factors influencing expansion of the metastatic mass are similar to those modulating growth at the primary tumor site. These factors include properties inherent to the metastatic cell itself such as accelerated and uninhibited growth, as well as the ability to co-opt the resources of the secondary target site for the cell's own metabolic requirements.

In addition to its inherent characteristics, the metastasizing cell also relies on a receptive microenvironmental *soil* to achieve optimal growth at the secondary site. As the site of

the primary tumor location, the immunologic, angiogenesis-promoting and growth-stimulatory milieu of the secondary site modulates the extent of metastatic tumor expansion.²⁰²⁻²⁰⁶ Further understanding of those variables that promote successful completion of this last metastatic step may afford new insights into strategies directed at preventing and vanquishing metastatic disease.

Discovery of Tumor Metastasis-Related Genes

Ultimately, conquering metastatic disease will likely derive from a more thorough characterization of the genes expressed during each step of metastasis. Transcriptional and functional analysis of metastatic gene products may provide new insights into the molecular mechanisms underlying the process of metastasis and identify potential targets for therapeutic intervention.

Molecular technologic advances have made it possible to discover genes that are differentially expressed between normal physiologic and aberrant pathologic states. Two of the more versatile techniques that permit identification of variably expressed genes are differential display and microarray analysis.²⁰⁷ Differential display employs reverse transcription and the polymerase chain reaction using mRNA derived from different cellular states, allowing, for example, the identification of genes that are expressed during the process of metastasis and not expressed during nonpathologic states. Another technique used to examine differential gene expression, microarray analysis, characterizes gene expression based on the relative hybridization of reversed transcribed gene products to a prefabricated, nucleic acid-containing matrix. Demonstrating their power and utility, these techniques have been used to discover metastasis suppressor genes²⁰⁸ and metastatic molecular signatures.²⁰⁹⁻²¹¹

The endeavor to discover metastasis-related genes has inspired innovative investigative approaches including the use of phage display technology. Ngaiza and colleagues²¹² employed this technique to identify colon cancer genes mediating metastasis to the liver. The gene products from a highly metastatic colon cancer cell line were expressed on the surface of the phage. Genes involved directly in the process of liver metastasis were identified by *in vivo* biopanning, that is, by injecting the phage into the circulation and selecting those phages that specifically bound to the liver. One theoretical advantage of this technique is that it identifies genes whose expression is not merely correlated with the process of metastasis but rather those whose function is directly integral to the mechanism itself.

As more novel and precise methods for metastasis gene discovery are developed and consequently, more specific metastatic gene products are identified, so also, ideally, will the therapeutic targeting of the metastatic process become more focused and efficacious.

Antimetastasis-Directed Therapies

Investigations of metastatic genes and the mechanisms driven by these genes have afforded new therapeutic modalities for the treatment of cancer. Novel therapies have been directed against specific molecules implicated in the metastatic process, for example, erb-B2,^{213,214} the epidermal growth

factor receptor,²¹⁵ and caveolin 1.²¹⁶ New treatments have sought to modulate the expression of classes of metastatic-related molecules such as the metalloproteinases^{217,218} and metalloproteinase inhibitors.²¹⁹ To reduce metastatic tumor growth, innovative approaches such as activating the transcription of metastasis suppressor genes²²⁰ and deactivating putative metastatic switches, for example, hypoxia-inducible factor,²²¹ have also been employed. Therapies have also been directed against specific steps of the metastatic cascade. One primary target has been angiogenesis,²²² with focused approaches aimed at neutralizing the effects of proangiogenic molecules such as VEGF^{223–225} to curtail tumor growth and metastasis and increase patient survival. Phage display technologies have made possible the identification of tumor vascular homing peptides, and these peptides have been employed to exploit tumor-associated angiogenesis and to selectively deliver anticancer agents to tumor sites.^{226,227} Accompanying the further clarification of the molecular biology of the metastatic process is the development of potentially more effective and potent antimetastatic clinical interventions.

Summary and Conclusions

The ravaging sequelae of metastatic disease underscore the eminent need for effective therapies. The metastatic process comprises an intricate sequence of complex events. Current research initiatives aimed at defining the molecular basis of these events are providing new insights into the targeting and prevention of cancer metastasis. Future research efforts, it is anticipated, will contribute to the optimization of current and introduction of innovative antimetastasis therapeutic modalities.

Tumor Immunology and Immunotherapy

Jeffrey Weber, Sophie Dessureault,
and Scott Antonia

The principles of basic cellular immunology as elucidated during the past decade include a much greater understanding of the way cytolytic T cells and helper T cells are generated in the host, how immune tolerance mechanisms lead to the deletion of reactive T cells centrally within the thymus or peripherally within the tissues, and the molecular mechanisms by which T cells recognize cognate antigen and transduce signals to become activated effector cells. A significant level of attention has been paid in recent years to how those principles of basic immunology may be applied to the generation of immunotherapy strategies for cancer. In this chapter, we review recent data on the existence of tumor-specific and tumor-associated antigens that might be recognized by immune effector cells; discuss the development of immune molecules and cytokines that might be effective in mediating tumor regression by an immunologic mechanism; mention new developments on mechanisms of immunosuppression in cancer patients; and review the most recent data on the use of nonspecific and antigen-specific immunotherapies that have promise in the treatment of human malignancy.

Tumor Antigens Recognized by Immune Cells

Melanoma Tumor Antigens

Tumor-reactive lymphocytes derived from patient peripheral blood or found to infiltrate metastatic melanoma lesions have been grown *in vitro*,¹ permitting the cloning of melanoma antigens recognized by T cells^{2,3} (Table 20.1, Figure 20.1). The antigen called MAGE (melanoma antigen E) defined a family of antigens not previously identified. MAGE-1 and members of its multigene family were present on melanomas and other tumors as well as testis and placenta but no other normal tissue.⁴

A second group of antigens is the melanosome-related differentiation proteins. MART-1/Melan A was defined via recognition by cytotoxic T lymphocyte (CTL) clones from melanoma patient peripheral blood and by tumor-infiltrating lymphocytes (TIL).⁵ MART-1 is expressed by virtually all metastatic melanoma lesions, and also by melanocytes, but not normal tissue. The nonamer sequence AAGIGILTV and decamer EAAGIGILTV, representing amino acid residues 27–35 and 26–35 of MART-1, respectively, bound most

strongly to human leukocyte antigen (HLA)-A2.⁶ These peptides stimulated the growth of specific CTL from peripheral blood mononuclear cells (PBMC) of HLA-A2-positive melanoma patients and normals.⁷ In a clinical study of patients with melanoma who had resected lymph nodal disease, class I peptide tetramers were employed to detect MART-1 and tyrosinase-specific CTL in tumor-infiltrating lymph nodal tissue. From 0.1% to 3% of CD8+ lymphocytes infiltrating tumor-involved lymph nodes were MART-1 specific. In contrast, the proportion of MART-1-specific cells in nontumor-containing lymph nodes was not different from background.^{8,9}

Antigen pMel17/gp100 was defined via recognition by CTL clones from melanoma patient peripheral blood and by TIL. This 100-kilodalton (100-kDa) transmembrane glycoprotein is recognized by the HMB-45 and NKI-beteb monoclonal antibodies on melanocytes and melanoma cells.^{10,11} CTL clones derived from melanoma patients, and TIL grown from a melanoma patient, recognized melanoma cells that expressed gp100 in association with HLA-A2.1.¹² Multiple peptides derived from gp100 that fit the consensus motif for binding to HLA-A2 were recognized by TIL from melanoma patients, including gp100 209–217 (ILDQVPSFV) and gp100 154–162 (TKTWGQYWQV), as well as gp100 457–466 (LLDGTAATLRL).^{13,14} TIL specific for gp100 have been reported to induce regression of metastatic melanoma in patients also receiving interleukin (IL)-2 therapy.¹⁴ These data suggest that gp100 may be a relevant tumor regression antigen.

Tyrosinase is a membrane-bound protein involved in melanin synthesis¹⁵ that is expressed by virtually all primary cutaneous melanomas and by up to 90% of metastatic lesions. It encodes several epitope peptides that are presented by HLA-A2 to CTL reactive with human melanomas.¹⁶ A peptide derived from tyrosinase, amino acids 368–376, YMNGTMSQV, was shown to be posttranslationally modified by deamidation of asparagine to aspartic acid, resulting in a sequence recognized by human CTL, YMDGTMSQV, known as tyrosinase 368–376 (370D).¹⁷ The tyrosinase 368–376 (370D) peptide encodes a biologically important epitope and can induce CTL *in vitro* and *in vivo*¹⁸ (also Weber et al., unpublished data).

Recently, “cancer-testis” antigens distinct from the MAGE family, called NY-ESO-1 and SSX-2, were discovered that both elicit a strong humoral response yet encode epitope peptides recognized by CTL clones, TIL, and T helper cells

TABLE 20.1. Tumor antigens.

Tumor antigen	Specificity	Immunogenicity	Reference
Melanoma antigen E (MAGE)	Melanoma; other tumors; testis; placenta	MAGE-specific T cells derived from peripheral blood mononuclear cells (PBMC) of melanoma patients and from melanoma tumor specimens	1–4
MART-1/Melan A	Melanoma; melanocytes	MART-1/Melan A-specific cytotoxic T lymphocytes (CTLs) derived from PBMC and tumor-infiltrating lymphocytes (TILs) of melanoma patients	5–9
pMel17/gp100	Melanoma; melanocytes (recognized by the HMB-45 antibody)	CTL clones generated from PBMC and TIL of melanoma patients; TILs specific for gp100 induce regression of metastatic melanoma in patients also receiving interleukin (IL)-2 therapy	10–14
Tyrosinase	Melanoma	Tyrosinase 370D can induce CTL activity in vitro and in vivo	15–18
“Cancer testis antigen” (NY-ESO-1 and SSX-2)	Melanoma; a number of adenocarcinomas (breast, prostate, lung, esophagus); testis; placenta	Elicits a strong humoral response; recognized by CTL clones, TIL, and T helper cells from patients with melanoma and breast cancer	19–23
Carcinoembryonic antigen (CEA) differentiation antigen	Gastric, pancreatic, colorectal, breast, and non-small cell lung cancers; epithelial surface of the colon and some fetal tissue	CEA-specific CTL responses can be detected after immunization, but they are difficult to generate	31–33
HER-2/neu	Breast cancer; normal breast epithelial cells	CTL responses detected by ELISPOT after immunization	34–39
Alpha fetoprotein (AFP)	Hepatocellular carcinoma	Peptides defined from AFP glycoprotein have been pulsed onto dendritic cells and shown to be immunogenic in patients who are HLA A*0201 positive	40
MUC-1	Normal epithelial cells in the gut, pancreas, gallbladder, and mammary tissue	Both major histocompatibility complex (MHC) restricted and unrestricted effector cells have been shown to recognize the MUC-1 repeat backbone	41

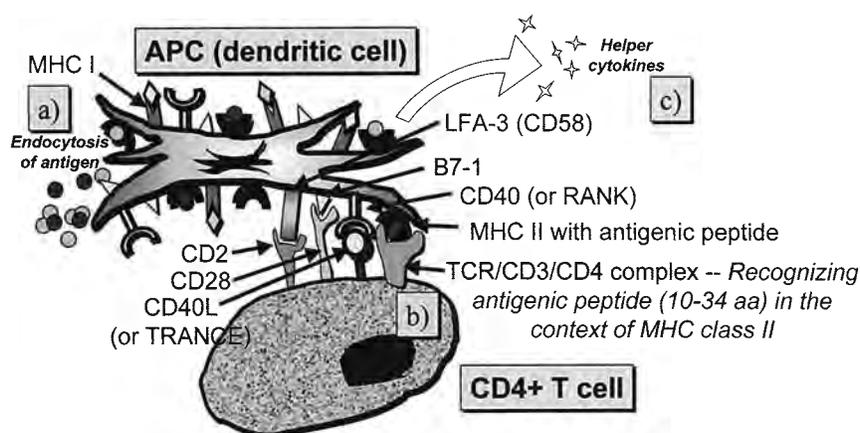

FIGURE 20.1. Schematic indicating the cellular events involved with processing and presenting antigens to T cells. (a) Specificity: Antigen uptake and presentation by antigen-presenting cells (APC) with peptide in the groove of a major histocompatibility complex (MHC) class II molecule (e.g., DR, DP, or DQ) to a naïve CD4⁺ T cell. (b) Activation: APC–T cell interaction: cross-talk and mutual activation. In addition to TCR ligation with antigenic peptide in the context of MHC (signal 1), costimulatory molecules such as B7 (signal 2) on the APC must interact with CD28 to achieve full T-cell activation. CTLA-4 (not shown) competitively binds B7 and results in

downregulation of the T-cell response. Interaction of adhesion molecules such as LFA-3 and CD2 assists during MHC–TCR ligation. Interaction of activating signals to the APC such as CD40–CD40L interaction results in activation of the APC. (c) Differentiation: T-cell activation by an activated APC. Interleukins (IL-12, IFN- γ , IL-2, TNF- α versus IL-4, IL-5, IL-10, TNF- γ) are produced and help determine T-cell differentiation. Expression of APC surface molecules is increased. In the absence of signals 1 and 2 (antigenic peptide and costimulatory molecule), T-cell antigen receptor (TCR) ligation results in anergy rather than activation.

from patients with melanoma and breast cancer.^{19,20} These antigens were expressed by a variety of adenocarcinomas (breast, prostate, and lung), as well as esophageal cancers and melanomas, suggesting wide potential utility. NY-ESO-1 is immunogenic, inducing spontaneous serologic and T-cell responses in 50% of patients whose tumors express it.^{21–23} NY-ESO-1 is expressed only by tumors and tissues lacking class I major histocompatibility complex (MHC) (testis, placenta), suggesting that it may not induce tolerance. CD4 T-cell responses have been seen to bind NY-ESO-1, as well as other melanoma differentiation antigens.^{24–30}

Although many tumor antigens have been defined in patients with melanoma, a number of self-“differentiation” antigens from epithelial cancers have been shown to be immunogenic. Carcinoembryonic antigen (CEA) is a glycoprotein normally expressed in low levels on the epithelial surface of the colon and in some fetal tissue that functions as an intercellular adhesion molecule.^{31,32} Increased expression of CEA on tumor cells mediates attachment of tumor cells to normal cells and promotes metastasis.^{31,32} It is expressed in a majority of gastric and pancreatic carcinomas and colorectal, breast, and non-small cell lung cancers.³¹ Early clinical studies of peptide-based vaccination with CEA antigen involved the use of autologous dendritic cell (DC) to deliver the CEA-derived peptides.³³ The results of these studies indicate that peptide-specific CTL responses against the CEA peptides were difficult to generate. Heteroclitic peptides that contain a substitution of one or more amino acids in the site of T-cell receptor contact may cause enhanced proliferation and cytotoxic activity directed toward cells bearing the native antigen. A known and commonly targeted CTL epitope of CEA has been designated as CAPI, and studies have shown that the peptide CAPI-6D, which has asparagine substituted for aspartic acid at position 6, greatly enhances CEA-specific CTL activity compared to the CAPI epitope.³¹ A trial using this epitope pulsed onto DC is described next.

HER-2/neu is a transmembrane protein that is expressed on most breast epithelial cells and tumor cells and overexpressed on 20% to 30% of invasive breast cancers. HER-2/neu functions as an epidermal growth factor receptor consisting of an extracellular domain (ECD) and an intracellular cytoplasmic domain (ICD).³⁴ HER-2 is weakly expressed on the epithelial surfaces of normal tissues in adulthood but highly overexpressed on the surface of tumor cells in many cancers.^{34,35} The HER-2/neu p369–377 moiety is an immunodominant, HLA class I-binding peptide that is part of the ECD of the HER-2/neu protein.³⁵ After immunization, CTL responses detected by ELISPOT assay were apparent in some patients, but the responses were undetectable after 5 months. Combined with a previous study, the results indicate that CD4+ T-cell help is required for lasting immunity to the p369–377 epitope.³⁶

A HER-2/neu ECD vaccine containing subdominant peptides p42–56, p98–114, and p328–345, and ICD peptides p776–790, p927–941, and 1166–1180, was administered intradermally monthly for 6 months with granulocyte macrophage-colony-stimulating factor (GM-CSF) adjuvant and shown to be immunogenic in 94% of patients.^{37,38} A recent Phase I/II clinical study examined the efficacy of peptide-pulsed DC vaccinations in 10 patients suffering from metastatic breast or ovarian cancer utilizing HER-2/neu and Muc-1 peptides.³⁹ They identified and used two HLA-A2

restricted HER-2/neu peptides designated as E75 and GP2^{38,39} and two novel Muc1 peptides, M1.1 and M1.2.³⁹ After vaccinations, the major CTL response in vivo was induced with the immunodominant E75 and M1.2 peptides.

The alpha fetoprotein is elevated in patients with hepatocellular carcinoma, and peptides defined from that glycoprotein have been pulsed onto dendritic cells in vitro and in vivo and shown to be immunogenic in patients who are HLA A*0201 positive.⁴⁰ A unique antigen found on many different tumors of epithelial origin is MUC-1,⁴¹ which is a polypeptide repeat core peptide derived from a transmembrane glycoprotein from which many branched sugars are bound on normal epithelial cells in the gut, pancreas, gallbladder, and mammary tissue. The sugar side chains are truncated in many tumors, exposing the core polypeptide for recognition by T cells. Both MHC-restricted and -unrestricted effector cells have been shown to recognize the MUC-1 repeat backbone, suggesting that it might serve as a tumor-specific target.

Cytokines and Activation Molecules as Cancer Therapy

Interferon-Alpha: A Cytokine That Is an Effective Adjuvant Treatment for Melanoma

Interferon-alpha, a biologic compound that has both antiproliferative and immune modulatory activity in vitro and in vivo, has been tested in a number of Phase II studies in metastatic melanoma, yielding response rates of 10% to 25% with a small proportion of complete responses (CRs) and median survival of 6 to 9 months.^{42,43} Response rates appeared to be dose related. These modest results, however, have led to a number of trials of high-, moderate-, and low-dose interferon as adjuvant treatment in patients with resected intermediate (stage IIB and IIC) and high-risk (stage III lymph nodal) melanoma. In Europe, low-dose extended-duration regimens have been tested with fixed doses of 3 million units/m² for up to 3 years. A total of seven well-conceived randomized trials have compared low-dose interferon to a control arm, usually observation (Table 20.2). For patients with high-risk disease, no differences in overall and relapse-free survival were observed in those six European and one American studies.^{44–48} For those with intermediate-risk disease, there is no clear survival benefit, but with brief follow-up, several studies have shown a relapse-free survival advantage to the low-dose interferon arm. However, in the most recently published and largest trial to date, the “AIM-HIGH” trial in the UK, which compared low-dose interferon for 3 years with observation, did not show any difference in either overall survival or time to relapse.^{49,50} In that study, 674 patients with stage IIB or III disease received either interferon at a dose of 3 million units subcutaneously three times a week for 2 years or observation. There was no difference in overall survival (odds ratio, 0.94; *P* = 0.6) or in relapse-free survival (odds ratio, 0.91; *P* = 0.3). The overall survival at 5 years was 44%, interestingly, considerably better than the 37% figure for the interferon arm of the EST 1684 trial that resulted in U.S. Food and Drug Administration (FDA) approval for high-dose interferon.⁵¹ In an editorial that accompanied the recent publication of the results of the AIM-HIGH trial, it was concluded that except for the nearly mature EORTC 18952

TABLE 20.2. Low-dose interferon-alpha trials for adjuvant therapy of melanoma.

intermediate-dose interferon trial, the end had been reached for low-dose interferon in Europe. In the United States, low-dose interferon has never been routinely employed for melanoma. It is noteworthy that low-dose interferon has been licensed in the European Community for intermediate-risk primary melanoma, based on early data suggesting a relapse-free survival advantage for that regimen.

In the United States, a number of large cooperative group studies have compared a regimen of intravenous high-dose induction therapy followed by maintenance high-dose interferon with observation or vaccine therapy for high-risk disease (Table 20.3). The only equivalent trial in Europe is the EORTC 18952 trial, which we discuss later. Three well-powered trials have tested high-dose interferon as adjuvant therapy for resected high-risk melanoma, although the best quality data suggesting an advantage in relapse-free and overall survival are derived from the smallest and oldest trial, the EST 1684 trial of 280 patients.⁵¹ In that trial, patients were randomized to either observation or the by now standard high-dose regimen of 20 million units/m² intravenously daily times five for 4 weeks in the induction phase. The maintenance phase ensued in which interferon was administered at a dose of 10 million units/m² subcutaneously three times a week for 11 months. In that trial, one-third of the patients either discontinued the regimen or required a dose modification because of toxicity. The differences in relapse-free and

overall survival significantly favored the interferon arm, with 5-year survival of 37%, median survival of 2.78 years, and $P = 0.04$. Interestingly, over time the advantage for overall survival has diminished with $P = 0.09$ at 12 years follow-up, although other causes of death in that aging cohort may obscure the results. Following the EST 1684 study, the U.S. Intergroup performed two subsequent trials of high-dose interferon. In the EST 1690 trial, 683 patients were randomly allocated to receive either observation, high-dose interferon, or the European regimen of a fixed low interferon dose of 3 million units three times a week for 2 years.⁵² No differences in overall or even relapse-free survival were seen in that larger trial. As accrual to that trial ended, a follow-up trial comparing high-dose interferon with a ganglioside vaccine for 2 years in high-risk patients was initiated. In that EST 1694 trial, 780 patients were accrued, and the study was stopped prematurely, because there was a significant difference in relapse-free survival favoring the interferon arm with a very low P value of 0.01 that met the monitoring committee requirement for early closure.⁵³ A statistically significant difference in overall survival was also observed in that trial, with a relatively brief period of follow-up. A fourth smaller trial of high-dose interferon, interferon with ganglioside, and ganglioside alone was conducted, with relapse-free survival data similar to the 1694 trial, albeit with small numbers and brief follow-up.⁵⁴ The conclusion from an analy-

TABLE 20.3. High-dose interferon-alpha trials for adjuvant therapy of melanoma.

Reference	Cooperative group (PI)	N	Eligibility	Study summary: dosage, schedule, duration	Outcome

53	ECOG EST 1694 / SWOG 9512 (Kirkwood et al.)	780	T4, N1	IFN-2b 20 MU/m ² /day IV × 1 month (induction phase) then 10 MU/m ² SC TIW × 11 months (maintenance phase) versus GM2-KLH/QS-21 vaccine	+	+

TIW, three times per week; BIW, twice a week.

sis of these four trials was that all four demonstrated a relapse-free survival benefit for high-dose interferon, but any overall survival benefit was unclear and could only unequivocally be claimed for the trial with the most premature follow-up.

A meta-analysis of the randomized high-dose interferon trials has been conducted to increase the number of patients accrued and the statistical power to perceive small differences in survival.⁵⁵ The results of that meta-analysis indicate that the relapse-free survival advantage of high-dose interferon is significant and reproducible but that the data suggesting a survival advantage are much weaker. This brings us to the EORTC 18902 trial, in which patients with high-risk disease were randomly assigned to receive an intermediate-dose induction regimen of interferon. The induction consisted of 10 million units/m² of interferon administered subcutaneously every day for 4 weeks, followed by 1 year of 10 million units/m² three times a week, compared with 5 million units/m² three times a week for 2 years. The results of that study have been presented publicly, first at ASCO in 2001, with the final summary presented in 2003.⁵⁶ The data do not suggest that there is any difference in overall survival between the groups, although a modest difference in relapse-free survival was observed. If the high-dose regimen of EST 1684 truly resulted in a significant overall survival difference, why would that difference not be seen with a similarly dose intense, although subcutaneous regimen, in the EORTC 18902 trial? The answer is likely that there is no reproducible, significant, and biologically important overall survival difference for high-risk melanoma patients who receive the high-dose interferon regimen. Significant differences in relapse-free survival were observed in all four trials and were maintained in the meta-analysis after adjustment for prognostic variables, suggesting that the difference is genuine.

What conclusions can be drawn about recommending high-dose interferon to patients with resected high-risk melanoma? One is that it is likely to confer a moderate benefit in relapse-free survival, postponing the time to disease recurrence but not changing overall survival significantly. Is the acknowledged toxicity and cost of the year-long regimen justified by the relapse-free survival benefit? Admittedly, the Q-TWIST quality of life analysis, which assumed the level of survival benefit found in the EST 1684 trial, indicated that in spite of the side effects the use of high-dose interferon was justified.⁵⁷ However, the relapse-free survival advantage without the likelihood of ever observing a clear overall survival benefit renders interferon an acceptable but hardly desirable option. It should be offered to patients with resected high-risk melanoma but should not be a clearly superior option to a well-designed randomized Phase III or even a Phase II study. Given the difficulty and lack of acceptance of a randomized trial in high-risk melanoma that includes an observation arm, high-dose interferon is a reasonable and proper control arm against which new therapies in development may be measured.

Activity of Recombinant Interleukin 2 (IL-2) for Metastatic Melanoma

Given at high doses as a single agent, IL-2 produces significant clinical responses in some cancers, and it is now being tested in combination with tumor vaccines.⁵⁸⁻⁶⁰ IL-2 was

shown to mediate regression of melanoma and renal cell cancer and has activity in patients with non-Hodgkin's lymphoma. It was approved by the FDA for metastatic melanoma due to a multicenter Phase II experience of 270 patients with a 16% response rate and a median survival of 12.2 months.^{61,62} Survival of metastatic melanoma after treatment with high-dose IL-2 is associated with development of autoimmune thyroiditis and vitiligo, as well as the height of the lymphocyte rebound that occurs after cessation of treatment with IL-2 (Table 20.4). When given at the FDA-approved dosage and schedule of 600,000 international units/kg every 8 hours as an intravenous bolus, IL-2 was quite toxic, and it is not recommended for use in an inpatient hospital setting unless given by medical and nursing personnel experienced in its use. IL-2 could be beneficial in a variety of different ways. It could drive the expansion of tumor-specific T cells that are activated by the vaccine. It may also be beneficial during the effector phase of an antitumor T-cell response. For example, it has recently been shown that B7-H1, a member of the B7 family of costimulatory molecules, can be expressed by carcinomas and result in the induction of apoptosis of activated T cells.⁶³ This B7-H1-mediated negative effect on T cells is prevented in the presence of exogenous IL-2.⁶⁴ A very low dose IL-2 regimen has been shown to result in the prolonged persistence of transferred T cells in melanoma patients.⁶⁵ This dose of IL-2 is sufficient to saturate IL-2 receptors *in vivo*. Therefore, the vaccine augmentation effect can potentially be achieved with minimal toxicity.

TABLE 20.4. Known toxicities of interleukin 2 (IL-2).

Common toxicities (occur in 30% or more of patients)	<ul style="list-style-type: none"> • Low platelet levels; increases risk of bleeding • Low blood pressure • Flushing or rash of the face and body • Chills • Nausea and vomiting • Diarrhea • Tachycardia • Fluid retention • Changes in liver function tests • Arthralgias and myalgias • Reduced volumes of urine • Weight gain • Breathing problems • Fever • Dry skin
Less common toxicities (occur in 10% to 29% of patients)	<ul style="list-style-type: none"> • Weakness • Low levels of white blood cells; increases risk of infection • Low levels of red blood cells; increases risk of anemia • Mental changes, such as confusion or memory loss • Congestion • Itching • Loss of appetite • Dizziness • Mouth sores • Fatigue or weakness • Enlargement of the abdomen • Changes in electrolyte levels • Cardiac arrhythmias

Recombinant Interleukin 12 (IL-12)

Secreted by activated dendritic cells, IL-12 produces several effects that could enhance an antitumor T-cell response, including the induction of a T helper cell type 1 (Th1) response and the production of γ -interferon.⁶⁶ Recombinant IL-12 protein given to cancer patients at the maximum tolerated dose (MTD) in a Phase II trial produced unacceptable toxicity.⁶⁷ However, based on animal models, the administration of doses well below the MTD should be sufficient for use of this agent as a tumor vaccine augmentation strategy.^{68,69} Gajewski and colleagues conducted Phase I⁶⁹ and Phase II clinical trials⁷⁰ in melanoma patients combining subcutaneously injected IL-12 with a peptide-pulsed PBMC-based tumor vaccine. The IL-12 was given at a dose well below the MTD three times every other day after each vaccine. Toxicity was acceptable, and two patients (10%) had CRs. In other trials reported by Cebon et al.,⁷¹ melanoma patients were treated with IL-12 in combination with a tumor vaccine (Melan-A peptide vaccine). Cohorts of patients were treated with escalating doses of IL-12 given subcutaneously or intravenously on the day the first vaccine was given and once again 3 weeks later, with five vaccines given over an 8-week period. Toxicity was acceptable, and 1 of 21 patients had a partial response (PR). Before significant efficacy can be realized with this approach, considerable work needs to be done to determine the optimal dose and schedule of IL-12 administration as well as the optimal vaccine with which to combine it.

Recombinant Flt3 Ligand

Flt3 ligand stimulates progenitor cells in the bone marrow, resulting in an increase in DC in the peripheral blood when administered to normal subjects and to patients with metastatic cancer.⁷²⁻⁷⁴ This property of Flt3 ligand makes it a candidate for use as a vaccine augmentation strategy, making available an increased number of DC that could possibly respond and contribute to a tumor vaccine *in vivo*. Disis et al. recently reported the results of a clinical trial involving 10 patients with HER-2/neu-overexpressing breast or ovarian cancer.⁷⁵ Patients were given Flt3 ligand subcutaneously daily for 14 days of 28-day cycles and received a HER-2/neu peptide-based vaccine on day 7 of each cycle. Patients were treated for up to 6 cycles. Clinical responses were not assessable, as 9 of the 10 patients had no evidence of disease. However anti-HER-2/neu T-cell responses were induced in most of the patients. The clinical effectiveness of this approach needs to be tested.

Recombinant CD40 Ligand

Signaling through CD40 on dendritic cells is a potent activation stimulus.⁷⁶ Also, Mellman's group recently showed that CD40 ligation results in the activation of cross-presentation of exogenous antigens taken up by DCs on MHC class I molecules.⁷⁷ There is evidence to suggest that one target of the immunosuppressive mechanisms of tumor cells is CD40-expressing antigen-presenting cells (APC). Sotomayor et al. have reported, using a murine model, that the *in vivo* delivery of an activating anti-CD40 antibody prevented tumor cell-induced T-cell unresponsiveness.⁷⁸ In addition, others

have previously reported that CD40 ligand can prevent inhibition of DC function mediated by IL-10 (which is produced by some tumors)⁷⁹ and DC apoptosis that can be induced by tumors.^{80,81} Finally, Dotti et al. have shown that the bystander production of CD40 ligand at a tumor vaccine site improved the efficacy of the vaccine.⁸² These observations all support the use of CD40-activation strategies to enhance the development of antitumor T-cell responses in cancer patients.

A clinical trial has been reported using recombinant human CD40 ligand protein systemically in cancer patients⁸³; this was a Phase I, single-agent trial. Cohorts of patients with refractory cancer were treated with escalating doses of the CD40 ligand protein injected subcutaneously each day for 5 consecutive days. Patients without significant toxicity and no evidence of progression received additional courses at 4-week intervals. Thirty-two patients were treated, with the dose-limiting toxicity found to be liver transaminase elevation. This toxicity was transient in all but 2 patients, and no deaths attributed to this toxicity were reported. Interestingly, 2 patients had significant tumor regressions, with 1 patient developing a sustained CR.

Activating DCs in the setting of tumor vaccination by signaling through CD40 remains an attractive strategy that needs to be developed, with attempts to reduce the incidence of hepatic toxicity and to combine this approach with the use of tumor vaccines to improve therapeutic efficacy.

CpG Oligonucleotides

Signaling through toll-like receptors (TLR) can produce effects in DC that are similar to CD40 ligation.⁸⁴ Several TLR exist; however, TLR-9 may be one of the more important TLR involved in the induction of a relevant antitumor T-cell response.⁸⁵ The ligands for TLR-9 are immunostimulatory DNA sequences that contain unmethylated CpG sequences.⁸⁶ Among other actions, CpG oligonucleotide binding to TLR-9 increases DC surface expression of T-cell costimulatory molecules and secretion of TH1-promoting cytokines including IL-12.⁸⁷⁻⁸⁹ These compounds are quite effective in augmenting T-cell-mediated tumor rejection in a variety of murine models.⁹⁰⁻⁹⁵ When administered to humans, they have been found to be safe,⁹⁴ and there are indications that they can enhance the effectiveness of vaccines for certain infectious diseases.⁹⁶ Clinical trials involving cancer patients are ongoing. To date, only one trial has been briefly reported.⁹⁷ Patients with metastatic melanoma were immunized with a MAGE-3 protein-based vaccine, using a CpG compound as an adjuvant. One PR was reported in this Phase I trial. Considerable work remains to be done to determine if CpG oligonucleotides will augment the effectiveness of tumor vaccines, but the approach is promising.

Blocking Anti-CTLA.4 Antibody

CTLA.4 binding to its ligand, CD28, delivers an inhibitory signal to T cells.^{98,99} Removal of this potential inhibition is the rationale for administering a blocking anti-CTLA.4 monoclonal antibody in combination with tumor vaccines. Phan et al. conducted a clinical trial involving patients with metastatic melanoma.¹⁰⁰ Patients were treated systemically

with an anti-CTLA.4 antibody just before receiving a gp100 peptide-based vaccine every 3 weeks. Individual patients were treated with one to six cycles. Two of the 14 patients had CRs and 1 had a PR. Six of the patients developed significant autoimmune toxicities, all of which resolved spontaneously or with steroid treatment.

Hodi et al. also tested the anti-CTLA.4 antibody in melanoma and ovarian cancer patients, observing no objective tumor regressions.¹⁰¹ However, this was a single-dose trial and was not combined with a tumor vaccine. Tumor biopsies from three of the patients obtained after antibody administration revealed extensive tumor necrosis, providing compelling evidence that the antibody has the potential to produce a clinical effect. Interestingly, the tumor necrosis was only observed in patients who had previously been immunized with a GM-CSF-modified vaccine.

Antigen-Specific and Nonspecific Therapies

Evidence That Cell Vaccines Might Be Beneficial in Melanoma

Cell-based vaccines for melanoma have been evaluated in trials since the 1970s (Table 20.5). Melacine, consisting of two lyophilized melanoma cell line lysates administered with the Ribi adjuvant, and Canvaxin, consisting of three irradiated and frozen intact cell lines administered with bacille Calmette-Guérin (BCG), have been shown to mediate regression in a small proportion of patients with stage IV disease, in the range of 5% to 10%.¹⁰²⁻¹⁰⁵ Melacine was shown to have a 7% response rate in a small Phase II randomized trial with a survival no different from multiagent chemotherapy¹⁰² and has been tested in a large randomized Phase III trial as adjuvant therapy for patients with resected stage II melanoma compared with an observation arm.^{104,105} For all patients as randomized, there was no difference in overall and disease-free survival, but for patients who were HLA-A2 positive, a relapse-free survival advantage was seen, indicating that the

HLA-A2 population might be appropriate for further testing of that cell vaccine.

More current developments in this field include the use of cytokine gene-transduced tumor cells as vaccines. Dranoff and colleagues have pioneered the use of autologous GM-CSF gene-engineered tumor cell vaccines for cancer, a treatment strongly supported by preclinical murine experiments.¹⁰⁶ In a recent published trial in patients with stage IV melanoma treated with adenovirally transduced GM-CSF-secreting tumor cells, most subcutaneous lesions exhibited significant necrosis, and tumor regression [1 CR, 1 PR, and 1 mixed response (MR)] was seen in 3 of 26 evaluable patients.¹⁰⁷ Thirty-five patients were selected for the trial; 34 had sufficient tumor cells to generate vaccine, but 8 progressed and could not receive vaccine. A similar strategy in non-small cell lung cancer yielded 5 patients with stable disease and 1 mixed response of 25 evaluable patients.¹⁰⁸ As in the melanoma trial, 8 patients progressed before receiving vaccine, indicating that patients selected for this promising therapy must be carefully selected, limiting its applicability. Fourteen patients with pancreatic cancer who had a curative resection and were free of disease received an allogeneic GM-CSF-transduced cell vaccine as well as chemoradiotherapy.¹⁰⁹ Their 1- and 3-year survival was surprisingly favorable, with 3 patients alive 25 months after diagnosis, suggesting that the vaccine regimen, albeit in a heterogeneous group of patients, might have potential as adjuvant treatment.

Heat Shock Proteins

Several clinical trials have tested the notion that heat shock proteins (Hsp), which have been shown to bind tumor antigen peptides, can be extracted from fresh tumor and used to vaccinate patients. Parmiani described a trial of 42 patients treated with four weekly injections of tumor cell-derived Hsp gp96 in which 28 patients were assessable for response.¹¹⁰ There were 2 CRs as well as 3 patients with prolonged stable disease. All five had evidence of an immune response to autol-

TABLE 20.5. Types of vaccines.

<i>Type of vaccine</i>	<i>Advantages</i>	<i>Disadvantages</i>	<i>Examples</i>
Whole tumor cell-based vaccines	Diverse Ags without knowing the exact Ag(s) that may be responsible for tumor rejection	Limited immunogenicity	Melacine; CancerVax
Cytokine gene-transduced tumor cell-based vaccines	Same as for whole tumor cell vaccines, but more immunogenic	Cell culture and individualized gene transfer is expensive, labor intensive, and limited by variable levels of gene expression	GM-CSF; IL-2
Peptide-based vaccines	No need for patient-derived tissue; can monitor immune response	Limited number of Ags; patient selection based on HLA type; posttranslational modification; MHC class I versus class II	MAGE; MART; gp100; tyrosinase; gp75
Antigen-pulsed or gene-modified dendritic cell-based vaccines	Efficient and safe method of inducing antitumor immune response	Expensive, labor intensive	Tyrosinase-pulsed DCs; gp100-pulsed DCs
DNA and RNA-based vaccines	Genetic material delivered without the difficulties associated with the development of immune reactivity against viral vectors	Variable gene transfer efficiencies	B7-1; melanoma-associated antigens

AG, antigen; DC, dendritic cell; GM-CSF, granulocyte macrophage colony-stimulating factor.

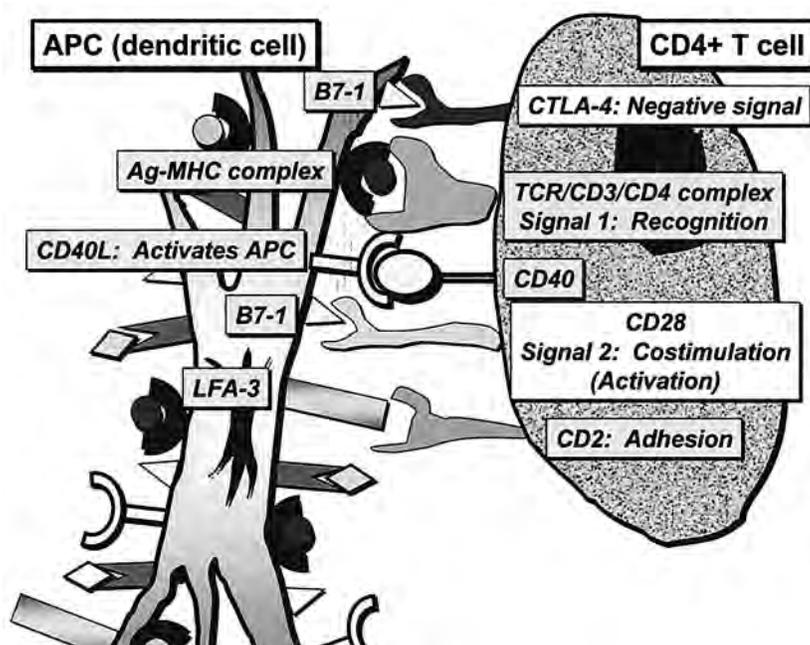

FIGURE 20.2. CTLA-4 binding leads to immunosuppression. T cells require two signals for activation. Signal 1 is the recognition of antigenic peptide in the context of MHC molecules; signal 2 can be provided by cell-surface molecules CD80 or CD86 (B7-1 and B7-2, respectively). CTLA-4 competitively binds B7 molecules and results in a damping of the T-cell response.

ogous tumor cells, and toxicity was minimal. The same group published a trial of autologous Hsp 96 therapy after resection of liver metastases from stage IV colorectal cancer patients.¹¹¹ There was a correlation between immune response to autologous tumor cells and overall as well as relapse-free survival, which was quite favorable compared to historical controls.

Development of Peptide Vaccines for Melanoma

Peptides of 8 to 10 amino acids are derived by intracellular cleavage of a variety of proteins, and are selectively conducted by the TAP transporter mechanism to the endoplasmic reticulum where they bind nascent class I molecules and are presented on the surface of the cell in association with class I molecules for interrogation by T cells. Because peptides are the smallest unit recognized by T cells, they might be useful as vaccine immunogens in the proper MHC class I context for recognition by T cells. A MAGE-3 HLA-A1-restricted peptide in aqueous solution was used to treat 39 patients with metastatic melanoma, of whom 26 finished four treatments every 4 weeks.¹¹² Four PR as well as 3 CR were seen, often with a prolonged time to attain response; 2 complete responders had a duration beyond 2 years. The full-length MAGE-3 gene encoding the same peptide was chimerically linked to an H. Flu protein as adjuvant and used to vaccinate 35 patients in a Phase I trial with adjuvant AS-02B.¹¹³ Two objective responses were observed in that trial, one in a patient with bladder cancer and one with melanoma. In both trials, no immune responses to the MAGE-3 peptide were observed. Jager and colleagues showed that 6 of 26 patients treated with MAGE-1, MAGE-3, MART-1/Melan A, and tyrosinase peptides exhibited tumor regression.¹¹⁴ Disease was stabilized in 22 of 26 evaluable patients with metastatic melanoma. A correlation was seen between strong MHC class I staining and response; there was also a correlation between the presence of skin/subcutaneous disease, low tumor burden, immune response, and clinical response.

Rosenberg's group has tested a gp100 peptide incorporating a single amino acid change to increase class I binding with IFA to which intravenous IL-2 was added, in patients with stage IV melanoma. A 41% response rate was observed, which was much higher than prior trials with the gp100 vaccine or with high-dose IL-2 alone. However, this result has not been confirmed in a subsequent multicenter study. The same substituted gp100 peptide vaccine was combined with an antibody that abrogated CTLA-4 signaling to augment T-cell reactivity (Figure 20.2). In that trial there were 3 responses (2 CR, 1 PR) in 14 patients with stage IV melanoma that were maintained beyond 12 months, with regression of a brain metastasis. Significant levels of reversible autoimmune side effects were observed that correlated with response. Slingluff and colleagues immunized 26 patients with stage IV melanoma who received multiple peptides including adjuvant and GM-CSF or with dendritic cells pulsed with the same peptides.¹¹⁵ Two PRs and 2 patients with stable disease (SD) were observed in the peptide/GM-CSF group, compared with 1 PR and 1 SD in the DC group. Immunity to the peptides was correlated with clinical response. The HLA-Cw*0702 restricted MAGE-A12:170–178 peptide emulsified in IFA was given to 9 patients with metastatic melanoma.¹¹⁶ One of 9 patients demonstrated a PR, but no systemic immune responses to the MAGE-A12 peptide by tetramer or gamma interferon polymerase chain reaction (PCR) assay were seen. A MART-1/Melan-A peptide without adjuvant but with IL-12 was administered intradermally to 28 patients with stage IV melanoma. Of 24 evaluable patients, there was 1 CR, 1 PR, and 2 patients with SD. Many of the aforementioned peptides have been tested as adjuvant treatment for their ability to promote a T-cell response in patients with resected high- or intermediate-risk melanoma and thereby prevent or prolong time to relapse. Interleukin-12 and GM-CSF are effective vaccine adjuvants in mice and have been tested for their ability to augment immunity in resected melanoma patients. Both cytokines were shown to increase immunity to a mul-

tipeptide vaccine with toll-based adjuvant Montanide ISA 51, with favorable median survival in high-risk disease of greater than 48 months, similar to the latest trials including high-dose interferon. Multi-peptide vaccines for melanoma are currently being tested in larger Phase II trials and represent the next logical experimental arm of a randomized clinical trial for high-risk melanoma.

Dendritic Cell-Based Vaccines

Dendritic cells (DC) are the most potent cells known in humans that prime and stimulate T-cell responses, and they are highly specialized cells which process and present antigens to immune cells. DCs have been grown from a variety of precursors, including peripheral blood monocytes, as well as selected CD34+ progenitors, and a number of cytokines and maturing stimuli have been used to generate human DC *ex vivo* for clinical trials of adoptive transfer after pulsing with antigen. Nestle and colleagues intravenously administered mature monocyte-derived DC cultured *in vitro* with IL-4 and GM-CSF and pulsed with tumor antigen peptides and/or tumor lysate to patients with stage IV melanoma.¹¹⁷ Five CR or PR were observed in 16 patients,¹¹⁸ and the trial has been extended to a larger multicenter Phase II trial.

Seven patients with metastatic melanoma received gp100 and MART-1 peptide-pulsed monocyte-derived DC.¹¹⁹ DC were administered intravenously four times at 3-week intervals in escalating doses. Only one of seven patients evaluated demonstrated an objective PR. Enhancement of CTL reactivity was seen in one of five patients who completed all four vaccines.

Eleven stage IV melanoma patients received mature monocyte-derived DC loaded with a MAGE-3A1 peptide.¹²⁰ The patients received five vaccinations at 2-week intervals. The first three vaccinations were administered subcutaneously and the last two were administered intradermally. Six of 11 patients had regression of their disease. ELISPOT assays indicated that peptide-specific CTL precursors were expanded in 8 of 11 patients. Intriguingly, immune responses declined after the regimen of injections.

Fourteen patients with malignant melanoma were given four intravenous injections of DC derived from CD34+ stem cells and matured with tumor necrosis factor (TNF)- α then pulsed with HLA-A1+ MAGE-1 and MAGE-3 peptides or with HLA-A2+ Melan-A, gp100, and tyrosinase peptides.¹²¹ Anti-tumor responses were observed in 2 patients and peptide-specific DTH reactions were found in 4.

Banchereau et al. immunized 11 patients with CD34+ progenitor-derived mature DC and achieved 3 CR. They showed that clinical response correlated with immune responses detected in the peripheral blood,¹²² and they have continued to treat patients with mature CD34-derived DC with excellent clinical results.

The CEA CAPI-6D-substituted peptide was pulsed onto DC in the presence of Flt3 ligand, a DC growth factor, in 12 patients with lung or colorectal cancer who were HLA A*0201+. Patients received subcutaneous cytokine for 10 days before immunization with escalating doses of intravenous peptide-pulsed DC. Lytic activity against target cells bearing CAPI-6D, as well as native CEA peptide, was observed in 7 of 12 patients. Five patients showed evidence of tumor regression, with 1 CR, 1 PR, 1 MR, and 2 with SD.

Evidence of clinical response correlated with the expansion of antigen-specific CTL by tetramer analysis. Dendritic cells that have been pulsed with autologous tumor lysates have been shown to mediate regression of pediatric tumors, including neuroblastoma and Ewing's sarcoma.^{123,124}

Adoptive Transfer of CTL

CD8+ T-cell clones specific for MART1MelanA or gp100 were administered to 10 stage IV melanoma patients by Yee and colleagues.¹²⁵ Adoptively transferred T-cell clones persisted *in vivo* in response to low-dose IL-2 treatment, trafficked to tumor sites, and eliminated antigen-positive tumor cells. Mixed response or stable disease was observed in 8 of 10 patients for up to 21 months.

Selected peptide-specific, tumor-reactive CD8+ T-cell clones derived from tumor-infiltrating lymphocytes were administered intravenously to 12 patients with stage IV melanoma after a nonmyeloablative conditioning regimen, followed by differing doses of IL-2.¹²⁶ Although no objective responses were seen, the same authors then administered oligoclonal populations of mixed CD4 and CD8 T cells to 13 patients after treatment with the same nonmyeloablative chemotherapy regimen.¹²⁷ Persistence of the transferred T cells for up to 7 months occurred and was associated with their proliferation *in vivo* and trafficking to tumor sites. Seven PR or CR were observed, with 3 patients having SD. Autoimmune vitiligo was associated with response. Ten HLA-A2+ patients with tyrosinase-positive melanomas received intravenous infusions of tyrosinase 369 < n.377 peptide-primed CTL on day 1 and 5 days later for four cycles.¹²⁸ Two patients experienced disease regression, but CTL were undetectable in the circulation within 5 minutes after injection. The T cells concentrated in the liver and the spleen but did not especially target tumor tissues.

Mechanisms of Immunosuppression in Cancer Patients

Cancers have multiple mechanisms that prevent the activation of, and evade, the immune response, as described next (Table 20.6). It is likely that a therapeutic vaccine may not be an adequate immunotherapy without the means to overcome immunosuppression. With adequate knowledge of how tumors evade T-cell-mediated rejection, strategies are being developed that should improve the efficacy of cancer immunotherapy.

TABLE 20.6. Mechanisms of immunosuppression in cancer patients.

- Downmodulation of MHC
- Tumor-derived immune inhibition (e.g., transforming growth factor (TGF)-beta, IL-10)
- Th2 dominant T-cell response
- APC dysfunction [e.g., as a result of tumor-derived vascular endothelial growth factor (VEGF)]
- Treg cells (including CD25+ CD4+ and CD25-CD4+ cells), both via direct contact and via secreted factors (such as IL-10 and TGF-beta)

Downmodulation of MHC

A number of small-scale assessments of MHC class I expression and its loss by metastatic melanomas have been conducted using IHC staining, indicating that loss of class I expression confers a worse prognosis.¹²⁹⁻¹³⁴ The majority of melanomas show normal staining for the nonpolymorphous class I A, B, C determinants, without evidence for allele-specific deletion or downregulation. Less than 10% of tumors show deletion of the beta-2 microglobulin gene, resulting in complete loss of class I expression. Approximately 10% to 40% of tumors demonstrate a decrease in class I staining or with antibody MA 2.1 recognizing class I allele A2 due to downregulation of mRNA expression or gene deletion causing absent expression of that allele. Fourteen primary melanomas were examined in one study, with MHC allele loss seen by IHC in 20%.¹³¹ In a study of 48 metastatic lesions from 39 patients, loss of HLA class I expression of more than 50% was seen and was associated with a poorer clinical outcome.¹³² Loss of HLA class I diminished immune recognition by melanoma-specific T cells *in vitro*,¹³⁴ although the effects on immune response to a vaccine are unclear.

The Tumor Microenvironment Is Toxic to T Cells

Tumors are known to express "tumor-rejection" antigens, and T cells specific for these tumor antigens are present either in the circulation or within tumors. If circulating T cells become activated and extravasate into the tumor parenchyma, they often encounter immunosuppressive molecules either secreted by or expressed on the surface of the tumor cells. For example, B7-H1, a member of the B7 family of costimulatory molecules, can be expressed by carcinomas and result in the induction of apoptosis of activated T cells.¹³⁵ Also, many tumors are known to secrete transforming growth factor (TGF)- β , or IL-10,¹³⁶ two cytokines known to downmodulate T-cell function. Regulatory T cells that function to suppress Th1 immune responses normally secrete both these cytokines.^{137,138} Ectopic secretion of those cytokines by tumor cells can suppress Th1 cell-mediated rejection of tumors.

Blocking tumor-specific B7-H1 molecules from binding to their ligands on activated T cells improved the efficacy of antitumor T cells in preclinical models,^{139,140} suggesting a therapeutic approach. IL-2 at high doses produces significant clinical responses in some cancers and is being tested in combination with tumor vaccines.^{59,60} The B7-H1-mediated negative effect on T-cell function is overcome in the presence of exogenous IL-2.⁶⁴ A very low dose IL-2 regimen has been shown to result in the prolonged persistence of transferred T cells in melanoma patients.⁶⁵ This dose of IL-2 is sufficient to saturate IL-2 receptors *in vivo*.¹⁴¹ Therefore an "immune augmenting" effect of IL-2 can potentially be achieved with minimal toxicity.

Th2 Skewing of the T-Cell Repertoire

The T helper cell subset that mediates tumor cell rejection are Th1 cells. A skewing of the tumor cell-specific Th population to Th2, which mediates antibody responses, would be expected to limit T-cell-mediated rejection of tumors. Tumor antigen-specific Th2 cells predominate in cancer patients¹⁴² and can be found in the tumor parenchyma; this may be

caused by the presence of plasmacytoid DC (DC2) recruited into tumors,¹⁴³ which favor a Th2 response.

IL-12 secreted by activated dendritic cells produces several effects that could enhance an antitumor T-cell response, including the support of a Th1 response; this suggests a possible approach to preventing the Th2 switch induced by tumors. Recombinant IL-12 protein given to cancer patients at the maximum tolerated dose (MTD) in a Phase II trial produced unacceptable toxicity.⁶⁶ However, based on animal models, the administration of doses well below the MTD should be sufficient for use of this agent as a tumor vaccine augmentation strategy, as previously suggested.^{67,68} Gajewski et al. conducted phase I⁶⁹ and Phase II clinical trials¹⁴⁴ in melanoma patients combining subcutaneously injected IL-12 with a peptide-pulsed PBMC-based tumor vaccine. The IL-12 was given at a dose well below the MTD, every other day after each vaccine for three injections. Toxicity was acceptable, and 2 patients (10%) had complete responses. In other trials reported by Cebon et al.,⁷¹ melanoma patients were treated with IL-12 in combination with a tumor vaccine (Melan-A peptide vaccine). Toxicity was acceptable, and 1 of 21 patients had a partial response. The optimal dose and schedule of IL-12 as well as the optimal vaccine to choose have yet to be defined, but well-tolerated doses of subcutaneous IL-12 has a clear immune-potentiating effect with peptide vaccines (Weber et al., unpublished data).

Antigen-Presenting Cell Dysfunction

Antigen-presenting cells in cancer patients are dysfunctional. Tumor-derived vascular endothelial growth factor (VEGF) can interfere with the differentiation of DCs,¹⁴⁵ as can IL-6 and MCS-F.¹⁴⁶ Also, IL-10 has been shown to interfere with dendritic cell function.¹⁴⁷⁻¹⁴⁹ Tumor cells are also capable of inducing DCs to undergo apoptosis.^{150,151} There is evidence that this tumor-induced APC dysfunction can be rescued by signaling through CD40. Signaling through CD40 on dendritic cells is a potent activation stimulus.^{78,152} The *in vivo* delivery of an activating anti-CD40 antibody prevented tumor cell-induced T-cell unresponsiveness.⁷⁹ In addition, CD40 ligand can prevent the inhibition of DC function mediated by IL-10¹⁵³ and tumor-induced DC apoptosis.⁸¹ Finally, the bystander production of CD40 ligand at a tumor vaccine site improved the efficacy of that vaccine in an animal model.⁸² These observations all support the use of CD40-activation strategies to circumvent tumor-induced DC dysfunction and augment antitumor T-cell responses in cancer patients.

A Phase I clinical trial has been reported using recombinant human CD40 ligand protein systemically in cancer patients. Cohorts of patients with refractory cancer were treated with escalating doses of the CD40 ligand protein injected subcutaneously each day for 5 consecutive days. Patients without significant toxicity and no evidence of progression received additional courses at 4-week intervals. Thirty-two patients were treated with the dose-limiting toxicity, which was found to be liver transaminase elevation. This toxicity was transient in all but 2 patients, and no deaths attributed to this toxicity were reported. Interestingly, 2 patients had significant tumor regressions, with 1 patient developing a sustained complete response. Activating DCs in the setting of tumor vaccination by signaling through CD40 remains an attractive strategy that needs to be developed,

with attempts to reduce the incidence of hepatic toxicity, and to combine this approach with the use of tumor vaccines to improve efficacy.

Technologies in Molecular Biology: Diagnostic Applications

Timothy J. Triche

For more than 100 years, cancer has been diagnosed by empirical, largely subjective means, not unlike clinical medicine itself. A consequence of this is that universal acceptance of a diagnosis, particularly any beyond benign versus malignant, has been an elusive goal. In one published study of rhabdomyosarcoma diagnosis involving more than 800 blinded cases and more than a dozen pathologists working in teams of two at eight institutions, with a 20% resampling, concordance between groups for subclassification (with clinical and therapeutic consequences) was no better than 60%. (The figure for individual reproducibility was marginally better, of the order of 70%.¹) It should be noted that these pathologists were acknowledged to be the world's experts in the diagnosis of this disease at the time. Thus, it is reasonable to conclude that cancer diagnosis is less than a perfectly objective science.

On the other hand, it is also important to note that there is no better alternative, at least until recently. This situation is changing rapidly, as new, relatively objective, and certainly dichotomous or quantitative methods are introduced into practice as diagnostic tools in cancer. This in turn is progressively rendering the diagnosis of cancer more precise, reproducible, and yes, objective. To be clear, *the initial diagnosis of cancer of any type remains a histologic diagnosis*. That said, all further refinement (and even as a factor in the initial decision of benign versus malignant) increasingly relies on an ever-enlarging panoply of diagnostic tools, most rooted in biotechnology and disparate medical fields such as immunology, biochemistry, molecular genetics, and bioinformatics. This chapter describes these methods and illustrates how they augment and clarify the diagnosis of cancer. Of note is the further benefit of these methods: they frequently also provide information about prognosis and potential therapy, as is shown.

Cancer Diagnosis

“Subjective” Versus “Objective” Cancer Diagnosis

The towering achievements in histologic diagnosis of cancer, as evidenced by treatises such as *Ackerman's Surgical Pathology*, are testimony to the remarkable ability of the human mind for pattern recognition. The issue is not knowledge or

insight, but consistency and reproducibility, as noted previously. Further, it is self-evident that no form of morphologic diagnosis, nor its practitioners, can hope to identify genomic alterations that bear directly on diagnosis, prognosis, and potential therapy by histologic examination. The consequences of genomic alterations may in some way be evident, but that is not direct or objective evidence. For example, anaplasia is often considered a marker of higher-grade malignancy in cancer diagnosis and has been linked to mutations in p53, the most commonly mutated gene in human cancer.²⁻⁵ However, the correlation between anaplasia and p53 mutations detected by DNA sequencing or similar methods is poor⁴; rather, multiple genes may contribute to the phenotype.⁶ Thus, morphology is not a surrogate of genomic analysis. The goal, then, of the diagnostic technologies discussed here is to provide objective evidence of class, character, genotype, phenotype, prognosis, and potential therapy, but *not* a diagnosis of cancer per se. That remains the domain of morphologic diagnosis. Nonetheless, the certainty of such diagnoses, and especially their value to the practice of oncology, can be markedly enhanced by these methods.

Diagnosis Versus Prognosis and Therapy

As intimated previously, the real value of sophisticated molecular technologies is their potential impact on precise, objective, unambiguous cancer diagnosis. To place this in context, however, it is important to remember that the only reason to establish a diagnosis of cancer in the first place is to determine prognosis and therefore therapy. In the first instance, a diagnosis of any form of cancer (specifically, solid tumors) implies that the tumor must be completely removed and potentially treated systemically with chemotherapy and/or radiotherapy. If benign, or a pseudoneoplastic condition (fibromatosis, for example), these issues do not apply. Function, cosmetic effect, interference with normal bodily function, and similar concerns dominate such diagnoses; life-threatening consequences are rarely part of the dialogue. Thus, the first and paramount issue in cancer diagnosis, whether a tissue is or is not cancerous, relates directly to therapy. However, as cancer therapy has become progressively more sophisticated and multimodal, a simple diagnosis of “cancer” is obviously inadequate. Furthermore, a diagnosis of “high grade” or “grade III” is fraught with some degree of

uncertainty. One need only consider the conflicting grading of brain tumors espoused by WHO versus other authors (notably, the existence of three versus four grades of astrocytic brain tumors) to appreciate the conundrum. Clearly, a glioblastoma multiforme is a deadly tumor. But what of a grade II astrocytoma, and in which diagnostic scheme? This, then, is the sole purpose of diagnosis, and of the methods described herein: to establish the best possible course of action based on the best available diagnostic and prognostic information. The purpose of the diagnostic technologies discussed here is therefore to *augment* the precision and utility of a cancer diagnosis and its direct relevance to treatment.

Integration of Diagnostic Information with Therapy

As appealing as extensive data on a given tumor may be, the ultimate test of the relevance of such data is whether these can be integrated into patient management. It is of no value to determine that a given tumor has a p53 mutation, for example, unless there is a body of literature that suggests that such mutations are associated with more aggressive clinical behavior.² Fortunately, for many tumors, this is the case,⁵ and p53 mutational analysis is now a commercially available test, offered by Roche Diagnostics. However, for most genes, there is little or no such compelling information, and mutational analysis of, for example, RB, MDM2, E2, or any other cell-cycle control gene, while of research interest, is at present of little or no clinical value.⁷

Despite the need to distinguish between clinical research and practice, there are a number of assays that are, or are becoming, the standard of care. Some examples include HER2/neu in breast cancer, p53 analysis in many forms of cancer, gene translocation analyses in leukemia, MYCN amplification in childhood neuroblastoma, and c-KIT and platelet-derived growth factor receptor (PDGFR) mutational analysis in gastrointestinal stromal tumor (GIST). The latter is of particular interest because it is primarily of importance as a predictor of response to targeted therapy with gleevec (imatinib), a kinase inhibitor that inhibits not only its original target, the cytosolic kinase ABL, in chronic myelogenous leukemia (CML), but also c-KIT and PDGFR, both receptor tyrosine kinases often mutated and constitutively activated in GIST. This is an important paradigm shift as well: here, for the first time, a diagnostic assay is performed specifically to determine eligibility for therapy, or at least to predict the likelihood of response to, a targeted cancer therapeutic agent of a new type, a kinase inhibitor. This pairing of agent with target, and its mutational status, is rapidly emerging as a major change in approach to cancer chemotherapy: response to targeted agents is predicated on the presence in the tumor of a suitable target, in this case, a mutated phosphokinase. This specificity also explains the narrow therapeutic response window (e.g., mutated versus wild type) for agents such as iressa (gefitinib). This kinase inhibitor is specific for epidermal growth factor receptor (EGFR), another RTK that is commonly actively overexpressed or overactive in a wide variety of cancers. However, enthusiasm for iressa has been tempered by the reality that only about 10% of patients with lung cancer, for example, respond to therapy. Recently, it was shown that this is precisely the group with mutations in their EGFR RTK; those with wild-type EGFR fail to respond and do not benefit from therapy with iressa.⁸ Interestingly, it

appears that this is true of other types of lung cancer (e.g., nonsmokers) and other kinase inhibitors.⁹ It will be interesting to see if this becomes a standard of care, whereby eligibility for treatment with a selective agent such as iressa or gleevec will require diagnostic assay for a specific mutation in the tyrosine kinase domain of the receptor or cytosolic kinase.¹⁰

Therapeutic Targets

The examples cited previously of directed therapies specific for a particular protein or a mutation therein are likely to grow rapidly in number as new agents and new targets are identified. One consequence of the widespread use of molecular biologic methods in the analysis of cancer tissue is the increasing awareness of recurring patterns of genes or proteins preferentially expressed by certain types or classes of tumors. Examples are illustrated in more detail later in the discussion of technologies used to identify these genes, but here we focus instead on the consequence of their identification.

Although identification of mutated kinases has captured the imagination of oncologists and cancer biologists, the reality is that mutations are commonplace in cancer, and the consequences of these mutations are widespread in all forms of cancer. As a general rule, proliferation in cancer cells is increased for lack of cell-cycle control, and apoptosis is inhibited for lack of a viable apoptotic pathway in many cancer cells. The causes of this are too numerous (and often unknown) to document in detail here. Rather, it is fair to state that no one defect explains enhanced cell proliferation and diminished apoptosis in cancer. Thus, a comprehensive analysis of contributing genes to both processes, both promoting and suppressing, can identify potential therapeutic targets, if the gene or its protein product is a *druggable target*. Receptor tyrosine kinases are obvious examples, based on prior comments, and so are cell-cycle regulatory genes such as MDM2 and P53, as well as a huge number of other genes involved in one or another aspect of these two basic defects in cancer cell control. Thus, adenoviral-mediated p53 replacement therapy has been explored in lung and head and neck cancer for many years,^{11,12} and recently Roche has developed an MDM2 inhibitor for those tumors with unopposed MDM2 activity.¹³ In a broader sense, gene targets identified by a variety of biologic and genomic studies have also promoted development of agents that selectively inhibit tumor characteristics, such as their ability to promote angiogenesis to develop a vascular supply necessary for growth beyond microscopic tumorlets. In this case, at least five compounds that target the vascular endothelial growth factor, VEGF, or its receptor, FLT1, have been developed to specifically inhibit angiogenesis in cancer.^{14,15} Early clinical results are promising but it is too early to draw conclusions.

In general, it should be apparent that the more one knows about a given cancer, the more precisely it can be targeted with therapeutics intended to exploit features unique to that tumor. In the future, the list of candidate targets is likely to expand far beyond the current short list of kinase inhibitors, monoclonal antibodies against receptor tyrosine kinases (e.g., Herceptin for HER/neu amplified breast cancer), and angiogenesis inhibitors. Proteasome inhibitors are currently being evaluated, for example,^{16,17} while many other candidate targets remain to be exploited, individually (integrins such as

the vitronectin receptor, alpha V beta 3, for example)¹⁸ or as a class (of which there are many).¹⁹

In view of these concerns, it is reasonable to examine the contributions of molecular technologies to the characterization of cancer, and ultimately the choice of therapy, based on knowledge of candidate targets amenable to targeted therapies such as these.

Diagnostic Technologies

In general, all the methods to be described here can be characterized as analytic tools for the characterization of DNA, RNA, or protein, paralleling the sequence of genomic function, from archival information in DNA, its encoding in mRNA, and its translation into a functional molecule, protein (Figure 21.1). However, this simple schema, although largely correct, overlooks great complexity in the structure, organization, function, and modification of genetic information. To note only a few examples, only about 3% of the genome is associated with genes; the function of the rest is largely unknown, although there is clear evidence that this is not just “junk” DNA, as has been supposed.²⁰ Similarly, although only 40,000 genes, more or less, are known, thousands more noncoding RNA transcripts have been detected in expressed RNA pools in cells.²¹ Thus, genetic and epigenetic controls over DNA replication, RNA expression, and even nuclear chromatin structure are also relevant to cancer origins, grade, and outcome, but are not explored here. Instead, we examine the proven and widely used methods for analysis of the functional genome, starting with proteins, known in aggregate as the proteome.

Protein Based

IMMUNOHISTOCHEMISTRY

By far the most established method of detecting protein in cancer cells is immunohistochemistry (IHC) (Figure 21.2). This technique is widely employed in routine cancer diagnosis in surgical pathology, but it is also used for a number of assays to determine eligibility for directed therapy, or at least to assess the likelihood of efficacy for such therapies. A typical example of this is HER2/neu. Even though HER2

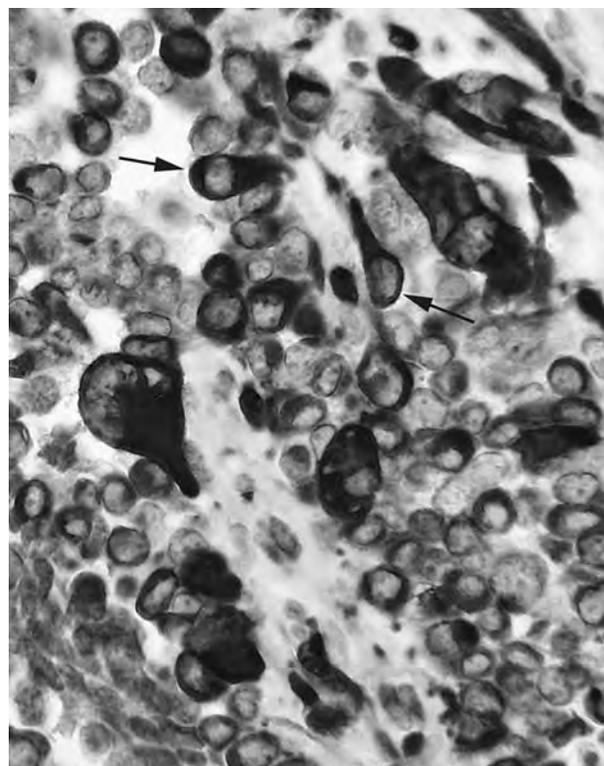

FIGURE 21.2. Immunohistochemistry (IHC) photomicrograph.

amplification is most significantly associated with prognosis in breast cancer, because there is a close association between amplification and elevated protein expression, it is generally sufficient to simply detect the protein by IHC. However, there is significant disagreement as to the superiority of IHC (e.g., protein detection) as opposed to FISH (fluorescent in situ hybridization to detect DNA copy number), and whether DNA amplification is more important than protein expression. A similar controversy surrounds childhood neuroblastoma, where MYCN amplification detected by FISH is the standard diagnostic procedure for MYCN determination; polymerase chain reaction (PCR) for elevated MYCN expression levels is occasionally misleading and not a reliable marker for genomic amplification. Similarly, detection of MYCN protein by IHC is not a reliable surrogate either.

Despite these potential limitations, IHC is far and away the most common technique employed to augment morphologic diagnosis. It is enjoying something of a resurgence, as genes detected by other methods (as described next) need to be validated at the protein level. To serve this burgeoning need, innumerable biotechnology companies producing vast numbers of antibodies specific for a given gene product have arisen and increasingly supply the specific antibody paired with the gene of interest. Two benefits accrue: protein staining is considered the diagnostic gold standard (as not all expressed genes necessarily result in expressed protein), and the technology is simple, cheap, reproducible (with some caveats), and technically straightforward.

WESTERN BLOTS AND IMMUNOPRECIPITATION

Historical problems with nonspecificity of antibody staining on tissue sections, coupled with a relative lack of quantita-

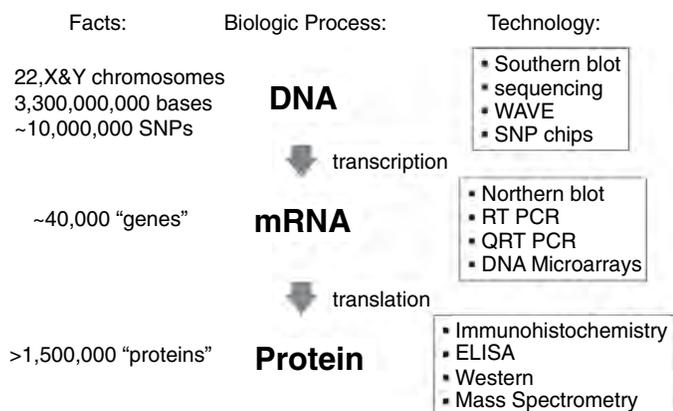

FIGURE 21.1. Diagram: DNA to RNA to protein.

tion, led to the development of a method to detect protein and confirm identity based on objective criteria such as molecular mass and reactivity with an allegedly specific antibody. In this method, the crude protein extract is incubated with an antibody and the antigen-antibody complex is precipitated from solution, then separated into antigen and antibody by gel electrophoresis. Conversely, the mixture can be electrophoresed and separated by molecular mass, then transferred to a filter membrane (the "Western" blot, as opposed to a DNA Southern blot or RNA Northern blot) and incubated with the antibody. Either way, the protein can be identified by its reactivity with antibody and its relative mass, or molecular weight. An example of a comparative Western analysis of the same protein from a series of Ewing's tumors is illustrated in Figure 21.3. It is immediately apparent that the relative amount of the protein in erstwhile identical tumors is in reality markedly different, thereby documenting a quantitative difference in protein content that would be difficult to assess by IHC, for example, where only

FIGURE 21.3. Western blot, same protein.

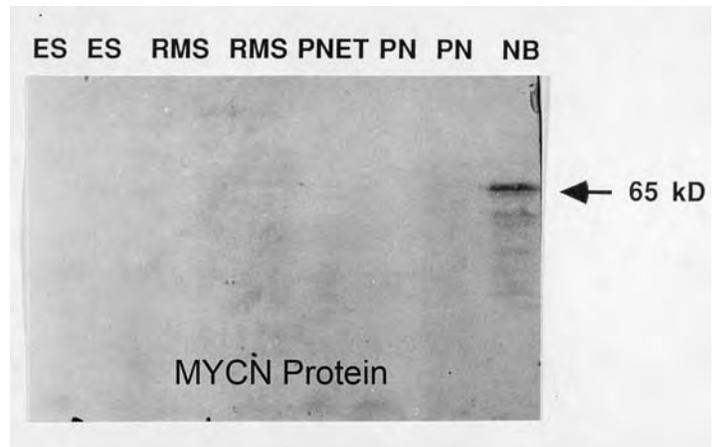

FIGURE 21.4. Enzyme-linked immunosorbent assay (ELISA).

degrees of antibody staining can be assessed, generally nonquantitatively.

ELISA

Enzyme-linked immunosorbent assay, or ELISA, is a widely used laboratory procedure for identifying proteins or other antigens present at concentrations as low as one part in a billion within complex mixtures such as serum and urine. As such, the assay has been employed to detect viral antigens, tumor antigens, and many other protein moieties for years. Two basic methods are commonly used: (1) the specimen containing the suspected target antigen is coated on the substrate, then detected by enzyme-linked specific antibody, or (2), in the sandwich ELISA assay, the plate is coated with specific antibody and washed, the serum, urine, or similar complex protein mixture is added then eluted, and finally an enzyme-linked version of the same antibody is added and subsequently detected by chromogenic or fluorescent methods. The latter method presumes the existence of more than one epitope on the antigen; otherwise, the second antibody will not bind and no antigen is detected. Thus, either multiples of the same epitope must be present on the antigen, or two different antibodies directed against two epitopes must be used in the assay. Quantitation is readily performed when dilutions of the target mixture are performed and assayed, as the optical density of the mixture following enzymatic chromogen generation (as with horseradish peroxidase, a commonly used enzyme) increases linearly with increasing concentration of the target antigen. When suitable positive controls are performed in parallel, the concentration of the antigen in the serum or urine can be readily calculated from a simple $y = mx + b$ graph of optical density (OD) versus dilution. A typical result performed in a 96-well format is illustrated in Figure 21.4.

ELISA assays are probably the most common laboratory procedure performed for immunodetection of protein antigens. However, the confluence of several factors has lent a new life to this venerable assay: as genomic methods increasingly identify gene targets, their protein end product can be predicted with accuracy and a suitable ELISA assay established. This method is of particular value in serum-based diagnostics, where the presence of enormous concentrations

of albumin and immunoglobulins vastly overshadows the relatively rare tumor cell products. However, by virtue of the remarkable ability of solid-phase immunoabsorption to retain even rare proteins on an immobilized immunoglobulin-coated solid substrate, it is possible to both detect and quantify such proteins. The presence in serum and urine of many tumor-associated proteins or peptides makes detection and quantitation of these antigens by ELISA an attractive means of early detection and monitoring of tumor persistence or recurrence. The marked sensitivity of the assay, coupled with its low cost, proven sensitivity and specificity, and amenability to rigorous laboratory quality control procedures, has made it the method of choice for such assays. However, successful use presumes both knowledge of the antigen, as well as the availability of a suitably specific antibody. Initially, these requirements are rarely satisfied, and tumor antigens must be identified by other methods. This process has been markedly enhanced in the past decade by rapid progress in mass spectrometry and related methods, well suited to detection, characterization, and even quantitation of unknown proteins and peptides.

PROTEOMICS AND MASS SPECTROMETRY

Although antibody-based protein detection methods are preferred when the antigen is known and a suitable antibody to detect it is available, such methods are of no value with unknown antigens, which is the more common situation when searching for novel tumor antigens. Although a high index of suspicion may derive from preliminary gene expression analyses on expressed mRNA, the ultimate identification requires detection and at least partial sequence identification. By far the most common method of doing so currently is mass spectrometry. However, mass spectrometry is not a single method; rather, there are many variations, too many to discuss here. Suffice it to say that increasingly, sample preparation methods that mimic ELISA or affinity capture methods are coming to dominate clinical proteomics, while rather more demanding, tedious, expensive, but ultimately unequivocal methods, such as tandem mass spectrometry are finding wide acceptance as research tools. Here, we focus on mass spectrometry with suitable interface for specimen complexity reduction coupled with high throughput.

Clinical proteomics, as opposed to research proteomics, necessitates high throughput, reproducibility, and reasonable cost. Most research methods that utilize preparative columns for sample cleanup before mass spectrometry are not suitable for clinical use. The columns are expensive and must be replaced frequently. However, raw serum or urine cannot be successfully analyzed by mass spectrometry because of the vast difference in concentration between target protein or peptide compared to contaminating proteins such as albumin. However, depletion methods that selectively remove albumin and serum globulins may have an untoward effect: a very high percentage of serum proteins, likely including tumor antigens, are in fact bound to albumin. Removal of albumin may thus remove a large amount of the target antigen. Thus, methods which selectively immobilize target proteins or peptides from complex mixtures are to be preferred, not unlike the solid-phase adsorption of ELISA assays discussed previously.

SELDI TOF is a currently popular method of preisolating a vast variety of proteins or peptides before mass spectrometry. This method relies on the selective elution with laser desorption and ionization of proteins, followed by time of flight mass spectrometry. Marketed by Ciphergen, this technology has been used for the majority of clinical proteomics publications to date.²²⁻³² In essence, this method utilizes a specimen target immobilization using a "protein chip," the characteristics of which vary widely, from strong anion or cation exchangers to immobilized antibody bases. Each spot is repeated several times in a row, and the adsorbed target is selectively eluted under varying elution conditions, from weak to strong. Each step is ionized and separated on the basis of the mass to charge (m/z) ratio. The resultant peaks are recorded and conditions optimized to identify the peak or peaks of interest. A typical example is illustrated in Figure 21.5. For identification, the same protein chip can be incubated with one or more proteases, such as trypsin and the resultant peptides spectrographed. The peptide pattern is highly reproducible and by definition identifies partial sequences within the intact protein. When compared to the vast online libraries of peptide fragments that result from any protein treated with any common protease, it is possible to make an identification from peptide mapping more than 90% of the time. If any doubt remains, the same specimen can be subjected to tandem mass spectrometry with quadrupole-based, collision-induced dissociation of individual amino acids, which can then be readily identified and the amino acid sequence deduced. This finding is then easily compared to genomic or protein library data for a positive identification, regardless of whether prior knowledge exists.

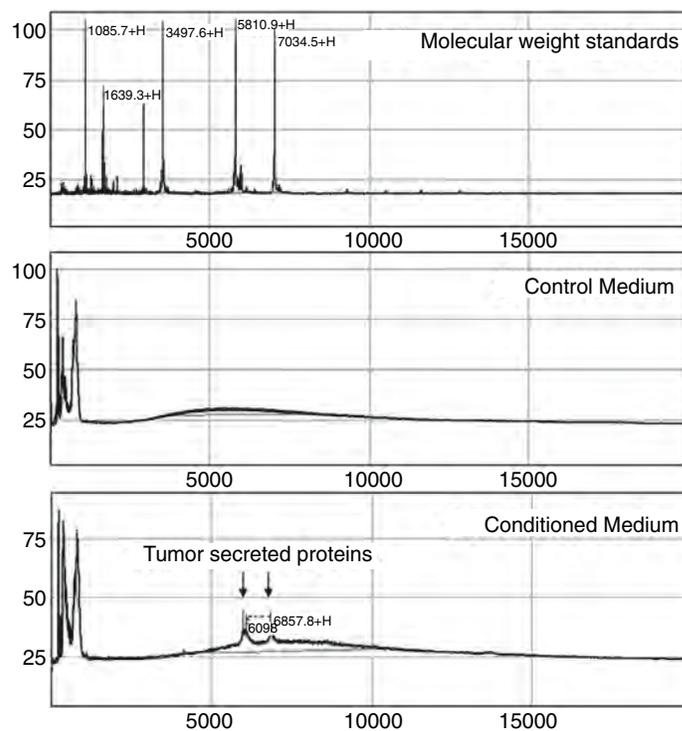

FIGURE 21.5. Mass spectrum, protein peak.

RNA Based

All protein is ultimately the product of mRNA coding information translated into amino acid sequences that constitute proteins, which then undergo a vast number of posttranslational modifications, resulting in more than a million identifiable proteins from fewer than 50,000 genes. In part, it is the potential to reduce this posttranslational complexity to manageable levels, as well as the precision and unambiguous result of RNA assays as compared to protein assays, which has driven the rapid development of RNA-based assays of interest to both biomedical research and clinical medicine. Nucleic acids are intrinsically more manageable; there are no issues with antibody specificity or ambiguous peaks on mass spectrometry. Even a single base is readily detected. Thus, many of the current methods for characterizing tumor or tissue gene expression use mRNA assays as surrogates for predicted protein gene product. Although it is true that mRNA assays fail to reflect the vast number of protein moieties that exist within a cell, many derived from the same gene, it is also true that all these proteins ultimately track back to mRNA message: if there is no message, there is no protein. The converse, of course, is not always correct: message may not result in protein, or the levels of protein may not parallel message levels, as a result of truncated or prolonged protein half-life, or even a failure of reliable translation without immediate proteasomal degradation, as occurs, for example, with mutated genes producing codon changes that result in premature stop codons and truncated protein. These are usually rapidly degraded, and in this case, abundant mRNA is not reflected in abundant detectable protein, which is rapidly degraded to undetectable peptides and amino acids. Despite these caveats, RNA assays are perhaps the most widely used assay for gene expression in cancer today. It is therefore useful to review the various methods used to identify and quantify mRNA expression.

RNA BLOTS (NORTHERN BLOT)

The oldest method to identify and roughly quantitate RNA is the Northern blot, named for its similarity to the DNA blot described by E.M. Southern.³³ Many variations have subsequently been described, including simple transfer without electrophoretic separation of RNA samples to nitrocellulose or nylon filters followed by detection with a suitably specific radioactive or fluorescently labeled probe. A virtue of this method is its ability to both determine relative molecular mass and quantify the amount of mRNA present in the sample, based on density (or fluorescence) measurements of the hybridized, labeled probe. However, a major shortcoming is the large amount of RNA required, the need for extensive laboratory handling (purification, electrophoresis, etc.), and the time required for a result. Most human tissues, and especially tumor biopsies, rarely provide sufficient material for Northern blots. Consequently, alternative methods of RNA detection and quantitation have been developed.

RNA AMPLIFICATION: POLYMERASE CHAIN REACTION

a. Basic PCR: Polymerase chain reaction, or PCR, has become the method of choice for detecting even minute amounts of RNA or DNA, even in contaminated, impure,

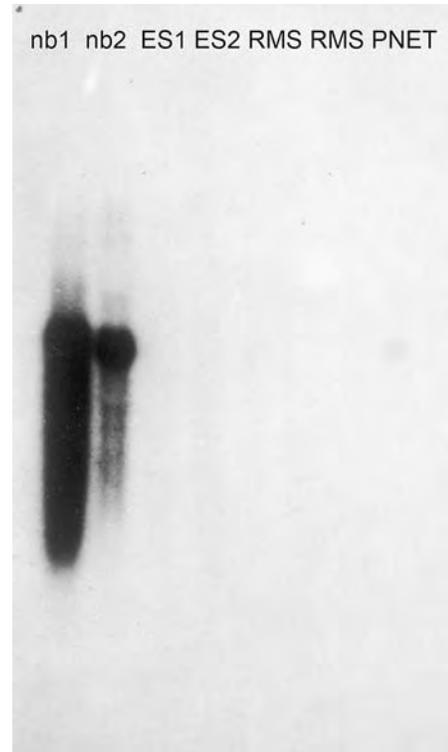

FIGURE 21.6. Polymerase chain reaction (PCR).

degraded, or otherwise unsatisfactory specimens. It is thus ideally suited to the small biopsies, cytology specimens, body fluids, or even laser-captured cells that are commonly used for nucleic acid assays. With suitable amplification (e.g., numbers of cycles), it is possible to detect the RNA from even single cells. A typical result for PCR amplification of MYCN in neuroblastoma after varying numbers of rounds of amplification is illustrated in Figure 21.6. Note that in this example, the MYCN-amplified and overexpressing specimen (from a needle biopsy) shows detectable product long before the single-copy control, indicating high-level expression. Despite the difference, this method is generally not used for absolute quantitation. Instead, quantitative real-time PCR has become the method of choice.

b. Quantitative PCR: Quantitative real-time PCR has become a standard laboratory diagnostic technology by virtue of its extraordinary sensitivity, amenability to quality control and reproducibility, speed, and cost. Although the product amplified is DNA, this is generally a cDNA produced by reverse transcriptase of mRNA. At least three manufacturers (e.g., Roche, ABI, and Cepheid) make devices and numerous reagent suppliers make various chemistries for DNA detection, including TaqMan (Roche, Basel, Switzerland) and Molecular Beacons probes, Amplifluor (Chemicon, Temecula, CA) and Scorpion primers (DxS, Ltd., Manchester, UK), and intercalating dyes such as SYBR Green (Finnzymes, Espoo, Finland). All have been used successfully. Regardless of the chemistry, in each case the point at which there is a detectable change in fluorescence intensity during the course of multiple cycles of DNA amplification is noted and termed the cycle threshold, Ct, the point termed the log-linear phase

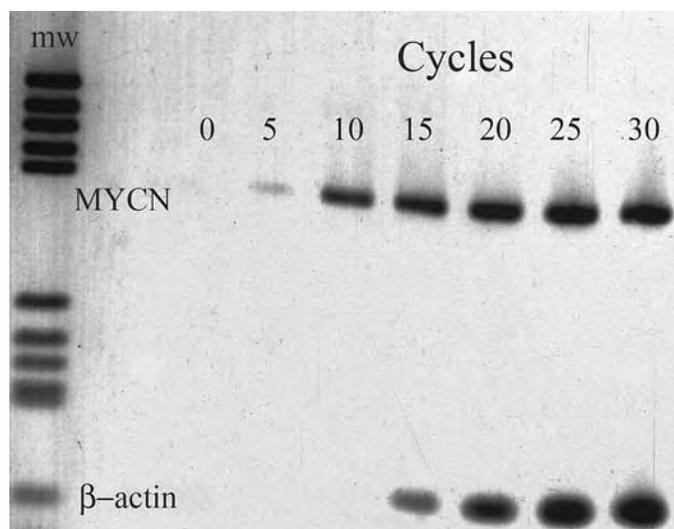

FIGURE 21.7. Quantitative real-time (QRT) PCR.

of amplification. This is a sensitive index of how much target is present in the sample, and is thus a highly reproducible measurement of the amount of RNA (or DNA) present in a sample. A typical result for detection of a chimeric oncogene in a Ewing's sarcoma (e.g., EWS-FLI1) is illustrated in Figure 21.7, where it is clear that the unknown sample shows a cycle threshold and subsequent amplification virtually indistinguishable from the positive control and quite distinct from the negative control.

MICROARRAYS

By far the most dramatic advance in the detection of mRNA has been the development of microarray technology during the past decade. These arrays, whether constructed of cDNA, oligomeric DNA, or in situ synthesized 25-mer oligomeric DNA, share the ability to detect thousands of RNA transcripts simultaneously. From a few hundred "spots" a decade ago, the current generation of arrays routinely assays all known, and many unknown, genes from the entire transcriptome. For example, the current generation of Affymetrix

(Santa Clara, CA) GeneChips, the U133 plus 2, assesses the expression of 47,000 unique RNA transcripts, a number considerably larger than the estimated number of genes in the human genome. The identity of more than half is unknown. The major impact of these arrays has been their ability to simultaneously measure the gene expression activity of any and all genes, and deliver a quantitative value, resulting in a vast number of gene by gene measurements. These gene expression profiles are markedly different for different tissues and tumors and have been shown to provide powerful diagnostic information that in many cases is superior to any antecedent diagnostic technology, on a par with an expert pathologist, and far more reproducible.

a. cDNA: The first-generation microarrays were created by spotting cDNAs of specific sequence, complementary to known genes, usually by fine-tipped metal probes held in physical arrays. The arrays were then "stamped" with the same cDNA in the same position, one after another. The resultant arrays are then incubated with a dual sample: a mixture of control and tumor, for example, in balanced proportion, each with a different color fluor (typically Cy3 and Cy5). The result is either red, green, yellow, or black, or variations thereon. A typical result is illustrated in Figure 21.8a. Red or green denotes 100% hybridization by only one of the RNA moieties in the mix (e.g., control or tumor, for example); yellow indicates balanced competitive hybridization of both in about equal proportion; and black indicates no hybridization by either. By calculating the ratios of red to green, the "fold change," or multiples of greater or lesser expression of sample versus control, can be calculated.

Although this method is still in use, it has become considerably less popular with recognition that cDNA clones are prone to cross-hybridization, are often not monoclonal, and may in fact be mislabeled. This intrinsic lack of control over the actual sequence present on the array has prompted the search for more precise nucleotide probes for arrays.

b. Spotted oligomeric DNA: In an effort to improve the reproducibility of spotted arrays, most laboratories are increasingly using defined oligomers (usually 50-mers or 60-mers) of known sequence. Advantages of this approach include the ability to precisely replicate arrays from newly synthesized oligomers and achieve the same results, the

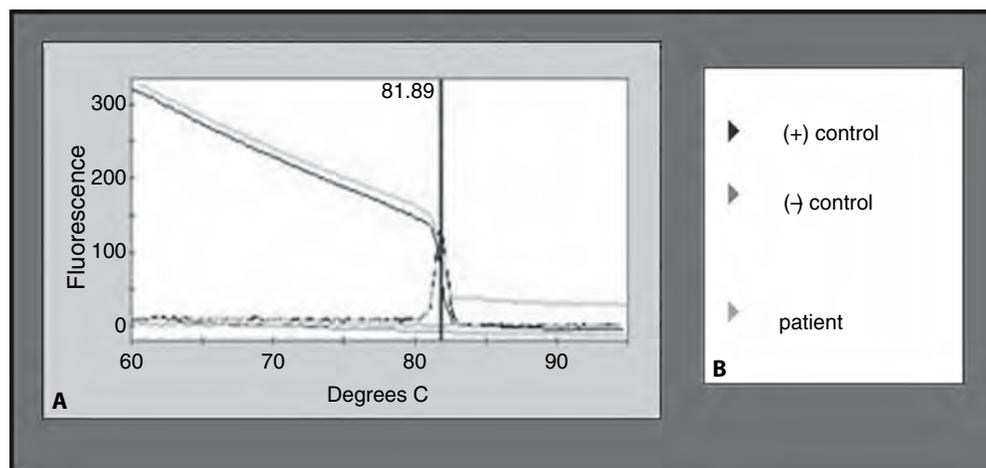

FIGURE 21.8. Microarrays: (a) spotted; (b) GeneChip.

ability to compare data from one lab to another, and the absence of cross-hybridization caused by mixed clones or conserved sequences within large cDNAs that result in non-specific cross-hybridization. In addition, variations in expressed gene sequence due to alternative exon usage, truncated message, and even mutations can be readily detected with custom arrays that are otherwise difficult to create from standard UNIGEN database information. Thus, the user is free to generate highly specific custom arrays to interrogate expressed in detail. Several commercial vendors, such as Agilent, have entered the field, which will result in standardization of arrays and results that would otherwise be difficult to achieve in "home brew" microarray facilities. This in turn will enhance their utility for clinical use, where reproducibility and reliability are of paramount importance.

c. Synthesized oligomeric DNA: Figure 21.8b illustrates the physical appearance of a typical commercial oligonucleotide array (Affymetrix GeneChip), where 25-mer segments of a gene are arrayed from 6' to 3' in "tiles," or areas containing that probe. Typically, 11 to 16 such 25-mers are generated across the coding sequence of the gene, paired with a one-nucleotide mismatch (below) (e.g., PM versus MM, or perfect match versus mismatch). The PM minus MM signal intensity for each pair is calculated, and the mean value for all tiles within a gene is calculated and reported as an expression value. A variety of correction algorithms are then applied to calculate a normalized value for each of the genes on the array, using values from internal standards on the array. In a typical analysis, the values for each gene in each sample are compared one to another in high-dimensional space, and the nearest neighbors, based on any of a number of criteria, are calculated and the patient samples "clustered" to identify those most similar to one another. When done well, very obvious clusters of "like" and "unlike" are readily appreciated, thereby establishing classes of tumor (Figure 21.9). Surprisingly, these clusters typically match known tumor groupings closely. Cases that do not frequently have subsequently been shown to be misdiagnosed. In other cases, the method identifies previously unrecognized subsets within tumor groups, many of which may have important clinical or

therapeutic features of value for patient management in the future. In general, whole-transcriptome expression profiling has had an enormous impact on biomedical research and is poised to enter the clinical practice of medicine, particularly in oncology, where gene dysregulation is a regular feature of most cancers. Finding which genes has been the challenge. Microarray technology appears to accomplish that, rapidly and facilely, to great effect.

DNA Based

Analysis of DNA takes many forms. Methods to do so span virtually the entire history of molecular biology, more so than RNA or protein (at least as defined by modern sequencing and characterization methods). Progress in DNA analysis has been remarkable: from crude biochemical methods to coarse RFLP (restriction fragment polymorphism analysis) to modern methods that embody rapid sequence determination and identification of DNA from virtually any source, the ability to obtain precise, voluminous DNA sequence information is now virtually unlimited. The achievements of the human genome sequencing project seem to pale in the face of potential individual whole-genome sequencing within days at minimal cost: all 3.3 billion bases, times two (sense and antisense), times two (both haplotypes). In this context, it also worth mentioning that about one-third of the DNA extracted from a cell is mitochondrial in origin, and mitochondria undergo mutational damage over time, with resultant disease onset as well. Analysis of this DNA, too, will be of importance. It is likely that as highly automated, inexpensive methods of doing so become commonplace, broad DNA sequencing will likely become central to analysis of genetic anomalies in cancer and other diseases. At present, however, assays of more limited scope are the norm, as is illustrated here.

SOUTHERN BLOT

The first widely used method for DNA identification without resort to laborious manual DNA sequencing methods was developed by E.M. Southern in 1975.³³ This method is based

FIGURE 21.9. GEP clustering.

on the remarkable specificity of binding between nucleotides in the DNA helix. If the double helix is denatured ("melted"), the single-stranded DNA is then readily annealed with complementary DNA sequences. By denaturing DNA, electrophoresing it to separate different fragments by molecular weight, transferring the gel to a solid substrate such as nylon or nitrocellulose membranes, and incubating these filters with radioactive or fluorescently labeled complementary DNA probes (e.g., short sequences sufficient to establish absolute identity), it is possible to identify any sequence from the mix of genomic DNA. A side benefit is that loss or gain of chromosomal DNA can also be ascertained; comparison of a single-copy DNA probe with an amplified gene, for example, allows ready determination of copy number. An example from an MYCN-amplified childhood neuroblastoma is illustrated in Figure 21.10. Here, a variety of tumors with a single copy of the gene show comparably dense bands at the appropriate molecular weight. In contrast, the amplified tumor shows a marked increase in signal strength. Scintigraphy of radioactive DNA probes, fluorography of fluorescently labeled DNA, or densitometry of chromogen-labeled DNA allows precise quantitation of the signal, and therefore a ratio that defines copy number.

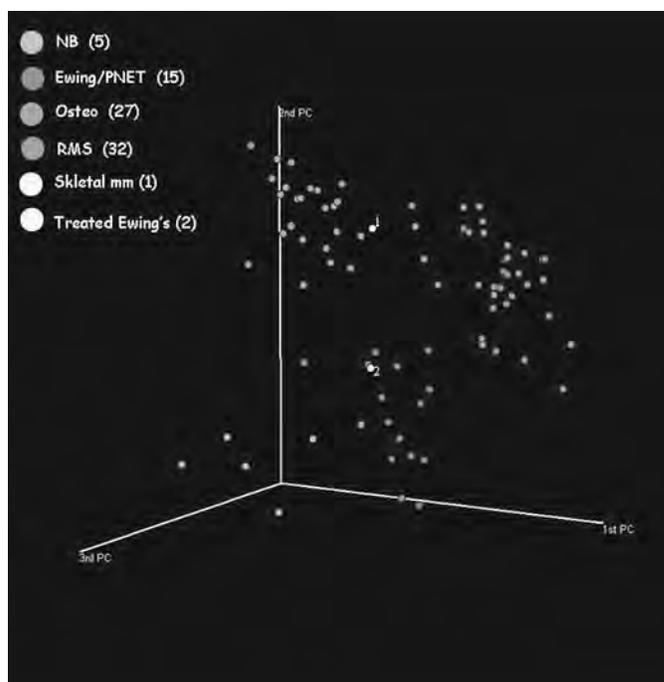

FIGURE 21.10. Southern blot.

Fluorescent In Situ Hybridization (FISH)

The remarkable specificity of DNA hybridization has given rise to many variations on DNA assays. One particularly useful method for clinical purposes is fluorescent in situ hybridization (FISH). In this method, fluorescently or affinity-tagged DNA probes some hundreds to several thousand bases in size are applied to tumor sections, cytopspins, or imprints, for example, and hybridized under denaturing then

reannealing conditions, conditions similar to those developed for Southern blots. The labeled DNA is now bound to target DNA and readily detected. This method can be used for a variety of purposes, such as detecting amplified genes, as in MYCN amplification in neuroblastoma (Figure 21.11) or, more commonly, to detect HER2/neu amplification in breast

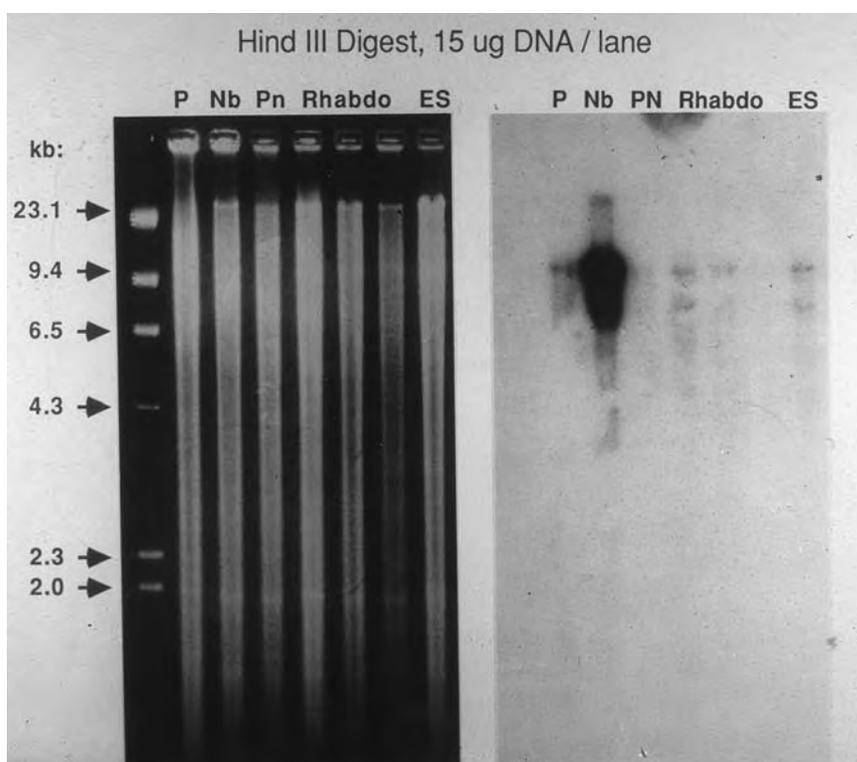

FIGURE 21.11. Fluorescent in situ hybridization (FISH); MYCN; tissue section.

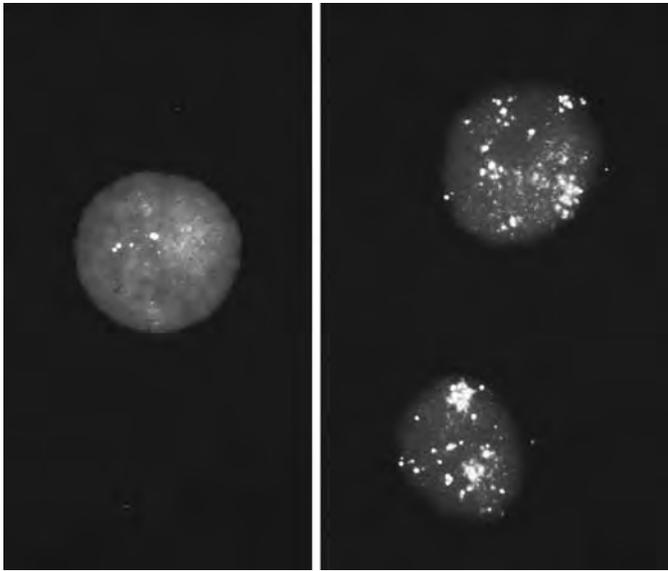

FIGURE 21.12. DNA sequence.

cancer. Both are of great prognostic importance, imparting a graver prognosis than would otherwise be the case, and establishing the basis for more-aggressive therapy. FISH, then, is a valuable diagnostic and prognostic tool that begets more aggressive therapy when an amplified gene is detected.

DNA SEQUENCING

Direct detection of sequence variation in DNA has been greatly facilitated by the advent of high-throughput, automated, multichannel DNA sequencers. These machines were in fact responsible for the rapid progress made in the human genome sequencing project. The technology is now routinely used in research and diagnostic laboratories to determine the identity of, for example, PCR-amplified DNA, and to detect mutations or polymorphisms in genomic DNA. An example of heterozygous mutation of a gene is illustrated in Figure 21.12, where both G and C peaks are identified at the same location, indicating that there is a mutation in one allele of the gene, whereas the other allele remains wild type. Most often in cancer cells the wild-type allele is subsequently lost, resulting in unopposed function of the mutant and total loss of wild-type functionality, common in oncogenes such as p53.

MUTATION DETECTION (WAVE, AND SIMILAR METHODS)

Indirect means of DNA sequence detection have proliferated, especially before the availability of cheap, fast DNA sequencing. Several of the methods are based on aberrant migration in a gel due to conformational changes in the DNA double helix that results from base mismatches. They retain their importance as screening methods in particular, due to their low cost, high sensitivity, and high throughput, superior even to DNA sequencing. Their value stems from the fact that most mutation or polymorphisms screening assays presume a low incidence of positives. Rather than laboriously sequencing all samples, a prescreen that detects the rare anomalous case is used. When an anomaly is detected, it is simple to confirm the anomaly by direct DNA sequencing of the anom-

alous case. This is the principle behind SSCP (single-strand conformation polymorphism) and its many derivatives such as dHPLC (denaturing high performance liquid chromatography).³⁴ A particularly useful method has been commercialized by Transgenomics, the so-called WAVE technology. In this method, homo- and hetero-DNA dimers are formed after denaturing and renaturing conditions and immobilization on a hydrophobic column matrix. Increasing concentrations of acetonitrile selectively elute triethylaminoethyl (TEAA)-bound DNA duplexes; heteroduplexes elute first, followed by homoduplexes. Mismatched dimers elute aberrantly, reflected in peak height and shape. Samples that show such anomalies are then subjected to confirmatory DNA sequencing, as described earlier. In this way, a large number of clinical samples can be screened, and only those showing anomalous elution patterns need be confirmed by DNA sequencing. A typical example of mutation detection by WAVE dHPLC is illustrated in Figure 21.13.

POLYMORPHISMS

An interesting aspect of genomic DNA organization is the presence throughout the genome of millions of single-base variations between individuals, called SNPs, for single-nucleotide polymorphisms. The HapMap project (<http://www.hapmap.org/index.html.en>) estimates there are 10 million such variants that occur with sufficient frequency as to warrant designation as polymorphisms. An example is illustrated in Figure 21.14, from the HapMap home page. These SNPs are not mutations; mutations occur rarely and are usually either inherited in the germ line from one parent

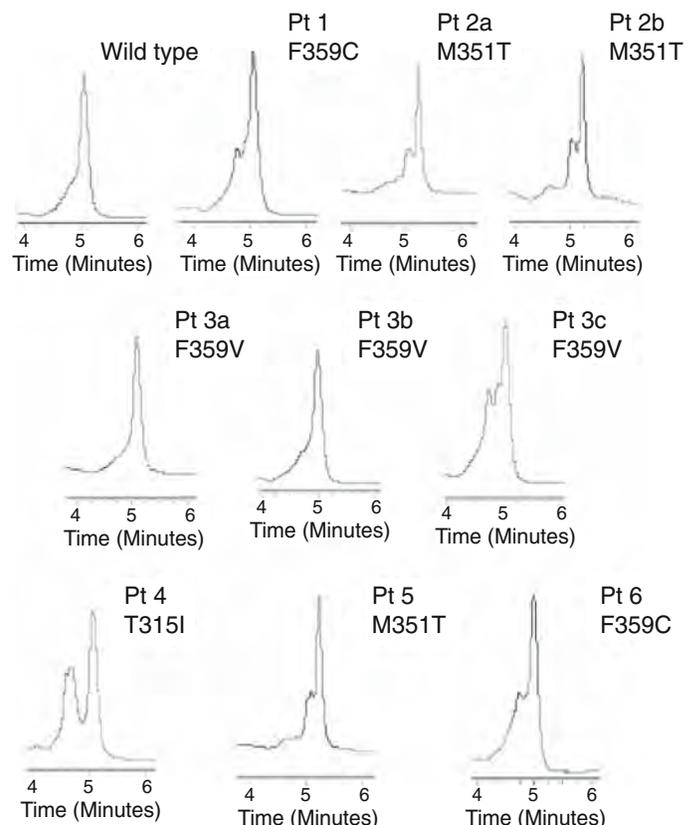

FIGURE 21.13. WAVE?

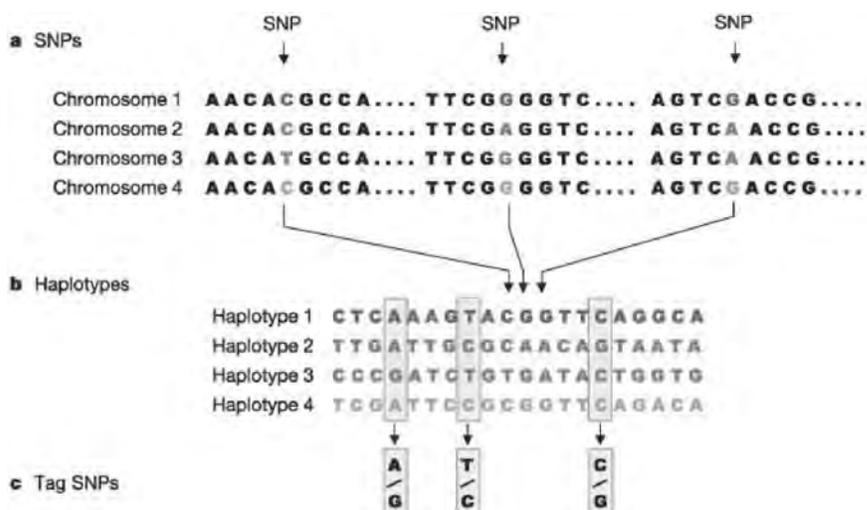

FIGURE 21.14. Single nucleotide polymorphisms (SNPs): illustration from HapMap.

or arise *de novo* as a somatic mutation. In contrast, polymorphisms reflect human genetic variation between individuals. During sexual reproduction, chromosomal cross-over events result in the creation of mosaics of large blocks of DNA ("haplotype blocks") inherited from one or the other parent (Figure 21.15, also from the HapMap home page). This overall pattern is called a haplotype. Because these blocks of DNA are inherited as blocks, each individual inherits two haplotypes, one from each parent. These haplotypes have generally arisen as much as 150,000 years ago in the human germ line in Africa and have undergone further diversification with the spread of humanity over the globe. They show marked ethnic variation, resulting from expansion of isolated groups of humans, and variable age, due to additional polymorphisms that arose subsequent to dispersion of ethnic populations. The aggregate effect is a *fingerprint* of genetic diversity that can be used to identify the genetic background of any individual and, further, to associate that genetic makeup with disease propensity, severity, response to drugs, and many other parameters. Polymorphic variants of CYP450, for example, are powerful tools to predict drug metabolism in individuals, potentially guiding dosage for the individual as opposed to the "average." In oncology, idiosyncratic responses to drugs such as cyclophosphamide are linked to specific polymorphic variants of CYP450.^{35,36} This burgeoning field, termed "pharmacogenetics," is likely to increasingly dictate individualized therapy based on haplotype variants of critical genes such as CYP450 and many others that in aggregate dictate an individual's disease susceptibility and likely response to therapy.³⁷⁻⁴²

WHOLE-GENOME ASSAYS FOR SNPs

Given the apparent importance of polymorphic variation among individuals to important clinical issues such as disease susceptibility and response to therapy and prognosis, a practical method for genotyping individuals is needed for clinical use. The HapMap project referenced earlier is providing the data, including tag SNPs that will enable identification of haplotype blocks and therefore the individual's haplotype; only about 500,000 of these are needed to predict an individual's genotype, as opposed to direct detection of all 10 million

SNPs, or any large fraction thereof. A variety of methods for large-scale detection of SNPs are being developed. At present, two approaches merit discussion, as both are used for whole-genome SNP analysis.

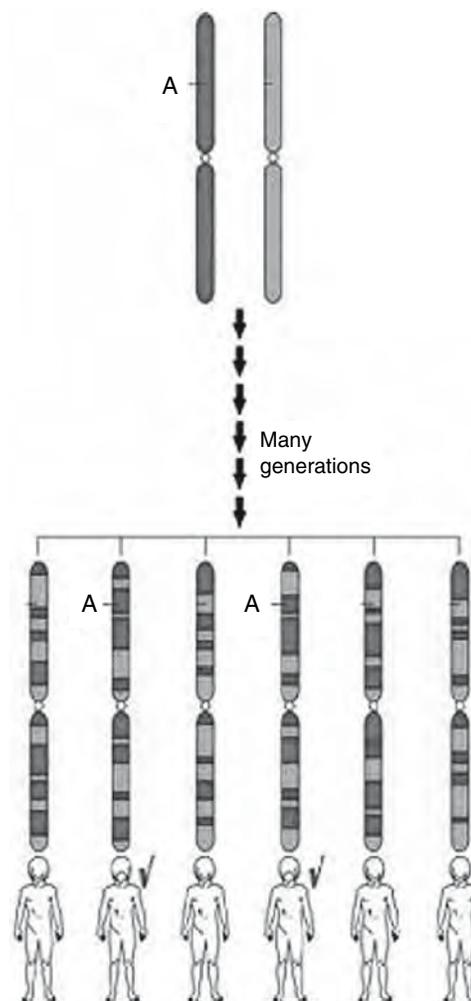

FIGURE 21.15. Genomic mosaicism.

a. **Bead Arrays:** The first, a multiplex bead assay developed by Michael et al.⁴³ and commercialized by Illumina, Inc. (San Diego, CA), termed Beadarray, is capable of identifying up to approximately 1,500 SNPs per assay, by adsorbing a random bead mixture (~1,000 to ~1,500 types, specific for one SNP) onto the etched ends of approximately 50,000 optical fiber complexes. Each fiber binds a bead, with 1,500 bead types, each is represented with about 30-fold redundancy. A unique decoding scheme, based on unique “address” sequences incorporated into PCR-amplified genomic DNA sequences, is then used to identify each bead and assign a call value for each SNP.^{44,45} The result is about a 90+% successful call for SNPs from dbSNP. High-quality, validated SNPs results in more than 95% calls. SNPs can be drawn from the entire genome, or regionally at high density. This flexibility lends itself to disease association studies, where a locus is first identified, then probed in detail with regional SNP beads. However, there is a significant design and validation component for each SNP, and the cost per SNP is higher than SNP arrays (see following). Nonetheless, this technology has been widely used by the HapMap project, with great success.

b. **SNP photolithography arrays:** The second high-throughput method, available commercially from Affymetrix, is based on the same technology employed for the GeneChips discussed earlier. For SNP detection, the region of interest for a specific allele, termed “A” (e.g., the SNP and 14 surround-

ing nucleotides, designated -7 through +7) is represented by 25-mer oligonucleotide sequences, with the specific nucleotide of interest represented in position 13. Target sequences bind most stably to such sequences and yield the brightest signal. The brightest signal should thus occur for the 25-mer representing the SNP at position 0. To further control for nonspecific hybridization, a one-base mismatch sequence is tiled on the array immediately below the perfect match, yielding a 2×7 matrix of 14 tiles. This is then doubled, to include the same setup for the alternate allele (“B”), yielding a 4×7 matrix. Finally, this is replicated in the antisense direction, for a grand total of 56 tiles. To detect the target DNA on these probes, genomic DNA is fragmented by one or more restriction endonucleases, PCR primer adapters ligated to the ends, and preferentially PCR amplified by fragment size (e.g., 400–800bp). These PCR products are then fragmented, denatured, end labeled, and hybridized to the SNP arrays, resulting in the hybridization pattern illustrated in Figure 21.16. With suitable software, the genotype for any given SNP can be called with greater than 95% confidence.^{46,47} At present, arrays capable of interrogating up to 126,000 SNPs are available, and the number is expected to rise to 500,000 and more in the near future. With reasonable selection of SNPs, this density will allow haplotyping with unprecedented precision and sensitivity across the entire genome. The disadvantage is that, unlike the bead array system already described, the user cannot specify specific SNPs for analysis.

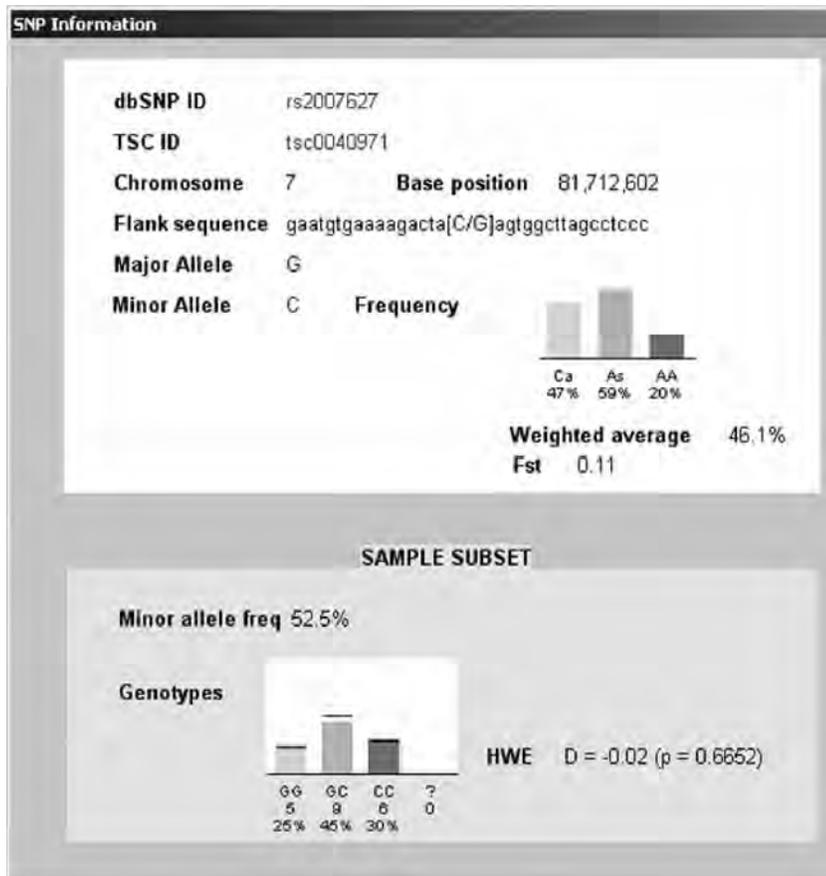

FIGURE 21.16. SNP: chip.

These methods may thus be complementary technologies for very high density SNP haplotyping.

Although high-density SNP haplotyping will ultimately be of value in oncology as a means to identify patient subpopulations with greater or lesser tolerance for certain cytotoxic drugs and perhaps even disease susceptibility, the immediate value of SNPs, particularly as high-density microarrays, is their phenomenal ability to detect DNA copy loss and gain, and to map these genomic alterations to very precisely defined regions of chromosomes.⁴⁸⁻⁵⁰ In one respect, this can be considered a logical extension of cytogenetic analysis, SKY, CGH, and even array CGH, none of which approach the power of this technology to detect DNA loss and gain by as few as 1,000 bases within specific regions of the genome. This approach is of enormous potential value for identifying recurring genomic abnormalities in cancer that is currently beyond the limits of detection by current technology. Wider use of this technology for this purpose is inevitable. Initial publications, including use of laser-captured and amplified DNA, have already appeared.⁴⁹ Many more are expected.

Bioinformatics in Medicine

An inevitable consequence of the use of large-scale genomic technologies in biology and medicine is the accumulation of vast amounts of data that must be reduced to useful knowledge. Each of the newer technologies discussed (e.g., mass spectrometry-based proteomics, microarray-based gene expression analysis, and SNP-based genotyping) of necessity create this challenge. This in turn has spawned an urgent need for those skilled in both biology and quantitative analyses. Unfortunately, the methods required for data management go far beyond data archiving and statistical analysis. Bioinformatics is the broadly defined discipline that has resulted from this need. Many different tools have and continue to be developed to meet this need. National Institutes of Health (NIH) sponsors NCBI, the National Center for Biotechnology Information, which both hosts genomic data and provides suitable browser and analytic tools. The HapMap project noted earlier offers similar tools for inspection and analysis of SNP data. Numerous commercial sources of software for analysis of gene expression data and linkage analysis are also available. The full scale of the endeavor is far beyond the scope of this chapter. It is fair to say, however, that as the technology advances rapidly, so does the need for analytical methods, but also the need for tools to integrate these data sets with one another and with other types of data that bear on the problem, such as clinical, biologic, and other molecular data. As a general comment, the steady intrusion of genomic methods on the practice of medicine, and especially in cancer, the most common genetic disease of all, will inevitably require different training for its practitioners in the future. At a minimum, the future oncologist, and allied disciplines, will likely need to concurrently deal with clinical, biologic, laboratory, genomic, and statistical data in the evaluation of a patient. Whether responsible for the primary analysis, or accepting or rejecting the result, this future oncologist will need to be conversant with at least a basic understanding of the quantitative analytical methods used for genomic studies.

Clinical Impact

Evidence of Efficacy

Whenever a new procedure or technology is introduced into medicine, there is inevitably a rush of enthusiasm, usually followed by unwarranted skepticism, in response to the inevitable failures that accompany any new method. The difference with genomic technologies is already apparent, however: although sequencing the human genome may have had little or no direct impact on the practice of medicine, the derivative information and technology are responsible, to a greater or lesser degree, for nearly all the technologies discussed in this chapter. The characteristic of all these newer methods is that all have resulted in publications that document their actual or potential efficacy in patient management, most notably in oncology. This, then, is the real value of these technologies: they enhance our ability to both understand and treat cancer, in ways unheard of a short time ago. The impact going forward can hardly be less.

Integration with Morphologic Diagnosis

As powerful and promising as genomic technology is for the field of oncology, it is also important to place this enthusiasm in context. Osler allegedly admonished his students to be neither the first to adopt new medications nor the last to abandon them. A similar comment can be made with reference to diagnostics and technology: new and unproven technologies are no substitute for older methods with proven efficacy. Even new technologies that offer more precise diagnoses or better indications for therapy may not be warranted when viewed in context with cost-versus-benefit considerations. Is a \$3,000 genetic test that indicates you have a 60% lifetime risk to develop cancer of value, when 33% of the population will develop cancer in their lifetime? In a similar vein, is a diagnostic genetic test with 90% reliability that costs \$1,000 preferable to a pathologic review of a glass slide for a total of \$150? Further, what genetic test determines whether the submitted specimen is in fact cancer?

The real value of genetic tests is the enormous contribution they can make to refined, objective, reproducible diagnoses. Most of the methods discussed here are in actual use, some as clinical research tools, other as ancillary diagnostics, to be considered in aggregate with other methods, starting with routine histologic examination. When the innate precision and scope of genomic testing is paired with basic pathologic evaluation for the presence of cancer, diagnoses result that are far more likely to be replicated and to direct optimal therapy. Thus, in actual practice, morphologic and genetic methods are overwhelmingly synergistic, and should be employed whenever possible, when there is clinical need and the result will likely aid therapy.

Implications for Directed Therapy

The most direct impact of precise diagnostic methods is, of course, to tailor therapy for patients most likely to benefit, the "Holy Grail" of "personalized medicine."^{40,42,51} As laudable as these goals may be, the reality is that to date very few examples of this exist. Herceptin for HER2/neu amplified

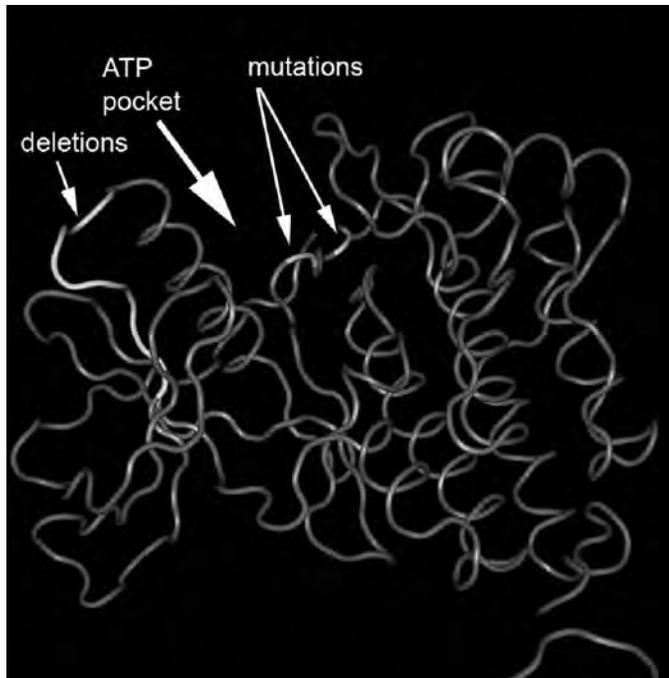

FIGURE 21.17. Three-dimensional (3-D) structure of TK domain of epidermal growth factor receptor (EGFR).

breast cancer, gleevec for GIST, and ATRA for APL are clear exceptions, but broad-based “personalized medicine” remains an unattained goal. This reality may change rapidly, however, as suitable genomic profiling methods become readily available at reasonable cost. A striking example of this is the recent recognition that iressa (gefitinib), which has only a 10% response rate in most solid tumors, is in fact 100% effective in inducing a dramatic reduction in tumor size in non-small cell lung cancer patients.⁸ The fact that response is directly linked to mutations in the ATP-binding pocket of the tyrosine kinase domain of the EGFR (Figure 21.17), and that these mutations can be detected by any of a number of methods, will almost certainly revolutionize the selective use of iressa for this tumor.^{10,52} In fact, pairing of a routine diagnostic test with therapy has already been proposed by the authors of this landmark study, and several national commercial labs are apparently in negotiations with that group to license the intellectual property and offer widespread testing. It is likely this paradigm will be repeated many times as many new selective agents (kinase inhibitors, growth factor receptor blockers, proteasomal inhibitors, angiostats, etc.) go into clinical trials. It is worth remembering in this regard that iressa might not have been FDA approved if the response rate had been any lower. One wonders how many drugs that showed little efficacy in an unselected population are in fact highly efficacious in selected patient populations. Diagnostic testing using the methods described herein will likely answer that question, at least in some cases.

Integration Within Evidence-Based Medicine

To put the preceding information within the broad context of evidence-based oncology, it is useful to observe that, although Osler observed that medicine was an art based on science, it

is increasingly driven by that science, which inexorably seeks to mechanically define human disease. As the basic biology of cancer is increasingly understood, the opportunity to employ that knowledge to diagnostic and therapeutic advantage will increase in direct proportion. Given the rapid increase in our knowledge of the functions of the human genome in health and disease, it is incumbent on the practitioner to incorporate this knowledge into the daily practice of oncology. This is no small task; the rate of accumulation of new and relevant knowledge of cancer mechanisms, diagnostic tests, and potential new therapies is set to increase exponentially, as the true value of research on the human genome is realized. Ideally, as in the iressa and lung cancer example noted previously, this new knowledge should be applied as soon as practical. In reality, the need for convincing evidence will limit the rate at which this knowledge and its associated therapies become standard of care. In between is a vast landscape of clinical research that will be required to provide this evidence. The need for targeted translational and clinical research to move discovery from the basic science laboratory to the patient has never been more acute, a point recognized and well articulated by the current director of the NIH.⁵³

Concluding Remarks

The preceding discussion attempts to place the many useful technologies derived from molecular biology within a clinical context. While the technology is powerful, it is no substitute for clinical acumen and experience. One need only consider the results of the most cutting edge technology applied to cancer diagnosis and therapy, when the starting material is breast adipose tissue instead of tumor, to appreciate that it is the basic oversights that most commonly result in equivocal or flatly erroneous information. Thus, technology is no substitute for common sense and clinical judgment.

The reverse is also true: untoward affection for historical norms has no place in the future of medicine. Evidence-based medicine demands objective evidence of diagnoses and information used for clinical management. The obvious consequence of this is a need for integration of new technologies within diagnostic evaluations of cancer. However, too often proponents of one or another technology overlook the valid and potentially more efficacious and cost-effective contributions of established or alternative technologies to clinical diagnosis. As a general rule, any diagnostic technology that cannot be delivered for less than a few hundred dollars will not be accepted as a routine diagnostic modality. Consequently, many if not most of the technologies discussed in this chapter are not yet ready for “prime time” within the context of clinical medicine, as opposed to clinical research. Despite this caveat, there is no question that with increasing appreciation of the power of these technologies, coupled with relentless reductions in cost, genomic methods in general will progressively augment the diagnostic armamentarium of clinical oncology.

SECTION THREE

*Cancer
Prevention and
Control*

Cancer Epidemiology

Melissa L. Bondy and
Shine Chang

With examples from the literature, this chapter clarifies aspects of epidemiology, including study designs and prevention or correction of potential biases. This chapter provides insight to clinicians and other health professionals on cancer epidemiology and helps them communicate and interpret research findings to patients. In addition, the chapter reviews the epidemiologic literature, discussing examples and the magnitude of cancer-related risk factors.

Central Concepts of Cancer Epidemiology

Cancer epidemiology is the comparative study of the *distribution* and *determinants* of health-related conditions, especially disease, within defined human populations. *Distribution* of disease means identification, description, and interpretation of patterns of cancer occurrence; determinants are causative or contributing factors to that occurrence, or to the prevention, control, and outcome of cancer.^{1,2} Historically, epidemiology strove to identify and control sources of infectious diseases, but now, especially in industrialized countries, it focuses on chronic diseases such as cancer. Its studies of smoking and lung cancer in the 1950s developed strategies and statistical methods of current cancer research. More recently, the Human Genome Project included studies classified as “molecular epidemiology” that make use of molecular genetic markers, now of interest in cancer and other epidemiologic studies.

Although research capabilities grow and change, cancer epidemiology relies on the historical principles of the general discipline. Epidemiology incorporates research from biologic, clinical, social, and statistical sciences to explore the patterns and causes of disease within a defined population to show influences from patterned, and measurable (i.e., nonrandom), factors. Many (not single) endogenous and exogenous factors cause disease. Analytical epidemiology concentrates on identifying and measuring the relative contribution and interaction of these factors.

Surveillance and Descriptive Studies in Cancer Epidemiology

Public health surveillance, a major aspect of epidemiology, requires systematic gathering and analysis of data related to health outcomes. This gathering and analysis, crucial to public health efforts, is enabled by surveillance systems such

as the Surveillance, Epidemiology, and End Results (SEER) Program established by the National Cancer Institute in 1973. The SEER program includes 14 population-based cancer registries invaluable to epidemiologists (<http://www-seer.ims.nci.nih.gov>).³

SEER collects cancer information on about 26% of the U.S. population and, offering more data than other surveillance projects, now serves as the primary source of insight into U.S. cancer incidence and trends. SEER verifies and describes virtually every new case of cancer in its reporting area, and thus its population-based data span the disease spectrum and are more representative of cancer trends in the United States than reports from individual hospitals. These reports are limited by referral patterns, specialized patient populations, and small case sizes and do not permit accurate analysis of trends and incidence patterns. For epidemiologists, SEER, and SEER-type registries, indispensably delineate case-originating populations for calculating reliable incidence rates.⁴

Public health and epidemiologic research also gain from the efforts of other agencies. Annually, the American Cancer Society publishes *Cancer Statistics*, available on its Website (<http://www.cancer.org/>). It estimates the U.S. rates of cancer occurrence, the numbers of deaths, newly diagnosed cases, and survival rates, and describes behaviors affecting risk of cancer and use of screening tests. A resource available for international cancer incidence, prevalence, mortality, and survival data is the International Agency for Research on Cancer (IARC) at <http://www-dep.iarc.fr/>.⁵ Several IARC-designed software packages permit online calculation of cancer trends by geographic location, age, and gender. IARC also has on its Website the Automated Childhood Cancer Information Systems, a database of childhood cancer in Europe.

Analytical Study Designs

Some epidemiologic studies, such as randomized intervention trials and randomized controlled clinical trials, follow the principles of scientific experimentation in which a treatment or intervention of interest and the control condition are randomly assigned.² Although such studies attempt to minimize systematic or methodological errors through randomization, other well-designed and well-conducted nonexperimental (observational) studies also can provide accurate estimates of treatment effects.⁵⁻⁸

Nonexperimental analytical studies assess the causal influence of potential risk factors, which, because of ethical

or practical issues, cannot be evaluated experimentally. Observation of *naturally* occurring exposures identifies risk factors and their weight in disease incidence. A subtle point is that such exposures must show a difference between healthy and diseased participant groups of such quantity to make comparison possible and useful. Exploring them, epidemiologists often employ cohort and case-control studies.

Cohort studies: Cohort studies evaluate participants initially free of a specific disease of interest whose exposure status can be quantified. Subjects are followed for a defined time period to ascertain endpoints, such as new events in, or death from, disease. The disease rate in the exposed group is then compared statistically to the rate in an unexposed group to generate a relative rate ratio or relative risk that indicates the increase or reduction in risk associated with the exposure of interest. A prospective cohort study resembles a clinical trial in which subjects are not randomly allocated to an exposure arm. Rather, as already mentioned, exposure (or lack of exposure) occurs “naturally” and the investigator uses variations in the levels of exposure to evaluate differences in the risk of disease during some follow-up period.

An example of a notable cohort, the Nurses’ Health Study, began in 1976 to track 120,000 U.S. registered nurses. The initial goal of the cohort was to evaluate the effect of oral contraceptives and risk of breast cancer,⁹ but data from the Nurses’ Health Study have also provided insights into health outcomes such as heart disease and other types of cancer and important clues about estrogens and the etiology of breast cancer. Because they trace subjects over time, cohorts permit efficient study of relatively common diseases with a reasonably long latency period from exposure to disease onset. They may be impractical for the study of rare cancers because, in studies of rare cancers, statistically meaningful results can be achieved only by assembling and long-term following of higher than average risk individuals, whereas cohorts used in studies include people of average risk and experience. Cohort studies may be forward looking or *prospective*, as in clinical trials following up subjects in real time, or historical or *retrospective*, using records to identify the study population and then reconstructing their exposure and subsequent disease experience.

Case-control studies: To evaluate potential causal associations of rare cancers, *case-control studies* are more efficient than cohort studies. They identify and recruit individuals diagnosed with cancer from a defined population, location, and time period. These subjects are compared to a group with identical characteristics as the case but without the disease. The investigators employ comprehensive and carefully analyzed self-reports, health records, and biologic specimens to reconstruct the cases’ prediagnosis exposure experience. They assign a “reference” date substituting for a diagnosis date to each control, whose exposure experience before that date is reconstructed. The exposure frequency of the case group is then compared statistically to the exposure frequency among the control group. The resultant statistic, known as an odds ratio (OR), is analogous to a relative risk and serves as a measure of the strength of the association between the exposure and the disease.¹⁰

Cluster investigations: Clinicians often encounter concern in their communities about multiple cancer occurrences (i.e., a cancer cluster) that are feared to have resulted from a shared environmental exposure. Cluster investigations

use standard epidemiologic study designs, primarily case-control studies, to ascertain the existence of area-specific excess of cancer cases (i.e., spatial cluster) or in a limited time period (i.e., temporal cluster) or both (space-time cluster).^{11–13} Public health agencies must investigate cancer clusters and communicate findings to the public,¹⁰ and in the United States, clinicians should refer cluster inquiries to local health departments or the U.S. Centers for Disease Control and Prevention (<http://www.cdc.gov> or <http://www.atsdr.cdc.gov>). Such investigations, however, seldom verify cancer clusters.¹⁰

Statistical Measures in Epidemiology

Epidemiologic analyses generally focus on the strength or magnitude of an exposure–disease association, rather than on statistical hypothesis testing using a *P* value.² *P* values provide a measure of probability for observing the study results, or results more extreme than those observed, if indeed no true association exists. *P* values provide limited information on the strength, direction, or precision of an effect measure or on the extent to which confounding or other bias explains an association (or lack of an association) between exposure and disease.

One of several measures of *relative risk* is often used to estimate either/or, or dichotomous, outcomes, such as disease occurrence versus no disease.² In a cohort study, where disease rates can be calculated directly, the ratio of incidence of those exposed to an agent can be compared with the rate of those unexposed. If the rates are the same in the two groups, the ratio is 1:1, or the relative risk is 1.0, indicating no association between exposure and disease. A ratio larger than 1, for example, 2:1, shows the exposed group has a higher rate of disease than the unexposed group. If the rate is lower in the exposed than the unexposed group, the ratio will be less than 1, suggesting exposure provides protection.

The further the effect measure is away from the “null” value of 1.0 in either direction, the stronger the association. Notice that a relative risk of 2.0 (2-fold-increased risk compared with the reference group) is equivalent in strength to a relative risk of 0.5 (half the risk of the reference group). In case-control studies, in which rates of disease are not calculated directly, the *odds ratio* used is an effect measure on a ratio scale and, as mentioned previously, is functionally equivalent to a relative risk. Other types of ratio-based relative risks are rate ratios, hazard ratios, standardized mortality ratios (SMR), standardized incidence ratios (SIR), and proportional mortality ratios.

Confidence intervals measure the precision of an effect measure, such as relative risk and odds ratios. As with *P* values, confidence intervals are functions of the variability of the data and the sample size. For example, a confidence interval provides a likely range in which the true effect measure lies within some level of confidence, often calculated as 95% confidence intervals.

Relative risks are important to help judge whether an association is causal and to estimate the degree that exposures increase or decrease risk. Relative risks, however, are comparative measures, not “absolute” measures of risk from exposure.

Attributable risk measures (expressed as a number or percentage) provide estimates of the actual rate of cases “due to” exposure, assuming there is a causal relationship.¹⁰ Attribut-

able risks indicate the proportion of the disease possibly preventable if an exposure were removed from a specified population at risk. Estimating attributable risk for specific exposures helps understand the importance of some exposure in a larger public health context.

Bias and Its Control in Epidemiologic Studies

To varying degrees, all human studies are susceptible to bias, that is, inaccurate measures of the effect of a treatment or exposure on disease. An important goal of any study is to make every effort feasible to minimize the effect of bias.

Three general types of bias can occur: (1) *confounding bias*, when an extraneous factor distorts (increases or decreases) the true magnitude of the exposure–disease association; (2) *information (misclassification) bias*, when information collected on exposure, treatment, disease, or other study factors is inaccurate or incomplete; (3) *selection bias*, when subjects who are sampled, recruited, enrolled, and complete the study are unrepresentative of the population at risk, and inaccurately reflect the exposure–disease relationship in the target population or population at risk.

Confounding: In clinical trials, investigators use randomization to reduce the probability that an extraneous factor will cause bias in the results because “nuisance” factors should be randomly and evenly distributed among treatment groups. In the absence of randomization, however, confounding particularly threatens the validity of results derived from observational studies. For a factor to exert a confounding influence requires that factor to be associated with, or a marker for, the disease of interest and for it to occur at a differing frequency between the exposure (or treatment) groups. When these two conditions hold, the extraneous factor (i.e., the confounder) may bias the exposure–disease association.

Statistical methods to correct (i.e., control or adjust for) confounding, such as pooled stratified analysis or multivariate regression analysis, are available but are effective only if data on the potentially confounding variables are collected and accurate. Thus, observational studies often collect data on many factors for statistical analysis that are not directly related to the cause–effect relationship being investigated. Design strategies can also minimize or eliminate confounding. For example, a study of asbestos exposure and lung cancer could avoid confounding from smoking status by recruiting only nonsmokers. In many instances, confounders are adjusted to correct for residual error based on reports from other investigations that have demonstrated notable associations between the confounder and the outcome. Such an approach may guard against potential error from that confounder but, in cases of limited sample size, overadjusting, or adjusting for too many confounders, can also introduce error as well. In such circumstances, a more conservative approach to the statistical analysis of data may be preferred.

Information bias: The major concern for the validity of epidemiologic research of cancer is inaccurate or incomplete information on study participants’ exposure relevant to etiology. It is usually impossible, especially in retrospective studies, to measure exposure dose and duration during a time thought to be biologically relevant to cancer initiation. In lieu of direct measures, indirect or surrogate measures of exposure are used. For instance, a proxy for blood levels of cotinine, a biomarker of tobacco use, could be self-reported recall of

smoking behavior. Such proxy measures may be useful to approximate real exposure, but they provide only imprecise information on dose, duration, and exposure time. When exposure measures are equally inaccurate between study groups (i.e., nondifferential error), the cause–effect relationship may be attenuated or completely obscured. Nondifferential misclassification of exposure has no doubt been one reason why few environmental agents have been firmly established as known risk factors for cancer.

Differential information bias occurs when comparison groups show differences in the accuracy and completeness of exposure information. Recall bias in case-control studies, for example, can occur when cases are more likely to remember exposures differently from controls. Cases may be more likely to remember relatives having a disease of interest compared with controls, leading to a biased estimate of the effect of the family history. However, some investigators suggest that recall bias may be more theoretical than factual.²

Selection bias: Because human studies include investigation of samples of people from larger populations of interest (i.e., target populations), they potentially include sample selection bias. This problem occurs when exposure or disease frequency in the sample, the study participants, is unrepresentative of that experienced by the target population. Case-control studies are vulnerable to this bias because it is difficult to identify and recruit healthy controls who accurately reflect the baseline exposure in the population that gave rise to the cases. Cohort studies and randomized trials, on the other hand, are susceptible to selection bias from attrition. If participants who are lost during the follow-up period have a different outcome experience from those who remain in the study, final results may also be biased. For this reason, great effort must be expended in prospective studies to ensure the most complete follow-up possible of study participants.

Determining Causality

Epidemiologic studies strive to provide accurate and precise risk estimates of an exposure–disease association. Widely applied concepts originally derived from two papers by Sir Austin Bradford Hill, describing the philosophy and epidemiologic reasoning in causal inference,² include the following criteria to evaluate study results and guide judgments on the likelihood that an association is indeed causal and not merely a random or chance finding.

1. *Strength of the exposure–disease association*. Although their existence does not preclude other sources of error, large relative risks are less likely than small relative risks to result from chance or uncontrolled confounding.
2. *Temporal relationship between exposure and disease onset*. Studies gain strength if they can establish that an exposure preceded onset of disease.
3. *Biologic coherence*. When a plausible biologic mechanism and/or when experimental evidence from animal studies supports the hypothesized relation, more confidence may be placed in the observed relationship.
4. *Dose–response gradient*. If exposure intensity or duration is associated with increased disease frequency, the results appear coherent and believable.
5. *Consistency of results within and across studies*. If multiple reports evaluating the same type of exposure show

similar effects, and/or if multiple studies using different target populations and study designs report consistent results, there is greater evidence to favor a true relationship.

Molecular Epidemiology

Classic or traditional epidemiology, as discussed previously, permits epidemiologists to evaluate risks and environmental causality in cancer. Molecular epidemiology, a hybrid of epidemiology and molecular genetics, enables researchers to assess biologic characteristics influencing cancer susceptibility. The combination of epidemiologic approaches and bench science has effectively “broken open the black box of epidemiology,” a discipline historically left to speculate as to the biologic mechanisms underlying its detected exposure–disease associations.^{14,15} The concept that risk of cancer from a given exposure differs between subgroups of a population is an example of what is known in the epidemiologic vernacular as *effect modification*. Biostatisticians often refer to this heterogeneity of effect as *interaction*. With the advent of polymerase chain reactions and other advanced laboratory methods, epidemiologists incorporating molecular markers into their studies can begin to identify specific suspect endogenous or exogenous host factors at the biochemical or molecular level that put individuals at considerably higher (or lower) cancer risk.¹⁶

Molecular epidemiologic studies aim to determine the roles, including interactions, of environmental and genetic factors in the initiation and progression of cancer. Incorporating genetic markers in epidemiologic studies of cancer etiology shows promise for revealing details of carcinogenic pathways that can provide strategies for prevention and, ultimately, reduce cancer risk. Although the promise for critical advances in understanding cancer is great, molecular epidemiology faces important challenges, such as ensuring the appropriate interpretation of molecular testing and resolving associated ethical, legal, and social concerns.

The use of molecular epidemiology to identify biomarkers also may provide useful information on the extent of exposure to carcinogens and cancer risk. Perera and Weinstein¹⁵ delineated four characteristics important for biomarkers to predict risk: internal dose, biologically effective dose, response, and susceptibility. Describing and determining the occurrence of such suitably selected biomarkers has already advanced research on the mechanisms of cancer initiation and promotion and enabled improved assessment of the cancer risk of healthy individuals. Moreover, the knowledge that gene mutations and changes in their expression underlie carcinogenesis has spurred the hunt for aberrant genes and their associated proteins.

Molecular parameters added to population-based studies should help to identify genes, proteins, and pathways involved in cancer development caused by environmental exposures and susceptible or resistant subpopulations. The exponential growth of scientific technology and information promises rapid expansion of knowledge about the identity of potentially mutant genes and cancer pathways.

As a hypothetical framework for dissecting the development of cancer in individuals, current studies of molecular epidemiology consider both the complex, multistage process of carcinogenesis and heterogeneous responses to carcino-

genic exposures. Improving continuously, measurements of human exposure to carcinogens have been successfully applied in a number of molecular epidemiologic studies. Inherited and acquired genetic predispositions to cancer have been, and continue to be, identified. Correlating inherited genetic polymorphisms with other cancer risk factors shows considerable promise that molecular epidemiologists will gain in their ability to assess multiple biomarkers and to predict an individual's risk for specific diseases. The field has the near-term potential to impact regulatory quantitative risk assessments, useful in the determination of allowable exposures, and molecular epidemiologic data may also help identify individuals most apt to benefit from cancer prevention strategies.

Molecular epidemiology investigators employ traditional epidemiologic study designs, including case-control and cohort studies that focus on one or more biologic markers that may show an association between exposure and disease outcome. Molecular studies often raise the “nature versus nurture” question, with evidence supporting consensus that gene–environment interplay explains many chronic diseases, including cancer: “Genetics is the loaded gun, and the environment pulls the trigger.” Among studies supporting such a statement is a recent large, although statistically limited, study of twins concluding that environment plays a substantial role but requires genetic potential in causing sporadic cancers.¹⁶

Molecular epidemiology studies also face the methodological challenges to traditional epidemiologic studies, such as precise measurement of exposure and effects, appropriate selection of study samples, and reduction of the influence of confounders and potential competing risk factors. One important issue is assuring an adequate sample size for study because the prevalence of a specific genetic polymorphism or other biomarker under investigation is often either very rare or quite high, either of which situations require a large number of cases to detect an association.¹⁷ One approach to this problem is to combine data from several studies, particularly of rare cancers, to obtain adequate statistical power for meaningful conclusions. When sample sizes are modest, especially, caution in interpretation of data or linking findings with further implications is in order.

The Global Cancer Burden

Estimates of the global cancer burden have been made for 1975, 1980, 1985, and 2000.¹⁸ These estimates include all forms of cancer except nonmelanoma skin cancer, poorly registered on incidence statistics and infrequently fatal. In 2000, cancer deaths among men totaled 4.7 million, and an estimated 5.3 million new cases were diagnosed, an increase of 1.5 million from 1985, lung cancer being the most common form of cancer in men, with an estimated 902,000 new cases in 2000. The estimated number of lung cancer cases has increased by 35% over the 5-year period covered by these estimates. Other cancers showing notable increases are colorectal, prostate, bladder, melanoma, and lymphoma, particularly non-Hodgkin's lymphoma. Some increases may be due to better surveillance or impaired precision in the estimation of rates but likely have a real etiologic component.

In 2000, it was estimated that 4.7 million new cases of cancer occurred in women, an increase of almost 1 million new cases over the previous 5 years. Breast cancer, the most common form of female cancer, has shown an increase of 94% in the past 25 years, nearly doubling, with an estimated 1 million new cases in 2000. A similar increase has taken place in oral cavity and colorectal cancers and in lymphoma. The largest relative increase of cancer in women has been in lung cancer, up from 126,700 new cases in 1975 to 337,000 in 2000, an increase of 26%, almost entirely explainable by women's increase in smoking.¹⁹

The number of new cases of cancer worldwide apparently doubled between 1970 and 2000 and should show even further rates of increase. The estimated number of new cases of cancer was 5.9 million in 1975, 6.4 million in 1980, and 7.6 million in 1985. If age-specific rates remain constant at the 1985 levels, 8.4 million new cases would occur in 1990 and 10.3 million new cases in the year 2000. Beyond 2000, the absolute number of cancer cases should continue to rise as the post-World War II generation crosses the age-risk threshold. In many countries, this generation is the first whose numbers were not reduced by a great war and the first to have benefited from the advances in medical care and treatment witnessed in the second half of this century. In contrast to earlier populations, most members of this generation are still alive at ages where cancer risk rises.

Geographic and Temporal Variation in Cancer Risk

The notable international variation of cancer rates and types has led to the growing interest in geographic pathology or cancer mapping as a tool in cancer epidemiology. These descriptive studies offering data on disease in varied groups in multiple locations are important for generating hypotheses in epidemiology, as in-migrant or ecologic studies evaluate exposure and disease on a population rather than individual level. For example, one can look at general exposures, such as smoking, sunlight, or dietary fat intake, and plot them against the incidence of the disease. If one plots dietary fat consumption by country with the incidence of breast cancer, for example, one finds greater rates of breast cancer in countries with high dietary fat intake. Because the dietary intake for a country reflects intake of its people en masse and is not directly measured and linked to each individual cancer patient's intake, this association might be false. However, such associations can help investigators identify new avenues for further investigations.

Cancer mapping produces other data useful for hypothesis-generating studies. Geographic variation can be seen from cancer mortality or incidence maps using computer-generated mapping programs for areas as small as a county and used to uncover spatial clusters or geographic variation of common tumor types. The National Cancer Institute (NCI) has published an atlas of cancer mortality maps at the county and state level, available for viewing on the NCI Website (<http://www-seer.ims.nci.nih.gov>). These maps revealed high rates of oral cancer among rural Southern women and prompted investigators to conduct case-control studies into a long-standing practice of snuff dipping among the cases, leading to implementation of smokeless tobacco prevention programs.

Cancer Risk Factors

Epidemiology shows that, because different world populations show different types of levels of disease, much human cancer may be avoidable. For example, immigrants take on the cancer pattern of their new home, as immigrants to Australia have within decades, or Japanese immigrants experience higher breast cancer rates after a few decades in the United States than in comparative populations in Japan. Further, groups with unique and differentiating cultural or lifestyle characteristics such as Seventh Day Adventists, Mormons, or African-Americans in parts of the United States have cancer patterns distinct from those of the general community. Comparisons support the generally agreed-upon estimate that upward of 80% to 90% of cancer may be attributable to environmental factors such as dietary, social, and cultural practices.¹⁹

However, such factors have not been clearly delineated, nor has it been made clear how individuals are affected by combination or accretion of factors. Cancer prevention efforts have focused on efforts to reduce exposures or behaviors suspect in incidence, such as smoking, and to promote those with protective effects, such as physical exercise, and, as well, to reduce concerns over exposures or acts that may have trivial or no impact on cancer, such as cell phone use. Cancer control studies thus embrace a variety of elements and approaches and aim to reduce the incidence of cancer, and failing which, to reduce mortality, either by finding disease at an early and curable stage or by improving survival rates stage-for-stage by therapeutic improvements. Cancer prevention, control, and education programs bring epidemiologists into contact and cooperation with several other disciplines including clinical science, behavioral science, and health education and communication.

Tobacco

Tobacco smoking, the single most lethal human carcinogen, remains the largest single avoidable cause of premature death worldwide.²⁰ Estimates connect at least 16% of all cancers in developed countries to tobacco use, with a higher proportion of tobacco-related cancers among men (25%) than women (4%). Tobacco-related cancers include those of the oral cavity, pharynx, larynx, lung, bladder, pancreas, kidney, renal pelvis, and endometrium. However, in the last case, reduced rather than increased risk is thought to result from antiestrogenic effects of tobacco use rather than exposure to the more than 55 carcinogenic compounds identified by the International Agency for Research on Cancer.²¹ For more than 40 years, it has been clear that prevention of smoking would lead to substantial reductions in death associated with lung and other cancers and heart disease, bronchitis, emphysema, and other conditions. Nonetheless, tobacco-related disease has increased in many parts of the world, especially in developing countries where tobacco use has started within the past 30 years and involves 80% of the world's daily smokers, now estimated at 1.1 billion.

Tobacco addiction mechanisms are complex. As suggested by reports of associations between smoking quit-rates and specific polymorphisms in the dopamine receptor gene (DRD2),²² a key receptor in the mesolimbic dopaminergic reward system, the genetic susceptibility of individuals to

tobacco addiction varies considerably. Just as multiple factors affect behavior, multiple factors likely influence susceptibility to tobacco-related cancers, which helps explain why not all tobacco users get cancer.

Important smoking outcomes appear to be related to gender, ethnicity, and life experiences. Women, relative to men, and African-Americans, compared to white Americans, appear to have higher risk of bladder cancer associated with tobacco use. Age is also an important factor because smokers usually begin during their teens or early adult years. Early-start smokers persist and smoke higher amounts than late starters, increasing their risks over time. Synergistic effects with tobacco use have been observed with asbestos and crystalline silica in occupational settings, and with alcohol acting as a solvent, probably facilitating absorption of smoking by-products, whereas a diet high in intake of fruits and vegetables may impede the formation of smoking-related DNA adducts, reduce the DNA damage from tobacco carcinogens, and promote other mechanisms that prevent cellular damage and reduce risk.

Recent tobacco research includes the evaluation of exposure to environmental tobacco smoke and outcomes of exposure-related adverse health events, including lung cancer. Based on 30 epidemiologic studies, the United States Environmental Protection Agency (EPA) concluded that environmental tobacco smoke was a human lung carcinogen and that nonsmokers who are exposed to environmental tobacco smoke faced increased risk of lung cancer.²³ Although diluted with ambient air, environmental tobacco smoke tends to have more carcinogens than smoke inhaled through filters. However, the current emphasis of research and health policy in Western countries on passive smoke inhalation should not divert attention from the major public health issue of active cigarette smoking: smokers are at much higher risk of cancer

than others involuntarily inhaling cigarette smoke. Therefore, any program of cancer control should put control of smoking first; such control is likely to have greater impact on reducing cancer incidence and cancer mortality than any other current strategy.

Viruses and Infection

The contribution of viruses to the public health burden of cancer incidence is greatest in young to middle-aged individuals, the age-incidence curve peaking before middle age.²⁴ The estimated attributable risk associated with viruses and cancer is about 15% worldwide.²⁵ However, to date, only five viruses have been firmly established associated with increased cancer risk: human papilloma virus (HPV), with an increased risk of cervix cancer in women; Epstein-Barr virus (EBV) with an increased risk of nasopharyngeal cancer and Burkitt's and Hodgkin's lymphoma; human T-lymphotropic virus type 1 (HTLV-1), with adult T-cell leukemia and some types of non-Hodgkin's lymphoma; hepatitis B and C with an increased risk of primary liver cancer; and human herpesvirus 8 (HHV-8) infection with Kaposi's sarcoma and some forms of non-Hodgkin's lymphoma (Table 22.1).²⁴ Advances in technology and laboratory techniques, such as polymerase chain reaction (PCR) have facilitated research, but because the mechanisms by which viruses cause cancer may leave little evidence of infection and because some viruses can remain latent for many years, definitive implication of specific viruses in carcinogenesis has been difficult.

Long latency periods between infection and cancer diagnosis, and the fact that only a portion of people who are infected develop cancer, suggest that although viral agents may increase the risk of individuals for developing cancer they are not the sole determinant for developing the disease.

TABLE 22.1. Known viral risk factors for selected human cancers.

<i>Viral risk factor</i>	<i>Cancer type</i>	<i>Other factors that influence risk</i>
Epstein-Barr virus (EBV)	Burkitt's lymphoma Nasopharyngeal carcinoma B-cell lymphoma Hodgkin's disease Breast cancer ^a	Malaria Nitrosamines Immunodeficiency, human immunodeficiency virus (HIV)-1
Hepatitis B virus (HBV)	Liver cancer	Aflatoxin, alcohol
Hepatitis C virus (HCV)	Liver cancer Splenic lymphoma	Aflatoxin, alcohol
Human herpesvirus-8 (HHV-8)	Kaposi's sarcoma Primary effusion lymphoma Multicentric Castleman disease	HIV-1 EBV, HIV-1 HIV-1
Human papillomavirus (HPV)	Cancer of the cervix, vulva, vagina, penis, anus, skin, and oropharyngeal region	Smoking, oral contraceptive use, multiparity, other sexually transmitted diseases
Human T-cell lymphotropic virus type 1 (HTLV-1)	Adult T-cell leukemia/lymphoma (ATL)	
Simian virus 40 (SV40)	Mesothelioma Non-Hodgkin's lymphoma, brain and bone tumors, B-cell lymphomas ^a	Asbestos
<i>Helicobacter pylori</i> ^b	Gastric cancer	Smoking, chronic inflammation, poor diet

^aUnconfirmed, but suspected.

^bBacterial risk factor.

However, great geographic variation in rates of infection and virally related cancer worldwide suggests that much infection-related cancer could be prevented by control of viral infection. This is no trivial matter, because viral infection rates are high in many parts of the world and the types of cancers associated with them often have poor prognoses and few successful treatment options. Obviously, effective vaccination programs against these viral infections would considerably reduce the burden of these forms of cancer and the global problem.

Bacterial infection has also been linked to cancer risk in the example of *Helicobacter pylori* (*H. pylori*) infection and increased risk of gastric cancer, the second leading cause of cancer mortality in the world.^{24,25} Incidence rates of gastric cancer vary geographically, particularly for the intestinal type, which is typically accompanied by chronic atrophic gastritis and intestinal metaplasia. Both chronic atrophic gastritis and intestinal metaplasia, possible precursors to gastric cancer, are thought to result from *H. pylori* infection, suggesting an important role for *H. pylori* infection in gastric carcinogenesis.²⁶ Other evidence comes from epidemiologic investigations linking areas with high rates of *H. pylori* infection to regions with high rates of gastric cancer, although the consistency of such findings is hampered by multiple bacterial strains that vary in virulence and promotion of conditions that enhance carcinogenesis, such as chronic inflammation and decreased stomach acid secretion.^{27–29} Risk factors for *H. pylori* infection are associated more with socioeconomic factors, such as overcrowding, family size, and bed-sharing rather than lifestyle behaviors, such as tobacco use, or diet. Despite the apparent complexity of the relationship between *H. pylori* infection and gastric cancer, increasing evidence supports efforts to control and reduce *H. pylori* infection as a means to reduce cancer risk, particularly among children, for whom infection rates are high and reach nearly 100% by adulthood in areas of high infection rates.

Sunlight Exposure

Exposure to sunlight has been well established as the major agent in the development of skin cancer, particularly solar ultraviolet (UV) A and B wavelengths. Exposure to UVA can result in DNA base damage, strand breaks, and DNA-protein cross-links, whereas exposure of DNA to UVB mainly results in dimerizations between adjacent pyrimidines, which may predispose for *p53* mutation hotspots.³⁰ Knowledge of the underlying molecular mechanisms for sunlight's role in skin carcinogenesis contributes to efforts in prevention and control in human populations, but for successful public health interventions, other information is necessary.

The rapid rise in the worldwide incidence of skin cancer in the past decade is hypothesized to result in part from the migration of Caucasian populations to areas for which their skin is not well adapted. This hypothesis is supported by reports linking skin cancer incidence with solar radiation at different geographic latitudes.³¹ Locales with greater annual sun exposure tend to have higher incidence of skin cancer, but many other factors also contribute to skin cancer risk, such as age at exposure, ethnicity, skin color, lifestyle, occupation, and individual genetic susceptibility.

Important differences between the subtypes of skin cancer suggest differences in carcinogenic pathways. Squamous cell cancer (SCC) develops from stem cells in the follicular and interfollicular region of the dermis; basal cell carcinoma (BCC) arises from basal cells in the skin and follicular infundibulum; and melanoma develops mainly from melanocytic nevi. Most lesions develop on the face in BCC, the most common form of human skin cancer worldwide, but nearly a third of BCC lesions occur on skin typically protected from the sun. It rarely appears on sun-exposed sites such as the forearms and the backs of hands, as SCC does. Some research suggests childhood or adolescent exposure during childhood and adolescence, both intermittent sun exposure and severe sunburns, predisposes for adult BCC and melanoma and associates adult sunlight exposure with SCC risk.³²

During the past 30 years melanoma incidence, particularly for lesions appearing on women's legs and men's torsos, where sunlight exposure tends to be intermittent, has increased worldwide. Melanoma is the rarest type of skin cancer, but its mortality rates can be high without early detection and treatment. Such efforts can be directed toward groups at high risk, such as those with pale skin, or red or blond hair, who freckle easily, particularly those with higher numbers of nevi from sun exposure during childhood.

Two major hypotheses have emerged to explain variation in skin cancer incidence related to sun exposure: first, that the pattern of exposure (i.e., intermittent or steady) and total accumulated exposure contribute to risk independently; and second, that exposure before age 10 strongly determines lifetime risk, although sun exposure in adulthood may influence the manifestation of outright cancer. Major support for the importance of childhood sun exposure comes from Australian studies, where early age at immigration predicts increased risk of skin cancer.³³ Intermittent sun exposure with sunburn in childhood has been associated with later increased BCC risk, and other research suggests that adult exposures may promote skin carcinogenesis through response to short-term exposure to sunlight.

The main factor responsible for the dramatic increases in skin cancer rates is generally held to be the increased levels of recreational sun exposure (as during sunbathing sessions or outdoor recreational activities), a result of the economic improvement of many white communities. Since 1980, the sun tanning fashion has fostered marketing of sunbeds and their use,³² as in Sweden where nearly half of women 15 to 35 years old reported regular sunbed exposure.³⁴ This habit is suspected to increase the risk of skin cancers, but further studies are needed to correctly assess the magnitude of risk associated with the so-called "UVA sun tanning."³⁴ The important message is to avoid overexposure to sunlight and, in particular, to avoid sunburns at all times and to be particularly careful to protect children.³⁵ Australia and New Zealand, where sun exposure can be intense and of high annual duration, have effectively mounted solar protection campaigns that suggest the possibility of achieving population-wide success in skin cancer prevention and control.

Diet

Diet and nutritional factors became the focus of serious attention in the etiology of cancer after the 1940s.³⁶ Initially dealing

with the effect of feeding specific diets to animals receiving chemical carcinogens, research turned to the potential of associations with human cancer risk. Estimated national per capita food intake data and cancer mortality rates were compared, and data established risk with diet, particularly associating higher dietary fat intake and increased rates of breast cancer. Improved dietary assessment methods and the identification and correction of certain methodological difficulties gave rise to the science of nutritional epidemiology.³⁷

As the complexity of the association with cancer for fats and fatty acids has unfolded, research interest has broadened to include other foods and food compounds. In general, high consumption of fruits and vegetables is associated with a reduced risk of a number of forms of cancer including lung, oral, pancreatic, laryngeal, esophageal, bladder, and gastric cancer, with three major exceptions being the lack of strong association with hormonally related cancers, such as those of the prostate, breast, ovary, and endometrium.³⁸

Investigation into reduced risk associated with consumption of dark green, leafy vegetables and red and yellow fruits and vegetables with high levels of micronutrients thought to have antioxidant and other anticarcinogenic properties, have identified components of interest. Compounds, such as phytoestrogens in soybean products and lycopene and other carotenoids in high concentrations in tomatoes and other fruits and vegetables, have been the subject of recent studies developing interest in testing these food compounds as chemopreventive agents in prevention trials.³⁸ Investigators are showing interest not only in the micronutrient compounds but also in how foods may be metabolized (e.g., glycemic index) and prepared (e.g., grilled meats have become suspect). Interest in the potential for diet and nutrition to help determine cancer risk is flourishing.

Alcohol Consumption

The strongest evidence of a causal role for alcohol consumption in carcinogenesis comes from investigations of cancers of the oral cavity, pharynx, larynx, and esophagus.³⁹ To assess alcohol's effect independently from the strong confounding effect of tobacco use, another important risk factor for these cancers, studies have evaluated risk associated with alcohol consumption among groups of nonsmokers, although carefully conducted studies among smokers suggest a synergistic effect for alcohol consumption linked to tobacco use.⁴⁰ Another confounding factor associated with alcohol consumption is poor diet, particularly low fruit and vegetable consumption. Modification of alcohol's effect on cancer risk suggests the importance of antioxidant or other anticancer components of fruits and vegetables, such as vitamin A, depleted from liver stores by alcohol.

For risk of liver cancer, evidence suggests a modest effect of alcohol, but risk appears to be synergistically enhanced by viral hepatitis infection. The literature is unclear about whether alcohol-induced liver cirrhosis increases risk of liver cancer because not all alcoholics with liver cancer have cirrhosis. Epidemiologic studies that rely on self-reports may include underreporting of intake by alcoholics and neglect physiologic differences between alcoholics and others consuming alcohol, but it is plausible that heavy, but not moderate, drinkers may consume quantities of alcohol necessary to demonstrate an association with liver cancer.

A number of investigations suggest a role for alcohol in the development of pancreatic and colon cancers, as well as hormonally responsive cancers of the breast and prostate for which the mechanistic pathways may differ from those of cancers of the oral cavity, pharynx, larynx, and esophagus.⁴¹⁻⁴³ Both acute and chronic intake have been shown to increase circulating estrogens and to decrease circulating androgens in both men and women, consistent with the increased breast cancer risk observed for higher consumption of alcohol.⁴³ However, only heavy alcohol intake, not moderate consumption, has been associated with increased prostate cancer risk, suggesting an alternative pathway rather than the putative increased androgen exposure mechanism.

The influence of the type of alcohol and its metabolites remains of interest but unclear. Mouthwash with more than 25% alcohol has been associated with higher risk of mouth cancer, and studies for some cancers suggest that distilled liquors have more potent effects than other types of alcohol. Other studies suggest some compounds in alcoholic beverages heighten or lessen carcinogenic effects. Ethyl carbamate and acetaldehyde, by-products of alcohol metabolism, are both animal carcinogens; conversely, resveratrol, a compound in wines, beer, and grape skins, has received much recent attention for several of its anticarcinogenic properties.⁴³ Although high consumption of alcohol is clearly not recommended in regard to cancer risk, it remains unresolved whether consumption that is more moderate increases risk sufficiently to cause concern.

Obesity

Large-scale prospective studies assessing the long-term effects of obesity have shown that obesity increases cancer risk. The American Cancer Society Study described the pattern of mortality related to relative body size for 900,000 subjects followed for 16 years.⁴⁴ Obese women had an increased risk of cancer of the endometrium, cervix, ovary, and breast; obese men had an increased risk of stomach and prostate cancer; and both obese women and men had increased risk of esophageal, colorectal, liver, gallbladder, pancreatic, and kidney cancer, as well as non-Hodgkin's lymphoma and multiple myeloma. The Danish Record-linkage Study comparison of a cohort of nearly 44,000 obese persons with the whole Danish population found the obese had an increased incidence of cancers of the esophagus, liver, pancreas, colon, prostate, and kidney.⁴⁵ More recent studies indicate in women a clear relationship between obesity and increased risk of endometrium, renal cell, gallbladder, and colorectal cancer, and among men, greater risk of colon cancer, renal cell cancer, gallbladder cancer, and esophageal and gastric cardia adenocarcinoma. Lung cancer is the one neoplasm that the obese may be less prone to develop than leaner individuals, possibly because of smoking-related effects on resting energy expenditure, although some have argued that residual confounding by smoking or weight loss due to presymptomatic disease may bias findings.

The relationship between breast cancer and obesity is less clear. Among postmenopausal women, the obese have a greater risk of breast cancer than their leaner counterparts, whereas among premenopausal women, the obese appear to experience modest protection from breast cancer compared to leaner women.⁴⁶ For postmenopausal women, the effect of

obesity and breast cancer risk appears to be greater in those who have never used hormone replacement therapy, supporting the hypothesis that in the absence of ovarian sources of estrogens, increased risk is derived from excess estrogen converted from adrenal hormones in the fat tissue of heavier women.

For prostate cancer, no strong relationship for either risk or mortality has been consistently demonstrated with adult obesity, usually measured as body mass index (BMI) equal to or greater than 30 kg/m². BMI, the most widely used measure of body composition in epidemiologic studies, serves as the basis for the NHLBI/NIH and WHO clinical definitions for underweight, normal, overweight, and obesity.^{47,48} The components of BMI, height and weight, are easy to recall accurately, easy and inexpensive to measure, and generally recorded in a variety of documents, all considerations for conducting research in large populations. However, using BMI to quantify obesity and body composition has drawbacks because the same BMI result will be found in people with vastly different height and weight, BMI is correlated with both lean mass and fat mass, and it provides no information about the ratio of lean to fat mass or about body fat distribution, which has metabolic implications for steroid hormone balance. Characterizing body composition using only BMI thus may mask associations between carcinogenesis and specific components of obesity.

Other measures of body composition, particularly the ratio of waist and hip circumferences and skin-fold thickness, have also been used in epidemiologic research. Ratio measures must be interpreted carefully within the context of underlying body size distributions of the study sample, whereas assessing body composition using skin-fold thicknesses requires special training for accurate measurement. Recent work identifying hormones, growth factors, and cytokines that are associated with specific components of body composition present new opportunities for better mechanistic investigations. Overall, although the mechanisms underlying the obesity–carcinogenesis relationship are not fully understood, they are likely to be complex, because both obesity and cancer are multifactorial diseases involving many genetic pathways.

Physical Activity

The most consistent evidence supporting a role for physical activity in the prevention of cancer comes from studies of colon cancer. As reviewed by Colditz et al., nine of nine case-control studies and six of seven cohort studies across different populations consistently reported significantly reduced risk of colon cancer as a result of physical activity independent of BMI effects.⁴⁹ In general, a dose–response pattern exists for levels of physical activity and colon cancer; increases in intensity, frequency, or duration show an inverse relationship to risk. Hypothesized mechanisms include reduced exposure time in those whose physical activity increases gut motility and reduces the bowel transit time of potential carcinogens. For breast cancer, a protective effect of physical activity in premenopausal and postmenopausal women measured at different intensities and times is indicated by a growing number of studies in the United States and abroad, as reviewed by McTiernan et al.⁵⁰ Likewise, but in far fewer studies than for colon or breast cancer, is emerging a

pattern of reduced risk of pre- and postmenopausal endometrial cancer associated with physical activity. Other investigations report protective effects associated with physical activity for prostate and testicular cancer, albeit less consistently so than for colon and breast cancer.

The beneficial impact of physical activity on cancer risk may result from its direct influence on biochemical factors important in the carcinogenic pathway, such as growth factors, hormones, and immune function. Physical activity lowers levels of insulin, glucose, and triglycerides, and raises HDL cholesterol, which may protect against proliferation of colon and breast cancer lesions. Exercise appears to increase the number and/or the activity of macrophages, natural killer cells, and their regulating cytokines, although epidemiologic data on immune function are limited. Physical activity may also prevent cancer indirectly by prevention and control of obesity and producing physiologic changes in hormone profiles suspect in tumorigenesis. High levels of exercise delay menarche and reduce the number of ovulatory cycles, thereby reducing lifetime exposure to endogenous estrogen and the risk for estrogen-dependent cancers.⁵¹ Exercise may also reduce the risk of hormone-dependent cancers by increasing the production of sex hormone-binding globulin (SHBG) in men and women, lowering levels of circulating bioavailable testosterone and estradiol.

Epidemiologic research on physical activity has been limited in the past by poor quantification. Recent studies have improved efforts to capture, at a minimum, the intensity level, frequency, and duration of physical activities and to factor in nonrecreational or formal exercise. Increasing data have permitted derivation of standardized expenditure values that may serve as a basis for calculating metabolic—and health—values of specific activities. Other approaches include direct measurement devices or even biologic markers, such as doubly labeled water, to quantify physical activity. Ultimately, because it is a modifiable lifestyle factor, physical activity holds great promise for a large positive impact on public health, in addition to reducing cancer incidence.

Occupational Exposures

Occupational exposures have been estimated to account for approximately 4% of all cancers.⁵² Many occupational risk factors for cancer have been identified through epidemiologic research, particularly carcinogenic chemicals commonly used in industry. The International Agency for Research on Cancer furnishes a comprehensive source of occupational exposures associated with cancer in its series of monographs, and the U.S. National Toxicology Program's annual report on carcinogens offers another useful resource. These reports reflect a considerable body of work conducted by scientific researchers in many disciplines including toxicology, carcinogenesis, and epidemiology.

Epidemiologic studies, including retrospective cohort and nested case-control studies, identify increased cancer risk associated with single occupational exposures, particularly when the exposure–disease relationships are clear,⁵³ as for benzene exposure in rubber hydrochloride workers. Studies of rare histopathologic types of cancer in occupational settings have also revealed occupational carcinogens, as, for example, studies relating exposure to vinyl chloride to angiosarcoma of the liver,⁵⁴ a rare (less than 1% of all hepatic cancers) subtype

of hepatic cancers. The impact of mixtures suspected to be occupational carcinogens is harder to characterize because their precise makeup may resist description or be unknown and may vary between exposures. Exposure duration may be short and/or transient.⁵⁵ These issues impede research on the relationships between cutting and lubricating oils and bladder cancer and between diesel exhaust and lung cancer, the first and second most common occupation-related cancers, respectively. Useful research has resulted from the evaluation of large occupational cohorts, such as farmers, laundry and dry-cleaning workers, and painters. However, cohort studies require long follow-up for development of disease and sufficiently large numbers so that enough numbers of cancers of the same organs can be analyzed.^{52,56} Moreover, results from cohort studies may be influenced by secular trends during follow-up, and workers with the same job titles may experience different levels of exposure.

Today, with an improved safety profile in the workforce apparent in many industrialized countries, it is important to ensure that exposure to known carcinogenic hazards in the workplace is not transferred to the preindustrialized countries, whose workers deserve at least the standards of protection achieved in industrialized countries. Specifically, for identified carcinogens, enforced legislation that clearly defined exposure restrictions and dose limits could reduce occupational cancers.

Radiation

Ionizing radiation can damage DNA directly or indirectly by causing the formation of highly reactive free radicals that can damage DNA or induce chromosomal instability in nearby cells not directly damaged by radiation (i.e., the “bystander” effect). Unlike other types of exposures, radiation exposure tends to induce DNA strand breaks that then lead to chromosomal rearrangements, such as translocations, inversions, additions, and deletions. Exposure to ionizing radiation in humans has been consistently associated with leukemia and cancers of the breast, thyroid, and lung.⁵⁷ Evidence comes from studies of radiotherapy-treated patients, residents exposed to environmental radon, workers with occupational exposure to radiation, and, for the largest part, survivors of the Japanese atomic bomb (UNSCEAR) and the nuclear accident at Chernobyl in 1986.⁵⁸

Some studies have focused on children, as excess risk of cancer appears inversely related to age at exposure. From long-term studies of the Japanese atomic bomb survivors, a linear dose–response pattern has emerged for exposure to ionizing radiation and risk of solid cancers, and a linear quadratic dose–response relationship has appeared for leukemia except for the highest levels of exposure.⁵⁹ However, findings from the atomic bomb survivors are based on a single, acute radiation exposure unreflective of the low-level, chronic, or fractionated exposures occurring more commonly in contemporary occupational and environmental settings, for which epidemiologic data often lack good dosimetry information, or show inadequate ascertainment of cancer outcomes, possible screening biases, short length of follow-up for cancer development, and small sample sizes.⁵⁹

With increasing numbers of cancer patients experiencing longer survival, interest has grown in the possible long-term

effects and interplay between radiotherapy and chemotherapy drugs and the effect of radiation exposure in patients with altered immune function. Elevated risk of cancers, such as Hodgkin’s lymphoma, leukemia, and cancers of the skin and lung, has been associated in some studies with previous radiotherapy and chemotherapy treatment for cancer. In such reports, the strength of association has been modified by other risk factors, including smoking and Epstein–Barr virus infection.

Hormones

Initially, evidence from many studies seemed to support an increased risk of breast cancer in young women (less than 35 or perhaps less than 45 years of age) associated with current prolonged use (more than 5 years) of oral contraceptives. However, a recent study by Marchbanks et al.⁶⁰ of findings of the Women’s Contraceptive and Reproductive Experiences (Women’s CARE) study found no association between past or present use of oral contraceptives and breast cancer. The findings of this well-conducted, population-based study of 4,575 women with breast cancer and 4,682 controls has enormous importance because more than 75% of the women in the study had used oral contraceptives. Thus, even a small risk associated with such a common exposure could account for a substantial number of new breast cancer cases. The study also reported no difference by dose of estrogen (low or high).

A 1996 meta-analysis of 54 epidemiologic studies of oral contraceptives and risk of breast cancer showed a slightly increased risk of breast cancer to those who took oral contraceptives, compared to nonusers [relative risk (RR), 1.24; 95% confidence interval (CI), 1.15–1.33].⁶¹ The risk diminished steadily after cessation of use, with no excess after 10 years. This meta-analysis had the virtues of large size and inclusion of data from published and unpublished studies conducted around the world, and its finding strongly supports two main conclusions. First, breast cancers diagnosed in women who had used combined oral contraceptives were clinically less advanced than those diagnosed in women who had never used these contraceptives: long-term users, compared to women who never used contraceptives, had lower relative risk for tumors that had spread beyond the breast compared to localized tumors (RR, 0.88; 95% CI, 0.81–0.95). No obvious association appeared in the results for recency of use by women with different background risks of breast cancer, from different countries and ethnic groups, with different reproductive histories, and those with or without a family history of breast cancer.

Other features of hormonal contraceptive use, such as duration of use, age at first use, and the dose and type of the hormone within the contraceptives, had little additional effect on breast cancer risk once recency of use had been taken into account. Further reassuring news is that the relative risks are small and the period at risk appears confined to times of life when the incidence of breast cancer, although not negligible, has not reached the highest levels attained in the latter part of the sixth and seventh decades of life.

In 1995, approximately 38% of postmenopausal women in the United States were using hormone replacement therapy (HRT) consisting of either estrogen or estrogen and

progesterone. Although data from both case-control and cohort studies suggested that HRT may increase the risk of breast cancer, similar studies suggested that HRT decreased the risk of cardiac disease among postmenopausal women. The results from these observational studies led to randomized controlled clinical trials evaluating the safety and efficacy of HRT for primary or secondary prevention of cardiac disease, which, so far, it has not been shown to be.

The Women's Health Initiative (WHI) study, a primary prevention trial, has focused on strategies for preventing cardiac disease, breast and colorectal cancer, and osteoporosis in postmenopausal women.⁶² The 15-year study had several research arms, including an intervention arm of combined HRT with estrogen and progesterone that found combined HRT increased risk of breast cancer and cardiovascular disease. For other medical problems, such as menopausal symptoms or osteoporosis, it was recommended that its use be minimized and that physicians counsel their patients about the potential benefits and risks of combined HRT. The estrogen-only arm of the WHI study ended, so it is more difficult to make recommendations for these women, but women should be aware that the results from the observational studies have consistently suggested that estrogen alone may also be a risk factor for breast cancer, especially after use for more than 5 years.

Other important recent studies have shown support for the association of breast cancer risk and HRT use. The Nurses' Health Study follow-up was extended to 1992, recording 1,935 cases of invasive breast cancer in the 725,550 woman-years of postmenopausal women tracked.⁶³ The risk of breast cancer was significantly increased among women using estrogen alone (RR, 1.32; 95% CI, 1.14–1.54), compared to postmenopausal women who had never used hormones. The risk of breast cancer was also significantly increased among women using estrogen plus progestin (RR, 1.41; 95% CI, 1.15–1.74). Among current HRT users, such therapy for 5 to 9 years was associated with higher risk (RR, 1.46; 95% CI, 1.22–1.74), with a similar risk for 10 years of use. This effect of duration of use for 5 or more years was greater among older women (RR for women aged 60 to 64, 1.71; 95% CI, 1.34–2.18). The relative risk of death from breast cancer was also increased among women who had taken estrogen for 5 or more years (RR, 1.45; 95% CI, 1.01–2.09).

Previous studies of postmenopausal ovarian cancer risk disagree, with some reporting increased risk with estrogen use and others finding either a protective or null effect. Most of these studies were relatively small and limited by incomplete information about ovarian cancer risk factors, but two recent large studies linked hormone use and ovarian cancer. A large prospective study⁶³ associated postmenopausal estrogen use for 10 or more years with increased risk of ovarian cancer mortality, and a recent Swedish study⁶⁴ reported that estrogen use alone and estrogen-progestin used sequentially (progestin used on the average of 10 days/month) may add to risk for ovarian cancer. In contrast, estrogen-progestin used continuously (progestin used on average 28 days/month) seemed to confer no increased ovarian cancer risk.

A study of ovarian cancer risk of women in the Breast Cancer Detection and Demonstration Project, who used estrogen-only replacement therapy, particularly for 10 or

more years, found them at significantly increased risk of ovarian cancer.⁶⁵ Women using short-term estrogen-progestin-only replacement therapy were not at increased risk, but risk associated with short-term and longer-term estrogen-progestin replacement therapy warrants further investigation.

Risk Factors for Childhood Cancer Occurrence

Environmental risk factors for adult cancer generally involve long latency periods from exposure start to clinical onset of disease. Cigarette smoking illustrates this point; smoking usually begins during adolescence, but associated malignancies become apparent only after many decades. However, the genetic processes that go awry and lead to childhood cancer are likely different from that of adult malignancies, as suggested by a shorter time for the carcinogenic process to occur in children. Infancy, when embryonal neoplasms such as neuroblastoma predominate, is when childhood cancer incidence rates are highest.⁶⁶ One may reasonably surmise, therefore, that many childhood cancers result from aberrations in early developmental processes.

To our dismay, from a prevention standpoint, little current evidence supports a major etiologic role for environmental or other exogenous factors in childhood cancer. A comprehensive review of epidemiologic studies of childhood cancer is available elsewhere.⁶⁶ The major types of childhood cancer and risk factors that are reasonably well documented are shown in Table 22.2. Many other factors, suspected to raise or lower increase or decrease risk, are not well established, and even the known risk factors shown in the table explain only a small proportion of childhood cancer cases.

Concluding Remarks

Cancer is, and will be for the immediate future, a major public health problem; but several already-identified causes suggest many human cancers may be avoidable. Cancer rates would be lowered dramatically by reduction of tobacco smoking and factors influencing breast cancer. Although tobacco control could be achieved by government and societal actions, prospects for the prevention of breast cancer are more remote. In this regard, ongoing intervention trials of selective estrogen receptor modulators (SERMs), such as tamoxifen and raloxifene, in healthy women have a unique role in being the only available intervention with a reasonable probability of prevention. Other important reductions could be brought about by vaccination against hepatitis B and human papilloma virus and control of *H. pylori*. A growing concern, not just for cancer but for other chronic diseases, such as diabetes and heart disease, is the impact of epidemic rates of overweight and obesity. As evidence accumulates for a role of excess weight and lack of physical activity in both the etiology of and survival from cancer, strategies to prevent and effectively treat obesity and to promote increased physical activity and other healthy lifestyle behaviors are likely to be critical for improving public health. However, greater efforts in behavioral research and development of successful interventions are integral to such an effort. Failing primary prevention, screening for cancers of the breast, cervix, and colon could reduce mortality

TABLE 22.2. Known risk factors for selected childhood cancers.

<i>Cancer type</i>	<i>Risk factor</i>	<i>Comments</i>
Acute lymphoid leukemia	Ionizing radiation	Although primarily of historical significance, prenatal diagnostic X-ray exposure increases risk. Therapeutic irradiation for cancer treatment also increases risk.
	Race Genetic conditions	White children have a 2-fold higher rate than black children in the U.S. Down syndrome is associated with an estimated 20-fold increased risk. Neurofibromatosis type 1, Bloom syndrome, ataxia telangiectasia, and Langerhans cell histiocytosis, among others, are associated with an elevated risk.
Acute myeloid leukemias	Chemotherapeutic agents Genetic conditions	Alkylating agents and epipodophyllotoxins increase risk. Down syndrome and neurofibromatosis 1 are strongly associated. Familial monosomy 7 and several other genetic syndromes are also associated with increased risk.
Brain cancers	Therapeutic ionizing radiation to the head Genetic conditions	With the exception of cancer radiotherapy, higher risk from radiation treatment is essentially of historical importance. Neurofibromatosis 1 is strongly associated with optic gliomas, and, to a lesser extent, associated with other CNS tumors. Tuberous sclerosis and several other genetic syndromes are associated with increased risk.
Hodgkin's disease	Family history Infections	Monozygotic twins and siblings of cases are at increased risk. Epstein-Barr virus is associated with increased risk.
Non-Hodgkin's lymphoma	Immunodeficiency Infections	Acquired and congenital immunodeficiency disorders, and immunosuppressive therapy, increase risk. Epstein-Barr virus is associated with Burkitt's lymphoma in African countries.
Osteosarcoma	Ionizing radiation Chemotherapy Genetic conditions	Cancer radiotherapy and high radium exposure increase risk. Alkylating agents increase risk. Increased risk is apparent with Li-Fraumeni syndrome and hereditary retinoblastoma.
Ewing's sarcoma	Race	White children have about a 9-fold higher incidence rate than black children in the U.S.
Neuroblastoma		No known risk factors.
Retinoblastoma		No known nonhereditary risk factors.
Wilms' tumor	Congenital anomalies Race	Aniridia and Beckwith-Wiedemann syndrome, as well as other congenital and genetic conditions, increase risk. Asian children reportedly have about half the rates of white and black children.
Rhabdomyosarcoma	Congenital anomalies and genetic conditions	Li-Fraumeni syndrome and neurofibromatosis 1 are believed to be associated with increased risk. There is some concordance with major birth defects.

from these common diseases, and screening for other forms of cancer will emerge as public health strategies are given proper evaluation. Cancer cases are expected to rise in the new millennium, so cancer control strategies will increase in importance. Implementing current knowledge could prevent thousands, if not millions, of premature deaths.

Evidence-Based Cancer Prevention Research: A Multidisciplinary Perspective on Cancer Prevention Trials

Stephen D. Hursting, Michele R. Forman,
Asad Umar, Nomeli P. Nunez,
and J. Carl Barrett

More than 1 million Americans were expected to be diagnosed with cancer in 2004. This fact is especially tragic given that many cancers are preventable. The ongoing challenge to the medical, scientific, and public health communities is to formulate evidence-based decisions and implement effective and safe interventions for cancer prevention.

Randomized controlled clinical trials remain the gold standard to test cause and effect in human research and inform evidence-based medical decisions. The era of cancer prevention trials began with the seminal paper by Peto in 1981,^{1,2} who examined the role of β -carotene and vitamin A in cancer prevention. Since 1981, there have been numerous cancer prevention trials of nutritional interventions and pharmacologic agents. Some of these prevention trials reported clearly positive results while other trials reveal mixed results, null findings, and even unsuspected adverse effects.

A comprehensive review of all cancer prevention trials is beyond the scope of this chapter. We present here a brief review of multistage carcinogenesis and possible molecular targets for cancer prevention. We then discuss examples of randomized, controlled clinical trials that examine the effects of five different cancer prevention modalities. These *case studies* of human trials in cancer prevention were selected to explore the reasons why several trials did not achieve the expected cancer preventive outcomes, whereas others reached their goals. We describe the state of the art before each series of trials followed by the design, some background on the preventive agent or dietary intervention used, primary endpoints, results, and future directions. Reflections on the results are threaded with investigations of the complexities inherent to prevention trials and mechanisms underlying the adverse or null endpoints. Finally, we explore the lessons learned from the trials to identify achievable goals and the

underpinnings to, and the relevant criteria for, future human research in the prevention of cancer.

Multistage Carcinogenesis Process and Targets for Prevention

Humans are exposed to a wide variety of endogenous and exogenous carcinogenic insults, including chemicals, radiation, physical agents, bacteria, and viruses. Recent progress in the study of the multistep process of carcinogenesis, particularly on the mechanisms of chemically and virally induced cancer, has revealed several points along the carcinogenesis pathway that may be amenable to cancer prevention strategies. The classic view of experimental carcinogenesis, in which tumor initiation is followed by tumor promotion and progression in a sequential fashion, has undergone significant revision as our understanding of cancer-related genes and the biosystem has evolved. However, the concepts and underlying processes of initiation, promotion, and progression remain theoretically important. Tumor initiation begins in cells with DNA alterations resulting from inherent genetic mutations or, more commonly, from spontaneous or carcinogen-induced genetic or epigenetic changes. Alterations in specific genes modify the responsiveness of the initiated cell to its microenvironment, eventually providing a growth advantage relative to normal cells. The tumor promotion stage is characterized by clonal expansion of initiated cells caused by alterations in the expression of genes whose products are associated with hyperproliferation, apoptosis, tissue remodeling, and inflammation.³ During the tumor progression stage, preneoplastic cells develop into invasive tumors through further clonal expansion, usually associated with alterations in gene expression

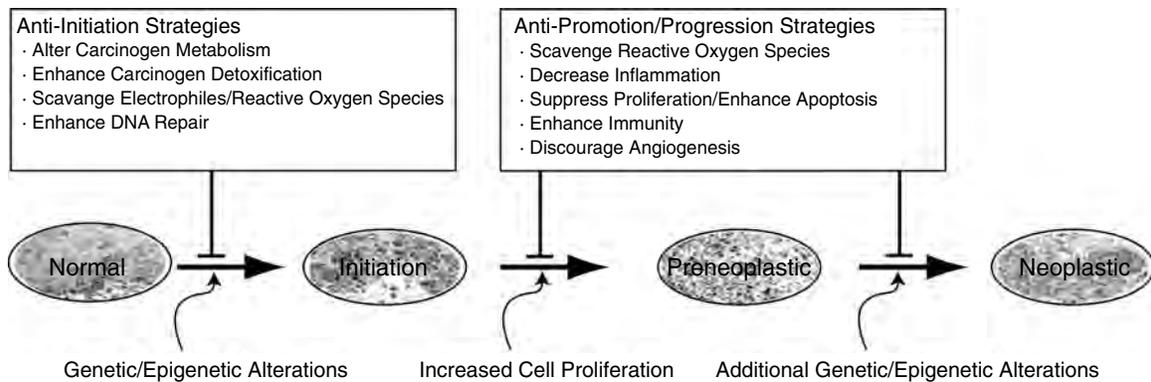

FIGURE 23.1. Multistage carcinogenesis model: a schematic presentation of stage-specific prevention strategies. The initiation stage is characterized by the conversion of a normal cell to an initiated cell in response to genetic or epigenetic changes in the cell's DNA. The conversion of an initiated cell to a preneoplastic population of cells

and ultimately to a tumor is determined by additional genetic/epigenetic changes that affect the balance between growth and death in these cells. Strategies to intervene in these processes to decrease rates of mutation epigenetic change and maintain the growth–death balance in cancer cells are listed in the boxes.

and additional genetic damage due to progressive genomic instability.³

As depicted in Figure 23.1, possible ways of interfering with tumor initiation events include (i) modifying carcinogen activation by inhibiting the enzymes responsible for that activation or by directly scavenging DNA-reactive electrophiles and free radicals; (ii) enhancing carcinogen detoxification by altering the activity of detoxifying enzymes; and (iii) modulating certain DNA repair processes. Possible ways of blocking the processes involved in the promotion and progression stages of carcinogenesis include (i) scavenging reactive oxygen species; (ii) altering the expression of genes involved in cell signaling, particularly those regulating cell proliferation, apoptosis, and differentiation; (iii) decreasing inflammation; (iv) enhancing immune function; or (v) suppressing angiogenesis.

We now appreciate that the nature of initiation, promotion, and progression events is complex. For instance, we know from the work of Fearon and Vogelstein and others that multiple mutational and epigenetic events are involved in the formation of cancers.⁴ Furthermore, humans are generally exposed to mixtures of agents that can simultaneously act at different stages of the carcinogenesis process. Thus, rather than three discrete stages occurring in a predictable order, human carcinogenesis is best characterized as an accumulation of alterations in genes regulating cellular growth, death, and malignant properties. These alterations occur through a series of clonal selections influenced by endogenous and exogenous factors. Epigenetic changes often develop in a cancer or the microenvironment and may also drive this multistep process.⁵ Nonetheless, the processes involved in cancer initiation, promotion, and progression already described remain important and relevant targets for cancer prevention. Interventions that increase or decrease rates of mutation, rates of epigenetic change, or the balance between growth and death in cancer cells can significantly influence the ultimate development of cancer. One of the most important questions in contemporary cancer research is this: What safe and effective interventions should be recommended to prevent cancer?

Case Study I: Trials of β -Carotene Supplementation and Lung Cancer Chemoprevention

In 1976, Sporn defined the term chemoprevention as the use of natural or synthetic agents to reverse or suppress multistage carcinogenesis.^{6,7} There are numerous examples in the literature demonstrating that bioactive food components or chemopreventive agents can influence one or more of these targets and interfere with the carcinogenesis process.³ In the oft-cited paper entitled “Can dietary β -carotene materially reduce human cancer rates?,” Peto described the role of retinol and the retinoids in later-stage carcinogenesis and recommended β -carotene, rather than vitamin A, chemoprevention trials in the general population aged 50 years or older, because high doses of β -carotene for treatment of erythropoietic protoporphyria were not associated with toxicity as was the case for vitamin A.^{1,8}

Following Peto's paper, four large-scale randomized placebo-controlled clinical trials of β -carotene (summarized in Table 23.1) revealed no protection but rather adverse effects or no difference in rates of lung cancer among participants in the β -carotene arm compared to the placebo arm. Two trials enrolled high-risk individuals while the other two enrolled apparently healthy individuals. The Alpha-Tocopherol β -Carotene Trial (ATBC) in Finland included male smokers at high risk of lung cancer (mean, 36 years of smoking) who were administered β -carotene, α -tocopherol, both, or a placebo for 6 years on average. The β -Carotene Retinol Efficacy Trial (CARET) in the United States enrolled men and women who were either smokers (mean, 49 years) or asbestos-exposed workers, and administered β -carotene, retinyl palmitate, both, or a placebo for 4 years on average. In these two trials, the β -carotene-supplemented group experienced an increased risk of lung cancer (by 18% in ATBC and 36% in CARET) compared to the placebo group, and the effect appeared stronger in participants who drank greater than average amounts of alcohol daily (i.e., a 35% versus 3% increase in lung cancer risk, respectively, in ATBC).^{9–11} Also, more of a systemic effect appeared in subsequent analysis, as illustrated

by a 23% and 25% increase in prostate and in stomach cancers, respectively, in the supplemented (versus placebo) group in ATBC, and an 18% and 26% increase in total mortality and in cardiovascular deaths among the β -carotene group in CARET.

In contrast, participants in the Physicians Health Trial and the Women's Health Study were apparently healthy, had a low rate of smokers, and were administered an alternate-day schedule of β -carotene for 12 and 2 years of follow-up, respectively. Compared with the placebo group, β -carotene supplementation in these participants was not associated with an increased risk of lung cancer; rates of lung cancer did not differ by treatment arm. In all four trials, participants in the β -carotene-supplemented arm compared to the placebo arm had significantly higher concentrations of β -carotene in blood, indicating uptake of the supplement but not necessarily efficacy. The search for reasons why β -carotene supplementation was associated with adverse effects occurred in several areas of study, including a reevaluation of the epidemiologic results, animal experiments, and clinical nutrition research.

Evidence from Observational Epidemiology

A review of epidemiologic studies covering the period before, during, and soon after the four trials revealed more significant inverse associations between serum concentrations of and dietary intake of β -carotene and lung cancer in case-control than cohort studies.¹² Methodological differences in estimation of intake and blood values may have complicated comparisons and contributed to the inconsistent results.

Evidence from Animal Research

A few experimental studies had been conducted examining the effect of β -carotene on skin cancer before the randomized

clinical trials in humans. Two research groups subsequently addressed major questions arising from the trials. The USDA-Tufts group focused on research to explain the "apparent exacerbation of lung carcinogenesis by β -carotene supplementation in smokers."¹³ In a study of ferrets with and without exposure to cigarette smoke and with and without β -carotene supplementation for 6 months, a strong proliferative response in lung tissue and squamous metaplasia was observed in the β -carotene-supplemented animals without smoke exposure and was especially enhanced in the smoking + β -carotene group. In vitro incubation of lung tissue from smoke-exposed ferrets with all-*trans*- β -carotene revealed that the β -carotene molecule is unstable. It forms oxidative by-products that induce cytochrome P-450 enzymes, interfere with retinoic acid metabolism, and downregulate retinoic acid receptor (RAR)- β .¹³ Indeed, the downregulation of RAR- β expression observed in the lungs of ferrets who were receiving both β -carotene supplementation and smoke exposure suggests this modulation of RAR- β may play a role in the enhancement of lung tumorigenesis in response to β -carotene.

In contrast, a recent follow-up study showed that lycopene, a carotenoid found chiefly in tomato products, has protective activity in the same ferret model. Ferrets were either exposed to a smoking chamber at levels of cigarette smoke comparable to one to two packs/day, or not exposed to smoke, and administered supplements of lycopene at either 15 or 60 mg/day for 9 weeks.¹⁴ Both low- and high-dose lycopene supplementation inhibited lung squamous metaplasia in this model. Compared with ferrets exposed to smoke alone, ferrets supplemented with lycopene and exposed to smoke had significantly higher plasma insulin-like growth factor-binding protein 3 (IGFBP-3) and lower insulin-like growth factor 1 (IGF-1)/IGFBP-3 ratio, thereby reducing serum levels of bioavailable IGF-1. In addition, cigarette smoke exposure increased phosphorylation of the apoptosis protein BAD and significantly decreased cleaved caspase 3 (an apoptosis-related

TABLE 23.1. Beta carotene supplementation trials of lung cancer.

<i>Trial</i>	<i>Agent(s)</i>	<i>Population</i>	<i>N</i>	<i>Follow-up</i>	<i>Risk effect</i>
ATBC	β -Carotene (20 mg/day)	Male smokers	29,133	5–8 years	876 cases
(Finland)	Vitamin E (50 mg/day) (2 × 2 design)	50–69 years (μ = 57 years) 36 years of smoking		μ = 6 years	RR = 1.18 (1.03, 1.36)*
CARET	β -Carotene (30 mg/day)	Men and women	18,314	4–7 years	286 cases
(U.S.)	Retinyl palmitate (25,000 IU) (2 × 2 design)	Smokers (μ = 58 years) 49 years of smoking	14,254	μ = 4 years	RR = 1.36 (1.07 – 1.73) β -carotene supplement RR = 1.28 (1.04, 1.57)* β -carotene + retinyl palmitate
		Asbestos (μ = 57 years) 43 years of smoking	4,060		RR = 1.40 (0.95 – 2.07) asbestos exposed RR = 1.23 (0.96 – 1.56) heavy smokers
PHS I	β -Carotene (50 mg/alternate/day)	Male MDs	22,071	12 years	82 cases in β -carotene
(U.S.)		40–84 years 11% smokers			88 cases in placebo RR = 0.98 (0.91, 1.06)*
WHS	β -Carotene (50 mg/alternate/day) of 8 groups	Women	39,876	2.1 years	30 cases in β -carotene
(U.S.)		45 years + 13% smokers			21 in placebo*

protease) in the lungs of ferrets; however, lycopene supplementation reversed the smoke-induced suppression of apoptosis and prevented the smoke-induced elevation of BAD phosphorylation.¹⁴ These findings, along with other recent studies,¹⁵ begin to elucidate the potential chemopreventive capacity and limitations of carotenoids, as well as the mechanisms underlying the effects of β -carotene on lung cancer observed in human trials.

Evidence from Pharmacokinetic and Pharmacodynamic Research

Limited pharmacokinetic research was conducted before the trials, and determinations of an optimal dose and the duration of supplementation were not established. Single-dose studies of β -carotene that demonstrated peak plasma response within 24 to 48 hours were conducted in healthy young men before the trials.¹⁶ Chronic-dose studies, ranging from 15 to 180 mg/day β -carotene, were conducted in healthy participants at the same time as the trials.¹⁷⁻¹⁹ The chronic-dose studies began to reveal large interindividual variation in response to the varying dosages. Along with limited information on the bioavailability of β -carotene was the issue of identifying responders from nonresponders, a phenomenon later reported in trial participants.²⁰ Human nutrition research was not conducted to test the effects of β -carotene supplementation in high-risk groups such as smokers and drinkers of alcohol in the ATBC and CARET. The publication of adverse effects in human trials led to animal research as the only ethical approach to examine the interaction of multiple risk behaviors and a pharmaceutical dose supplementation as well as the complex molecular pathways leading to lung carcinogenesis.

Case Study II: High-Fiber, Fruit, and Vegetable Interventions and Colon Polyp Recurrence

During the 1980s, three lines of evidence suggested that certain aspects of lifestyle, especially dietary factors, were associated with colon carcinogenesis. First, mortality rates for colorectal cancer (CRC) varied across regions of the world. The variation in worldwide rates of CRC was a recognized "ecologic" association. The second line of evidence appeared in the rapid changes in CRC incidence within a country. During a 40-year period in Japan, for example, CRC incidence rose at a dramatic rate, in men more than women. The third line of evidence came from migration studies demonstrating that risk of CRC changed with adoption of a new diet. For example, the CRC incidence rate for American-born Japanese approached or was higher than the rate in Japan.²¹ Indeed, in most cases, migrants adopted the CRC rates of their new country within a generation. Moreover, animal evidence overwhelmingly revealed a protective effect of fiber on colon carcinogenesis.²²⁻²⁴ Thus, by 1988, the *Surgeon General's Report on Nutrition: Diet and Colorectal Cancer (CRC) Risk* and the 1989 *National Academy of Sciences Diet and Health Report* summarized the field by concluding there was sufficient evidence that a high-fat diet increased risk and a high-fiber, high-fruit-and-vegetable diet decreased CRC risk.

During this era, the progression of colorectal carcinogenesis was depicted as a series of sequential steps from normal

epithelium to development of aberrant crypts, followed by early adenomatous polyps, the formation of advanced adenomas, and finally cancer.⁴ Population-based incidence rates of adenomatous polyps were not available, and identification of a high-risk group other than those with familial adenomatous polyposis syndrome (FAP) was difficult. Therefore, investigators in cancer prevention focused on trials of dietary interventions to reduce recurrence of adenomatous polyps in individuals with prior adenomatous polyps.

High-Fiber, Fruit, and Vegetable Trials of Polyp Recurrence

In the early 1990s, several cancer prevention trials tested the effect of a low-fat and high-fiber intervention on adenomatous polyp recurrence.²⁵⁻³⁰ In each trial, summarized in Table 23.2, individuals had a complete colonoscopy and removal of at least one adenomatous polyp. Eligibility criteria differed by trial according to polyp size, number, and time interval from polypectomy to enrollment. The intervention plan varied as well from a wheat bran or fiber supplement, to combinations of low-fat diet plus wheat bran supplements, to an overall dietary plan of a high-fiber, high-fruit-and-vegetable, low-fat regimen. Actual percent of calories from fat on the intervention ranged from 20% to 25%, compared to the usual dietary regimen of 33% to 37% of calories from fat. The approach to fat reduction ranged from removal of butter and/or visible fat from meat to use of low-fat dairy products through to major changes in categories of food intake. In addition, several trials included a supplement of 20 mg/day β -carotene or a placebo.²⁷ Given the randomization schema, as many as eight distinct combinations (including the placebo + usual diet group) of the trial might be tested in a factorial design.

The length of the trials ranged from 1 to 4 years, with assessment of polyp recurrence by colonoscopists who were blinded to the patient's group status. The randomized trial design was followed according to strict guidelines established at the beginning of the studies, including random assessment of dietary compliance by dietitians,²⁷ annual completion of (previously validated) dietary food frequency questionnaires, and multiple-day food records in randomly selected subcohorts of the Polyp Prevention Trial (PPT) participants.³⁰ In addition, blood specimens were collected in the fasting state to measure micronutrient levels as biomarkers of dietary change.²⁷ Rates of recurrence in the intervention and control/usual dietary regimen groups did not differ at the end of each trial, thereby revealing no significant prevention of adenomatous polyp recurrence by dietary intervention.

In an effort to explain why recurrence was not prevented or lowered in those randomized to an intervention scheme compared to those on the placebo/usual diet, several possibilities were presented, including (1) the wrong endpoint; (2) inadequate trial length for the study population; and (3) wrong intervention.

The Wrong Endpoint

By the time the trials were completed, it was recognized that less than 10% of adenomas developed into CRC and not all CRC developed through the adenoma pathway. In several trials, secondary outcomes such as the rates of large adeno-

TABLE 23.2. Colorectal neoplasia prevention trials evaluating dietary fat and fiber.

Reference	Sample size ^a	Design/cohort ^b	Intervention	Primary results
DeCosse ¹⁰⁸	58	DBRCT in familial adenomatous polyposis (FAP) patients	Wheat bran fiber (2.2 g/day) + placebo vs. wheat bran fiber (2.2 g/day) + vitamin C (4 g/day) + vitamin E (400 mg/day) vs. wheat bran fiber (22.5 g/day) + vitamins C + E × 48 months	Rectal adenoma number: nonsignificant reduction with high-dose fiber + vitamins
McKeown-Eyssen ²⁹	201	Partially blinded RCT in patients with prior adenoma	Low fat (50 g/day or 20% of total calories) + fiber (≥50 g/day) vs. customary diet × 24 months (average)	Adenoma incidence/recurrence: no effect
MacLennan ²⁷	424	Factorial, partially DBRCT in patients with prior adenoma	Low fat intake (<25% of total calories) vs. wheat bran (25 g/day) vs. beta-carotene (20 mg/day): 7-arm factorial trial × 24–48 months	Adenoma incidence/recurrence: no overall effect; reduction in large (≤1 cm) adenomas with combination of wheat bran + low-fat diet*
Alberts ^{26,109,110}	1,429	DBRCT in patients 40–80 years old with prior adenoma (≥3 mm)	Wheat bran fiber 2 g/day vs. 13.5 g/day × 36 months	Adenoma number: 1% reduction (NS); persons with adenomas: 12% reduction (NS)
Schatzkin ²⁵	2,079	Partially blinded RCT in patients 35 years or older with prior adenoma	Low fat (≤20% of total calories), fiber (18 g/1,000 kcal), fruits and vegetables (5–8 servings/day) vs. typical U.S. diet × 48 months	Adenoma incidence/recurrence: no effect (RR = 1.00)
Faivre ^{28,111}	655	DBRCT in patients 35–75 years old with prior adenoma	Fiber 3.8 g/day (ispaghula husk) vs. calcium 2 g/day vs. placebo	Adenoma incidence/recurrence: 34% reduction with calcium (NS); 67% increase* with fiber
Women's Health Initiative ⁹²	45,000–48,000	Complex factorial, 3 × 2 × 2 factorial DBRCT in postmenopausal women 50–79 years old	Low-fat diet vs. calcium + vitamin D vs. hormone replacement therapy × 9 years	Colorectal cancer incidence: ongoing

NS, nonsignificant.

*Statistically significant result ($P < 0.05$).

mas (10 mm or larger), which have a greater malignant potential than small adenomas, were reduced by an intervention such as low-fat diet plus wheat bran supplement²⁷ and the overall dietary intervention (high-fiber, high-fruit-and-vegetable, low-fat) in the study.²⁵ However, the numbers of participants were too small to indicate whether the observed effects on this secondary endpoint were significant.

Inadequate Trial Length

Trial participants were adults with a history of at least one polyp before enrollment and therefore already at risk of another polyp. While they were at high risk of a recurrence, their mean age was typically in the sixties, and their colonic mucosa might be less amenable to (molecular, cellular, or tissue) modulations from diet than a younger, healthier group. The duration of the intervention(s) was not tested before the trials to define the time interval for optimal effect. Therefore, questions arose regarding the adequacy of the trial length, with passive follow-up of trial participants frequently occurring postintervention.^{25,26} Dietary instruments to assess

intake have limitations, including measurement error contributed by degree of completion based on instrument length and the number of days reporting, as well as the respondent's accuracy in estimation of portion size and frequency, which varied by the participant's education and age.³¹ In the trials providing high-fiber supplements, adverse side effects were rarely mentioned, but attrition due to the inability to continue on the high-fiber regimen is a potential factor. Across trials, some patients refused to have the follow-up colonoscopy, thereby leading to selective subcohorts with endpoint ascertainment.²⁹

Wrong Intervention

Dietary change from a high-fat, low-fiber diet to a low-fat, high-fiber and/or -fruit-and-vegetable plan offers choice of food substitutes and therefore more opportunity for long-term compliance. The downside of this broad application of dietary change is the difficulty in identifying which phytochemicals were eaten, their frequency and amount of intake; and whether food preparation and processing enhances or reduces absorption. For example, the length of time cooking dark

green leafy vegetables modifies folate concentrations and the amount of insoluble fiber, whereas reducing water content from tomatoes increases lycopene concentrations from raw tomato to sauce to paste.

Fruit and vegetables contain more than 25,000 recognized phytochemicals. The search for the protective constituents in plants involves identifying the major sources of variation. For example, seasonality and soil content can alter the concentration of plant phytochemicals, and inter- and intraindividual variability in intake of phytochemicals modifies concentrations in human sera. Phytochemical databases to estimate intakes are limited to a few components such as carotenoids.³² Thus, the effects of food constituents on cancer endpoints are difficult to determine.

Prior Evidence

Reviews of earlier research revealed a fairly consistent inverse association between fiber intake and CRC in case-control studies, whereas large population-based, prospective cohort studies such as the Nurses' Health and Health Professional Studies^{33,34} did not demonstrate an association. Questions arose whether biases inherent to the case-control design led to spurious associations. For example, dietary reporting by patients *after* colon cancer diagnosis and telescoping of exposure assessment might bias the estimate of the effect of dietary fiber intake on cancer risk. Specifically, patients report dietary intake during the period of appearance of symptoms and illness rather than before this period, which could lead to an effect when indeed it did not exist.

An Update

Two articles in *The Lancet* in 2003 presented data from observational, prospective research suggesting a significant inverse association between dietary fiber intake and risk of polyps³⁵ or CRC.³⁶ Both studies had a larger and more varied range in dietary fiber intake (i.e., from 12 to 36 g/day) than in earlier cohort studies of more homogeneous populations.^{33,34} The major protective dietary source was fiber from grains, cereals, and fruit,³⁵ and no food source of fiber was significantly more protective than another in the European Prospective Investigation into Cancer and Nutrition (EPIC) study.³⁶ Interestingly, use of fiber supplements was not associated with reduced risk. The adenomatous polyp study was based on sigmoidoscopy rather than colonoscopy for detection of polyps, reducing the area of the colon that was screened and therefore the potential to identify all polyps. A major strength of both studies was that participants were reporting intake potentially reflective of chronic, long-term habits. Identifying the duration and phases of the life cycle during which the intake occurred would be a major contribution to elucidate the timing of mechanisms of action in polyps and CRC. Thus, the dietary intervention trials had not determined the optimal range in intake for reduction in polyp recurrence, as evidenced by the breadth of dietary exposures in the two recent observational studies. Further analysis of the trials to explore the subset of individuals who met or went beyond the dietary goals of the trials might elucidate whether the duration of the trial was adequate to confer reduction in risk of polyp recurrence.

Case Study III: Chemoprevention Studies of Retinoids and Second Primary Cancers of the Upper Aerodigestive Tract

One of the first definitive proofs of principle for chemoprevention came from the translational studies of Kim and Hong and colleagues, who have studied retinoids and other chemopreventive agents in upper aerodigestive tract cancers since the early 1980s. Clinical, epidemiologic, and animal studies in the 1970s and 1980s had suggested that vitamin A could positively influence epithelial cell differentiation and thus, retinoids may be effective agents for preventing epithelial cancers in the upper aerodigestive tract.³⁷

Chemoprevention Trials of Upper Aerodigestive Tract Cancers by Retinoids

As summarized in Table 23.3, Hong et al. established that high-dose 13-*cis* retinoic acid (13-CRA) is more effective than placebo in reversing oral premalignant lesions (OPLs)³⁸ and later showed that low-dose 13-CRA is more effective than β -carotene and less toxic than high-dose 13-CRA.^{39,40} These studies demonstrate that retinoids can indeed be used to reverse OPLs, as suggested by several reports in animal models.⁴¹⁻⁴³ Further explorations of less toxic and more effective agents and regimens were accomplished by incorporating multidisciplinary studies of biomarkers into their trials and the development of statistical methodologies for analyzing multiple biomarkers for the prediction of cancer development in patients with OPLs.⁴⁴ Studies by Hong and colleagues demonstrate the importance of conducting parallel basic and translational studies. They observed that the synthetic retinoid fenretinide induces apoptosis through retinoic acid receptor-independent mechanisms and induces cell death in cell lines resistant to all-*trans* retinoic acid, 13-CRA, 9-CRA, and other nuclear receptor-dependent retinoids.⁴⁵ These findings have led to an ongoing trial of fenretinide in patients with retinoid-resistant OPLs and to the characterization of several novel retinoids with even more potent apoptosis-inducing effects than fenretinide.⁴⁶ Further studies are needed to determine whether these agents reduce mortality after treatment is completed.

The Hong group, along with many groups studying chemoprevention of OPLs, are currently moving away from retinoids toward less toxic agents, including bioactive food components, such as vitamin E and green tea polyphenols, or pharmacologic agents that target specific pathways, such as inhibitors of farnesyl transferase, cyclooxygenase 2, or the epidermal growth factor receptor. However, these initial studies of retinoids were critical to establish the feasibility of developing a translational chemoprevention strategy.

These translational research findings also led to new combination approaches to preventing OPLs. Retinoid resistance was shown to be associated with higher levels of genetic instability and mutant p53 expression.⁴⁷ Combination regimens of 13-CRA, α -tocopherol, and interferon- γ have been very effective in reversing laryngeal premalignant lesions but not OPLs,⁴⁸ probably because some, but not all, of the p53-mutated OPL clones can be eliminated, suggesting that some genotypically altered clones can regrow and manifest as phenotypic lesions after treatment is discontinued.^{49,50}

TABLE 23.3. Prevention trials evaluating chemoprevention of upper aerodigestive tract cancers by retinoids.

Reference	Sample Size	Design	Intervention	Primary results
Papadimitrakopoulou ⁴⁸	36	Prospective nonrandomized trial	Oral isotretinoin (100 mg/m ² per day), oral alpha-tocopherol (1,200 IU/day), and subcutaneous interferon- α (3 megaunits/m ² twice weekly) for 12 months	A striking difference in response was observed in favor of laryngeal lesions 9/19 [47%] complete response rate at 6 months and 7/14 [50%] at 12 months vs. 1/11 [9%] and 0/7 [0%], respectively, for oral lesions)
Papadimitrakopoulou ⁴⁰	59	RCT	30 mg/day beta-carotene, or 0.5 mg/kg/day isotretinoin for 12 months	Isotretinoin 8% reduction Beta-carotene 55% reduction in oral premalignant lesions (OPL)
Lippman ⁴⁷	40	RCT	1.5 mg/kg/day isotretinoin for 3 months	Inverse relation of levels of p53 protein and response to isotretinoin in OPL
Lippman ³⁹	70	Phase I, RCT in Phase II	1.5 mg/kg/day isotretinoin for 3 months: patients with stable lesions given 1.5 mg/kg/day isotretinoin ($n = 26$) or 30 mg/day beta-carotene ($n = 33$) for 9 months	55% response in Phase I of 59 in the RCT, 92% vs. 45% response in isotretinoin vs. β -carotene arms
Hong ⁵¹	103	RCT	Oral isotretinoin (100 mg/m ² /day) or placebo for 12 months	No significant difference between groups in the number of local, regional, or distance recurrences of the primary cancers, but second primary tumors were 4% for isotretinoin vs. 24% for the placebo
Hong ³⁸	44	RCT	13- <i>cis</i> -Retinoic acid ($n = 24$) or placebo ($n = 20$), 1–2 mg/kg/day for 3 months, and followed them for 6 months	Decrease in lesion size in 67% of those given the drug and in 10% of those given placebo ($P = 0.0002$); dysplasia reversed in 54% (13 patients) of the drug group vs. 10% (2 patients) of the placebo group ($P = 0.01$)

RCT, randomized controlled clinical trial.

The Hong group also established that second primary tumors (SPTs), the leading cause of cancer-related death among individuals cured of an initial primary head and neck tumor, can be prevented by retinoid treatment. Patients definitively treated for an initial head and neck cancer showed a marked decrease in SPTs in response to a high-dose 13-CRA regimen for 1 year.⁵¹ However, significant side effects were associated with the high-dose 13-CRA treatment. Also, the effectiveness of the retinoid treatment diminished over time; in fact, the SPT rate by 3 years after cessation of 13-CRA treatment was the same as the placebo group.⁵² A follow-up study of the effect of low-dose 13-CRA for 3 years for preventing SPTs is nearing completion.⁵³ Again, linking laboratory studies with these clinical trials has proven beneficial. For example, Hong, in collaboration with Margaret Spitz and colleagues, showed that susceptibility of peripheral blood lymphocytes to chromosomal breaks induced by the mutagens bleomycin or benzo[*a*]pyrene diol epoxide is an independent risk factor for head and neck cancer.^{54,55} The mutagen-sensitive phenotype has also been shown to be a significant predictor of SPT risk.⁵⁶ Thus, the Hong group illustrates the model of the multidisciplinary approach to cancer prevention that takes advantage of conducting basic research on biomarkers and clinical research on pharmacokinetics of the agent in the prevention of OPL and SPT. This model is elaborated in Figure 23.2.

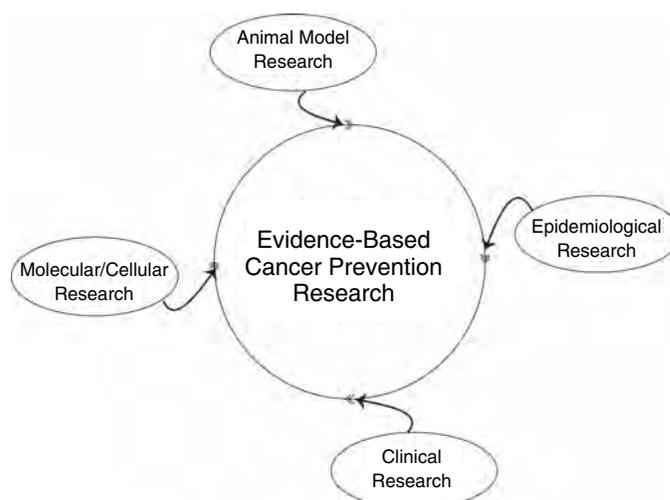

FIGURE 23.2. The transdisciplinary nature of evidence-based cancer prevention research. Research progress in the principles and practice of cancer prevention will increasingly require the integration of observational epidemiologic and clinical findings, the development and use of relevant animal models, the characterization of basic mechanisms at the molecular and cellular level, and the ultimate test of an hypothesis in clinical research.

Case Study IV: Tamoxifen and Breast Cancer

Breast cancer is the most common noncutaneous cancer among women in the United States.⁵⁷ Although breast cancer mortality has declined in the United States over the past decade, it remains the second leading cause of cancer-related deaths in women, after lung cancer.⁵⁸ Approximately 211,300 women in the United States were diagnosed with invasive breast cancer in 2004, and about 39,800 women will have died of the disease.⁵⁷

Hormonal therapy has an important place in the treatment and prevention of breast cancer. Because the antiestrogen drug tamoxifen decreased contralateral breast cancer incidence, in 1992, the National Surgical Adjuvant Breast Cancer and Bowel Project (NSABP) started the Breast Cancer Prevention Trial (NSABP P-1) to test the hypothesis that tamoxifen could be used for the prevention of breast cancer in a group of healthy women at high risk for the disease.⁵⁹⁻⁶³ Before the Breast Cancer Prevention Trial, anecdotal evidence suggested that primary breast cancer could be prevented by tamoxifen chemotherapy; however, there was no evidence from a randomized clinical trial to support this notion.⁵⁹⁻⁶³ In the NSABP P-1 trial, women considered at high risk for breast cancer were (1) more than 60 years of age; or (2) aged 35 to 59 years with a 5-year predicted risk for breast cancer of 1.66% or more based on the Gail model risk for breast cancer (this risk is equivalent to that of a 60-year old woman⁶⁴); or (3) having a history of lobular carcinoma in situ. In this trial, 13,388 women were randomized to receive tamoxifen 20mg/day ($n = 6,681$) or placebo for 5 years ($n = 6,707$). The main objective of the trial was to determine whether tamoxifen prevented invasive breast cancers; secondary aims were to determine whether tamoxifen would lower the incidence of fatal and nonfatal myocardial infarctions and the incidence of bone fractures. Results from this trial, summarized in Table 23.4, showed that tamoxifen reduced the risk of invasive breast cancer by 49% and the risk of noninvasive breast cancers by 50%. These effects were observed in estrogen receptor positive (ER+), not estrogen receptor negative (ER-), breast cancers. Women on the tamoxifen arm had 19% fewer bone fractures, but this reduction was not statistically differ-

ent from the placebo group. With respect to vascular events and endometrial cancer, tamoxifen increased the risk of endometrial cancer (risk ratio = 2.93; 95% CI = 1.35-4.97) and increased the rates of stroke, pulmonary embolism, and deep-vein thrombosis.

Overall, this trial showed that tamoxifen use was associated with fewer ER+ breast cancers in pre- and postmenopausal women with a high-risk profile.⁶¹ However, there is a cautionary note for sexually active premenopausal women taking tamoxifen, because tamoxifen was initially developed as a fertility drug.⁶⁵ Also, results from the Breast Cancer Prevention Trial showed that tamoxifen does not increase the risk of other cancers (besides endometrial), but may increase the risk of cataracts. Similar findings to the Breast Cancer Prevention Trial have appeared in other trials (Table 23.4), such as the Italian Randomized Trial of Tamoxifen and The International Breast Cancer Intervention Study 1.^{66,67} Preliminary analysis of the Italian study revealed no difference between the tamoxifen and placebo groups⁶⁸; however, by the end of the trial, women in the tamoxifen arm did have a lower risk of breast cancer.⁶⁶ On the other hand, the Royal Marsden Hospital Tamoxifen Chemoprevention trial reported no differences in the tamoxifen and placebo groups.⁶⁹ Women recruited for the latter trial had a strong family history of breast cancer; because of this, it is likely that carriers of familial breast cancer genes have an intrinsically different response to estrogen antagonism. For example, a subsequent study in the same population by the NSABP group found that tamoxifen reduced breast cancer incidence by 62% in BRCA2, not BRCA1, carriers.⁷⁰ The reason why tamoxifen did not decrease breast cancer incidence among women with BRCA1 mutations may be that *BRCA1* tumors are frequently ER negative.⁷¹ As the Royal Marsden Hospital Tamoxifen Chemoprevention Trial included women with a strong family history of breast cancer, it is possible that many of them could have been ER negative.

Because tamoxifen increases the incidence of stroke and endometrial cancers, and long-term tamoxifen treatment may eventually lead to tamoxifen-resistant breast cancers, a search for alternative agents for breast cancer prevention and therapy, such as aromatase inhibitors, is under way. Aro-

TABLE 23.4. Breast cancer prevention trials with tamoxifen and raloxifene.

Reference	Trial	Sample size	Design	Intervention	Primary results
Fisher ⁶¹	Breast Cancer Prevention Trial	13,388	Randomized Trial	Tamoxifen (20 mg) for 5 years	Tamoxifen reduced the risk of invasive breast cancer by 49% and the risk of noninvasive breast cancers by 50%; these effects were observed in estrogen receptor positive (ER+), not estrogen receptor negative (ER-)
Cuzick ⁶⁷	International Breast Cancer Intervention Study	7,152	Randomized Trial	Tamoxifen (20 mg) for 5 years	Tamoxifen reduces the risk of breast cancer by about a third
Veronesi ⁶⁸	Italian Randomized Trial of Tamoxifen	5,408	Randomized Trial	Tamoxifen (20 mg) for 5 years	Tamoxifen reduces the risk of breast cancer
Powles ⁶⁹	Royal Marsden Hospital Tamoxifen Chemoprevention Trial	2,494	Randomized Trial	Tamoxifen (20 mg) up to 8 years	No differences in the tamoxifen and placebo groups
Dickler ⁷⁸	Multiple Outcomes of Raloxifene Evaluation (MORE) Trial	7,705	Randomized Trial	Raloxifene (60 mg) for 4 years	65% reduction in risk of both in situ and invasive breast cancer

matase is a cytochrome P-450 enzyme that catalyzes the rate-limiting step in the synthesis of estradiol from androgens.⁷² The aromatase inhibitors represent a new class of agents in the treatment and prevention of breast cancer. Recent evidence suggests that aromatase inhibitors have several advantages over tamoxifen for the prevention and treatment of breast cancer.⁷³⁻⁷⁵ For example, aromatase inhibitors are effective in treating tamoxifen-resistant cancers as second-line agents, and they do not increase the risk of endometrial cancers.⁷⁶ It is likely that the aromatase inhibitors may replace tamoxifen in the management of metastatic breast cancer.⁷⁷ However, there is concern that these estrogen-lowering drugs may promote osteoporosis or decrease bone density and, in turn, increase the risk of bone fractures. Because aromatase inhibitors cannot prevent the production of estrogen by the ovaries, the use of aromatase inhibitors may be limited to postmenopausal women.

Another potential alternative to tamoxifen that prevents bone loss and does not appear to increase the risk of endometrial cancer is raloxifene.⁷⁸ Results from the Multiple Outcomes of Raloxifene Evaluation Trial showed that raloxifene has positive estrogenic effects on bone and lipid metabolism and antiestrogenic effects on breast tissue.⁷⁸ Even though this trial was designed to assess raloxifene's effect on bone density, results showed a 65% reduction in risk of both in situ and invasive breast cancer in women taking raloxifene⁷⁸; moreover, raloxifene did not appear to increase risk of endometrial cancer. These results have led to further evaluation of raloxifene as a possible alternative to tamoxifen. Currently, raloxifene is being evaluated in the Study of Tamoxifen and Raloxifene (STAR) trial.⁶⁵

Case Study V: Finasteride and Prostate Cancer

The Prostate Cancer Prevention Trial (PCPT) is a double-blind chemoprevention trial of prostate cancer in 18,882 non-symptomatic, healthy men who were randomized to 5 mg/day of finasteride or placebo for 7 years.⁷⁹ Finasteride is an inhibitor of (~90% of) 5- α -reductase, an enzyme involved in hormone metabolism of testosterone to dihydrotestosterone (DHT), the most active androgen in the prostate. Intraprostatic DHT is thought to be a major stimulus for prostate cancer cell growth, as evidenced by in vitro and in vivo studies.^{80,81} Thus, reducing DHT by inhibiting 5- α -reductase activity is a plausible strategy for preventing prostate cancer development.

There was significant preclinical and clinical experience with finasteride before the initiation of the PCPT. Numerous animal model studies suggested finasteride had prostate cancer preventive activity in several rats,⁸² and finasteride had been approved and was in wide clinical use as treatment for benign prostatic hyperplasia.⁸³ The toxicity profile for finasteride was well characterized as being low and well tolerated by healthy subjects.

At the end of the 7-year trial, an endpoint biopsy was performed in all men, demonstrating a 24.8% lower cumulative incidence of prostate cancer in the finasteride compared to the placebo group.⁷⁹ However, the finasteride group also had a higher rate of high-grade cancers (higher Gleason scores) than the placebo group. In addition, men in the finasteride group reported more problems with sexual function but fewer

urinary problems than men in the placebo group. Thus, this prevention trial identified multiple issues, including (1) a significantly higher detection rate in both arms of the study compared to earlier studies⁸⁴ and (2) a 27% increase in high-grade Gleason scores in the treatment arm based on central review by pathologists blinded to treatment assignment, whereas the proportion in the placebo group was similar to other series.⁸⁵ Fortunately, this was a well-designed trial with well-planned tissue collection and storage, so despite the mixed results the trial will certainly yield tremendous information about prostate carcinogenesis. Another large trial (8,000 men) using the 5- α -reductase inhibitor dutasteride for a 4-year intervention is also currently under way.⁸⁶

Case Study VI: Calcium Supplementation and Colon Polyp Recurrence

The epidemiologic data on colon cancer incidence rates around the world, as well as the increase in rates among recent Japanese migrants to Hawaii, provide supporting evidence to the trials of high-fiber and fruit and vegetable as well as calcium supplementation and adenomatous polyp recurrence.⁸⁷ In addition, separate epidemiologic observations consistently demonstrate an inverse relation between dietary intake of calcium and incidence of colon cancer, as summarized by Sorenson et al.⁸⁸ Animal experimental research led by M. Lipkin and colleagues was the forerunner to the approach of identifying colon cell proliferation kinetics in mouse models and human subjects.⁸⁹ This team moved back and forth between the two biosystems to develop the first multistage model of colonic tumor development in 1974. Lipkin and Newmark have also demonstrated that calcium supplementation reduced cell proliferation in the mouse and in human subjects at high risk of colon cancer.⁸⁹

Calcium Supplementation Reduces Polyp Recurrence

As summarized in Table 23.5, three trials of calcium supplementation alone (or with other micronutrients) were reported in the 1990s with the endpoint of polyp recurrence.^{28,90,91} Calcium carbonate was the form of supplement administered in doses ranging from 1.6 to 3g/day, with participants having a follow-up colonoscopy at 1 and 3 years on trial, similar to the design of the fiber, fruit, and vegetable trials. Participants in two of the three trials experienced a reduction in recurrence of 15% to 34%,^{28,91} but no significant difference was found in the third trial.⁹⁰ Secondary data analysis of the third trial revealed a reduction in recurrence in patients aged less than 65 years and in those with one adenoma at baseline. There are other ongoing trials with calcium supplementation arms such as the Women's Health Initiative.⁹²

Lipkin and colleagues recently completed a series of animal model experiments demonstrating the carcinogenic role of diet alone in de novo development of colon tumors, using rodents unexposed to a carcinogen but administered a "Western-style diet" of high fat, low fiber, and low calcium and other micronutrients associated with cancer prevention. This same team reported the protective effects of dietary calcium add-back to the Western-style diet to reduce risk of colon tumors in mice relative to rodents who remained on

TABLE 23.5. Colorectal neoplasia prevention trials evaluating calcium.

Reference	Sample size ^a	Design/cohort ^b	Intervention ^c	Primary results ^d
Hofstad ⁹⁰	116	DBRCT in patients with current adenomas (those <1cm were retained)	1.6g/day + beta-carotene 15 mg + vitamin C 150mg + vitamin E 75 mg + selenium 101 µg/day × 36 months	Growth of small adenomas: no effect, Adenoma incidence/recurrence: increased* Fecal bile acids: no effect
Baron ⁹¹	930	DBRCT in patients with prior adenoma	3.0g/day × 48 months	Patients with adenoma recurrence, 19% reduction*; adenoma number, 24% reduction*
Faivre ^{28,111}	655	RDBCT in patients with prior adenoma; 35–75 years old	2.0g/day (vs. 3.8g/day ispaghula husk) vs. placebo × 36 months	Adenoma incidence/recurrence, 34% reduction (NS)
Women's Health Initiative ⁹²	45,000–48,000	Complex factorial, DBRCT in postmenopausal women 50–79 years old	Calcium + vitamin D; hormone replacement therapy; low-fat diet × approximately 9 years	Colorectal cancer incidence (among many others): ongoing

the Western diet alone.⁸⁹ The challenges rest in how well the Western-style rodent diet is mirrored in the complex arrays of current Western-style human diets and the identification of the windows of human development that are sensitive to their reported dietary modulations.

Case Study VII: Nonsteroidal Antiinflammatory Drugs, Selective Cyclooxygenase 2 Inhibitors, and Cancer Prevention

As a class, nonsteroidal antiinflammatory drugs (NSAIDs) are structurally diverse, yet seem to share several common activities that might be relevant to the prevention of cancer. Antineoplastic effects may include modulation of cell cycle, apoptosis, proliferation, and invasion. Although many of these effects are linked to cyclooxygenase (COX) inhibitory activity, a number of COX-independent effects are well established. COX inhibition by NSAIDs is exerted on at least two distinct isoforms: COX-1 and COX-2. COX-1 is constitutively expressed in most tissues, whereas COX-2 is found generally at low levels of expression unless induced by inflammatory factors, growth factors, or tumor promoters. Most NSAIDs, including aspirin or sulindac, suppress the activities of both isozymes. This indiscriminate inhibition causes anticancer effects as well as collateral damage, including gastric ulceration and renal toxicity. COX-2-selective inhibitors (COXIBs), including celecoxib (Celebrex) and rofecoxib (Vioxx), burst on the scene in 1999 with the potential to revolutionize the relief of inflammation and pain arthritis, without the collateral side effects of aspirin and the other nonselective NSAIDs. It was soon discovered that these agents also had tremendous potential as safe and effective chemopreventive agents for some cancers. However, Vioxx was withdrawn from the market on September 30, 2004, because of concern that it increases the

risk of heart attacks and strokes in patients taking it longer than 18 months.⁹³ Although recent findings suggest a higher risk of admission for congestive heart failure in users of rofecoxib but not celecoxib, relative to non-NSAID controls,⁹⁴ further studies and analyses are imperative to determine if the increased cardiovascular risks are limited to Vioxx or are characteristic of the entire class of COXIBs.

Evidence from Animal Studies

COX-2 is commonly overexpressed in many cancers, including many stages of colorectal carcinogenesis; some studies report overexpression in more than 50% of adenomas and more than 80% of adenocarcinomas, but it is rarely expressed in normal colorectal epithelium. The role of NSAIDs in cancer prevention was first investigated in rodent models in the early 1980s.⁹⁵ NSAIDs, such as aspirin, indomethacin, piroxicam, and sulindac, exhibited inhibitory effects on tumors of the colon; however, tumor growth often resumed when NSAIDs were discontinued. Overwhelming preclinical data suggest that COX-2 is functionally important for neoplastic progression, as evidenced by the regression of intestinal polyps in rodent models of colorectal cancer prevention as well as in COX-2-deficient mice. As recently reviewed,⁹⁶ almost 400 reports in PubMed are published on rodent models of both genetic and carcinogen-induced carcinogenesis that used NSAIDs or their derivatives. The majority of these studies demonstrate NSAIDs are relatively effective against most stages of colon cancer, including aberrant crypt foci; adenoma and adenocarcinoma multiplicity, incidence, and size; metastasis; and survival.

Nine studies of COXIBs—two with NS-398, one with MF tricyclic, two with nimesulide, one with rofecoxib, and three with celecoxib—have proved this class of chemopreventive agents is promising in reducing aberrant crypts and colorectal tumors in carcinogen-induced and genetically driven

rodent models of intestinal neoplasia.⁹⁶ COX-2 is overexpressed at very early stages of colorectal carcinogenesis in animals, as reported by Oshima et al.⁹⁷ This study also showed that the COX-2-selective agent MF tricyclic was as effective as the nonselective COX inhibitor sulindac. This study further provided direct evidence of the mechanistic importance and significance of COX-2 inhibition, as COX-2 knockout (+/-, and -/-) mice had a reduction in adenomas in a dose-dependent (COX-2 gene) manner.⁹⁸

Evidence from Epidemiologic Studies and Randomized Clinical Trials

Among 21 retrospective and 9 prospective observational studies, all but 2 reported statistically significant inverse associations between use of NSAIDs or COXIBs and colorectal neoplasia risk.⁹⁶ Reductions in neoplastic lesions by NSAIDs use ranged from 16% to 92% with an average reduction in adenomas of about 40% to 50%. In contrast, a prospective study of 12,180 individuals for 8.5 years reported an association between daily aspirin use and increased CRC risk for men (RR = 1.38) and women (RR = 1.10).⁹⁸ A major difference in this from other observational studies is that the median age of participants was 73 years. In a report from the Physicians' Health Trial and Follow-Up Study ($n = 22,071$ healthy men aged 40–84 years in 1982), aspirin was not associated with risk of colorectal cancer in those randomized to 325 mg every other day for the first 6 years [RR = 1.03 (95% CI = 0.83–1.28)] nor associated with risk in the postrandomization interval in men who used aspirin frequently [RR = 1.07 (95% CI = 0.75–1.53)].⁹⁹ A much larger number of studies show a positive cancer preventive effect of NSAIDs and COXIBs. In nested case-control analysis of a population-based cohort study of 940,000 individuals in the UK, a significant 40% reduction in colorectal cancer risk was reported in long-term aspirin users of 300 mg daily, but no significant benefit appeared in users of 75 or 150 mg daily.¹⁰⁰

Numerous clinical trials showing protective effects of NSAIDs against colon polyp formation or colon cancer are summarized in Table 23.6. In 2003, three studies reported dramatic findings that reveal aspirin as a major player in the defense against cancer. Two randomized controlled studies considered patients at risk of colorectal cancer. Both studies found a clear reduction in polyp recurrence from aspirin use. In one study, 1,084 patients with a history of polyps were followed with a colonoscopy 3 years after their entry into the study.¹⁰¹ The greatest benefit was observed in the low-dose (81 mg daily) group, who experienced an unadjusted risk ratio of 0.81 (95% CI = 0.69–0.96) whereas those in the high-dose (325 mg daily) group experienced a RR of 0.96 (95% CI = 0.81–1.13). When large or malignant polyps were considered separately, the benefits were clearer; risk ratios of 0.59 (95% CI = 0.38–0.92) in the low-dose group, and to some extent in the high-dose group (RR = 0.83; 95% CI = 0.55–1.23). The second study followed 517 patients with previous malignant CRC for a year and reported the RR for new polyps of 0.65 (95% CI = 0.46–0.91) in the 325 mg daily aspirin treatment group.¹⁰² Meanwhile, a third study, which combined three earlier case-control studies into a cancer patient base of 965 and 1,779 controls,¹⁰³ showed a dramatic reduction in the incidence of tumors of the mouth, throat, and esophagus with long-term use of aspirin. After controlling for factors, such as

smoking and diet, the incidence of the three types of cancer in people who had taken aspirin regularly for at least 5 years was a third that in nonusers [OR = 0.33 (95% CI = 0.13–0.82)]. Similarly, more than 15 case series and reports have described the benefits of NSAIDs for prevention of prevalent adenomas in persons with familial adenomatous polyposis (FAP).

Selective COX-2 inhibitors (COXIBs) recently approved for treatment and management of pain and arthritis provide a unique opportunity in terms of sparing COX-1 beneficial functions while inhibiting COX-2 in the process. On the basis of preclinical and observational studies just described, COXIBs have now advanced to human clinical trials in cancer prevention. A recent randomized, placebo-controlled trial of celecoxib administered over 6 months to 77 individuals with FAP showed significant regression and reduction in colorectal adenoma number and size. As an added benefit, celecoxib treatment also decreased duodenal polyps, suggesting a dual-organ benefit in this cohort. The importance of this study is underscored by FDA's approval of celecoxib to complement the endoscopic surveillance and prophylactic surgery in FAP individuals. Furthermore, based on these preliminary but landmark results, celecoxib is now under study in several clinical trials involving persons at elevated risk for CRC because of either a genetic predisposition or a history of prior sporadic neoplasia.

Summary and Lessons Learned

Randomized clinical trials remain the most robust test of an intervention, and a review of cancer prevention trials provides valuable lessons. In this chapter, we discussed examples of trials that highlight the effects of several prevention modalities on different stages of cancer, from late-stage intermediate endpoints (such as colon polyps) through second primary cancers (such as head and neck tumors). Of the five modalities discussed (diet, pharmacologic agents, selective hormone therapies/modulators, nonsteroidal antiinflammatory drugs, and vitamin and mineral supplements), two of the modalities, notably the NSAIDs and calcium supplements, were true successes without significant side effects. Both these interventions were effective at reducing risk of colonic malignancies, perhaps because the colon is an organ with higher cellular turnover in the adult years than other targeted organ sites.¹⁰⁴ The other case studies provided examples of either null results, mixed results (i.e., some preventive activity accompanied by significant adverse effects), or, in the case of the β -carotene-lung cancer trials, a small but significant cancer-enhancing effect that could only have been detected by conducting a clinical trial.

What have we learned from the failures and successes in the prevention trials? In the lung cancer prevention trials, we learned that β -carotene supplementation was the wrong intervention for individuals at high risk for lung cancer. Nonhuman primates administered β -carotene supplements had squamous metaplasia of the lungs that was markedly enhanced in the smoke exposed. In vitro work revealed that β -carotene molecules increased radical oxygen intermediates and reduced apoptosis, thereby defying the oft-cited role of β -carotene as an antioxidant and increasing its provitamin A capacity for cellular proliferation. In contrast, administration of another carotenoid, lycopene, in several doses inhibited

TABLE 23.6. Nonsteroidal antiinflammatory drugs (NSAIDs) in the prevention/treatment of sporadic colorectal adenomas or colorectal cancer prevention.

Reference	Sample size	Design	NSAID	Dose and duration (months)	Primary result(s)
Matsuhashi, 1997 ¹¹²	15	CS	Sulindac	300 mg po qd × 4	13 of 20 polyps in 15 patients shrank or disappeared*
Ladenheim, 1995 ¹¹³	44	DBRCT	Sulindac	150 mg po bid vs. placebo × 4	8% probability of >50% sporadic adenoma regression
Hixson, 1993 ¹¹⁴	9	CS	Sulindac or piroxicam	200 mg po bid (sulindac) or 20 mg po qd (piroxicam) × 6	Discontinued due to toxicity in 2; piroxicam more toxic than sulindac; no dramatic adenoma regression
Carbone, 1998 ¹¹⁵	Step 1 = 12 Step 2 = 31	Steps 1 & 2: CS	Piroxicam	Step 1: 10 mg po qd or qod Step 2: 10 mg po qod + DFMO 0.5 gm/m ² × 6	Step 1: 10 mg qod tolerable; no changes in ODC or urinary polyamine concentrations Step 2: combination is tolerable; possible synergistic effects
Calaluce, 2000 ¹¹⁶	96	DBRCT	Piroxicam	7.5 mg po qd vs. placebo × 24	Reduced mucosal prostanoid concentrations*; significant GI side effects*
Chow, 2000 ¹¹⁷	27	DBRCT	Ibuprofen	300 or 600 mg po qd vs. placebo × 1	Reduced mucosal prostanoid concentrations*; 300 mg po qd recommended for future studies
Barnes, 1999 ¹¹⁸	10	DBRCXT	Aspirin	81 mg po qd vs. placebo × 3	Reduced mucosal prostanoid concentrations*; reduced TGF- α staining*; both effects returned to baseline levels following 3 months off aspirin
Ruffin, 1997 ¹¹⁹	65	DBRCT	Aspirin	40.5, 81, 162, 324, or 648 mg po qd vs. placebo × 2 weeks	Reduced mucosal PGE ₂ * with 81 mg po qd; reduced mucosal PGF ₂ - α with 40.5 mg po qd
Gann, 1994 ¹²⁰	22,071	DBRCT	Aspirin	325 mg po qod vs. placebo × 60	CRC RR = 1.15 (95% CI = 0.80–1.65); In situ cancer or adenoma RR = 0.86 (95% CI = 0.68–1.10)
Baron, 2002 ¹²¹	1,121	DBRCT	Aspirin	80 mg po QD vs. 325 mg po QD vs. placebo × 48	Adenoma recurrence: all and advanced 80 mg: RR (all) = 0.81* (0.68–0.96); RR (advanced) = 0.60 (0.35–1.03) 325 mg: RR (all) = 0.96 (0.82–1.13); RR (advanced) = 0.81 (0.49–1.32)
Benamouzig, 2002 ¹²²	291	DBRCT	Aspirin	160–300 mg po QD vs. placebo × 48	Interim adenoma recurrence at 1 year (preliminary result): OR = 0.56* (95% CI = 0.31–1.01)

Sample size is the number of subjects evaluated at study completion. Intervention is the duration of agent administration until described effect.

po, administered by mouth; qd, once per day; qod, every other day; bid, twice per day; CR, case report; CS, case series; DBRCT, double-blind, randomized, controlled trial; DBRCXT, double-blind, randomized, controlled, cross-over trial; CCTRL, case-control.

*Statistically significant result ($P < 0.05$).

bioavailable IGF-1 and reduced risk of lung cancer.¹⁴ Baboons administered β -carotene supplements and given alcohol suffered from hepatotoxicity. Therefore, β -carotene supplementation in the presence of carcinogens—smoking and alcohol intake—increased risk, whereas lycopene reduced risk.

The finasteride and tamoxifen trials illustrate the risks and benefits of long-term pharmacologic manipulations of the sex hormones. Finasteride reduced the incidence of low- and intermediate-grade prostate cancer but increased the incidence of high-grade prostate cancer, possibly by enhancing clonal expansion of prostate cancer cells in an androgen-deficient environment. Tamoxifen reduced risk for ER+ breast cancers, but had no effect on ER– breast cancers and increased endometrial cancer risk. Side effects from an intervention may limit acceptance, as illustrated by problems in sexual function reported in the finasteride group and hot flashes in women on tamoxifen.

The timing of the intervention is an important factor, especially for the prevention of early or intermediate steps in the carcinogenesis process. From our trial examples, lung epithelium with 20–30 person-years of cigarette smoke exposure (as was the case in the β -carotene trials) might be too far along the carcinogenesis process to expect a relatively brief period of β -carotene supplementation, or other interventions that target early or intermediate cancer processes, to prevent cancer. Similarly, in the Polyp Prevention Trial, the effects of relatively brief period of dietary change late in life on polyp recurrence may have also been a case of too little too late.²⁷

What have we learned from the successes? The successful trials have demonstrated proof of principle that nutritional interventions or chemopreventive agents can reduce the risk of carcinogenesis across the entire cancer spectrum, from precursor lesions to second primary tumors. The successful trials were able to avoid the pitfalls discussed above and use what

turned out to be the right intervention, the right at-risk population, and the right dose and timing to hit an appropriate target for cancer prevention. Another key lesson learned from these trials is the utility of combinations of drug regimens to reduce toxicity, for example, the addition of α -tocopherol to 13-*cis* retinoic acid in the upper aerodigestive tract cancer prevention trials.

As mentioned previously, an important predictor of a successful prevention trial was the identification of the right intervention for the appropriate high-risk group or tumor type. An illustrative example is the inhibition of COX-2 activity by NSAIDs or COXIBS; these agents appear to hold great promise for the prevention of colon cancer and possibly many other cancers. It is important to note, however, that the *right* intervention does not have to be a pharmacologic agent developed to hit a specific molecular target. The example from the trials of calcium supplements to reduce polyp recurrence reminds us that a safe, inexpensive lifestyle intervention could have a large-scale public health impact. Several lifestyle interventions, including physical activity, prudent dietary change in total calories or reduction in fat intake, and increased fruit and vegetable intake, may significantly reduce the risk of many cancers.

Opportunities for tool refinement arise from the conduct of these trials. For example, dietary change from a high-fat, low-fiber to a low-fat, high-fiber, fruit and vegetable plan offered individual choice of food substitutes. However, food composition databases were not available to examine which bioactive food components reduced polyp recurrence. One of the challenges for breast cancer prevention is that 30% to 40% of breast cancer cases can be attributed to a major risk factor(s) (e.g., early age at menarche, family history), but the remainder of breast cancer patients will not be identified in the high-risk groups.¹⁰⁵ Risk assessment tools are important since they are used to counsel women about their disease management and to identify individuals at high risk who may be eligible for chemoprevention therapies. Risk assessment models such as the Gail model, which uses known risk factors to estimate breast cancer risk in women, may not be suitable for specific ethnic groups, such as African-Americans.¹⁰³ Indeed, few African-American women participated in the Breast Cancer Detection and Demonstration Project (BCDDP), which was the data source for the Gail model.¹⁰⁶ No such tools exist to assess breast cancer risk in Hispanic-white women nor are there algorithms to identify the at-risk for prostate cancer.

Concomitant with increasing longevity, a plethora of comorbidities appear in the aging population. Prescriptives, such as statins, are now being advocated for use in all Type 2 diabetics by the American College of Physicians, while over-the-counter medications, such as NSAIDs, are frequently taken in these same individuals for arthritis and other pain relief. However, the effective dose of each agent may be dependent on the disease and vary by age, gender, and the presence of other drugs. Simultaneous use of multiple therapies creates the challenge to identify appropriate dosages in combination for efficacy. An understanding of their beneficial or adverse effects in early or late stage chronic disease is essential.

A final lesson learned from the successful trials is the importance of integrating animal and human research into translational science. This approach involves linking clinical, behavioral, epidemiologic, animal, and molecular studies for

a tremendously powerful approach to cancer prevention.¹⁰⁷ Three aspects of this integrated approach include (1) testing the efficacy and safety of the particular agent and identifying potential targets for other agents or combinations of agents; (2) having the tools available to test the efficacy of an agent at the same time as examining whether the agent confers protection from cancer and/or also increases risk of another disease; and (3) having the ability to accelerate the pace at which interventions are moved from the bench to bedside. Through the interface of animal and human explorations, calcium supplementation arose as a successful intervention for polyp recurrence and colon neoplasia with benefits for the overall biosystem. Similarly, an interdisciplinary approach led to the approval of the COX-2 inhibitor celecoxib for the prevention of familial adenomatous polyposis. Thus, perhaps the clearest lesson from this brief review of several cancer prevention trials is that future progress in cancer prevention will depend on the confluence of energies and expertise from a multidisciplinary team, as illustrated in Figure 23.2.

Screening

Stephen H. Taplin, Sarah Dash,
Paula Zeller, and Jane Zapka

Proving the Efficacy of Screening Tests Is Only the Beginning

Primary care providers, including physicians, nurse practitioners, physician assistants, and the people who work with them, operate at the interface of the medical and lay communities. It is frequently stated that one in eight women gets breast cancer sometime in her lifetime. Oncologists consider the care of that one woman and others like her, whereas primary care physicians work with all eight, seven of whom will not get cancer. Oncologists deal directly with the consequences of delayed diagnoses and the morbidity of late-stage diagnoses while primary care physicians see the effects of false-positive tests. The difference in populations affects how each healthcare provider judges the evidence regarding cancer screening and may tip decisions in different directions in the face of ambiguity. However, ultimately the decision to encourage screening does depend on evidence. This chapter is about the evidence-based daily practice of screening in the primary care setting, where providers discuss screening, cancer, and the consequences of each.

Screening looks for cancers or precancerous lesions before the disease has had a chance to appear symptomatically. Some call this *early detection*. Because the idea that early detection saves lives has become so intuitively appealing, cancer screening captures the imagination and emotions of individuals, their families, and their physicians.¹ The appeal is so high that 87% of U.S. adults surveyed in 2002 believed that routine screening is almost always good, and 74% believe that finding cancer early saves lives most or all of the time.¹

The medical community operates from a different paradigm and does not have such faith in screening.^{1,2} Clinicians must “first, do no harm” and are compelled to identify an overall benefit before offering a test. Much of the controversy regarding screening is about whether it offers a net benefit—and by that we mean whether it reduces mortality. To reduce mortality, screening must meet at least two conditions: (1) that the test can find a cancer or precursor to cancer before it becomes symptomatic; and (2) that treating an early lesion changes the natural history of the disease and gains additional life for the patient. For example, at the center of the debate about prostate cancer screening is the fact that many men die of other causes even when prostate cancer is present, so it is not clear that all prostate cancer treatment contributes to additional life.

Even if it can be shown that cancer screening saves lives, there are serious concerns about its potentially negative

impact on people who will never get the disease. Unnecessary biopsies, additional tests, and the treatment of conditions that do not represent disease are common concerns. These concerns have generated major debates and a careful approach by the medical community to deciding whether and how often to recommend cancer screening³⁻⁵ (see Chapter 12). The medical community’s approach to screening recommendations includes identifying that the cancer has a substantial impact on society, there is a presymptomatic stage, the cancer can be found by screening during this stage, finding the cancer early leads to additional life compared with waiting for symptomatic detection, and the benefit of screening is worth the risk.⁶ Using such an approach, the U.S. Preventive Services Task Force (USPSTF) sorted through the evidence and reached the conclusion that screening for cervical, colon, and breast cancers is beneficial.⁷⁻⁹ The American Cancer Society agrees.¹⁰ Prostate cancer is more controversial.¹¹ This chapter summarizes the evidence regarding the benefit of currently available screening tests for breast, cervical, colon, and prostate cancers among average-risk individuals. Genetic screening (which is covered in Chapter 26) is not discussed here because it is not recommended for average-risk people. Similarly, screening for new cancers or recurrence after a cancer diagnosis is a special case that is not considered here; however, it is covered in Chapter 102.

Screening Is a Process

Understanding the literature on the benefit of screening in average-risk populations is a necessary step toward evidence-based practice, but it is only the beginning. Although there is a great deal of discussion about the various screening tests, it is really the entire screening process that matters. The test is only one part of a screening process that begins with the recruitment of eligible people and continues by conducting the screening test, evaluating those with positive results, and treating those with disease (Figure 24.1).¹² A successful screening process means mortality is reduced because those steps and transitions occur. For example, the proportion of people who make the transition from a positive test to evaluation and treatment varies between 27% and 93%, depending upon the screening test, the person’s insurance status, patient and provider factors, and the organization of the healthcare setting in which the test is administered.¹³ Making sure that transition occurs is the final subject of this chapter, and it is clear that without it screening cannot have an impact on mortality.

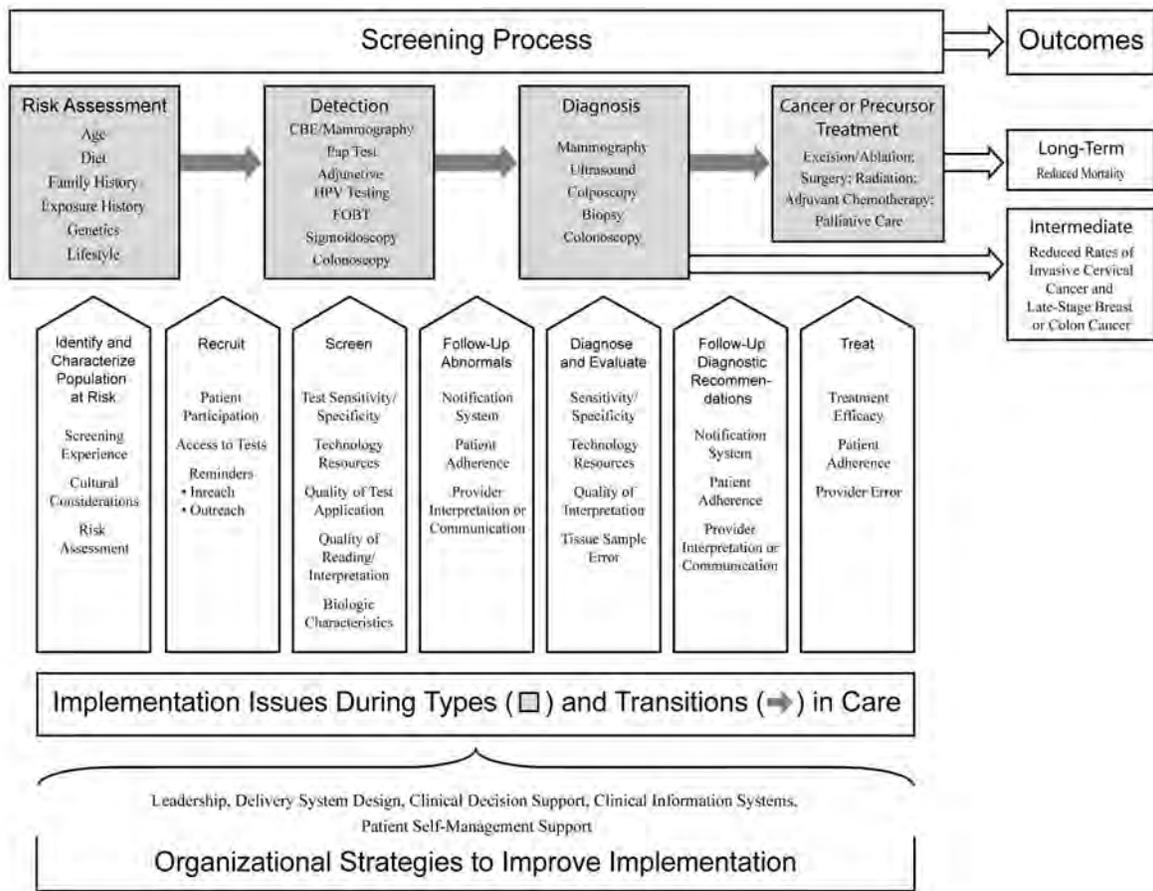

FIGURE 24.1. The screening process involves types of care and the transitions between them. (Adapted from Zapka et al.,¹² by permission of *Cancer Epidemiology Biomarkers & Prevention*.)

The Evidence for Screening

Clinicians and scientists have difficulty proving the intuitive notion that early detection results in longer life, because the observation of selected cases is deceiving and ascertainment of all relevant data for an entire population is difficult. Collections of cancer cases from a practice or screening center do not represent the full spectrum of the disease, so conclusions are not valid for the condition as a whole. Furthermore, watching cases from the day of diagnosis forward almost always makes survival look better for those at early cancer stages because there is more observation time, not necessarily because the process adds years to patients' lives.

People evaluating screening tests hope to minimize bias by designing and conducting studies carefully. Randomized trials reduce concerns about the inference drawn because it is more likely that the intervention and control populations are comparable, but how the study is implemented also influences its quality. Randomization, cause-of-death assessment, selection bias, and population characteristics all can affect inferences drawn from a study, and these factors can also affect whether the conclusions apply to the general population. The risk of these biases differs with study designs and has led the medical community to rank the design types based on the ability to draw valid conclusions. The highest quality results are likely to come from well-conducted randomized trials because they create similar groups and allow the assign-

ment of an intervention to one of the groups so that selection bias is avoided.¹⁴ One persistent concern, however, is that people willing to be in a randomized trial differ from people in the general population. Data from case-control studies are rated below randomized trials but allow for assessment of factors associated with rare conditions. The limitation of this design is that conclusions are affected by how well the cases and controls reflect similar populations and whether all potential confounders and effect modifiers have been identified.¹⁵ Despite being considered of lower quality, observational studies can provide powerful insights when conducted where comprehensive data are collected for entire populations.¹⁶⁻¹⁹ Such studies are especially important for evaluating whether the impact of screening in practice is consistent with expectations from randomized trials. In fact, some recent analyses show that well-designed and carefully conducted observational studies of interventions may obtain results that are indistinguishable from randomized trials.^{19,20} Given the rapid progression of technology, observational studies are a necessary part of evaluating new technologies that may be implemented in practice before randomized trials can be conducted.

The following section summarizes the evidence on screening for breast, cervical, colon, and prostate cancers, covering the following topics: (1) epidemiology and natural history; (2) screening test characteristics; (3) review of the literature on benefit; and (4) summary recommendations from

the American Cancer Society (ACS) and the U.S. Preventive Services Task Force (USPSTF), the organizations to which U.S. primary care practitioners look most often for recommendations.^{6,10} Specialty societies such as the American Academy of Family Physicians, American Academy of Obstetrics and Gynecology, American Academy of Physicians, and American College of Gastroenterology have also reviewed the evidence. We have included the recommendations that most strongly influence primary care, recognizing that providers are also strongly influenced by their patients and colleagues.²¹

The test characteristics discussed in this chapter include sensitivity, specificity, and positive predictive value. "Sensitivity" is the ability of a test to find the screened-for condition when it is present. "Specificity" is the ability of the test to determine that the screened-for condition is absent when the screened person is disease free. The "positive predictive value" (PPV) of a test is the proportion of positive tests due to the condition of interest.

Breast Cancer Screening

Epidemiology and Natural History

New invasive breast cancer was expected to affect 215,990 U.S. women in 2004; an additional 59,390 will have had in situ disease.^{22,23} One in 8.3 women will have breast cancer sometime in her lifetime, assuming she lives to age 85.²⁴ The incidence of invasive breast cancer rises from about 43.5 in 100,000 among women aged under 40 to more than 468 in 100,000 among women aged over 75 years.²⁵ Breast cancer incidence is lower among African-Americans than Caucasian-Americans (121.7 versus 140.8 in 100,000), but higher than in Asian-Americans (121.7 versus 97.2 in 100,000).²⁶ An estimated 40,580 women in the United States will have died of breast cancer in 2004. Although the risk of death due to breast

cancer for all races has decreased since the 1970s, African-Americans are more likely to die of breast cancer today than in 1969.²⁶

An important factor in screening is the *sojourn time*, defined as the length of time from when a cancer can be found in humans by a particular technology to when it has grown enough to cause symptoms.²⁷ By contrast, *lead time* is the length of time between when a cancer is actually found by a screening test and when it would become symptomatic. Screening must occur at intervals that are the same or shorter than the sojourn time.

The heterogeneity of breast cancer biology poses challenges for screening. Although the estimated sojourn time for a breast cancer is about 2 years among women ages 40 to 49, it may be as long as 4 years among women ages 60 to 69.^{28,29} Although some ductal carcinoma in situ (DCIS) progresses to invasive disease, some does not,³⁰ and much invasive cancer arises in the ducts and lobules of the breast without an in situ component being apparent.²⁷ Investigators are evaluating whether biologic markers such as high- and low-grade nuclear changes, rather than morphology, would clarify whether some of what we call DCIS is actually a benign condition that does not need treatment.²⁷ This important issue is at the heart of some people's concern about screening, because fully 16% of cancers found at screening in the United States are DCIS.³¹

Screening Tests

There are four tests commonly discussed for breast cancer screening: clinical breast examination, breast self-examination, film-screen mammography, and digital mammography. Table 24.1 summarizes the characteristics of these tests. Breast self-examination has been encouraged for years and consists of women systematically searching their own breasts in both supine and upright positions. Clinical breast examination is a similar systematic search by the healthcare provider.³²

TABLE 24.1. Summary of screening test characteristics: breast cancer.

Test	Sensitivity	Specificity	Who administers	% Positive in practice	Recommended follow-up	Comment
Film-screen mammography ^{7,43}	77%–96%	94%–97%	Radiologists	10%–12%	Additional mammography Ultrasound Clinical evaluation Biopsy	By definition, only cancers that are referred for biopsy will be identified and make up the denominator for these estimates. This verification bias results in an overestimate of the sensitivity.
Digital mammography ⁴³	64%	86%	Radiologists	12%	Additional mammography Ultrasound Clinical evaluation Biopsy	A randomized trial of digital mammography compared with film-screen mammography began in 2001.
Clinical breast examination ^{32,194,195}	17%–58%	94%	Clinicians	7%	Mammography Surgical evaluation	Testing sensitivity of clinical breast examination (CBE) is often done against mammography so the distribution of cancer sizes includes very small tumors.
Breast self-examination ⁵³	42%–72%	N/A	Women	N/A	Clinical evaluation	These estimates are based on testing women on silicone models.

Film-screen mammography uses low-dose radiation, radiographic film, and equipment dedicated to breast imaging. Two plates on the machine compress the breast so that the radiation dosage is minimized. The process is highly regulated by the Mammography Quality Standards Act (MQSA), which specifies parameters for technical (radiation exposure, development, etc.) and clinical (positioning, contrast, etc.) image quality. Since the passage of the Act in 1992, technical image quality in the United States has improved,³³ but there are persistent concerns about the quality of the clinical image and reader's interpretations.³⁴⁻³⁶

The American College of Radiology has created guidelines for the terminology used to describe and summarize findings on film-screen mammography.³⁷ These guidelines encourage consistent assessments and explain how to measure interpretive performance using the following terminology: 0, need additional imaging and/or prior mammogram for comparison; 1, normal; 2, benign finding; 3, probably benign finding—initial short-interval follow-up suggested; 4, suspicious abnormality—biopsy should be considered; and 5, highly suggestive of malignancy—appropriate action should be taken.³⁸ The American College of Radiology updated their assessment categories in 2003 and added a sixth category for images done after a breast cancer has been identified by biopsy.

Film-screen mammography sensitivity varies between 77% and 96%, although most healthcare providers expect a sensitivity of approximately 80% in clinical practice.^{39,40} Many factors influence the sensitivity of film-screen mammography, including younger age of patients, dense breast parenchyma, and having been screened within 1 or 2 years of the current mammogram.^{7,40,41} Specificity varies between 94% and 97% and is also influenced by these factors. For film-screen mammography, PPV is between 2% and 12% when a positive test is defined as one that leads to any additional evaluation with more mammograms, ultrasound, or visits to a clinician. The proportion of women found to have cancer among those referred to biopsy is higher (20% to 75%) because those women frequently have already been evaluated by ultrasound or additional mammographic imaging.⁷

Digital mammography uses equipment dedicated to breast imaging similar to film-screen mammography, but with a different receptor that creates the potential for a dynamic image.⁴² Photons that pass through the breast are collected by the receptor and counted. The information is digitized to allow display as a function of the photon count associated with a square micrometer of breast tissue. Unlike film-screen mammograms, which are preserved as fixed images similar to photographs, digital mammography stores data that can be manipulated by the radiologist.

The challenge in digital mammography is how to record and display the wealth of data that can be collected. For example, one receptor in digital mammography can detect and record up to 246 shades of gray. Designers make trade-offs between information devoted to recording this contrast and information needed to establish spatial relationships.⁴² The radiologist can print a hard-copy image or review the image on a cathode-ray tube display (soft copy).

Digital mammography is not widely used because its advantages over film-screen techniques have not been proven.⁴³ Recent work from a randomized trial suggests that digital and film-screen mammography have comparable accuracy, but the number of women recalled for additional

imaging is lower with digital mammography.⁴ A randomized trial comparing digital mammography with film-screen mammography began in 2001.⁴⁴

Computer-assisted reading uses software to analyze the output of digital mammography or the digitized image from equipment that scans a film-screen mammogram. The computer analysis identifies and marks areas of concern and displays them on an image shown on a cathode-ray tube adjacent to the view box where the original image is reviewed. Some, but not all, evaluations have shown that its use increases detection,^{45,46} and it has been approved by the U.S. Food and Drug Administration (FDA) for the second reading of films.⁴⁵

Other technologies, such as ultrasound, are used for breast imaging but are not approved for screening use by the FDA. Ultrasound's application involves scanning the breast with a hand-held transducer that projects sound waves and captures them bouncing off the tissue. This information is processed to provide two-dimensional images that can be recorded on film and displayed on a lighted box as with any radiologic image.⁴⁷ Ultrasound is time intensive and subject to some subjectivity because the operator must decide which images to record and how carefully to scan the breast, limiting this technology's effectiveness for screening. On the other hand, it is used effectively for the diagnostic workup of palpable lesions or abnormalities found via mammography.⁴⁸

Although it is possible to identify individuals at high risk for breast cancer due to genetic defects, this is not recommended for the general population.^{49,50} As noted in Chapter 19, the search for genetic defects usually begins with the affected individual and then proceeds to the family if a defect is found. Currently, less than 10% of breast cancers are estimated to be associated with a genetic defect.⁵⁰

Summary of the Evidence for the Benefit of Breast Cancer Screening Tests

Among the three screening tests commonly considered for breast cancer, only one has been shown to be efficacious: film-screen mammography. Clinical breast examination has never been studied as the sole intervention in a randomized trial.³² One randomized trial of film-screen mammography compared its benefit to regular screening with clinical breast examination and found no advantage for film-screen mammography.⁵¹ Some argue that the lack of film-screen mammography benefit in this trial supports the belief that clinical breast examination is effective. At present, however, no evidence-based guideline recommends clinical breast examination as the sole screening approach, even in countries with low resources.⁵² The systematic teaching of breast self-examination was examined in a large study conducted among women working in China. Groups of factory workers were trained in breast self-examination and brought back regularly for retraining. Despite demonstrating that women receiving the intervention had a higher sensitivity for finding lumps in silicone models, cumulative breast cancer mortality after 10 years was no different between the intervention and control populations.⁵³

The evidence for the benefit of film-screen mammography, which has been collected in randomized clinical trials since the 1960s, is summarized in Table 24.2. The American Cancer Society and the USPSTF both recommend screening beginning at age 40 based on evidence for a 16% reduction in

TABLE 24.2. Evidence for the efficacy of film-screen mammography.

Study name	Years of intervention	Longest follow-up	Site of study	Age group (years)	Study design	Exposure (intervention vs. control)	Screening rounds	Screening interval (months)	Views	% Exposed to intervention (round)	Contamination	Relative risk (odds ratio) of breast cancer mortality	Comment
HIP ¹⁹⁶	1963–1966	18	Staff-model managed care plan	40–64	Randomized controlled trial (RCT)	Mammography + CBE vs. usual care	4	12	2	67% (1); 54% (2); 50% (3); 46% (4)	Unknown	0.83 (0.7–1.0)	The first study to test mammography and have surgeons operate based on nonpalpable lesions.
CNBSS-1 ¹⁹⁷	1980–1985	11–16	National healthcare system	40–49	RCT	Mammography + CBE vs. usual care (all women prescreened and instructed in breast self-examination [BSE])	4–5	12	2	100% (1); 85%–89% (2–4)	25%	0.98 (0.73–1.31)	Used community radiologists; all women screened by CBE at baseline.
CNBSS-2 ⁵¹	1980–1985	13	National healthcare system	50–59	RCT	Mammography + CBE vs. usual care (all women prescreened and instructed in BSE)	4–5	12	2	100 (1); 90.4% (2); 86.5% (5)	16%	1.14 (0.83–1.56)	Used community radiologists; all women screened by CBE at baseline.
Edinburgh ¹⁹⁸	1978–1985	14	Primary care practices in Scotland	45–64	RCT	Mammography + CBE vs. usual care	4	24	1–2	66% (1); 44% (7)	Not reported	0.71 (0.53–0.95)	Randomization by physician practice resulted in population differences. Recent meta-analyses exclude this study.
Gothenburg ^{7,199}	1983–1984	12	Clinics in county health system	39–59	RCT	Mammography vs. usual care; controls offered screening after year 5, completed screening at approx. year 7	5	18	1–2	85% (1); 75%–78% (2–5)	20%	0.86 (0.54–1.37)	
Stockholm ²⁰⁰	1981	11	Clinics in county health system	40–64	RCT	Mammography vs. usual care; controls offered screening after year 5	2	24–28	1	81% (1); 81% (2)	Not reported	0.71 (0.4–1.2)	
Malmö ²⁰¹	1976–1994	11–13	Screening clinic outside main hospital	45–70	RCT	Mammography vs. usual care; controls offered screening after year 14	9	18–24	1–2	74% (1); 70% (2–5)	25%	0.81 (0.62–1.07)	
Swedish 2-County Trial ²⁰²	1977	20	Mobile vans managed by county health system	40–74	RCT	Mammography vs. usual care; controls offered screening after year 7	3	24–33	1	89% (1); 83% (2); 84% (3)	13%	0.68 (0.5–0.93)	Most commonly cited study. Used 2-year interval for women 40–49 and 3-year interval for women 50–74.

breast cancer mortality over 14 years of follow-up among women aged 40 to 49 years and 22% breast cancer mortality reduction over 14 years among women ages 50 to 74.⁷ Although the difference in cumulative mortality appears to increase with follow-up among intervention women ages 40 to 49 compared with controls, the benefit decreases with time among women ages 50 to 74.⁷ Some have suggested that screening may actually result in higher breast cancer mortality based on the cumulative mortality for the first 3 to 4 years among intervention women compared with control women.⁴ Whether that difference is real or not, it disappears with time. Because film-screen mammography technology has improved since the randomized trials began, some groups believe that the benefit is greater for those seeking screening today.⁵⁴

Despite the consensus in the United States to begin screening at age 40, there is some controversy about the findings on which this recommendation is based.^{4,5,55,56} In all randomized trials, the number of cancers found within a particular age group is relatively small, so there are advantages to combining results from several trials. However, each trial has unique characteristics and was implemented by different teams. Most of the controversy has to do with the internal validity of the trials and whether their results can be combined to provide an overall estimate of film-screen mammography's impact.^{7,27}

Two investigators, Olsen and Gotzsche, reviewed eight trials and raised questions about randomization, comparability of the cases and controls, assessment of cause of death, and exclusions after randomization.⁵⁵ These investigators concluded that only two trials met standards of research quality that justify inclusion in meta-analysis; neither trial showed a benefit. The USPSTF reviewed the same list of trials and kept all but one in its analysis.⁷ A separate meta-analysis by an international group produced the same conclusion as the USPSTF regarding which trials to exclude from meta-analyses, and estimated a 19% mortality reduction at 14 years among women ages 40 to 49 and a 25% mortality reduction among women ages 50 to 69, but only the latter was statistically significant.²⁷

Because of the controversies surrounding mammography, there is widespread agreement that the determination of whether to screen should be based on an informed decision that acknowledges that any benefit among populations of younger women is evident only after many years and that the overall benefit for all women is modest.^{4,5} Part of the informed decision-making process should include the information that one reason for the modest benefit is that many women diagnosed with breast cancer do well when detected in the course of usual care.⁵⁷ To show a benefit, screening must perform better than usual care. Furthermore, because the effect on mortality is moderate, a high quality of screening implementation is important to reproduce the impact demonstrated in the trials.

There are persistent questions regarding the optimal frequency with which to screen, and there is no randomized trial comparing 1- versus 2-year screening intervals. There has been a trial to compare film-screen mammography intervals every 1 versus 3 years among women aged 50 to 62 years.⁵⁸ In this trial, the investigators estimated expected deaths based on the observed stage differences between two screening groups and concluded there was no advantage to annual film-screen mammography compared to triennial screening.⁵⁸

However, because the sojourn time for young women is close to 2 years, some argue that the screening interval for this age group should be 1 year.^{28,59}

Recommendations

The ACS recommends annual film-screen mammography and clinical breast examination beginning at age 40.⁵⁹ They recommend individualizing decisions about when to stop screening.

The USPSTF recommends screening film-screen mammography, with or without clinical breast examination, every 1 to 2 years for women aged 40 and older and also recognizes the need to individualize when to stop screening.⁷

Cervical Cancer Screening

Epidemiology and Natural History

Cervical cancer was the most common cause of cancer death among women during the early part of the 19th century. It is now uncommon in the United States, but it is second after lung cancer as the cause of cancer death for women worldwide.⁶⁰ In 2004, an estimated 10,520 cases were expected to be diagnosed in the United States.^{22,25} Incidence and death rates differ by race: incidence is higher among African-Americans (13.6 in 100,000)²⁵ than among Caucasian-Americans (8.1 in 100,000; ACS). In 2004, an estimated 3,900 cervical cancer deaths were expected (2.7 in 100,000), and there is concern that mortality will be highest among recent immigrants to the United States, among whom screening rates are lowest.^{23,25,61}

Cervical cancer is directly related to the presence of an infectious disease. Some 93% to 100% of cervical squamous cell carcinomas contain DNA from human papillomavirus (HPV). Thirteen types of HPV (16, 18, 31, 33, 35, 39, 45, 41, 52, 56, 58, 59, and 68) are associated with increased risk for cervical cancer and are transmitted during sexual intercourse.⁶² The transformation of cervical cells from atypical squamous cells of unknown significance (ASCUS) through low-grade squamous intraepithelial (LSIL) to high-grade intraepithelial lesions (HSIL), cervical intraepithelial neoplasia (CIN), and invasive cancer takes 10 or more years. The terminology for these changes is described next. The transformation process may be reversible in the early stages.⁶³ Ninety percent of LSILs in adolescents and 50% to 80% of LSILs in adults regress to normal tissue. However, some lesions progress to CIN and invasive cancer.⁶³ Once a cervical intraepithelial grade 2 (CIN2) lesion exists, it progresses to cervical cancer over a period of about 41 months.⁹

Several factors increase women's risk of cervical cancer, including sexual intercourse, smoking, a history of multiple sexual partners, immunosuppression, and in utero exposure to diethylstilbestrol (DES).⁶⁴ Based on a representative sample of U.S. women in the mid-1990s, 23% reported having unprotected intercourse in the previous 3 months, including 25% of unmarried women ages 15 to 18.⁶⁵ Smoking is associated with the secretion of nicotine and cotinine in cervical mucus, but the mechanism through which this facilitates cancer development in the presence of HPV is not clear.⁶⁶ Women with high-grade squamous intraepithelial lesions are more

likely to be current smokers who are HPV positive compared with women with LSIL (OR 3.0; 95% CI, 1.2, 7.7)⁶⁷ Women with multiple sexual partners in their lifetime may have as high as a threefold increased risk for cervical cancer, which is likely due to acquisition of HPV.^{64,68} Finally, immunosuppressed women are at increased risk of developing CIN.⁶⁹

As we acquire more information about genetics, we gain insights into why not all women who harbor high-risk HPV types develop invasive cancer. There are specific DNA mutations associated with increased risk, but the mechanism is not yet clear. For example, one study found two mutations associated with a three- to fourfold increase in risk of invasive cervical disease. The author of that study suggested that the mutations affected how cigarette smoke was metabolized into compounds that facilitated cell transformation in the presence of HPV.⁷⁰

Screening Tests

Cervical cancer screening has been available for many years. This section reviews the Papanicolaou (Pap) test, first used in the 1940s, and other tests used for cervical cancer screening. The purpose of these tests is to identify precursor lesions that can be treated to prevent the subsequent development of invasive cervical cancer. Two tests, the Pap smear and liquid-based cytology, sample cells shed from the cervix. The other tests look directly at the cervix to evaluate abnormalities.

For the Pap test, a clinician takes a sample of endocervical cells by scraping a flat spatula around the surface of the cervix and sampling within the cervical entrance using a swab or brush. The endocervical brush is now suggested as an alternative to the cotton swab, although there has been some evidence that it does not improve sensitivity over the standard technique.^{9,71} The cell sample is spread on a glass slide and fixed with a preservative so that a cytopathology technician and/or pathologist can review it for abnormalities. Detection errors occur when cells from the transformation zone between the endo- and ectocervix are not captured, the cells dry on the slide before they are preserved, or abnormal cells are not recognized at the time of the cytology review. Liquid-

based cytology (LBC) uses the same collection technique as a conventional Pap smear, but the cells are immediately placed in a receptacle with fixative solution rather than spread on a glass slide. The solution is filtered, and the collected cells are then spread on a slide for review.

Ratings of cervical cell abnormalities evolved to the current Bethesda System through a consensus process and review of the literature between 1988 and 2001.⁷² This system rates specimen adequacy (satisfactory or unsatisfactory) and then provides three summary categories: negative for intraepithelial lesion or malignancy, epithelial cell abnormality (see interpretation), and other (see interpretation). The interpretation of epithelial lesions falls into four major categories (one with subcategories): (1) atypical squamous cells, with the subcategories "of undetermined significance" (ASCUS) and "cannot exclude HSIL" (ASCH); (2) LSILs, encompassing mild dysplasia and low-grade CIN1; (3) HSILs, which include moderate and severe dysplasia, carcinoma in situ, CIN2, and CIN3; and (4) squamous cell carcinoma. The source of the specimen (i.e., LBC or conventional Pap) is also reported, because LBC specimens may be used for subsequent HPV testing as indicated.⁷² If glandular cells are present, they also are described.

Although the purpose of cervical cancer screening seems clear, the many precursor lesions and neoplasias that may occur influence the evaluation and comparison of screening tests. Screening test sensitivity and specificity will vary depending upon what condition investigators choose to identify. For example, HPV testing may have high sensitivity for the high-risk HPV virus (types 16 and 18), but there may not be any squamous cell change of the cervix, which is the primary concern. For squamous cell changes, HPV screening specificity is low because many women harbor the virus for prolonged periods before any cellular changes are visible. In a meta-analysis by Nanda and colleagues, the standard was to use an interpretation of LSIL or worse as the definition of a positive test and presence of CIN2 or CIN3 as histologic confirmation of disease.⁷¹ As shown in Table 24.3, Pap sensitivity is 30% to 87% (mean, 47%) and specificity is 46% to 100% (mean, 95%) in low-prevalence populations.^{71,73}

TABLE 24.3. Summary of screening test characteristics: cervical cancer.

<i>Test</i>	<i>Sensitivity</i>	<i>Specificity</i>	<i>Who administers</i>	<i>% Positive in practice</i>	<i>Recommended follow-up</i>	<i>Comment</i>
Papanicolaou screen ^{73,76,203,204}	30%–87% (mean 47%)	86%–100% (mean 95%)	Clinician	8%–13%	Repeat testing of ASCUS, HPV testing of ASCUS in which HSIL cannot be excluded, and colposcopy of anyone with LSIL or higher lesions	Follow-up is based on consensus guidelines. ²⁰⁵
Thin-Prep ⁷⁶	80%*	98%	Clinician	NA	Same as above	*Based on abnormalities of LSIL or greater.
HPV DNA testing ^{73,206,207}	83%–100%	46%–89%	Clinician	5%–40% depending upon age	Pap smear and/or colposcopy and biopsy as indicated by either	Sensitivity based on ≥LSIL. Specificity based on <LSIL. Risk of positive HPV is higher in younger women.
Acetic acid and direct visualization ⁷⁷	80% [‡]	81%	Clinician	NA	Biopsy of abnormalities at the time they are identified	[‡] Based on abnormalities of HSIL or greater.

Follow-up is based on consensus guidelines.²⁰⁵

Specificity based on <LSIL. Risk of positive HPV is higher in younger women.

*Based on abnormalities of LSIL or greater. Sensitivity based on ≥LSIL.

[‡]Based on abnormalities of HSIL or greater.

The true-positive rate was reported by some investigators as 13% higher for LBC compared with conventional Pap, but the false-positive rate was also increased by 12%. These findings suggest that LBC has a higher sensitivity and lower specificity than the conventional Pap smear.^{71,74}

Because detection errors limit the efficacy of Pap and LBC techniques, there has been an effort to automate the interpretive process and improve detection.⁷⁴ Studies are under way to use computer software to analyze images of LBC preparations, but these systems are not yet in widespread use.⁷⁴⁻⁷⁶

Although cytology remains the accepted screening method in the United States, other methods exist, including direct visualization of the cervix and analysis of intrinsic or reflected light emission from the cervix. Direct visual inspection (DVI) is a technique first used in the 1930s and then abandoned with the introduction of the Pap smear. However, DVI is reappearing in the developing world because it has the advantage that when an abnormality is identified, it can be dealt with during the same visit.⁷⁷ Sensitivity for CIN appears comparable between DVI and Pap smear, but specificity is lower with DVI. An alternative to DVI is to use a photograph that can be analyzed by a physician (cryptography). However, this technique appears to have lower sensitivity than either Pap or DVI and is, therefore, not recommended. Finally, new technologies are being developed that involve the spectroscopic evaluation of light reflected from the cervix. Although this technology is in its infancy, it holds promise for the detection of CIN2 and CIN3 because the early neoplastic cells present with these conditions reflect light differently from normal tissue.⁷⁷

HPV testing may someday be an alternative to cytologic screening for cervical cancer, but current knowledge is inadequate to adopt it as the primary screening tool.⁶⁴ HPV testing involves identifying and typing HPV in cervical mucus. It appears most useful in managing women with ASCUS as only those with HPV may need monitoring.⁷⁸

Summary of the Evidence for the Benefit of Cervical Screening Tests

Evidence for the benefit of cervical cancer screening comes from cohort studies conducted in countries with active screening programs. This evidence is summarized in Table 24.4; it shows a 24% to 70% reduction in invasive cervical cancer incidence and a 22% reduction in mortality with the implementation of screening programs. The evidence is so convincing across published studies that virtually no one advocates for randomized trials or questions the impact of cervical cancer screening by cytology.

One area of controversy, however, is the frequency with which cervical cancer screening should occur. As our understanding of the slow progression of this disease has grown, screening intervals recommended by U.S. organizations have widened. As noted above, even change from HSIL to invasive cancer takes an estimated mean of 41 months, so most now believe that screening may occur successfully at intervals as infrequent as every 3 years with a low risk of invasive cancer development.⁹ One group of investigators estimates that after three negative Pap smears, the risk associated with screening every 3 years, compared with annually, is as low as 3 in 100,000.⁷⁹ Others suggest that setting a fixed screening rate for all women does not make sense. Because the risk varies

with age and sexual history, they recommend varying the frequency from 1 to 5 years depending upon risk.⁸⁰

Recommendations

The ACS recently reviewed the new data on cervical cancer and updated its recommendations. ACS now recommends that screening begin 3 years after onset of sexual activity or by age 21 and may stop at age 70 if the low-risk status of the woman is established (i.e., three or more negative screens within 10 years and no high-risk conditions such as HIV, in utero DES exposure, immunocompromise by organ transplantation, chemotherapy, or chronic corticosteroid treatment). The ACS recommends an annual Pap up to age 30, and then every 2 to 3 years after three successive adequate negative Pap smears. Because of the greater sensitivity of LBC, the Society recommends screening every 2 years to age 30 if LBC is used, then every 2 to 3 years if it has been established by history and Pap results that the woman is at low risk.

Based on indirect evidence, the USPSTF recommends that screening begin within 3 years of onset of sexual activity or by age 21 and that it end at age 65 if women have had negative Pap smears and are otherwise at low risk. They recommend screening at least every 3 years.^{81,82}

Colorectal Cancer Screening

Epidemiology and Natural History

In 2004, an estimated 146,940 people in the United States were expected to be diagnosed with colorectal cancer (CRC), and an estimated 56,730 were expected to die of the disease.²² African-Americans are more likely to be diagnosed with and die of CRC than Caucasian-Americans (62 in 100,000 versus 55 in 100,000 and 29 in 100,000 versus 21 in 100,000, respectively).²⁵ Data on other groups, such as American Indian/Alaska Natives, Asian/Pacific Islanders, and Hispanics, are limited, but individuals in these populations are less likely to die of CRC than Caucasian-Americans (14.8 in 100,000, 13.1 in 100,000, and 14.2 in 100,000, respectively).²⁵

As with other cancers, the estimated length of time for the development of CRC from normal tissue has implications for screening. Unlike other cancers, the sequence of mutations occurring with CRC is well described and provides a model for cancer progression, from abnormal cell through polyp to invasive cancer. This knowledge of CRC mutations holds promise for diagnosing and determining prognosis in screening and treatment programs.⁸³⁻⁸⁹ The time it takes for CRC to develop varies from as little as 2 years for individuals with the hereditary nonpolyposis colorectal cancer (HNPCC) gene to 10 or more years for individuals at average risk for CRC.^{85,90} Recommended screening intervals are, therefore, shorter for people at higher CRC risk.¹⁰

Most CRC arises from adenomatous polyps (adenomas). The potential of adenomas to progress to CRC varies; in general, larger polyps have a higher potential for malignancy. The goal of CRC screening is to detect adenomas that are likely to become CRC. A minority of cancers may not progress through the adenoma-to-carcinoma sequence; in these cases, existing screening tests are relied upon to detect early-stage cancers rather than adenomas.^{8,91}

TABLE 24.4. Evidence for the efficacy of cervical cancer screening.

Study name	Years of intervention	Longest follow-up (years)	Site of study	Age group (years)	Study design and screening comparison	Exposure (intervention)	Screening rounds	Screening interval (months)	% Exposed to intervention (round)	Measure of effect	Comment
Finland ¹⁶	1960–1987	27	Entire country	30–55 (60)	Obs	Pap smear	Up to 5 screens	60	80%	60%–70% reduction in incidence	Women ages >60 added in 1987. An evaluation of outcomes in the population as a whole without individual-level data.
Norway 1 ²⁰⁸	1959	20	Ostfold county	25–29	Obs	Pap smear	4	24	80% (1) 66% (4th)	38% reduction in incidence	Screening through primary care began in early 1960s.
Norway 2 ²⁰⁴	1995–2000	5	Entire country	25–69 w/o screens in 3 years	Obs	Pap smear	2	36	8% more than without exception system	24% decreased incidence 1999–2000	The most recent study showed an additional reduction in incidence with outreach reminders added to the program. Total population screening went from 65.2% to 70.7%.
Denmark ^{209,210}	1967–1982	8	Entire country	30–54 vs. >54	Obs	Pap smear	0–13	24	88%	22% lower mortality	Implemented screening in the 1960s by counties. Full implementation of organized program with mailed reminders in the late 1980s. National recommendation is screen every 3 years.
Sweden ²⁰⁸	1967	5	Entire country	30–49	Obs	Pap smear	NA	48		72% reduction in incidence (30–54 years)	Population-based analysis without individual-level data.

Screening Tests

Available screening tests for CRC are fecal occult blood testing (FOBT), sigmoidoscopy, and colonoscopy.⁹² Barium enema also remains an option for CRC screening and is discussed briefly. Digital rectal examination (DRE) has been used but is not effective and is not recommended as a CRC screening tool.^{10,93}

Fecal occult blood testing requires that a person collect three stool samples and place them on a special card that is mailed or taken to the laboratory for processing to identify whether the sample contains blood. A reagent placed on the card identifies hemoglobin in the stool through two main mechanisms: guaiac-based tests that detect blood through the pseudoperoxidase activity of heme (FOBT; not specific for human blood) and immunochemical techniques (IFOBT; immunochemical FOBT) that use antibody reactions to identify human hemoglobin.^{89,90,94–96} Guaiac-based tests generally require the patient to eliminate nonsteroidal antiinflammatory medications, red meat, and certain vitamins for 3 to 5 days before testing.^{89,96–98}

The disadvantages of FOBT are its low sensitivity for CRC (approximately 25% to 50% for Dukes stage A or B) and the precursors to CRC (10% to 20% for most polyps 1.0cm or larger), and its low specificity (approximately 88% to 98% for single use).^{88,99,100} Rehydration of test slides may increase sensitivity by 2% to 4%, but it also substantially increases the false-positive rate from 8% to 16%.^{100–103} Median completion and return rates of FOBT (when individuals are given the test to take home) vary between 40% and 50%.¹⁰⁴ Adherence depends upon the population studied, the test type, and the level of dietary restriction required.^{88,90,97–99,105–107} One recent randomized trial demonstrated a 40% completion rate when a two-sample brush approach was used in people without dietary restriction compared to 23% and 30% for two three-sample techniques among people on peroxidase-restricted diets before testing.⁹⁷ The distinct advantage of FOBT, however, is that the test is inexpensive and it is the one technique demonstrated to reduce mortality in randomized trials.^{8,96}

IFOBT may improve on the sensitivity and specificity of guaiac-based tests and does not require dietary restrictions.^{108,109,110} However, the cost of IFOBT is two to five times higher than that of FOBT, and at least one study comparing IFOBT and FOBT showed no improvement in the rate of completion of tests.^{59,89,94,96,108,110} At present, evidence suggests that sensitivity of IFOBT is 66% to 69% and specificity is 95% to 97%.^{94,95}

Sigmoidoscopy is the direct visual examination of the rectum and lower colon using a flexible lighted tube (sigmoidoscope). It requires 1% to 2% saline enemas for preparation and takes about 10 minutes to perform.¹¹¹ Administration of the test requires special training, but it is routinely performed by primary care physicians, physician assistants, and nurses, as well as by specialists such as gastroenterologists.¹¹¹ Sigmoidoscopy is estimated to detect 68% to 78% of advanced neoplasia in the distal colon.⁸ However, its effectiveness is reduced compared to colonoscopy because it cannot reach the proximal part of the colon and, therefore, misses 40% to 50% of advanced neoplasms.^{18,112} In addition, its sensitivity may be reduced in women because they are more likely than men to have a shorter, more limited examination.¹¹³

Colonoscopy uses a flexible scope to visualize the entire colon. Preparation for colonoscopy is more extensive than for sigmoidoscopy, typically involving 1 day of clear liquids and laxative preparation.¹¹¹ The test itself requires sedation, skilled support personnel, and a trained endoscopist. It takes about 30 minutes to perform colonoscopy and 2 to 3 hours of patient recovery time.¹¹¹ It is the most accurate test currently available for detecting CRC or adenomas, with sensitivity of a single test ranging from 75% to 92%, depending on the size of the lesion detected and training of the operator.^{114,115} However, colonoscopy is not a perfect test, missing on average 13% to 27% of adenomas less than 1 centimeter in diameter.¹¹⁶

The disadvantages of both endoscopic procedures are that they carry a risk of perforation (1.96 per 1,000 colonoscopies, 0.88 per 1,000 sigmoidoscopies) or bleeding and require that the bowel be completely cleared.¹¹⁷ Patients may also experience pain or discomfort during the procedure, particularly with sigmoidoscopy, which is not performed under sedation.^{111,113,118} In general, rates of endoscopic evaluation after a positive FOBT are suboptimal. In a study of 24,246 Medicare beneficiaries who underwent FOBT, only 34% of those with positive results underwent a complete colonic evaluation consisting of either colonoscopy or flexible sigmoidoscopy with air-contrast barium enema; an additional 34% underwent either flexible sigmoidoscopy or a barium enema.¹¹⁹ Rates of recommended follow-up testing (colonoscopy or flexible sigmoidoscopy with air-contrast barium enema) in other studies have ranged from 21% to 90%, with the highest rates of follow-up achieved in randomized trials.¹¹⁹ Low follow-up rates may be due to a lack of follow-through on the part of physicians—in one study, primary care physicians ordered a complete diagnostic evaluation of the colon for only 70% of patients with positive FOBT¹²⁰—and of patients, who need to schedule the colonoscopy upon physician recommendation.

Double-contrast barium enema (DCBE) provides a radiographic image of the entire colon and rectum. It does not require sedation, although it does require full colon cleansing and has occasionally been associated with anaphylactic reactions to the latex bulb used to administer the contrast agent.^{121–123} Table 24.5 contains sensitivity and specificity estimates for DCBE.

Emerging screening methods: Screening methods currently in development include virtual colonoscopy [also known as spiral computed tomography (CT) or CT colonography] and tests for altered DNA in the stool.^{88,89,114,124,125} A new technology called capsule video endoscopy, approved in 2001 by the FDA for diagnosing small-intestine disorders, may prove useful for CRC screening in the future.⁸⁹ Cost-effectiveness, system capacity, and other issues relating to these technologies are also important and remain to be demonstrated.^{114,126,127}

Summary of the Evidence for the Benefit of CRC Screening Tests

Table 24.5 summarizes the test characteristics of the technologies used for CRC screening.^{8,10,90,92,128,129} As noted in Table 24.5, FOBT is the only CRC screening method that has been evaluated in randomized clinical trials. These trials have demonstrated that annual FOBT reduces CRC mortality by 15% to 33%.^{102,106,130} Biennial (every 2 years) FOBT screening

TABLE 24.5. Summary of screening test characteristics: colorectal cancer.

Test	Sensitivity (%)		Specificity (%)		Who administers	% Positive in practice	Recommended follow-up for positive test	Proportion of positives evaluated in practice*	Comment
	CRC**	Large adenoma	CRC	Large adenoma					
Fecal occult blood test (FOBT): unrehydrated ^{90,96,110,119,211,212}	11–86	21–30	91–99	91–92	Patient (at home)	2.4%–9%	Colonoscopy or DCBE with flexible sigmoidoscopy	34%–50%	Annual repetition of FOBT yields higher sensitivity than single FOBT. Screening FOBT in physician's office is not recommended.
FOBT: rehydrated ^{86,102,110,119,212}	50–92	22–53	94	94	Patient (at home)	8%–10%	Colonoscopy or DCBE with flexible sigmoidoscopy	34%–50%	In RCT by Mandel et al., rehydration increased positive test from 2.4% to 9.8%.
Immunochemical fecal occult blood test (iFOBT) ^{95,110,211,213}	69–100	25–79	86	86–95	Patient (at home)	9%	Colonoscopy or DCBE with flexible sigmoidoscopy	50%	Combination FOBT/iFOBT tests may have higher sensitivity than either type of test alone.
Double Contrast Barium Enema (DCBE) ^{115,214}	65–85	48	Not reported	85	Radiologist	N/A	Colonoscopy	N/A	Sensitivity of barium enema has been shown to vary by hospital & practitioner. ¹¹⁵
Sigmoidoscopy ^{111,116,136,137,215,216}	50–70 for advanced neoplasms	75% for polyps <1 cm	Not reported	Not reported	Primary care physician, physician's assistant, nurse, gastroenterologist	17%	Colonoscopy	74%–85%	Positive rate includes all adenomas.
Sigmoidoscopy + FOBT ^{134,137,212}	76 for advanced neoplasias**	Not reported	Not reported	Not reported	Primary care physician, physician's assistant, nurse, gastroenterologist (patient for FOBT)	10%–17%	Colonoscopy + or DCBE	77%	The addition of FOBT increased the sensitivity by 0.05% in the one study with a direct of Sig vs. Sig plus FOBT. ¹³⁷
Colonoscopy ^{114–116}	95	88–94	Not reported	Not reported	Gastroenterologist	>5%	Endoscopic or surgical resection	Not reported	Sensitivity of colonoscopy has been shown to vary by hospital and practitioner. ¹¹⁵
Virtual colonoscopy ¹¹⁴	100% (2 of 2) malignant polyps were detected	94	Not reported	96	Radiologist/CT technician	7%–8%	Optical colonoscopy	Not on market	Sensitivity for high-risk lesions and cancer.
Stool-based DNA testing (Multi-Target Assay Panel) ^{127,217,218}	44–91	48–86	Not reported	93–96	Not on market	Not available	Not on market	Not on market	

*This represents the proportion of positives followed up with the recommended procedure (e.g., colonoscopy). In the Lurie study, close to 100% of Medicare recipients with a positive FOBT were followed up, but only 34% had either colonoscopy or FS with barium enema, which were considered the recommended procedures for follow-up.

** Advanced neoplasias defined as cancer or high-risk adenomas ≥1cm or with villous/dysplastic features.

reduces mortality by 15% to 21%.^{102,106,130,131} Although research has suggested that CRC screening by FOBT would also reduce mortality from CRC,¹³² more needs to be done to evaluate its cost, accuracy, and adherence to its use by people to whom it is recommended.^{94,132}

Evidence for the benefit of sigmoidoscopy has been demonstrated in two case-control studies showing that people who died of CRC were 59% to 79% less likely than controls to have been screened even once by sigmoidoscopy.^{18,133} Research also suggests that using FOBT in conjunction with sigmoidoscopy could confer additional benefit compared with sigmoidoscopy alone because it may detect cancers in the proximal sigmoid colon that are missed by sigmoidoscopy.¹³⁴ Two ongoing randomized clinical trials (RCTs) to evaluate flexible sigmoidoscopy will report their initial results within the next several years,^{135,136} and an ongoing trial in Norway is evaluating the benefit of flexible sigmoidoscopy and flexible sigmoidoscopy combined with FOBT.¹³⁷ Consistent with the reduction in mortality conferred by screening endoscopy, several studies have shown reductions of 42% to 76% in CRC incidence among those offered endoscopy compared with those who were not offered the test.^{133,138,139}

There is little direct evidence of the efficacy of colonoscopy in reducing CRC incidence and mortality, although there is indirect evidence of its benefit from studies of other CRC screening methods (Table 24.6).^{90,112,140} The direct evidence to date consists of a case-control study of U.S. veterans that found that people who died of colon cancer were less likely than controls to have had colonoscopy (OR, 0.43; 95% CI, 0.30–0.63).¹³⁸ In this study, people with either colon or rectal cancer were also less likely to have had colonoscopy (OR, 0.47; 95% CI, 0.37–0.58; OR, 0.61; 95% CI, 0.48–0.77).¹³⁸ Colonoscopic polypectomy has been found to reduce the incidence of CRC, suggesting that the removal of polyps is the proximal reason for screening-based reductions in CRC incidence and mortality.^{140,141}

Emerging technologies such as virtual colonoscopy or stool DNA screening have not been demonstrated to reduce CRC incidence or mortality. Studies suggest that these methods hold promise for the future, and ongoing research is comparing emerging to current screening methods.

Recommendations

The ACS, USPSTF, U.S. Multisociety Task Force on Colorectal Cancer, and American College of Gastroenterology (ACG) agree that CRC screening is effective in reducing CRC incidence and mortality, and each has developed recommendations.^{8,10,112} The USPSTF strongly recommends screening for men and women 50 years of age and older but has concluded that there are insufficient data to determine which strategy is best in terms of the balance between benefits and potential harms.^{8,112}

Similar to the USPSTF, the ACS¹⁰ and U.S. Multisociety Task Force on Colorectal Cancer⁹⁰ recommend a range of options for screening average-risk individuals beginning at age 50. Both recommend annual FOBT, flexible sigmoidoscopy every 5 years, annual FOBT plus flexible sigmoidoscopy every 5 years, DCBE every 5 years, or colonoscopy every 10 years.

Despite strong expert consensus on the benefits of screening for colorectal cancer, actual screening rates in the popu-

lation remain low for all available CRC screening tests. In general, individuals at higher risk, such as those with familial adenomatous polyposis (FAP) or HNPCC, should be screened more aggressively than those at average risk.^{8,10,90,112} Genetic tests exist for individuals suspected to have a hereditary syndrome such as HNPCC or FAP. Chapter 26 covers genetic screening and counseling for high-risk populations.

Prostate Cancer Screening

Prostate cancer is a challenge in clinical care because 1 in every 6 men will be diagnosed with it in his lifetime but only 1 in 29 will die of it.¹¹ Therefore, prostate cancer will not affect the life expectancy of many men diagnosed with the disease, even if they were never screened. Because it is impossible for an individual to know the effect of the diagnosis on his life expectancy, many men diagnosed with prostate cancer overestimate the benefit they gain from screening.^{1,142} A smaller proportion (48%) of men who went untreated for prostate cancer were satisfied with their therapy compared with men treated with androgen (63%), radiation (70%), or radical prostatectomy (59%).¹⁴³ Although individuals may be satisfied with therapy, its effect has implications for morbidity and quality of life for those who are told they have the disease.^{1,144}

Epidemiology and Natural History

In 2004, an estimated 230,110 new cases of prostate cancer were diagnosed in the United States and 29,900 men will have died of the disease.^{22,25} The overall incidence peaked in 1992 at about 230 in 100,000 men, but the rate has dropped since that time to the current rate of about 173 in 100,000.²⁵ The incidence in Caucasian-Americans is lower (168 in 100,000) than it is among African-Americans (277 in 100,000), as is the mortality (30 in 100,000 versus 73 in 100,000). Overall, prostate cancer mortality has been falling since 1991, but the reason is not clear. Some have attributed the reduction to increased screening¹⁴⁵ but others conclude that cannot be the explanation because the decline is disproportionate to the change in incidence and too early in relation to increased use of prostate screening tests.^{146,147} Prostate cancer is a slow-growing tumor, with a lead time ranging from 5 to 11 years depending upon what test and criteria are used to determine a positive screen.¹⁴⁸ Mortality differences would therefore not be expected to closely follow increases in screening.

Screening Tests

Prostate-specific antigen (PSA) is an organ-specific protein secreted by the luminal epithelial cells of the prostatic ducts, acini, and periurethral glands. It may be found floating free or bound to a complex of proteins.¹⁴⁹ Levels of PSA are measured in blood and are elevated by benign prostatic hypertrophy, inflammation, and the presence of neoplastic prostatic tissue (Table 24.7). Recent work suggests that measuring PSA bound in a protein matrix (cPSA) may be more specific than measuring serum totals.¹⁴⁹ In practice, digital rectal examination (DRE) and transrectal ultrasound are often conducted before to PSA testing, but this does not cause increased serum PSA levels.¹⁵⁰ A positive test for prostate cancer is generally

TABLE 24.6. Evidence for the efficacy of colorectal cancer screening.

Study	Years of intervention	Longest follow-up	Site of study	Age group	Study design	Exposure or intervention and screening rounds	Screening interval (months)	% Exposed to intervention	Contamination	Relative risk (RR) or odds ratio (OR) of colon cancer mortality	Comment
Mandel ¹⁰²	1975–1992	13 years	Minnesota	50–80	RCT	FOBT annually or biennially (two intervention groups)	12 or 24	90% completed at least one of annual FOBT group completed all tests, 60% of biennial group completed all tests.	1.8% of colorectal cancer in controls had cancer detected by FOBT.	33% (annual); RR = 0.67 (95% CI, 0.50–0.87) 21% (biennial); RR = 0.94 (95% CI, 0.68–1.31)	The cumulative incidence of colorectal cancer was nearly identical in both intervention and control groups, suggesting all cancers were found in each; 28%–38% of 1- and 2-year group, respectively, had colonoscopy. 4% of intervention group had colonoscopy.
Hardcastle ¹³⁰	1981–1995	Median 7.8 years, but varied by time of enrollment. All follow-up stopped June 1995.	UK	45–74	RCT	FOBT without rehydration (3–6 rounds)	24	60% completed at least one screening.	Not reported.	15	
Kronborg ¹⁰⁶	1985–1995	10 years	Funen, Denmark	45–75	RCT	FOBT without rehydration (5 rounds)	24	67% for round 1; more than 90% for repeat screenings.	Controls continued to seek usual care.	RR = 0.82 (95% CI, 0.68–0.99)	Predictive value of positive FOBT: 17% in first round, 9% in final round; PPV for large adenomas was 32% at first round, 21% at final round.

Study	Years of intervention	Longest follow-up	Site of study	Age group	Study design	Exposure or intervention and screening rounds	Screening interval (months)	% Exposed to intervention	Contamination	Relative risk (RR) or odds ratio (OR) of colon cancer mortality	Comment
Selby ¹⁸	n/a	n/a	Kaiser Permanente Medical Care Program, Oakland, CA	45 or older	Case-control	Rigid sigmoidoscopy (single exposure)	n/a	8.8% of cases; 24.2% of controls.	n/a	For cancer of rectum and distal colon: adjusted OR = 0.41 [95% CI, 0.25–0.69] For cancer of rest of colon (out of reach of sigmoidoscope): adjusted OR = 0.96 [95% CI, 0.61–1.50]	Landmark case-control study that raised possibility of mortality reduction through use of sigmoidoscopy.
Newcomb ¹³³	n/a	n/a	Greater Marshfield Community Health Plan members (Wisconsin)	20–75	Case-control	Sigmoidoscopy (single exposure)	n/a	10% among cases; 30% among controls.	n/a	OR = 0.21 [95% CI, 0.08–0.52]	Reduction in risk appeared to be limited to rectum and distal colon.
Winawer ¹³⁴	1975–1979	9 years	Recipients of self-paid comprehensive medical examinations, Strang Clinic	40 and older	Prospective cohort	FOBT + rigid sigmoidoscopy compared with rigid sigmoidoscopy alone	12 months	80% for round 1; 20% for round 2; 16% for round 3; 28% for round 6.	?	50% reduction in mortality with FOBT + sigmoidoscopy compared with sigmoidoscopy alone	
Muller ¹³⁸	n/a	n/a	US military veterans	Mean age 57	Case-control	Endoscopy (sigmoidoscopy, colonoscopy) and/or tissue removal (at least one exposure)	n/a	2.7% among cases; 10.1% among deceased controls.	n/a	OR = 0.44 [95% CI, 0.36–0.53] (for any colorectal procedure)	

TABLE 24.7. Summary of screening test characteristics: prostate cancer.

Test	Sensitivity	Specificity	Who administers	% Positive in practice	Recommended follow-up	Comment
Prostate-specific antigen (PSA) ²¹⁹	63%–83%	81%–98% depending upon age	Laboratory test ordered by clinician	4%–27% depending upon age	Urology evaluation and consideration of 6-quadrant biopsy	Using PSA level >4ng/mL as positive and “clinically significant disease” as outcome of detection.
Digital rectal examination (DRE) ²¹⁹	59%–64%	NA	Clinician	NA	PSA, consideration of urology evaluation	Specificity figures are ambiguous because biopsy of any prostate in men >50 years may find cancer, but not necessarily disease.

defined as 4 nanograms per milliliter (ng/L). Using that definition, sensitivity of the PSA test for cancer occurring within 2 years is about 73%.¹¹ Between 4% of men in their fifties and 27% of men in their seventies will test positive based on this definition.¹¹ DRE finds localized cancer only 50% to 60% of the time.¹¹ Although investigators are looking for proteins that may provide more sensitive and specific prostate cancer screening tests, none have been found and reported to date.

Summary of the Evidence for the Benefit of Prostate Screening Tests

According to the USPSTF, the evidence that prostate cancer screening with either DRE or PSA testing is beneficial for reducing prostate cancer mortality is not convincing.^{11,150} The only published study of PSA designed as a randomized trial reported a screening benefit but did not maintain the randomized groups (screen, control) in their analysis (Table 24.8).¹⁵¹ When other authors reanalyze the data maintaining the original randomized groups intended for screening and control populations, the benefit is not apparent.¹¹ In observational studies, several factors make it difficult to determine whether finding prostate cancer early truly increases the length of life for men who are diagnosed: (1) the long lead time for prostate cancer, (2) the significant proportion of men who will develop some form of the disease, and (3) biases inherent in following cancer cases.

Demonstrating a benefit for prostate cancer screening is important because serious consequences are associated with overtreatment. Radical prostatectomy has a significant morbidity, including total incontinence (10%), partial incontinence (14%), requiring pads to stay dry (28%), diarrhea (21%), erection insufficient for intercourse (80%), and being bothered by sexual dysfunction (53% to 59%, depending upon age).¹⁴⁴ Radiation therapy also has a substantial morbidity that includes total incontinence (3%), partial incontinence (2%), requiring pads to stay dry (3%), diarrhea (37%), erection insufficient for intercourse (62%), and being bothered by sexual dysfunction (40% to 47%, depending upon age).¹⁵² Large randomized trials are currently under way in the United States, Austria, and Canada to evaluate the benefits of screening with PSA.¹⁵³

Recommendations

The USPSTF report concludes that there is insufficient evidence to recommend either for or against screening with PSA.

The ACS recommends offering PSA and DRE annually beginning at age 50 among men who have a life expectancy of at least 10 additional years, but only after appropriate discussion of risks and benefits.¹⁰

Screening for Other Cancers

The USPSTF recommends against routine screening for bladder, thyroid, ovarian, and pancreatic cancers in the general population, even for individuals at higher risk for ovarian and thyroid cancers, because the available tests are either inadequate or have not been proven beneficial.

For testicular, skin, and oral cancers, the USPSTF has determined that there is insufficient evidence to recommend for or against screening in the primary care setting, although discussions of screening options with selected patients at high risk for testicular cancer may be appropriate.¹⁴

Screening Is a Process

While screening trials fund teams of specially trained individuals to ensure that recruitment, screening, and follow-up occur, these resources do not exist in daily clinical practice.¹² In primary care practice, a number of organizations, institutions, and individuals must share responsibility for making sure that the entire screening process occurs. The number and complexity of steps in the screening process may lead to confusion or breakdowns in communication.¹² These breakdowns may result in failure to follow up on a positive test or to treat diagnosed cancer.^{13,154,155} Factors outside the doctor-patient relationship, such as healthcare insurance and the clinical setting itself, influence individual propensity to seek screening and the likelihood that the screening process will be complete.¹² This section summarizes some of what has been learned about the five major phases of the screening process: (1) identifying and understanding the population at risk; (2) identifying the method of recruitment; (3) clarifying the screening approach; (4) developing the follow-up approach; and (5) referring patients for treatment.

Identifying and Understanding the Population at Risk

The populations that should be screened for specific cancers are now easily identifiable from a strictly demographic

TABLE 24.8. Evidence for the efficacy of prostate cancer screening.

Study name	Years of intervention	Longest follow-up (years)	Site of study	Age group	Study design and screening comparison	Exposure (intervention)	Screening rounds	Screening interval (months)	% Exposed to intervention (round)	Measure of effect	Comment
Labrie ¹⁵¹	1988–1996	8	Quebec City	45–80 years	RCT	31,300 intervention (PSA & DRE), 15,432 control	Up to 7	Annual	23.00%	"Intention to treat" 4.6 vs. 4.8 deaths/1,000	Control group had 6.5% screened. Reported benefit was not based on intention to treat.
Friedman ²²⁰	10 years before diagnosis in 1979–1985	NA	HMO	Mean age 69.5 years	Case-control; cases were men with metastatic (stage D) prostate cancer dx	DRE in 10 years prior	N/A	N/A	2.45 exams among cases, 2.52 exams among controls	OR of DRE in cases vs. controls, 0.9 [95% CI 0.5–1.7]	
Jacobsen ²²¹	10 years before diagnosis in 1976–1991	NA	Olmstead County, Minnesota	Mean age at death 79 years	Case-control; cases were men with prostate cancer listed on death certificate; age-matched controls	DRE in 10 years prior	N/A	N/A	84% controls, 75% cases any DRE	OR of DRE in cases vs. controls, 0.51 [95% CI, 0.31–0.84]	No difference in timing of DRE exposure.
Richert-Boe ²²²	2–10 years before death in 1981–1990	NA	HMO	Mean age at death 70.3 years	Case-control; cases were men who died of prostate cancer	DRE in 10 years prior	N/A	N/A	Screen DRE; 77% cases, 80% controls	OR of DRE in cases vs. controls, 0.84 [95% CI, 0.4–1.46]	Results unchanged when looked at exposure within 5 years.
Lu-Yao ²²³	1987–1990	11 years	Two separate geographic areas: Seattle-Puget Sound and Connecticut	65–80	Ecologic study; cohort comparison	Relative PSA rate, prostate Bx rate, radical prostatectomy rate, mortality rate	N/A	N/A	Seattle to Connecticut: relative PSA 5.4 [95% CI, 4.76–6.1], Bx 2.2 [95% CI, 1.8–2.7]	Mortality 1.03 (0.95–1.1)	Radical prostatectomy was more common in Seattle: 2.7% vs. 0.5% of population.
Bartsch ²²⁴	1993 onward		One state in Austria compared with surrounding states	45–75	Ecologic study; cohort comparison	PSA screening			32%	Test of trend in deaths due to prostate cancer: 0.011e per year decrease in Tyrol compared with 0.0057 decrease in rest of Austria	

standpoint. For women, screening begins 3 years after onset of sexual activity or by age 21 to look for precursors to cervical cancer, by age 40 for breast cancer, and by age 50 for colorectal cancer. Screening for men begins at age 50 for colon cancer; a discussion of prostate cancer should also occur at that time so that men understand the strengths and weaknesses of current knowledge.¹⁰

However, identifying the population at risk involves more than specifying gender or age range. It is also important to understand the cultural characteristics of populations, their interest in screening, and their understanding of screening tests so that those at risk understand the recommendations and seek the appropriate tests.^{104,156,157} Those at highest risk of late-stage cancers after screening are those who have not been screened before.¹⁵⁵

Figure 24.2 shows that screening rates in the United States vary from as low as 10% of women having had a recent endoscopic evaluation of colorectal cancer to as high as 81% having had a recent Pap smear.¹⁵⁸ The figure shows that, as of the year 2000, less than 30% of men or women had undergone FOBT within the previous 2 years, and fewer had undergone endoscopy. Men are more likely to report having had a PSA test than either FOBT or endoscopic screening.¹⁵⁹ Because the potential mortality reduction among individuals screened for colon cancer is promising, encouraging CRC screening is becoming a high priority.^{10,160}

Although Figure 24.2 demonstrates rising rates of mammographic screening and sustained cervical cancer screening, women with lower incomes are less likely to have access to care and are less likely to be screened for these two cancers,

even though programs are in place to reach low-income women in all 50 states.^{161,162} Across the United States, an estimated 15% of individuals are without insurance coverage at any given time, and a much higher percentage is without coverage some time during the year.¹⁶³ Lack of insurance and lack of a regular source of health care are highly correlated with lack of screening.^{158,164,165} For example, African-Americans are less likely to have health insurance than Caucasians and are therefore less likely to undergo screening tests for CRC.^{162,166} It is estimated that cancer mortality is 19% higher in the lowest socioeconomic groups than in the highest.¹⁶⁷ Recently, levels of cancer screening among racial minorities have improved to the point that they approach the levels of screening among Caucasians; people without health insurance or a regular source of health care continue to be underscreened.¹⁶⁸ As a nation, we cannot achieve the maximum mortality reduction afforded by cancer screening if some populations go unscreened or untreated.

Identifying the Method of Recruitment

Reaching individuals, however, is not only a function of income and access. Even when they have access to care, not all people seek recommended screening.^{155,169,170} Providers may work with their teams, practices, health plans, third-party payers, and community to develop recruitment methods for screening. There is evidence that changes in practice that affect multiple levels of health care, including reimbursement, records systems, and tailoring of recruitment messages, have the strongest impact.^{171,172}

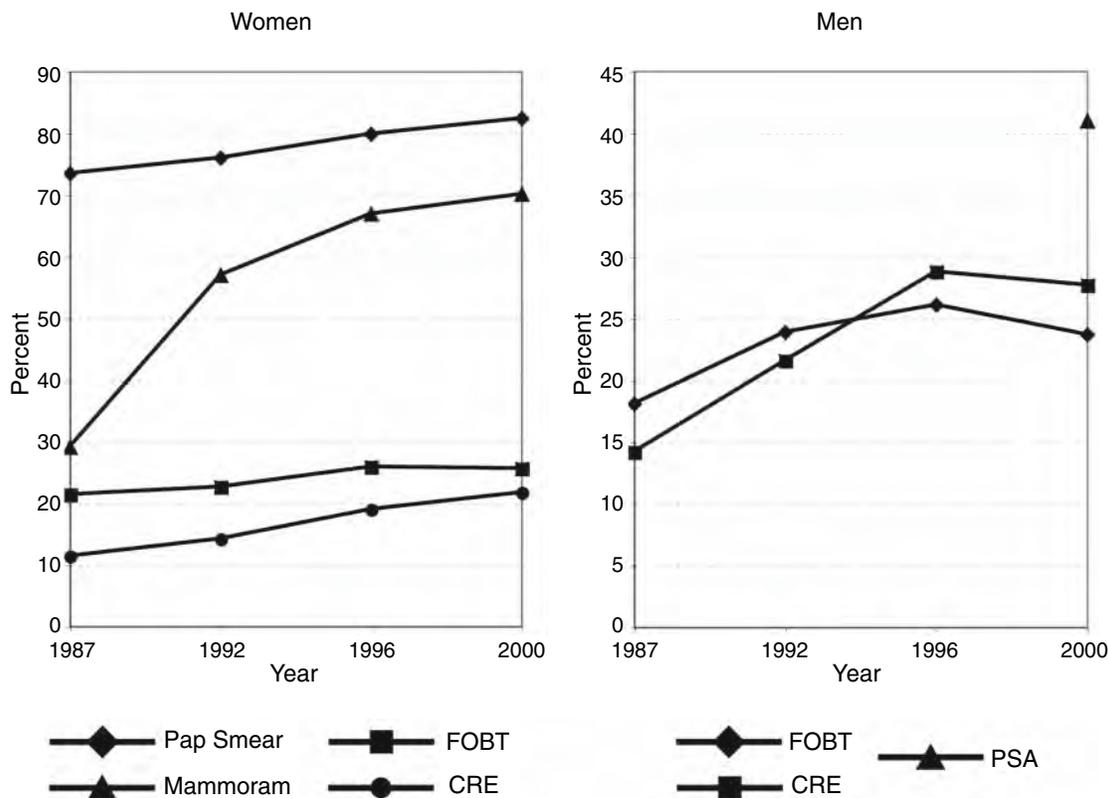

FIGURE 24.2. United States screening rates (1987-2000). (Adapted from Swan et al.,¹⁵⁸ by permission of *Cancer*.)

Ultimately, practitioners must make choices about how to reach individuals with appropriate recommendations and encourage them to consider screening. This is a crucial step in the screening process; for example, a recommendation from a primary care physician is a primary predictor of whether women seek colorectal cancer screening.¹⁷³ However, physicians' recommendations are not always consistent with screening guidelines; for example, a nationwide survey of primary care physicians suggested the presence of knowledge gaps and suboptimal screening delivery for CRC screening.¹⁶⁰ Primary care physicians also face substantial time limitations with regard to making all necessary and appropriate screening recommendations in light of their other prevention and treatment obligations¹⁷⁴; therefore, systematic changes may have the largest impact on making the screening recommendation.¹⁷²

One key systematic change is the implementation of clinical reminder systems, as there is strong evidence that issuing reminders leads to increased screening rates for film-screen mammography and cervical cancer.^{172,175-178} The two major types of reminders are inreach and outreach. Inreach reminders involve notifying a provider that a patient is due for a screening test while he or she is in the office. Systems to provide inreach reminders may be as simple as a chart review and paper alert or as sophisticated as an electronic note on an automated medical record. Overall, inreach reminders and physician feedback have been shown to result in the mammography screening of an additional 5% to 20% of the study population compared with "usual care" controls.¹⁷⁹ Outreach reminders consist of contacting individuals outside of an office visit. Studies involving telephone calls from a cancer registry, mailed recommendations, and motivational telephone calls addressing specific barriers to screening have shown that such reminders result in the Pap and mammography screening of an additional 15% to 31% of the study population compared with usual care.^{175,177}

Even after recommendations are made, ensuring that individuals seek screening may require adopting and adapting new strategies to encourage women to follow through on the recommendation. For example, McPhee and colleagues have shown that having female lay leaders discuss screening at gatherings in women's homes promotes the use of film-screen mammography among Cambodians.¹⁸⁰ Understanding factors that affect use of screening tests will help providers work with members of their organizations and communities to plan effective education and recruitment strategies for the populations they serve. The process of understanding and enabling individuals to manage their care has been called "self-management support" by some, and it may be critical to successful screening implementation.¹⁸¹

Clarifying the Screening Approach

In addition to ordering the screening test, the primary care provider may be responsible for conduct the screening. Organizing the care within a practice is therefore critical to getting screening accomplished. How that screening occurs, however, differs by the organizational setting of healthcare delivery, the cancer site, the set of screening tests recommended, and which test or set of tests the patient prefers. For example, screening mammography and colonoscopy depend

upon referrals whereas cervical cancer screening, FOBT, and sigmoidoscopy can be conducted by the primary care team. To incorporate cancer screening into a busy practice, primary care providers need to organize their approach and clarify who is talking with the patient, what is being said, and how tests are ordered. This is all part of organizing the approach to screening, and it has been shown to increase screening rates when implemented systematically in practice using the entire healthcare team.^{172,182-184}

Developing the Follow-Up Approach

When testing requires a referral, a tracking system to document the patient's progress through the care continuum can be helpful. The proportion of positive screening tests varies with the type of test but, in general, is about 10% (see Tables 24.1, 24.3, 24.5, 24.7). Follow-up for these individuals is not automatic, and failure to ensure successful follow-up compromises the mortality reduction achievable.¹⁷⁸ For example, follow-up for positive FOBT has been estimated to range between 49% and 79%,¹⁸⁵ and follow-up after a mammogram was as low as 35% women in one HMO even though access to care was assured.¹⁸⁶ In a review of published evaluations of follow-up after positive screening tests, Yabroff and colleagues found that two-thirds of reported studies had follow-up rates below 75%.¹³ Among the 45 observational studies in her review, only 1 showed follow-up greater than 90%.¹³ Factors that improved follow-up of abnormal tests included addressing the lack of health insurance for a patient, using peer counselors, making system-wide changes in a health plan or clinic, and more actively encouraging patients to manage their care.^{13,172}

Because of apparent problems with follow-up of abnormal tests, a framework has been outlined for thinking through the issues and developing methods to ensure follow-up of positive tests.¹³ Healthcare team members can use the work of Yabroff and others to guide their design of a system to ensure follow-up. Studies indicate that several elements are necessary for a successful follow-up system. First, a mechanism to ensure communication between the person performing the screening and the providers responsible for follow-up is necessary. Even if the provider conducts the test, as is usually the case with cervical cancer screening, clinicians need some method of ensuring that they receive the test results. Second, the provider team needs to have a plan for dealing with a positive result once it is received, because not all positive results need to be acted upon and the primary care provider is not always the responsible party. For example, radiology facilities are obligated by the MQSA to report mammography results to all women screened. Yet even in this case, a woman notified by the radiologist may not respond.

Communication with the patient about the follow-up plan is the next critical step in the implementation process. Such communication should clarify which tests are needed and what those tests involve for the patient. Research shows that communication from the provider to the patient about the importance of follow-up and the details about further workup will influence whether follow-up occurs.^{13,187} Women with fears of painful procedures or fatalistic views regarding cancer diagnosis are less likely to comply with follow-up recommendations.¹³ As shown in Tables 24.1, 24.3, 24.5, and

24.7, evaluations needed after a positive test vary from repeating the test or ordering additional mammograms or colonoscopy to surgical consultation. Incorporating the patient into the care plan has become an important part of follow-up care and may increase adherence to the plan.¹³ For example, telephone contact addressing women's perceptions of the cervical cancer screening test and educating them before or after the Pap test through interactive discussion improved follow-up by 24% to 26%.¹⁷⁸ Ultimately, improving follow-up requires the coordinated effort of providers, staff working with them, and patients.

Referring for Treatment

After developing the follow-up approach, the next critical step is ensuring that patients are referred to and receive appropriate specialty care. Referral to oncology specialists by primary care providers (PCPs) depends on some degree of coordinated care. Developing this coordination was highlighted in the National Cancer Policy Board's 1999 analysis as a key step toward improving the quality of America's health care. They concluded that optimal cancer care delivery should ensure, among other things, a "mechanism to coordinate services."¹⁸⁸ Also, a committee of the Institute of Medicine selected care coordination as one of 20 "priority areas" requiring concerted effort if the nation's healthcare system is to be transformed.¹⁸⁸

Literature is sparse regarding referral barriers relevant to screened cancers, but access and reimbursement for the uninsured are a clear challenge.¹⁶² However, difficulties are not confined to those traditionally considered underserved by the healthcare system. Access to quality cancer treatment in general is subject to numerous barriers, including patient characteristics such as old age, low SES,¹⁶² minority race or ethnicity,¹⁸⁹ and lack of health insurance. Researchers studying older cancer patients concluded that patient preference is a "major determinant in the referral decisions of primary care providers." Another potential issue is that PCPs might be unaware of cancer treatment options available to seniors.¹⁹⁰ Recent work raises questions regarding referral patterns and points out that the majority of patients are not seen by an oncologist who might help them with decisions.¹⁹¹

Although treatment options and systems are not a focus of this chapter, clinicians need to be mindful of the institutional and insurance barriers that may limit access. Successful referrals in any cancer patient depend on factors such as physician characteristics (e.g., specialty, training, experience, age), quality of patient-provider communication, and complexity and constraints of the current healthcare environment.¹⁸⁸

Steps are being taken to improve the coordination of cancer treatment after a positive screening. A pilot project that tested the effects of patient navigators ("proactive patient advocates") on removing barriers to diagnosis and state-of-the-art treatment found the concept promising.¹⁹² At the public policy level, Congress passed legislation in 2000 to fill the "treatment gap" in the National Breast and Cervical Cancer Early Detection Program by giving states the option to extend Medicaid benefits to uninsured women diagnosed through the program.¹⁹³ To date, the U.S. Department of Health and Human Services has approved proposals from 48 states and the District of Columbia to implement the act (CDC).

Summary and Conclusion

This chapter has reviewed the evidence related to the epidemiology, natural history, and screening of four common cancers (breast, cervical, colorectal, and prostate). It presents this evidence within the context of the challenges of primary care practice and emphasizes the need to view cancer screening as a process of care. Ensuring access to screening and treatment for all is necessary to achieve the potential for mortality reduction afforded by current screening technologies. Regardless of healthcare coverage, organized systems are needed to ensure progress throughout the continuum of care. Implementation of the numerous steps and transitions in this continuum requires the interest, commitment, and collaborative action of patients, primary care providers, specialty care providers, administrators, and public health officials. Only through this collaboration can mortality reduction be maximized.¹⁷¹

Genetic Screening and Counseling for High-Risk Populations

Mary B. Daly

As we enter the 21st century, we are witnessing a historic transition in science that will reveal the genetic basis of common medical conditions and have an enormous impact on biology, medicine, health care, and society. The role of genetics in understanding and treating cancer has traditionally been limited to the observation of cytogenetic abnormalities in certain tumor types. With the recent stimulus of the Human Genome Project, new opportunities to define all cancer in genetic terms are emerging. Efforts to characterize the several classes of genes involved in the transformation and growth of cancer cells have not only advanced knowledge of the genetic basis of cancer but also stimulated the development of sophisticated high throughput technologies that open a new generation of opportunities for the next decade of clinical research and application. Molecular genetic analysis will permit the identification of cancer susceptibility patterns decades before the onset of symptoms or the appearance of disease. The impact of this genetic revolution will shape the practice of medicine, and in particular, the practice of oncology, in many ways. The growing appreciation of the molecular basis of carcinogenesis will have clinical applications in understanding cancer etiology and assigning more precise estimates of risk; in tailoring screening and prevention approaches to populations at defined levels of risk; in improving accuracy of diagnosis and prognosis based on molecular profiles; and in the rational design of therapeutic modalities based on molecular targets.

Although the grouping of site-specific cancer clusters in some families has been recognized for decades, it was not until the past few decades, with the identification of genes such as *BRCA1* and *BRCA2*, that hereditary patterns of cancer could be definitively linked to discrete germ-line mutations. Although hereditary cancers account for only 10% of all cancers, the identification of these genes and the attention devoted to these discoveries have heightened awareness of the genetic contribution to cancer in general among both the medical profession and the lay community and have provided a means to begin to recognize individuals and families with an increased genetic risk of cancer.

Because deleterious mutations in genes associated with hereditary cancer syndromes diagnose a *risk* for cancer, not the disease itself, knowledge of germ-line cancer susceptibility genes has stimulated intense interest in preventive strategies that may be employed to alter an individual's risk and

that of his or her family members. Studies are under way to understand the functions of cancer susceptibility genes and how their alteration contributes to carcinogenesis. Gene-gene and gene-environment interactions are being explored to understand the significant variation in penetrance of these genes. This work is likely to elucidate the causal mechanisms of the traditional epidemiologic factors associated with cancer that will have implications for the more common sporadic forms.

This chapter explores the application of the rapidly expanding field of genetics to genetic screening and counseling for hereditary cancer syndromes in the clinical setting.

Kinds of Assays

One component of the success of the Human Genome Project, in concert with the realization that all diseases have a genetic basis, is the advent of rapid and relatively inexpensive molecular genetic technologies that can be run at high throughput. There are different technologies for different types of mutations, and most are limited to specialized genetic laboratories or cancer research settings. The technologies for detecting mutations in the major cancer susceptibility genes are constantly evolving but can basically be divided into tests of gene function, such as protein truncation tests, gel shift assays, enzymatic mutations screens, and methods to directly sequence the genes.

Because many of the genetic mutations associated with cancer syndromes result in premature truncation of the protein product, protein truncation tests have been widely used. This approach uses *in vitro* transcription and translation to produce a radiolabeled protein. Truncated forms can be detected when electrophoresed against normal controls on an agarose gel.¹ Protein truncation tests are misleading when the gene length is normal, but its function is altered, or when the protein products produced by the mutated gene are too small for detection by this method.²

Gel shift assays compare the mobility through a gel matrix of a test DNA sample to that of a control sample. The motility of DNA in a gel matrix is determined by its length, base composition, single- and double-strand characteristics, and double-strand mobility in the presence of mismatched controls. Examples of gel shift assays are single-strand con-

formation polymorphism (SSCP) analysis, denaturing gradient gel electrophoresis (DGGE), heteroduplex analysis (HA), and conformation-sensitive gel electrophoresis (CSGE). Although gel shift assays are relatively easy to perform and inexpensive, their sensitivity is lower than other types of assays, making them less appropriate for clinical genetic testing.

Based on the principle that heteroduplexes form between wild-type and mutant genetic sequences, enzymatic mutation detection (EMD) methods use enzymes with high specificity for insertions, deletions, and base-substitution mismatches. Normal and mutant alleles of the target gene are amplified and labeled with fluorescent dyes. The enzyme scans the double-stranded DNA until it detects a structural distortion, where it cleaves the genetic material, forming two shorter, radiolabeled fragments. These products are analyzed on an automated DNA sequencer for relative mobility. EMD is easy to use and highly specific for all types of alterations and has the advantage of detecting multiple sequence variants in the same polymerase chain reaction (PCR) product.²

Direct sequencing of the gene is the gold standard for mutation scanning. All the coding regions, as well as the intron-exon boundaries of a gene, are amplified by PCR and sequenced, either manually or by automated techniques, in 250 to 400 base pairs. This approach is costly and labor intensive. Direct sequencing can miss certain types of mutations or large deletions or can detect mutations of unknown clinical significance. Many of these technical limitations will most likely be eliminated as the technology is improved and as clinical correlations are established for each mutation.

Clinicians considering using a genetic testing facility for clinical purposes should consider the quality control circumstances of the testing facility being considered. All laboratories doing clinical genetic testing should be certified by the Clinical Laboratory Improvement Act (CLIA) and the College of American Pathology (CAP). Access to a medical geneticist is helpful to assist in test interpretation for difficult cases.

Hallmarks of Hereditary Cancers

A list of known inherited cancer syndromes and their associated genes is shown in Table 25.1.³ This chapter discusses in more detail the hereditary patterns of breast/ovarian cancer, colorectal cancer, and multiple endocrine neoplasias, syndromes for which there are clinically available tests and which comprise a large portion of all hereditary cancer syndromes.

The features of a pedigree that characterize hereditary patterns of cancer include early age of onset, high penetrance, bilaterality in paired organs, vertical transmission through either parent, and an association with other cancers.⁴ The actual prevalence of mutations leading to hereditary cancers varies considerably in the population and is sometimes related to ethnic ancestry. It is known that certain mutations, the “founder mutations,” are more common in families who are all traced to a certain ancestor believed to be the founder of the original mutation. In these cases, knowing the ethnicity of an individual may guide which mutations to explore.

Penetrance refers to the proportion of individuals carrying the mutation who actually develop the associated disease(s). The observation that there are mutation carriers

who never develop disease suggests that there are genetic, metabolic, and/or environmental events that can modify the effect of a mutation. A better understanding of these modifiers is likely to provide opportunities for prevention of the involved disease. There are also emerging data to suggest that the location of the mutation within the gene may influence the type and severity of the disease that is manifest.

Rationale for Genetic Screening

Screening for cancer susceptibility genes has the potential to reduce the burden of cancer by providing opportunities for tailored early detection or primary prevention interventions to at-risk individuals. It can also spare those who receive true-negative results the burden of unnecessary screening and prevention procedures. The success of this approach is dependent upon the availability of surveillance measures and preventive strategies with documented efficacy and limited risk. The widespread clinical application of genetic testing, however, also poses specific challenges, including the implications for other family members who may not be involved or interested in the receipt of genetic risk information, the consequences of labeling healthy individuals with a disease predisposition, and the profound social and cultural significance awarded to genetic traits. Our understanding of the genetic basis of disease, and the rapid evolution in the science of human genetics, is moving at such a pace as to challenge the ability of both families and medical professionals to process and communicate the information becoming available.

Several advisory bodies have issued guidelines for the application of genetic testing for cancer susceptibility to the clinical setting. In a statement adopted on March 1, 2003, the American Society of Clinical Oncology (ASCO) reaffirmed its commitment to the integration of cancer risk assessment and management into the practice of oncology. In this update of earlier guidelines, the society set forth a set of *indications* for clinical genetic testing, recommendations for counseling to accompany genetic testing, and a commitment to maintaining confidentiality of genetic information. At the same time, ASCO underscored the responsibility of the patient to communicate genetic test results to other family members. The ASCO statement supports the establishment of federal legislation to prevent discrimination on the basis of genetic status and urged public and private health insurance providers to cover genetic testing and counseling services. ASCO maintains its commitment to providing educational opportunities in genetics for healthcare providers.⁵

The American Society of Human Genetics (ASHG) also stated the importance of public and professional education to develop a responsible approach to genetic testing and supported the need for further research to determine optimal preventive strategies for individuals with a genetic predisposition to cancer.⁶ A position paper from the National Society of Genetic Counselors (NSGC) spells out in detail the components of the genetic testing process and stresses the need for a multidisciplinary approach, including genetic counselors, physicians, nurses, social workers, and behavioral scientists.⁷ As this field is moving so quickly, these recommendations continue to evolve, but constant is the need to protect the health and well-being of genetically susceptible individuals.

TABLE 25.1. Inherited cancer syndromes for which clinical testing is available.

<i>Syndrome</i>	<i>Involved gene(s)</i>	<i>Associated cancers</i>
Beckwith–Wiedemann syndrome	<i>BWS</i> critical region 11p15 Genes involved: <i>KCNQ1OT1</i> <i>IGF2</i> <i>H19</i> <i>CDKN2C</i>	Embryonal tumors, Wilms' tumor, adrenocortical carcinoma, hepatoblastoma, rhabdomyosarcoma, neuroblastoma, gastric teratoma
Bloom syndrome	<i>BLM (RECQL3)</i> at 15q26.1	Leukemia, lymphoma, aerodigestive tract, skin, breast, cervix
Breast ovarian cancer (BOC) syndrome	<i>BRCA1</i> at 17q21, <i>BRCA2</i> at 13q12	Breast, ovary, prostate, pancreas
Cowden syndrome	<i>PTEN</i> at 10q23	Breast, uterus, thyroid, kidney, melanoma, glioblastoma
Familial adenomatous polyposis (FAP)	<i>APC</i> at 5q21	Colorectal, upper digestive tract, thyroid, hepatoblastoma
Fanconi anemia	<i>FANCA</i> at 16q24.3 <i>FANCC</i> at 9q22.3 <i>FANCD2</i> at 3p25.3 <i>FANCF</i> at 11p15 <i>FANCG</i> at 9p13 <i>FANCE</i> at 6p22 <i>BRCA2</i> at 13q12.3	Leukemia, squamous cell cancers, hepatocellular, brain tumors
Hereditary nonpolyposis colon cancer	<i>MSH2</i> at 2p22, <i>MLH1</i> at 3p21, <i>PMS1</i> at 2q31, <i>PMS2</i> at 7p22, <i>MSH6</i> at 2p16	Colorectal cancer, endometrial, ovarian, gastric, small intestine, ureter and kidney cancers
Li–Fraumeni syndrome	<i>TP53</i> at 17p13.1	Sarcoma, breast cancer, leukemia, adrenocortical cancer, brain tumor
Familial melanoma	<i>CMM1</i> at 1p36, <i>TP16</i> at 9p21, <i>CDK4</i> at 12q14	Multiple melanomas
Multiple colorectal adenomas	<i>MYH</i> , 1p34	Multiple colorectal adenomas (15–100), autosomal recessive
Multiple endocrine neoplasia type 1 (MEN-1)	<i>MEN1</i> at 11q13	Parathyroid, pancreatic islet, and pituitary cancers
Multiple endocrine neoplasia type 2 (MEN-2)	<i>RET</i> at 10q11.2	Medullary thyroid cancer, pheochromocytoma, benign parathyroid tumors
Neurofibromatosis type 1	<i>NF1</i> at 17q11.2	Optic glioma, neurofibrosarcoma
Neurofibromatosis type 2	<i>NF2</i> at 22q12	Meningioma, astrocytoma, acoustic neuroma, spinal schwannoma, ependymoma, neurofibroma
Nevoid basal cell syndrome (Gorlin syndrome)	<i>PTC</i> at 9q22.3	Basal cell cancer, ovarian fibroma, medulloblastoma
Peutz–Jeghers syndrome	<i>STK11</i> at 19p13.3	Colon, breast, pancreas, uterus, lung, testis, and ovarian cancer
Retinoblastoma syndrome	<i>RB1</i> at 13q14.1	Retinoblastoma, osteosarcoma, Ewing sarcoma, leukemia, lymphoma, melanoma, lung and bladder cancer
Tuberous sclerosis	<i>TSC1</i> at 9q34, <i>TSC2</i> at 16p13.3	Childhood brain tumors, Wilms' tumor, renal cell cancer
Von Hippel–Lindau syndrome	<i>VHL</i> at 3p25	Renal cell cancer, pheochromocytoma, hemangiomas
Down's syndrome	Trisomy 21	Leukemia
Klinefelter syndrome	47XXY	Male germ cell and breast cancer
Turner syndrome	45X	Wilms' tumor, neurogenic tumors, uterine tumor, leukemia, and gonadal tumors

Ethical, Legal, and Social Issues

The exciting potential of the work emanating from the Human Genome Project has led to unbounded enthusiasm about our ability to affect the health of the population through population screening for genetic cancer predisposition, through a more sophisticated understanding of the molecular profile of the cancer phenotype, and through new gene-targeted drug development. However, the recent expan-

sion of technology into the field of medical genetics has outstripped our ability to conceptualize the ethical and moral dimensions of the application of molecular genetics to the clinical setting of oncology. There are outstanding ethical issues that concern patients and their families, the healthcare profession, and society at large.

Most of the ethical debate for the public has centered on the ability to genetically characterize individuals for inherited cancer susceptibility syndromes. Limitations of test

accuracy and the relative uncertainties about effective preventive strategies for those who test positive have led many to advise caution about the widespread adoption of genetic testing in the clinical setting. In fact, concern about the potential adverse consequences of genetic testing for cancer susceptibility has led to the view that genetic information is *qualitatively* different from other medical information because of its potential to be used in a discriminatory manner and its unique implications for family members. The public has expressed concern that the explosion of genetic information may result in an environment in which people will be labeled and disadvantaged in the workplace and in their ability to obtain insurance based on genetic information. In fact, the most common reason cited for not considering genetic testing for mutations in the *BRCA1/2* genes is fear of insurance discrimination.⁸ Legislation for protection against discrimination based on genetic test results is incomplete and has not been thoroughly challenged in the court system. Responsibility to other family members is another concern voiced by individuals who undergo genetic testing. Privacy and confidentiality issues place the burden of communicating genetic test results with the proband, who may not have a sophisticated medical background and who may face difficult family dynamics in the communication process. The application of the new genetics to the diagnosis, characterization, and treatment of cancer has not generated as much concern and attention among cancer patients, who are often overwhelmed by their situation and the details of the treatments proposed to them. A good example of this is the increasing use of microsatellite instability (MSI) testing of colon tumors in the clinical setting without full disclosure to the patient that the testing may uncover a hereditary cancer syndrome in their family.

The promise of the new genetic technologies is emerging at a time when healthcare resources are shrinking and when access to care is not shared by all members of society. Although advances in technology will most likely lead to more cost-effective assays, the costs will still put a significant strain on the healthcare budget. Disparities in cancer care will grow as more advanced technologies are introduced into the treatment setting. The role of insurance companies in providing coverage for these new costs is unclear. The magnitude of insurance and/or employment risks from discrimination on the basis of genetic risk information is also a major concern for state and federal government agencies and the insurance industry.

There has been considerable debate about the issue of "genetic exceptionalism," that is, whether genetic testing is sufficiently different from other types of medical tests to warrant special considerations. Because of some of the unique aspects of genetic information, the standard of care has evolved to obtain formal informed consent for the conduct of a specific genetic test, even when done strictly for clinical management and not in the context of research. Unique components of the consent process are the acknowledgment of potential social and family implications of the test results, including the potential for discrimination based on genetic risk status, the symbolic meaning of heritage in our culture, the probabilistic nature of the test results, and the potential for lifetime classification of an individual as "at risk."^{9,10} Suggested components of the informed consent process are shown in Table 25.2. This process should take into account the participant's prior experiences, beliefs, attitudes, concerns, expectations, and motivations concerning genetic risk and should be handled with attention to confidentiality and the needs of other family members.

One special circumstance is the issue of genetic testing of children and adolescents. The ASHG and the American College of Medical Genetics, as well as ASCO, have suggested a series of points to consider in confronting this situation. The primary indication for genetic testing of a minor should be the provision of timely medical benefit. If the cancer occurs predominantly in childhood and risk reduction strategies and therapies are available, such as medullary thyroid cancer, there is justification for testing. Psychosocial benefits to competent adolescents, including reduction of uncertainty and anxiety, and contribution to life decisions may also be an indication. For those diseases, such as adult-onset cancers for which the medical and/or psychosocial benefits will not occur until adulthood, genetic testing should generally be deferred. The involvement and preparation of the family should be an integral part of this process. It is the responsibility of the provider to weigh the interests of the children and their families in their delivery of responsible genetic services.^{5,11}

The ability to characterize individuals genetically facilitates the application of this technology on a global scale and, in addition to creating typologies of cancer susceptibility in the population, will permit the molecular definition of ancestry, ethnicity, intelligence, and other human features with the potential for misuse. All these issues call for public education about the issues the genetic revolution is raising and a general discourse on the use of genetics in the oncology setting.

TABLE 25.2. Components of informed consent for genetic testing.

Purpose of the test	The purpose of the genetic test must be clearly described.
Practical aspects of the test	Amount of blood to be drawn, length of time to receive results, other information to be collected, cost of testing, and a contact person should be included.
Interpretation of results	The potential types of test results should be clarified, including true-positive, true-negative, indeterminant, and inconclusive results.
Potential risks	Risks to be described are psychosocial, threats to family dynamics and health, and insurance discrimination.
Potential benefits	The use of genetic test information may provide both psychologic benefit as well as guidance in medical management interventions.
Privacy and confidentiality	Measures used to assure privacy and confidentiality of the test results should be described.
Alternatives	A description of alternatives to genetic testing, including risk assessment based on clinical history, should be provided.

Education of the Healthcare Providers

As the genetic contribution to cancer continues to evolve, primary care providers will assume a more pivotal role in the provision of clinical genetic services, including providing education to patients and their families about genetic information in general, genetic testing in particular, and the use of genetic technologies in cancer risk reduction surveillance, diagnosis, and treatment. The involvement of the entire healthcare team will be critical to assess the outcomes of family decisions regarding genetic information and to guide individuals and their families through the complex world of cancer genetics. There are data to suggest, however, that among members of the healthcare profession, knowledge regarding the criteria for hereditary cancer syndromes, the indications for associated genetic testing, and the role that molecular genetics plays in the prevention, diagnosis, and treatment of cancer is limited. A nationally representative random sample of physicians in primary and tertiary care specialties found that fewer than one-third of physicians had recommended cancer genetic testing to a patient. Barriers to the use of genetic tests in their patient populations included lack of confidence in their ability to recommend testing and lack of access to counseling and testing services.¹² Healthcare providers are often at a loss about how to understand and communicate genetic test results to individuals, about what is their responsibility to inform other at-risk relatives of their potential genetic risk, and about how to assure confidentiality and privacy of genetic information in the medical record system. Limited physician knowledge of genetics may pose a barrier to the referral of appropriate candidates for genetic testing and the standard utilization of genetic predictive testing in clinical practice for increased cancer surveillance, screening, and prevention. Based on the potential for identification, classification, prevention, and treatment for a wide variety of cancer types, physicians and other healthcare providers and their patients would greatly benefit from training in interpretation and use of genetic predisposition testing as part of their clinical practice.

Genetic Counseling

The development of technology to locate and isolate cancer susceptibility genes has brought together the fields of oncology, cancer control, genetics, and genetic counseling to create a new specialty of cancer risk counseling whose goal is to communicate more accurate information about personal cancer risk profiles based on personal and family histories.¹³ The field of genetic counseling has evolved and plays a growing role in the evaluation and risk estimation of families with known or suspected genetic conditions. The traditional elements of genetic counseling have included (1) an accurate diagnosis of the genetic condition or predisposition; (2) an estimate of the probable cause of the disorder; (3) an estimation of risk of future occurrences of the condition within the family based on the pattern of inheritance of the disease; (4) communication of an understanding of the genetic and medical facts of the disorder; (5) an exploration of appropriate courses of action to manage the genetic risk and to alter the risk of occurrence; and (6) ways of coping with the disorder or risk of the disorder.^{14,15} Building on this tradition, *cancer risk* counseling is an interactive education and communica-

TABLE 25.3. Basic elements of cancer genetic counseling.

-
- Documentation of extended family medical history
 - Development of a family pedigree
 - Collection of medical records from proband and appropriate family members
 - Collection of information about other risk factors (biologic, environmental, lifestyle)
 - Careful assessment of risk
 - Education about cancer, genetics, and preventive options
 - Communication of risk estimate in clear and simple language
 - Development of individualized prevention and surveillance strategy
 - Attention to emotional and social needs and concerns of proband and family
 - Long-term follow-up and support
-

tion process whose purpose is to evaluate an individual's potential risk of developing specific forms of cancer based on inherited susceptibilities, physiologic modulators, and lifestyle and environmental factors that contribute to cancer risk and to communicate this information in a comprehensible and sensitive way (Table 25.3). Familial cancer risk counseling uses a broad approach to place genetic risk in the context of other related risk factors, thereby customizing it to the experiences of the individual. In addition to addressing genetic risk and the clinical management of that risk, cancer risk counseling also considers the psychosocial needs of the individual and the family. Typically, the process involves the collection of pertinent medical, familial, and lifestyle information, the documentation of cancer diagnoses, the delivery of background information about cancer risks and cancer genetics, the identification of specific hereditary cancer syndromes, and the transmission of personalized risk estimates.¹⁶ The ultimate goal of the education and communication process is to help the individual and other family members make informed and appropriate decisions about genetic testing options and strategies for cancer prevention and/or early detection.

Genetic counseling for genetic cancer risk represents a new direction in genetics and has raised some particularly interesting and difficult issues. Risk estimates for cancer may be either empirical or based on actual gene identification but are typically complex and sophisticated, challenging the communication skills of the counseling team. The nature of the counseling situation often requires the involvement of other family members to supply missing information or even for genetic screening, a situation that may compromise privacy and confidentiality within the family. The options offered by the counseling team, including genetic testing, may involve emotional and ethical dilemmas for which there are no clear answers. Despite these problematic issues, cancer risk counseling is a growing field that has tremendous potential to assist families in understanding their risk for cancer and in making informed choices for prevention.

Components of a Counseling Program

Target Population

Individuals who seek cancer risk counseling are often highly motivated by a personal experience with cancer in their family

and by concern for the risks faced by themselves and their offspring. Participants in cancer risk counseling are often self-referred, but as physicians become more aware of the importance of family history in determining an individual's risk for cancer, they are increasingly referring their patients for genetic evaluation. Although the general indication for participation in a cancer risk counseling program is a perception of increased risk for cancer based on family history and/or other recognized risk exposures, individual participants come to the process with a wide variety of experiences, health beliefs, expectations, and needs. An assessment of individual differences that can influence comprehension and compliance with appropriate health recommendations, therefore, is one of the primary goals of the counseling team.

The Counseling Team

Traditionally, the medical genetics counseling team has included a medical geneticist, a genetic counselor, and often the referring primary care physician, usually an obstetrician or pediatrician. Genetic counselors typically earn a Master of Science degree at an accredited institution and are certified by the American Board of Genetic Counselors. Dedicated training in the field of cancer genetics has recently been added to the curricula of genetic counseling education programs. There is also a growing interest in genetics on the part of nurses, many of whom are beginning to seek specialized training in the field. As the field of genetic counseling has expanded to include adult diseases such as cancer, other disciplines, including oncology, molecular genetics, social work, and psychology have joined the team to provide the multidisciplinary approach needed. Originally, cancer risk counseling programs were mainly situated in cancer centers and academic institutions, but increasingly these services are expanding to community hospitals, worksites, and health centers where they are often one component of a more broadly based health promotion program.

Information Collection

The very first step in evaluating an individual's risk for cancer is to assess the individual's concerns and reasons for seeking counseling to guarantee that personal needs and priorities will be met in the counseling process. The next step is to collect the pertinent medical, family, and personal information to assemble a risk profile and begin to explore options for dealing with the risk. A detailed family history is the cornerstone of effective genetic counseling. The counselor begins with the health of the proband and proceeds outward to include first-, second-, and third-degree relatives on both the maternal and paternal side. In addition to cancer diagnoses by primary site, age at onset, bilaterality when appropriate, and current age or age at death are recorded. Cancer diagnoses are validated by obtaining medical records, pathology reports, or death certificates when possible. Other medical and genetic conditions that may predispose individuals to cancer risk (e.g., Crohn's disease and colon cancer, atypical ductal hyperplasia, and breast cancer) should also be noted. It is important to include information about family members unaffected with cancer to appreciate the penetrance of the disease and overall patterns of inheritance. Information about possible consanguinity is also valuable, particularly in the considera-

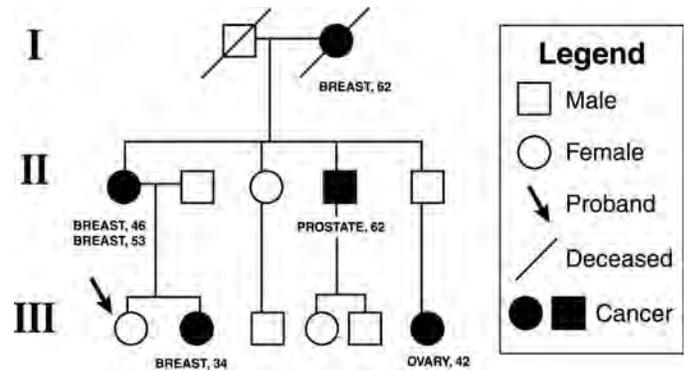

FIGURE 25.1. Sample pedigree with standard nomenclature to illustrate family relationships and disease information.

tion of recessive disorders. Ancestry and ethnicity should be recorded, as some inherited conditions are more common in certain ethnic groups (founder effects).

Family history data are graphically represented on a pedigree, which follows standard nomenclature to illustrate family relationships and disease information¹⁷ (Figure 25.1). Factors that limit the informativeness of the pedigree are small family size, early deaths in family members precluding the possibility of developing adult diseases, prophylactic surgeries that remove an organ from subsequent risk of cancer (e.g., total hysterectomy for uterine fibroids where the ovaries are also removed), and incomplete information about the health of family members. The degree of accuracy of reporting cancer diagnoses in relatives varies by how close the relatives are to the proband, with lack of information about specific cancer diagnoses in older second and/or third generations being a particularly common problem encountered in pedigree generation.

The collection of a targeted medical history of the proband serves two purposes: (1) the identification of premalignant conditions associated with subsequent cancer progression and (2) the estimation of other risk factors that may interact with or modify familial cancer risk. A careful reproductive history is pertinent to a number of common cancers in women. Exogenous hormone use and other medication history is also of value. The knowledge of other medical conditions may affect the management recommendations for reducing cancer risk. Caution about the use of exogenous estrogens in women with a familial predisposition of breast cancer, for example, may be tempered by a strong personal or family history of osteoporosis.

Environmental exposures and lifestyle factors, such as smoking, diet and alcohol use, and type of occupation may contribute to the overall estimation of risk, and their identification may offer opportunities for lifestyle changes to alter risk. Although occupational exposures to carcinogens such as benzene or asbestos account for a relatively small proportion of cancer, their recognition is very important in elucidating patterns of cancer and in eliminating other causes among exposed individuals. Environmental exposures and lifestyles are often shared by family members and must be recognized when assessing hereditary patterns of cancer. Finally, a record of past cancer screening practices establishes a history of health promotion behavior and will help guide the counselor in making reasonable and appropriate health recommendations.

The Education Component

Genetic risk information cannot be effectively communicated in the absence of general information about cancer risk, cancer genetics, and risk estimation. Individuals faced with a familial risk of cancer must assimilate complex and often highly technical information to make informed decisions about genetic testing, cancer screening, and preventive actions for themselves and to communicate that information to other family members. An integral part of the genetic counseling process is an educational preparation, provided either in a group or individual setting, to help the proband develop the understanding necessary to make informed decisions about his or her cancer risk. The basic educational components of cancer risk information include the following.

THE CONCEPTS OF CANCER AND CANCER RISK FACTORS

The multifactorial nature of cancer is explored with an emphasis on the pathways of cancer formation and expression. Persons seeking counseling who are affected with cancer may be particularly interested in information about the presentation, diagnosis, and treatment of cancer. The basics of cancer epidemiology can be presented, and examples, such as the importance of hormonal regulation in breast cancer and the importance of diet in colon cancer, can be used to illustrate the role of both external factors and internal metabolism in changing normal cells to premalignant and malignant tissue.

THE ROLE OF FAMILY HISTORY IN CANCER RISK ASSESSMENT

The interaction of shared environmental and genetic backgrounds among family members in determining risk is explored. Sample pedigrees can be used to illustrate the types of family cancer patterns (Table 25.4), and to demonstrate the concepts of vertical transmission through maternal or paternal lines, the significance of age at onset, and bilaterality of disease and penetrance issues. With this background, the counselor can then review the proband's own pedigree for the patterns expressed and for the identification of pertinent risk factors.

TABLE 25.4. Family cancer patterns.

Sporadic: A single occurrence of a cancer occurring on one side of the family.

Familial: A pattern of cancers on one side of the family, seen in one or more generations, that does not fit an autosomal dominant pattern of inheritance of cancer. The cancers on that side of the family do not fit a known cancer family syndrome. The pattern seen may represent a clustering of incidental cancers or may be the result of shared environmental or lifestyle factors.

Hereditary: A pattern of cancers on one side of the family, seen in two or more generations, in several members of the family, that fits an autosomal dominant pattern of cancers. The cancers on that side of the family may fit a known cancer family syndrome:
OR

Genetic testing performed on the proband or the proband's family member has detected a mutation in a cancer predisposition gene (e.g., *BRCA1*) and inheritance of this mutation has been established.

THE ROLE OF GENES IN CANCER DEVELOPMENT

The counselor introduces the concepts and language of chromosomes, genes, DNA, and how genetic alterations can lead to cancer. It is particularly important for the proband to understand the difference between the acquisition of genetic alterations during his/her lifetime that may affect his/her risk for cancer, and the inheritance of cancer-related genetic alterations from a parent, which can also be passed on to his/her offspring. Within this context, the counselor can introduce information about the recently identified cancer susceptibility genes, such as *BRCA1*, *BRCA2*, *APC*, the hereditary non-polyposis colorectal cancer (HNPCC) genes, etc., and the cancer syndromes associated with each, with an emphasis on those syndromes that appear to be most consistent with the proband's family history. The educational component of cancer risk counseling is meant to be interactive with ample opportunity for the proband to ask questions and to tailor the information to the needs of the individual.

THE ASSIGNMENT OF RISK

Cancer risk assessment is an attempt to quantify the probability of an individual's risk for a particular cancer using empirical models that account for a variety of personal, familial, and environmental risk factors. It is a complex process, both because it is based on imperfect and often conflicting data and because it involves probabilistic statements about the *chance* of an event occurring, concepts that are difficult to convey and to understand. The concept of risk can be presented in a variety of ways, each of which has a different interpretation. *Absolute risk* refers to the rate of cancer occurrence in the population and often serves as the background risk to which individuals compare themselves. *Relative risk* is the comparison of risk in an individual with a particular set of risk factors at a particular point in time to that of an individual without those risk factors, thus implying some magnitude of vulnerability.¹⁸ *Cumulative risk* is the risk over a defined time period calculated by accumulating relative risks over time.

Cancer risk counselors attempt to place the proband's risk of cancer within the context of population risk, both in quantitative and qualitative terms, to provide a rationale for recommended health behaviors. The majority of families do not exhibit the features of hereditary cancer syndromes but rather represent the effect of a combination of multiple genetic and environmental factors that interact to increase cancer risk to a moderate degree. For these families, counselors often use empirical approaches based on epidemiologic data that provide age-specific risks of cancer in tabular formats which can incorporate several pertinent risk factors. For some cancers, these empirical data have actually been integrated into mathematical models that can predict cumulative risk estimates of developing a cancer over a defined time period in an individual's lifetime. The Gail model, for example, predicts breast cancer risk from age 20 to 80 years, using a model that includes current age, age at menarche, age at first live birth, number of first-degree relatives with breast cancer, and number of breast biopsies.¹⁹ It has recently been validated by the Breast Cancer Prevention Trial²⁰ and is most accurate in predicting breast cancer among women who are being screened with regular mammograms.²¹ This model is now available from the National Cancer Institute on a floppy

disk, the “Risk Disc,” that can easily be used in the clinical setting.

For families in whom a hereditary pattern of cancer is suspected, the recent cloning of rare but highly penetrant cancer susceptibility genes, such as *BRCA1* and *BRCA2*, has made available the direct assessment of mutation status, thus obviating the need for empirical risk models. Other parameters, such as the Amsterdam Criteria and the Bethesda Guidelines for HNPCC,^{22,23} have been established to identify families who are candidates for genetic testing. In addition to these sets of criteria, mathematical models are appearing that, based on features of the family history, predict the likelihood of being a mutation carrier and help the counselor and clinician further refine genetic testing decisions.^{24,25} BRCAPRO is a statistical model based on published estimates of penetrance that uses information on personal and familial cancer status to calculate an individual’s probability of carrying a deleterious mutation on *BRCA1* or *BRCA2* and is used in the clinical setting to guide decisions about whether to undergo genetic testing.²⁶

Genetic Testing: Interpretation of Test Results

Genetic testing for cancer and its role, benefits, and limitations are discussed in the counseling session both in terms of the scientific merits of understanding the genetic basis of cancer and, when appropriate, as it may apply to further characterizing the cancer risk within the proband’s family. When possible, it is best to first consider testing an affected family member who meets the criteria for a hereditary cancer, as that individual is the one most likely to test positive. When a mutation is found, additional family members can be tested with an assay that specifically tests for that particular mutation.

There are four possible interpretations of a genetic test result (Table 25.5). If a known risk-associated mutation is found within a family, those family members who test positive for the mutation are considered “true positives.” They are counseled that they are at increased risk for a spectrum of cancers, and options for risk management are discussed (see following). It must be emphasized that a positive mutation result is not a positive cancer test but rather a susceptibility estimate. A positive test result does, however, confirm a 50% chance of passing on the mutation to each biologic child of the carrier. A second outcome of a positive test result is the discovery of a variant of the gene of *unknown clinical significance*. These genes are truly altered but have not yet been clearly linked to disease risk and may represent neutral alter-

ations in the gene structure that do not compromise its function. Over time, as more families are studied, most of these variants most likely can be separated into disease-related changes and benign changes, known as polymorphisms. Until then, families found to carry one of these variants must be counseled about the uncertain meaning of the result, and recommendations will be based on their family and personal history of disease. When a disease-related mutation has been identified in a family, subsequent family members who test negative for that mutation are thought to be “true negatives” whose risks for the relevant cancers are *not* increased over those of the general population. These family members may be spared the increased surveillance and/or consideration of prophylactic surgery offered to carriers. They can also be reassured that they will not pass on the deleterious mutation to their offspring. Finally, when no mutation is found in any family member (which is the most common situation), the meaning of a negative test result is ambiguous. It may mean that there truly is no mutation in the family and that the family history represents a clustering of sporadic cancers, it may mean a known disease-related mutation does exist in the family but no informative family members were available for testing, or it may mean that a mutation exists but cannot be detected by current technology. Again, counseling must emphasize the ambiguous nature of the test results. These families may still face a significantly increased risk of cancer and management should be based on other factors. A clear distinction is made between the probability of being a mutation carrier and the probability of developing cancer. Estimates of penetrance of the gene, that is, the chance that a mutation will actually result in cancer in a person, are also typically derived from small studies among narrowly defined families and are difficult to apply to any particular individual unless he or she matches the characteristics of the families studied. Information on other factors that may modify gene expression is rudimentary at this point for most of the genes identified.

Psychosocial Support

Just as important as a careful risk factor analysis and interpretation of risk to family members is attention to the psychosocial issues raised by the enhanced risk and the emotional needs of those involved.²⁷ This consideration is especially critical in the setting of counseling for cancer risk, which deals with the complexity of probabilities, which involves the entire family, and which may provide risk information that can become a source of discrimination. Cancer is one of the most feared diseases of modern times. Cultural beliefs about cancer, painful memories of relatives’ experiences with cancer, high levels of mental stress associated with cancer-related anxiety, unresolved grief, feelings of denial, guilt, and other family dynamics can all interfere with the receipt and understanding of risk information and with the formulation of strategies for risk reduction and can have a negative impact on quality of life. Both the information received during the process of genetic counseling and the information-seeking coping style of the individual may elicit further emotional reactions, especially if the counseling involves the receipt of genetic test results. The counselor takes an active role in helping the counselee identify his/her risk status, confront fears and anxieties about the meaning of

TABLE 25.5. Genetic test results.

True positive	The person is a carrier of an alteration in a known cancer-predisposing gene.
True negative	A person is not a carrier of a known cancer-predisposing gene that has been positively identified in another family member.
Indeterminant	A person is not a carrier of a known cancer-predisposing gene and the carrier status of other family members is either also negative or is unknown.
Inconclusive	A person is a carrier of an alteration in a gene that currently has no known significance.

that risk, develop coping strategies to deal with both the emotional and medical components of his/her unique situation and coping style, and facilitate decision making. The counselor can also assist the counselee in communicating cancer risk information to other family members, in dealing with their potential reactions, and in enrolling them in a counseling program. Follow-up genetic counseling sessions have been found to reinforce the information communicated in the original sessions, to solidify decisions made, to assess adjustment to risk status, and to make referrals for specialty consultations if needed.²⁸

General Management Strategies

One of the primary motivations for seeking cancer risk counseling is to identify ways to reduce or delay the risk of developing cancer or to enhance the possibility of detecting cancer at an early, curable stage. Individuals who seek these services clearly want recommendations for the medical management of their risk from their providers. By achieving a reliable estimate of cancer risk, either by considering personal and family history or by performing genetic testing, the cancer risk counselor, working with the medical team, can help to tailor primary and secondary prevention strategies to the individual. Although there are presently limited data on the long-term efficacy of prevention strategies directed at individuals with a familial or hereditary risk, clinical management decisions are being made based on the best available evidence. Recommendations fall into four general categories: increased screening, pharmacologic interventions (chemoprevention), surgical prophylaxis, and lifestyle changes. Screening recommendations are problematic for cancers, such as ovarian and pancreatic cancer, for which no early detection method has been found to be sufficiently sensitive and specific, and for situations such as the Li-Fraumeni syndrome, in which individuals are at risk for a wide spectrum of cancers during their lifetime. On the other hand, members of high-risk families are ideal candidates to participate in trials of newer imaging technologies and intermediate biomarkers to improve the early detection of cancer in younger individuals.

There is intense interest on the part of high-risk individuals to learn about opportunities to reduce their cancer risk by changes in diet, exercise, or other lifestyle modifications that may minimize their exposure to carcinogens. Preliminary data suggest, for instance, that the use of exogenous estrogens, including oral contraceptives and estrogen replacement, may confer an increased risk for breast cancer among women with a hereditary predisposition²⁹ and that limiting exposure to these agents may be beneficial. The exact role of diet and exercise remains elusive for most cancers, although recommendations can be made on the basis of general health and ideal weight maintenance. Dietary supplementation with micronutrients and other natural products to reduce cancer risk is so far unsupported by scientific data. Long-term studies are needed to assess the role of any of these strategies in the setting of familial risk for cancer. (See following for specific management options.) It is important that clinicians play an active role, in partnership with the genetic counselors, in the counseling of individuals predisposed to familial cancers to review current medical management strategies and to tailor recommendations to the unique needs of each individual.

Effectiveness of Cancer Risk Counseling

Several studies have attempted to assess the effectiveness and efficacy of genetic counseling and have identified a number of common predictors of response. Utilization of genetic counseling services is associated with higher socioeconomic status and educational level and, in the setting of prenatal genetic conditions, with intention to have children.³⁰ Understanding and retention of the information received have been found to be higher among individuals who are self-referred, those with higher educational levels, and among those families at the higher risk levels. Multiple counseling sessions have been shown to boost understanding and information retention.³¹ Another consistent observation has been that, although it is important, the information obtained at a genetic counseling session is not the only factor contributing to risk-related decisions. Rather, perception of risk is a concept formed over a person's lifetime and is a result of internalizing personal experiences and beliefs. Decisions made in the genetic counseling setting, therefore, reflect a complicated interplay of expectations, emotions, and value judgments. As a result, the genetic counselor is likely to be most successful when the information shared during genetic counseling is provided in the context of the counselee's personal orientation and belief system.

Risk Management for Hereditary Cancer Syndromes

Hereditary Breast/Ovarian Cancer

Approximately 5% to 10% of all breast cancer demonstrates an autosomal dominant pattern of inheritance. Hereditary breast cancer is characterized by early age at onset (5 to 15 years earlier than sporadic cases), bilaterality, vertical transmission through both maternal and paternal lines, and association with tumors of other organs, particularly the ovary and prostate gland.^{4,32,33} Syndromes most often associated with hereditary breast cancer are the hereditary breast ovarian cancer (HBOC) syndrome associated with mutations in the *BRCA1* and *BRCA2* genes, the Li-Fraumeni syndrome associated with p53 mutations, and Cowden's syndrome associated with mutations in *PTEN*. The clinical evidence of an autosomal dominant inherited predisposition to breast cancer was originally supported by segregation analysis, a quantitative method to determine if a particular trait is distributed in the population in a Mendelian manner of inheritance. Applied to the CASH data set, segregation analysis and goodness-of-fit tests of genetic models provided evidence for the existence of a rare autosomal dominant allele associated with increased susceptibility to breast cancer.³⁴

In 1990, a susceptibility gene for breast cancer was mapped by genetic linkage to the long arm of chromosome 17, in the interval 17q12–21.³⁵ The linkage between breast cancer and genetic markers on chromosome 17q was soon confirmed by others, and evidence for the coincident transmission of both breast and ovarian cancer susceptibility in linked families was observed.⁴ The *BRCA1* gene was subsequently identified by positional cloning methods and has been found to encode a protein of 1,863 amino acids. This susceptibility gene appears to be responsible for disease in 45%

of families with multiple cases of breast cancer only and up to 90% of families with both breast and ovarian cancer.³⁶ A second breast cancer susceptibility gene, *BRCA2*, was localized through linkage studies of 15 families with multiple cases of breast cancer to the long arm of chromosome 13. Germ-line mutations in *BRCA2* are thought to account for approximately 35% of multiple case breast cancer families and are also associated with male breast cancer, ovarian cancer, prostate cancer, and pancreatic cancer.^{37,38} The risk for breast cancer in female *BRCA2* mutation carriers appears similar to that for *BRCA1* carriers, but the age of onset is shifted to an older age distribution.³⁹

Of the several hundred mutations described in these genes, most lead to a frame shift resulting in missing or non-functional proteins.⁴⁰ In addition, tumors from individuals with *BRCA1/2* mutations show deletion of the wild-type allele, supporting speculation that these genes play a role in tumor suppression. Both *BRCA1* and *BRCA2* also are involved in the control of meiotic and mitotic recombination and in the maintenance of genomic stability, suggesting an additional role in the DNA repair process.⁴¹⁻⁴³ The growing body of data elucidating the functions of these genes suggests a gatekeeper role, characterized by interactions with other genes in the regulation of the cell cycle and DNA repair, which may provide novel opportunities to develop genotype-based therapeutic approaches to treatment and prevention. Although sporadic mutations of *BRCA1/2* are rarely described, inactivation or decreased expression of these genes by epigenetic phenomena, such as hypermethylation, may account for some cases of breast and ovarian cancer in the population.⁴⁴

The frequency of mutations in *BRCA1* in the general population has been estimated to be 0.0006, which corresponds to a carrier frequency of 1 in 800. Carrier rates are not distributed evenly, however, and tend to concentrate in families with multiple cases of breast and/or breast/ovarian cancer. *BRCA1* and *BRCA2* also demonstrate differential prevalence rates in certain ethnic groups. Most notably, in the United States, three specific founder mutations, the 185delAG mutation and the 5382insC mutation on *BRCA1* and the 6174delT mutation on *BRCA2*, have been found to be common in Ashkenazi Jews. The frequency of these three mutations approximates 1 in 40 in this population and accounts for up to 25% of early-onset breast cancer and up to 90% of families with both breast and ovarian cancer.⁴⁵ Additional founder effects have been described in the Netherlands (*BRCA1* 2804 delAA and several large deletion mutations), in Iceland (*BRCA2* 995 del5), and Sweden (*BRCA1* 3171 ins5).⁴⁶⁻⁴⁹

The actual expression of disease in gene mutation carriers is estimated to range from 36% to 85% for breast cancer and from 16% to 60% for ovarian cancer. Male carriers of *BRCA* mutations are also at increased risk for breast cancer, with lifetime estimates of approximately 6%.^{50,51} Among female *BRCA1* carriers who have already developed a primary breast cancer, estimates for a second contralateral breast cancer are as high as 64% by age 70 and for ovarian cancer as high as 44% by age 70.⁵² It is not generally known whether the specific location of mutations confer differential rates of penetrance, or what other genetic and/or environmental or lifestyle factors may interact with the presence of a mutation to determine expressivity. One region of *BRCA2*, however, the "ovarian cancer cluster region" in exon 11, appears to be

associated with an increased risk of ovarian cancer and decreased risk of breast cancer.⁵³ Ongoing studies are addressing the role of reproductive factors, endogenous and exogenous hormone exposure, diet, and lifestyle factors in the modulation of risk among carriers.

The clinical presentation of *BRCA1/2*-associated breast cancer indicates distinctive pathologic features. Historically, medullary, tubular, and lobular histologic findings and improved survival have been associated with familial breast cancer.⁵⁴ The Breast Cancer Linkage Consortium examined histopathologic features of breast cancer in women with *BRCA1/2* mutations and, when compared to controls, they showed an excess of high-grade tumors in *BRCA1* carriers and a relative lack of in situ component adjacent to invasive lesions.⁵⁵ High mitotic and total grade, as well as higher rates of aneuploidy, estrogen receptor (ER) negativity, and high proliferative fractions were also reported for *BRCA1* carriers in kindreds followed by Henry Lynch, who also noted higher rates of medullary histology.⁵⁶ The phenotype for *BRCA2*-related tumors appears to be more heterogeneous and may include an excess of lobular histology.⁵⁷ Recently, differential gene expression profiles have been described for *BRCA1*, *BRCA2*, and sporadic breast cancers, suggesting functional differences in tumors depending on their genetic characterization.⁵⁸ In accordance with the poor prognostic features noted histologically for *BRCA1*-related breast cancer, two European studies recently reported survival rates that were similar to or worse than sporadic cases, with a significantly increased risk of contralateral breast cancer.^{59,60}

Breast cancer is also a component of the rare Li-Fraumeni syndrome in which germ-line mutations of the p53 gene on chromosome 17p have been documented.⁶¹ First reported by Bottomley et al.,⁶² this syndrome is characterized by premenopausal breast cancer in combination with childhood sarcoma, brain tumors, leukemia and lymphoma, and adrenocortical carcinoma. A germ-line mutation in the p53 gene has been identified in more than 50% of families exhibiting this syndrome, and inheritance is autosomal dominant with a penetrance of at least 50% by age 50. Although highly penetrant, the Li-Fraumeni gene is thought to account for less than 1% of breast cancer cases.⁶³

One of the more than 50 cancer-related genodermatoses, Cowden's syndrome is characterized by an excess of breast cancer, gastrointestinal and gynecologic malignancies, and thyroid disease, both benign and malignant.⁶⁴ Skin manifestations include multiple trichilemmomas, oral fibromas and papillomas, and acral, palmar, and plantar keratoses. Germ-line mutations in PTEN, a protein tyrosine phosphatase with homology to tensin, located on chromosome 10q23, are responsible for this syndrome. Loss of heterozygosity observed in a high proportion of related cancers suggests that PTEN functions as a tumor suppressor gene. Its defined enzymatic function indicates a role in maintenance of the control of cell proliferation.⁶⁵ Disruption of PTEN appears to occur late in tumorigenesis and may act as a regulatory molecule of cytoskeletal function. Although it accounts for a small fraction of hereditary breast cancer, the characterization of PTEN function will provide valuable insights into signal pathways and the maintenance of normal cell physiology.⁶⁶

Ataxia telangiectasia (AT) is an autosomal recessive disorder characterized by neurologic deterioration, telangiectasias, immunodeficiency states, and hypersensitivity to

ionizing radiation. It is estimated that approximately 1% of the general population may be heterozygous carriers of the mutated gene, ataxia telangiectasia-mutated (ATM), which has been localized to chromosome 11q22–23.⁶⁷ The ATM gene encodes for a member of the phosphatidylinositol-3-kinase-like enzymes that are involved in cell-cycle control, meiotic recombination, telomere length monitoring, and DNA damage response pathways. AT cells are sensitive to ionizing radiation and radiomimetic drugs and lack cell-cycle regulatory properties after exposure to radiation.⁶⁸ In vitro studies of AT carrier-derived lymphoblastoid cell lines have demonstrated defective control of apoptosis and mitotic spindle checkpoint control.⁶⁹ Several epidemiologic studies have suggested a statistically increased risk of breast cancer among female heterozygote carriers, with estimated relative risks ranging from 3.9 to 5.1.^{70,71} ATM gene mutations associated with cancer in heterozygote carriers tend to be dominant negative missense mutations.⁷² Breast cancer among AT heterozygotes is characterized by early age at onset, bilateral disease, and prolonged survival.⁷³ A comparative analysis of ATM transcripts in invasive breast cancers, benign lesions, and normal breast tissue found decreased expression of the ATM gene in the invasive tumors compared to the other tissues, suggesting a dominant negative effect of the mutation on breast carcinogenesis.⁷⁴ Recently, two recurrent ATM mutations, T7271G and IVS10→G, were associated with an increased risk of breast cancer in multicase families in a population-based case-control study.⁷⁵ Given the high heterozygote carrier rate in the population, this association could account for a significant proportion of hereditary breast cancer and poses a potential risk related to diagnostic radiation exposure in these individuals.

Breast and/or ovarian cancer may also be a feature of Peutz–Jeghers syndrome, basal cell nevus (Gorlin) syndrome, multiple endocrine neoplasia type 1 (MEN1), and HNPCC. The identification and location of these and other breast/ovarian cancer genes will permit further investigation of the precise role they play in cancer progression and allow us to determine the percentage of total breast cancer caused by the inheritance of mutant genes. This development, in turn, will ultimately enrich our understanding of all breast and ovarian cancer, sporadic as well as hereditary, and will facilitate the identification of high-risk individuals.

Tailored management strategies for hereditary breast ovarian cancer (HBOC) are beginning to emerge. Individuals who appear to meet criteria for one of the BOC syndromes should be offered the opportunity to participate in clinical genetic counseling delivered by a team of trained healthcare professionals. Women who have tested positive for a *BRCA1* or *BRCA2* mutation are advised to start annual mammography between the ages of 25 and 35 years and to have clinical breast exams every 6 to 12 months.⁷⁶ Because of the very early onset of breast cancer in women with germ-line p53 mutations, routine screening is recommended starting at age 20 to 25 for this group.⁷⁷ There are preliminary data that magnetic resonance imaging (MRI) of the breast may be more sensitive in detecting early lesions in young women with dense breast tissue, although specificity is generally lower,⁷⁸ and several trials are under way to determine the role of this imaging modality, especially in the setting of familial risk. Men testing positive for a *BRCA1/2* mutation should also consider annual screening with mammography and clinical breast

exam as well as annual prostate cancer screening with digital rectal exam and prostate-specific antigen (PSA) testing.⁷⁶

Screening recommendations are problematic for ovarian cancer, for which no test or series of tests have been found to be sufficiently sensitive and specific. Despite the limitations, however, many practitioners have begun screening with the combination of pelvic exam, transvaginal ultrasound, and CA-125 in women with a family history of ovarian cancer. Although it is an important component of complete gynecologic care, the pelvic exam alone is clearly insufficient to detect most limited, early-stage epithelial ovarian tumors. Tumor markers, such as CA-125, lack the sensitivity and specificity to serve as the sole form of screening. Transvaginal ultrasound is currently being studied in a large screening trial nationwide and may prove to offer the best alternative to detect early-stage ovarian cancers. A recent report of the use of proteomics to identify early-stage ovarian cancer may represent a breakthrough for ovarian cancer screening. Proteomics is a new and emerging technology that can identify low molecular weight molecules in a high-throughput, non-biased discovery approach using patient serum, plasma, urine, or tissue specimens. Petricoin et al.⁷⁹ identified a small set of key protein values from patient serum that discriminated ovarian cancer cases from unaffected controls with a sensitivity of 100% and a specificity of 95%. Ultimately, a complementary series of markers may be combined for use in conjunction with ultrasonography to improve the predictive value of the screening process.

Outcome data from chemoprevention trials are just beginning to emerge. The recently completed Breast Cancer Prevention Trial, which randomized more than 13,000 high-risk women to the antiestrogen tamoxifen or placebo found a 49% reduction in the incidence of breast cancer among women in the tamoxifen arm.⁸⁰ The reduction in risk was limited to estrogen receptor-positive tumors. A very limited subset analysis of these data indicated that women with *BRCA1* mutations (who are more likely to develop hormone receptor-negative breast tumors) did not benefit from tamoxifen whereas those with *BRCA2* mutations did.⁸¹ A second large trial comparing tamoxifen to the selective estrogen receptor modulator raloxifene is under way.

To date, there have been no Phase III randomized chemoprevention trials for ovarian cancer. However, because of the strong epidemiologic association between oral contraceptive (OC) use and a reduction in ovarian cancer rates,⁸² many gynecologists are recommending their use in women with an increased risk from either family history or nulliparity. Preliminary data from studies of women with *BRCA1/2* mutations suggest that they enjoy the same degree of protection (approximately 40% reduction) from OCs as do women in the general population. Small pilot studies are now under way to determine the chemopreventive role of other agents, including members of the retinoid family as well as progestational agents.

Prophylactic oophorectomy is being considered by women with a family history of ovarian cancer, particularly those who are *BRCA1/2* mutation carriers, because of the uncertain nature of screening and the high case-fatality rate of advanced-stage cancer. Two large recent studies demonstrated an 85% to 96% reduction in ovarian cancer and a 50% reduction in breast cancer among women undergoing oophorectomy for prophylaxis.^{83,84} Prophylactic surgery does

not, however, eliminate the risk for primary peritoneal cancer, which is estimated to range from 1.9% to 10.7%.⁸⁵ Furthermore, premenopausal women choosing this option must consider the long-term consequences of surgically induced menopause. Similarly, prophylactic mastectomy does not completely eliminate the risk of subsequent breast cancer, although a recent retrospective review of 2,029 women who had elected the procedure for a variety of reasons estimates a greater than 90% reduction in risk.⁸⁶ This finding was supported by a prospective study of *BRCA1/2* carriers in which no breast cancers were observed in the 76 women who underwent prophylactic mastectomy.⁸⁷ This consideration occurs most commonly among women from high-risk families or those with known *BRCA1/2* mutations who are making treatment choices for their first primary breast cancer, given the increased rate of second cancers in the same breast as well as the contralateral breast in that setting. Another indication for the procedure among high-risk women is extremely dense breast tissue, which renders both clinical breast examination and standard mammography less reliable. Studies are now under way to prospectively follow women who elect prophylactic oophorectomy or mastectomy to monitor long-term disease reduction as well as to document the variables influencing the decision to pursue prophylactic surgery and the medical and psychologic consequences of the surgery.

Hereditary Colorectal Cancer Syndromes (FAP, HNPCC)

The adenomatous polyposis coli (*APC*) gene on chromosome 5q21 encodes a protein that is important in cell adhesion, signal transduction, and transcriptional activation. Germ-line mutations in *APC* are associated with familial adenomatous polyposis (FAP), a syndrome whose clinical phenotype includes hundreds to thousands of adenomatous polyps in the colon and rectum developing after the first decade of life and a 90% risk of developing colorectal cancer by the fourth decade of life.⁸⁸ Additional features include extracolonic tumors including thyroid, periampullary, pancreatic, and gastric, hepatoblastoma in children, and congenital hypertrophy of retinal pigment epithelium (CHRPE). In some variants of FAP, the disease presentation may include fewer polyps and later onset of disease. One variant, called Gardner's syndrome, includes osteomas, epidermoid cysts, fibromas, odontomas, and desmoid cysts.⁸⁹ These attenuated forms of FAP are often associated with distinct locations of the mutation on the gene, supporting a genotype–phenotype correlation in this syndrome. For example, a FAP mutation at I1307K, prevalent in 6% of people of Ashkenazi Jewish descent, appears to effect a modest (twofold) increase in colon cancer in that population.⁹⁰ Although highly penetrant, FAP accounts for less than 1% of all colon cancer. Genetic tests for FAP include protein truncation tests and full gene sequencing. The most common use of genetic testing for FAP is to determine if an unaffected relative of a patient with clinical manifestations of FAP has inherited the genetic mutation. Genetic testing is recommended at ages 10 to 12 years. Alternatively, at-risk individuals can pursue endoscopic screening for the phenotypic features of the syndrome. Annual endoscopic screening usually begins at puberty, with decreasing frequency with increasing decades of life. Some recommend screening for
