One of the serious late complications of Ewing's sarcoma is the occurrence of second malignancies, which ranges from 1 to 6.5% in several series.^{82,124-126} The outcomes of secondary osteosarcomas have been reported, with overall survival of the secondary sarcoma 41% at 8 years follow-up.¹²⁷ The late surgical complication rates for pelvic Ewing's and limb reconstruction with expanding prostheses in young children have also been high and constitute a longer-term problem requiring ongoing follow-up.^{39,104,128,129} Functional studies have supported rotation plasty lower extremity procedures for younger children over prosthetic reconstructions,¹³⁰ although multiple reconstructive options have decreased indications for amputation even in younger children.^{129,131} One additional

late complication of treatment that has been reported is diminished bone mineral density, and this may relate to the reported occurrence of late fractures.^{124,132,133}

The abnormal fusion protein transcription factor resulting from the 11:22 chromosomal translocation characteristic of many Ewing's family tumors, EWS-FLI1, has been shown to be capable of transforming neuroblastoma tumor cells to a Ewing's sarcoma phenotype, and also drives telomerase expression and cellular proliferation.^{134,135} Conversely, inhibition of this factor using small interfering RNA approaches inhibit proliferation and promotes apoptosis of the tumor cells¹³⁶; this has suggested EWS-FLI1 as a possible specific therapeutic target. Expression of cKIT has also been demonstrated in Ewing's tumors, along with associated sensitivity to tyrosine kinase inhibitors such as imatinib (STI571).¹³⁷ This has been proposed as a novel clinical treatment, although no clinical trial results have been reported as yet. FLI1 overexpression can aid in the diagnosis of Ewing's immunohistochemically, although it is not entirely specific for this disease.¹³⁸

Chondrosarcoma

Chondrosarcomas are characterized by secretion of a cartilaginous matrix of proteoglycans and chondrocyte-specific collagens such as type II, type IX, and type XI collagens. Unlike osteosarcoma and Ewing's family tumors, chondrosarcoma affects older individuals, most commonly in the fifth to seventh decades, and it is relatively unresponsive to either chemotherapy or radiotherapy.⁶ Chondrosarcoma can arise as a primary malignancy or as a secondary malignancy in a pre-existing benign cartilage tumor, such as an osteochondroma or enchondroma. Chondrosarcomas vary in histologic grade and are usually graded I-III.^{139,140} Dedifferentiated chondrosarcomas also exist, in which other elements such as fibrosarcomatous or osteosarcomatous components may be present.¹⁴¹

Several clinical and histological subtypes of chondrosarcoma are recognized, including mesenchymal chondrosarcoma,¹⁴² extraskeletal myxoid chondrosarcoma,¹⁴³ and clear cell chondrosarcoma.¹⁴⁴ Low-grade chondrosarcomas are slow-growing lesions that can be histologically indistinguishable from benign lesions. In such cases the clinical presentation (pain, enlarging mass) and radiographic or imaging characteristics (bone destruction, soft tissue invasion) are extremely important in diagnosis.^{6,145} Chondrosarcoma can also exhibit variable histologic appearance in different areas of the tumor, causing sampling error to be potentially misleading with small biopsy specimens or needle biopsies.^{141,145}

Patients generally present with pain or a mass at the primary site, although occasionally the lesion can be identified as an incidental finding detected radiographically. Systemic systems are usually absent. Metastasis of chondrosarcoma is most commonly to the lungs, as with the other bone sarcomas, and is rare in low-grade tumors, although quite common in grade III and dedifferentiated chondrosarcomas. Treatment is surgical excision of the lesion with wide margins, because traditional oncologic adjuvant treatments are not very effective with this tumor. Local adjuvants such as cryotherapy, phenol, and methylmethacrylate implantation have been used with intralesional or marginal excisions, especially with low-grade or borderline malignant lesions, with excellent success in prevention of local recurrence.^{145,146} Higher-grade lesions are not amenable to these approaches and carry a substantial local recurrence risk without wide surgical margins.¹⁴⁷

Radiographically, chondrosarcomas commonly contain calcifications within the cartilaginous matrix, which aids considerably in the differential diagnosis.¹⁴⁸ Staging of the tumor includes a CT scan, or more commonly an MRI scan, to delineate the local extent, a chest CT scan to evaluate for pulmonary metastasis, and a whole-body bone scan to rule out skip metastases or other bony metastases. Although

needle biopsy can be used to confirm the histogenesis of the tumor, the results with a small sample can be misleading in terms of the grade of the tumor. Open biopsy may be more helpful in ascertaining absence of higher-grade areas, which may influence the extent of the surgical procedure.^{139,145}

Published clinical studies of chondrosarcoma are unfortunately limited to retrospective case series, many with relatively small numbers of patients. There have been no randomized clinical trials involving radiotherapy or

chemotherapy, although limited evidence from the few published case series is not encouraging with regard to use of adjuvant modalities. The issues on which there would appear to be consensus in the literature are summarized as follows (see also Table 57.7)^{139,141,143,149–159}:

1. Surgical excision of the primary is the accepted method of treatment.
2. Tumor grade is the most significant prognostic variable.

3. Local recurrence is higher than with other bone sarcomas.
4. Progression of disease is often slow, and long-term follow-up is necessary.
5. Prognosis is excellent for the primary lesions in the hand.
6. Wide surgical margins are associated with lower local recurrence rates.
7. Prognosis in surgically difficult areas, such as the spine, scapula, and pelvis, may be worse.

The most striking findings from the published literature, as demonstrated in Table 57.7, are the high local recurrence rates of chondrosarcoma following surgical treatment and the correlation of higher-grade tumors with worse prognoses. The higher local recurrence rate than with osteosarcoma or Ewing's sarcoma may be related to the lack of effective adjuvant therapies such as radiotherapy or chemotherapy. The MDR1 gene and its product P-glycoprotein have been shown to be constitutively expressed in cartilage neoplasms and may account for the lack of sensitivity to chemotherapeutic agents.¹⁶⁰⁻¹⁶² As with other bone sarcomas, current technological improvements in prosthetic implants for bone and joint reconstruction, availability of allografts, and microvascular techniques enabling free tissue transfer to handle soft tissue coverage problems have led to a shift over the past two decades from amputations to limb salvage procedures for extremity and pelvic chondrosarcomas. Although some studies have found a worse prognosis with pelvic chondrosarcoma,¹⁵⁸ others have not corroborated this,^{154,155} so this issue remains unclear. However, there is consensus in the literature that wider margins are associated with lower local recurrence rates and better prognosis, and therefore the difficulty of achieving wide margins in surgically difficult locations such as the pelvis, scapula, and spine may affect outcomes with primaries at these sites.¹⁵⁹ The published case series examining scapular and spinal primaries specifically would support this conclusion.^{149,157} In contrast, two series that studied primary chondrosarcomas of the hand both showed an excellent prognosis in all patients in terms of lack of metastasis and long-term survival, regardless of tumor grade.^{150,151}

Secondary chondrosarcomas arising in osteochondromas or hereditary multiple exostoses appear to have overall an excellent prognosis, likely because of the preponderance of low-grade lesions.¹⁵³ Specific mutations in the EXT1 and EXT2 genes have been identified in more than 80% of individuals with multiple exostoses and in the chondrosarcomas that arise in this condition¹⁶³ and may contribute to the pathogenesis of the neoplasm. It is fairly well accepted that the rate of malignant degeneration is substantially higher in patients with multiple exostoses or multiple enchondromas (enchondromatosis, Ollier's disease) than in patients with solitary intraosseous or surface cartilage lesions, although a recent study of a large number of families failed to find an association with disease severity and development of chondrosarcoma.¹⁶³

Possibly because of the diagnostic difficulty in distinguishing between benign and low-grade malignant tumors, considerable investigation of possible markers of malignancy in chondrosarcoma has been undertaken. A number of markers have been associated with increased grade of malignancy, including urokinase-like plasminogen activator,^{164,165} cathepsinB,¹⁶⁵ MMP1,^{166,167} PTHrP and its receptor,^{168,169} INK4A/

p16,¹⁷⁰ tenascin-C splice variants,¹⁷¹ and telomerase reverse transcriptase.¹⁷² Although all these markers are more highly expressed in higher grades of malignancy, none definitively differentiates between benign and malignant low-grade lesions. Her2/neu has been studied and shown no correlation with chondrosarcoma grade.¹⁷³ A recent study has found that cyclooxygenase 2 (COX-2) is expressed in all high- and low-grade malignant cartilage tumors whereas it is absent in benign tumors.¹⁷⁴ Although this study involved a small number of specimens ($n = 29$), the absence of expression in benign lesions is in contrast to the continuum of expression from benign to higher-grade tumors observed in all the other published marker studies. This finding could have potential therapeutic as well as diagnostic significance, because prostaglandins stimulate chondrocyte proliferation and COX-2 inhibitors are widely available, but this area requires further study. Because PTHrP also drives chondrocyte proliferation and has been shown in several studies to be more highly expressed in higher-grade lesions,^{168,169} potential therapeutic use of antibodies to PTHrP or its receptor has been proposed, and efficacy of this approach in induction of chondrosarcoma cell apoptosis has been demonstrated in vitro.¹⁷⁵ At present, however, use of diagnostic markers has not assumed a place in clinical practice, and new therapeutic options remain theoretical.

Soft Tissue Sarcoma

T. Christopher Windham
and Vernon K. Sondak

Sarcomas are malignant tumors arising from mesenchymal cells. These tumors are usually—but not always—located in muscle, fat, and connective tissues. Sarcomas have varying clinical courses based on their histologic subtype, grade, location and size. These tumors are rare, with approximately 9,400 soft tissue sarcomas diagnosed annually in the United States, representing less than 1% of all newly diagnosed malignancies. In pediatric patients, sarcomas account for a greater percentage of malignancies, 15% of cancer cases. Deaths from soft tissue sarcomas exceed 3,400 and are 1,200 for bone sarcomas.¹ Sarcomas affect both genders equally.

Approximately two-thirds of soft tissue sarcomas are high-grade tumors, and histologic subtypes encountered vary by anatomic location.² The rarity of sarcomas, plus the vast array of histologic subtypes, have complicated our understanding of these tumors and impeded the development of effective therapies, as well as hindered efforts to establish “evidence-based” principles of diagnosis, treatment, and follow-up. For example, only 400 to 500 liposarcomas of the thigh (one relatively common histologic type in its most common anatomic site) are diagnosed per year in the United States, and literally only a handful of these patients ever enter onto prospective clinical trials, virtually none of which are randomized trials. Therefore, nearly all recommendations about sarcoma management are based on limited and often anecdotal evidence. Unfortunately, 50% of patients diagnosed with sarcomas ultimately succumb to their disease, and treatment is often associated with significant acute and long-term morbidity and limited if any benefit. Despite these limitations, significant progress has been made in our understanding and treatment of sarcomas. Information about molecular events involved in the development and progress of sarcomas has advanced dramatically during the past 15 years. Improvements in surgical techniques have resulted in significant decreases in morbidity of resection, allowing more-aggressive operations, and active chemotherapeutics have been identified, including the development of biologically targeted therapies. In this chapter, we attempt to take an evidence-based view of all aspects of sarcoma management. It will be readily apparent, however, that much of our clinical practice is based on very scanty, often conflicting data.

Risk Factors for the Development of Sarcomas

Hereditary Syndromes

Several hereditary genetic syndromes have been associated with the development of sarcomas (Table 58.1). Neurofibromatosis type I (c) is the most commonly encountered hereditary genetic syndrome associated with soft tissue sarcoma development. Affected patients usually present early in life with cutaneous findings of café-au-lait spots and freckling in skin folds, particularly in the axilla. These patients go on to develop benign tumors of the soft tissues (dermal neurofibromas) and tumors derived from perineural cells. In a long-term follow-up study of 212 patients with neurofibromatosis type I, Sorenson et al. found that malignant neoplasms or benign central nervous system tumors occurred in 45% of these patients.³ Neurofibromatosis type I is associated with mutations in the tumor suppressor gene NF1 on chromosome 17, which acts through the negative regulation of *ras*.⁴ The protein product of the NF1 gene is neurofibromin. Neurofibromin contains a functional GAP domain, which acts on GTP-*ras*.⁵ Homozygous deletion of NF1 in mice is lethal during embryologic development. Heterozygous NF1 knockout mice are viable; however, these mice develop leukemias and pheochromocytomas. Other functions of neurofibromin have yet to be elucidated. The clinically related syndrome of neurofibromatosis type II (NF2) is less common than NF1. This syndrome is associated with mutations of the NF2 gene on chromosome 22. Tumors most commonly encountered in NF2 are schwannomas, ependymomas, and gliomas. The protein product of the NF2 gene is the cytoskeletal protein merlin (also called schwannomin) that acts to link cell-surface glycoproteins to the cytoskeleton.^{6,7}

Li and Fraumeni identified an autosomal dominant inheritable syndrome associated with the development of soft tissue and bone sarcomas, breast cancer, brain tumors, acute leukemia, germ cell tumors, and adrenocortical cancer.⁸ Subsequent work identified a mutation of the tumor suppressor gene p53 associated with the Li-Fraumeni syndrome.⁹ Patients with germ-line inherited mutations of the p53 gene develop cancers at younger ages and at a significantly higher frequency than seen in the general population. The spectrum

TABLE 58.1. Major genetic syndromes associated with sarcoma development.

<i>Syndrome</i>	<i>Tumors observed</i>	<i>Genetic abnormality</i>	<i>Studies</i>

Source: Data from references 3–5, 7–14, 13, 15.

of cancer formation varies by the location of mutation within the p53 gene.¹⁰

Another tumor suppressor gene has been associated with the development of retinoblastoma, a rare neoplasm arising in the epithelium of the retina. Retinoblastoma represents the prototype for inheritable genetic disease involving tumor suppressor genes. As observed by Knudson, patients who inherit a single mutation of the Rb1 gene are at higher risk for developing retinoblastoma in the event of a sporadic mutation of the Rb1 gene occurring in a somatic cell.¹¹ The Rb1 gene product, p105 protein, plays multiple important regulatory roles in the regulation of cell cycle, survival, proliferation, DNA repair, and DNA replication. The p105 protein has direct interactions with the p53 regulatory pathway.¹² In an analysis of risk of second malignancy in long-term retinoblastoma survivors, Fletcher et al. observed a 69% incidence of second malignancies commonly associated with ionizing radiation or agents causing DNA damage.¹¹

Alterations in the adenomatous polyposis coli (APC) gene are found in patients with familial adenomatous polyposis (FAP). These patients have multiple polyps (usually more than 100) of the colon and rectum, as well as variable numbers of polyps in the stomach and small bowel.¹³ A subset of patients with FAP has a constellation of findings that has been termed Gardner's syndrome. In addition to the intestinal polyps characteristic of FAP patients, these individuals also have mandibular osteomas and intraabdominal desmoid tumors. Available evidence indicates that Gardner's syndrome is not a distinct entity. Instead, patients with germline APC mutations show a phenotypic spectrum of some or all of the manifestations of classic Gardner's syndrome, and this spectrum correlates with the specific site of the mutation within the APC gene.¹⁴ The APC gene acts to down regulate β -catenin, a regulator of cell proliferation.^{13,15}

Current studies of hereditary syndromes rely on cohort reports, epidemiologic studies, and molecular biologic investigations. The validity of these syndromes has been bolstered by the genetic alterations identified through molecular genetic studies identifying specific associations with clinical presentations. Future advances will allow us to better understand genetic alterations involved in sarcomagenesis and assist patients in genetic counseling and also shed light on the biology of sporadic sarcoma cases.

Radiation

The development of sarcomas following radiation exposure was first suggested in the early 1900s. One of the earliest reports was that of Martland, who in 1929 documented the development of bone sarcomas in young girls who painted radioactive luminescent paints onto watch dials.¹⁶ During the past century, other reports relating radiation exposure to sarcoma development began to emerge. Cahan et al. catalogued studies demonstrating the ability to create sarcomas in numerous animal models following treatment with radiation.¹⁷ They further summarized studies documenting development of sarcomas in humans following treatment with radiation therapy and added 11 additional patients from their experience. This was one of the first efforts to describe clinical characteristics of radiation-associated sarcomas. They noted a latent period from 5 to more than 20 years between radiation exposure and the development of sarcoma. Unlike radiation-associated carcinomas, development of sarcomas was primarily seen after higher doses were administered.¹⁸ In this work, Cahan and colleagues set forth criteria still used today for the diagnosis of a "radiation-induced" sarcoma:

1. There must have been microscopic or radiographic evidence of the nonsarcomatous nature of the initial condition.
2. The sarcoma must have arisen in the area included within the radiation field.
3. A relatively long latent period must have elapsed after irradiation before the clinical appearance of the sarcoma, in most cases longer than 5 years.
4. All sarcomas must have been proved histologically.^{18-24,25-33}

Sarcomas have been seen after radiation therapy for the treatment of breast cancer, gynecologic malignancies, head and neck diseases, and lymphoma. The incidence of sarcoma following irradiation has been estimated to range from 0.03% to 0.8%.^{21,34-36} These sarcomas are frequently high grade, clinically aggressive, and difficult to treat.¹⁹ Histologic sarcoma subtypes most frequently observed following radiation exposure include osteosarcomas, malignant fibrous histiocytomas, and angiosarcomas.¹⁹

From the 1920s through the early 1950s, the alpha particle-emitting radioactive contrast agent thorium dioxide (Thorotrast) was commonly used in radiologic studies. This compound is selectively taken up by the reticuloendothelial cells of the liver and spleen, where it deposits a very high dose of radiation over many years as a consequence of its very long half-life. Several case-control studies of patients exposed to Thorotrast have found a much higher than expected incidence of liver disease, leukemias, and liver cancers.³⁷⁻³⁹ In an updated report summarizing a Japanese Thorotrast follow-up study, Mori et al. reported increased mortality primarily as a result of liver cancers, of which 15% were hemangiosarcomas.³⁸ In their study, dos Santos Silva and colleagues also found an increased incidence of liver cancers; however, specific histology was not reported.³⁷ Platz and associates observed increased chromosomal aberrations in the peripheral blood of a group of eight patients exposed to Thorotrast when compared with five patients exposed to nonradioactive contrast during the same time period.⁴⁰ The studies to date strongly suggest an association between Thorotrast exposure and the development of sarcomas of the liver.

Although most studies have demonstrated a consistent association between irradiation and sarcoma formation, other factors besides radiation may account for the actual tumor development. Frequently, patients are treated with chemotherapy agents as part of their therapies. A number of studies have documented an increased risk of second malignancy formation following treatment with chemotherapy. Neglia et al., in a large retrospective cohort study, reported 60 bone and soft tissue sarcomas developing as a second malignancy (of 298 second malignancies) in children treated with chemotherapy.⁴¹ Of note, these results were not adjusted to account for patients also treated with radiation therapy. Tucker et al. evaluated bone sarcoma development in children previously treated with chemotherapy or radiation therapy compared with untreated matched controls. They reported an excess number of bone sarcomas in patients who received alkylating agents with or without radiation therapy.²² In a nonhuman primate study evaluating the effects of procarbazine, Sieber and associates identified 4 sarcomas in 55 monkeys following treatment.⁴² Moreover, it is likely that a significant percentage of patients who develop sarco-

mas after treatment with chemotherapy and/or radiation have underlying genetic susceptibility, as was first observed in sarcomas developing after irradiation for retinoblastoma.

Lymphedema

Sarcoma development has also been associated with chronic lymphedema. A clinical scenario was recognized by Stewart and Treves in which lymphangiosarcoma develops following mastectomy, axillary nodal dissection, and radiation therapy in a chronically lymphedematous limb.⁴³ Because lymphedema may be associated with radiation therapy, the ultimate association of causation can be difficult or impossible. However, lymphangiosarcomas have been noted to arise in congenitally lymphedematous extremities as well as other settings where no radiation was given, demonstrating that lymphedema alone is sufficient to result in sarcoma formation in some cases.

Foreign Body

Sarcoma formation secondary to the presence of a foreign body has been the subject of numerous case reports. Foreign bodies associated with sarcomas have ranged from shrapnel to medical implants such as vascular conduits and orthopedic hardware.⁴⁴⁻⁵³ Experimental studies have demonstrated foreign body carcinogenesis, identifying a mesenchymal pluripotent cell lineage in sarcomas arising in association with foreign bodies.⁵⁴ Other studies have demonstrated that foreign body tumorigenesis requires a solid material of at least 5 mm and the prolongation of a dense fibrous capsule.⁵⁵ Activation of surrounding macrophages, as seen in chronic inflammatory reactions, results in a failure in fibrous capsular formation and subsequent tumor formation.⁵⁵ Laboratory studies have demonstrated that surface shape characteristics are important in determining carcinogenic potential; this appears to be a result of variable induction of a dense fibrous capsule by differing surfaces of foreign bodies.⁵⁶ The strength of clinical evidence implicating foreign bodies in the development of sarcomas is limited to case reports and small series. Despite these limitations, experimental evidence supports a causative role for foreign body reactions in the induction of rare cases of soft tissue sarcoma.

Viruses

The first viral oncogene, Src, was described by Rous in 1911 and has been confirmed to be tumorigenic.⁵⁷ Its significance in humans, however, remains uncertain. The elevated risk for the development of Kaposi's sarcoma in patients diagnosed with acquired immunodeficiency syndrome (AIDS) prompted investigators to determine if viruses could play a causative role in the development of these cancers. Recent studies have implicated the development of Kaposi's sarcoma in AIDS patients who have the herpes simplex virus type 8 (HSV-8). This etiology appears to be secondary to unregulated vascular endothelial cell proliferation in immunosuppressed patients. Dictor et al. found 88% of classical forms of Kaposi's sarcoma and 100% of AIDS-Kaposi's sarcomas with HSV-8.⁵⁸

Epstein-Barr virus (EBV) has been linked to sarcoma development in immunosuppressed patients. McClain and

colleagues found evidence of EBV infection in five leiomyosarcomas and two leiomyomas from six human immunodeficiency virus (HIV)-infected patients. They did not find evidence of EBV infection in smooth muscle tumors tested from HIV-negative patients.⁵⁹ In a large retrospective study of patients who received a polio vaccine contaminated with simian virus 40 (SV-40), Engels and associates failed to identify an increase in cancer formation.⁶⁰ The evidence from case reports, epidemiologic studies, and molecular biology studies supports an association of HSV-8 infection and Kaposi's sarcoma development in HIV-infected patients and probably in sporadic cases as well, and a minor role of EBV infection in other sarcoma formation in HIV-infected patients. Outside the clinical setting of HIV infection and/or immunosuppression, there is a lack of compelling data to support a viral etiology of sarcomas.

Chemical Exposure

A number of studies have evaluated a possible association of chemical exposure and the development of sarcomas. Chemicals implicated by case-control and epidemiologic studies include phenoxy herbicides, chlorinated aromatic compounds (e.g., dioxins), and vinyl chloride. There exist certain limitations inherent in many of these studies. Reporting of visceral sarcomas is often placed under the International Classification of Diseases (ICD) codes assigned to that particular organ rather than as a soft tissue sarcoma.⁶¹ Several large epidemiologic studies of exposed workers have identified an association with chemical exposure, although others have not.⁶¹⁻⁷¹ Public concern surrounding exposure of Vietnam veterans to phenoxy herbicides ("Agent Orange") and subsequent health risks has been addressed through a number of studies. These herbicides contain dioxin, widely reputed to be highly carcinogenic. However, a study by Greenwald and colleagues found no increased risk of sarcomas in veterans exposed to Agent Orange.⁷² Subsequent studies, reviewed by Frumkin, have not demonstrated an increase in the development of soft tissue sarcomas in veterans exposed to these herbicides.⁷³ Further, Cole and colleagues summarized work evaluating dioxin and cancer, concluding that this agent is not a human carcinogen.⁷⁴

Another chemical reported to be associated with the development of sarcomas is vinyl chloride. Case-control, retrospective cohort, and epidemiology studies have linked vinyl chloride exposure with a variety of cancers.⁷⁵⁻⁷⁹ However, subsequent review by McLaughlin indicated that the increased cancer risk after vinyl chloride exposure was limited to angiosarcomas of the liver.⁸⁰ Subsequent review of epidemiologic literature by Bosetti and associates concluded that the only increased cancer risk was that of liver cancers, which they speculate may in fact represent angiosarcomas.⁸¹ At present, studies evaluating exposure to vinyl chloride support an association with the development of angiosarcomas of the liver.

Pathology

There is a wide variety of histologic subtypes of sarcomas, and clinical behavior can be subtly or significantly different depending on histologic type. Pathologists use histogenetic

classification schemes, which broadly distinguish soft tissue tumor subtypes based on the tissues they contain or are forming. Light microscopic evaluation is used to seek evidence of specific differentiation as the first step in classification. High-grade sarcomas are poorly differentiated, complicating classification. With advances in immunohistochemistry, cytogenetics, and electron microscopy, non-tissue-specific diagnoses, such as the once-common diagnosis of malignant fibrous histiocytoma, are increasingly being replaced by tissue-specific diagnoses based on direct or indirect evidence of characteristic tissue formation. However, many pleomorphic sarcomas are sufficiently undifferentiated that the tumors cannot be further classified or can only be classified after an extensive (and variably performed clinically) set of tests.

Molecular Pathology

The ultimate evidence of differentiation is provided at the molecular level, and molecular techniques have the potential to profoundly influence our notions regarding the classification and characterization of sarcomas. Our conceptual model of sarcomagenesis has evolved over recent years. Sarcomas are believed to arise *de novo* in nearly all instances. They rarely arise from preexisting benign neoplasms (one important exception being sarcomas arising within plexiform neurofibromas in patients with neurofibromatosis type I). Sarcomas are thought to develop from mesenchymal stem cells residing in muscle, fat, and connective tissues. The origin of these stem cells remains unclear, and sometimes even their mesenchymal derivation is in question (as for nerve or nerve sheath sarcomas, gastrointestinal stromal tumors, and primitive neuroectodermal tumors (Ewing's sarcomas)). Two prevailing theories suggest that mesenchymal stem cells are found in local tissue pools or arise from the bone marrow.⁸²

Advances in molecular pathology have enabled us to distinguish two general groups of sarcomas. One group consists of those tumors with simple karyotypes and specific reciprocal chromosomal rearrangements. Specific chromosomal translocations have been identified in a number of pathologic subtypes and may provide a specific diagnosis in the absence of other identifiable evidence of differentiation. Tumors in this group typically occur in younger patients, rarely have p53 mutations, and are not usually associated with genetic syndromes such as Li-Fraumeni syndrome. The second group consists of those tumors with complex karyotypes and random nonreciprocal chromosomal rearrangements; these are typically seen in older patients, frequently have p53 mutations, and are generally the ones seen associated with genetic syndromes.

Molecular signatures, such as provided by cDNA microarray analysis, are increasingly being used to investigate the genetic basis of the histogenetic classification scheme employed for sarcomas. Perhaps not surprising, those sarcomas characterized by specific translocations or mutations have well-defined signatures that correlate strongly with the histopathologic diagnosis. Conversely, the molecular signatures of other sarcomas, notably liposarcomas, leiomyosarcomas, and malignant fibrous histiocytomas, overlap to a significant degree.⁸³ This finding calls into question the validity of many of the pathologic distinctions that have been

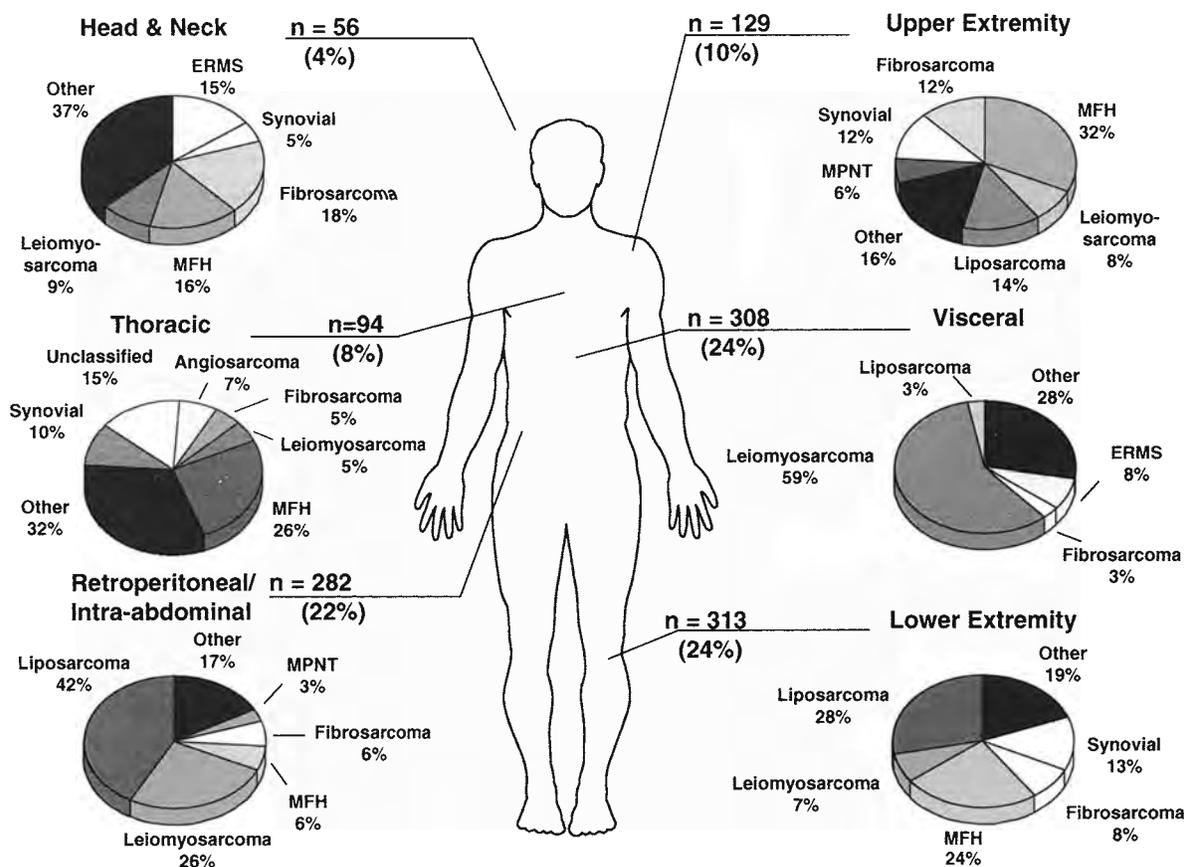

FIGURE 58.1. Certain histologic types of soft tissue sarcoma have a strong predilection for specific anatomic sites. (Pisters, P-Soft Tissue Sarcoma in Surgery Basic Science and Clinical Evidence, New York, Springer 2001. Norton JA, Bollinger R, Chang A, et al. eds.)

made over the years and further suggests that there may be hitherto unrecognized sarcoma categories of clinical relevance.

Patterns of Growth and Anatomic Distribution

Soft tissue sarcomas grow by direct local extension, infiltrating adjacent tissues and structures, occasionally with skip areas. They generally extend along tissue planes and uncommonly transverse or invade major fascial planes or bone. However, on gross inspection, many sarcomas demonstrate a characteristic pattern defined by a *pseudocapsule*, an apparently circumscribed tumor seemingly surrounded by a rim of compressed normal tissue. In fact, this pseudocapsule does not indicate the anatomic extent of the tumor, and removing the main mass from within the pseudocapsule invariably leaves tumor tissue behind. A minority of sarcomas, particularly dermatofibrosarcoma protuberans and cutaneous angiosarcoma, rarely if ever show a pseudocapsule and are instead characterized by very insidious infiltration of surrounding normal tissues that can greatly complicate attempts at complete resection.

Soft tissue sarcomas occur at all anatomic sites of the body, but the majority arise in the extremities.² At any given

anatomic location, the most commonly encountered histologic subtypes vary. Certain histologic types of soft tissue sarcoma have a strong predilection for specific anatomic sites (Figure 58.1). For example, 40% to 50% of epithelioid sarcomas arise on the forearm or hand, compared to only 14% of soft tissue sarcomas overall presenting anywhere in the upper extremity.⁸⁴

There exist a number of staging systems for soft tissue sarcomas. The most widely used system is the American Joint Commission on Cancer (AJCC) (Table 58.2). This system incorporates the traditional tumor size (T), lymph node status (N), and metastasis (M) categories as well as histologic grade (G). The incorporation of histologic grade reflects the observation that grade is a significant prognostic factor, with survival decreasing with increasing tumor grade.⁸⁵ A recent refinement in the staging of soft tissue sarcomas is the distinction of superficial and deep lesions, based on the location of the tumor relative to the investing muscular fascia. Sarcomas arising entirely above the investing fascia (i.e., cutaneous or subcutaneous) are "superficial" and designated in the AJCC system with the T modifier "a." Sarcomas involving the fascia or arising entirely below it are "deep" and given the T modifier "b." The majority (67%) of soft tissue sarcomas are high grade, deep, and more than 5 cm in greatest dimension. The evidence base for the AJCC staging system is reviewed subsequently.

TABLE 58.2. American Joint Committee on Cancer (AJCC) GTNM classification and stage grouping of soft tissue sarcomas.

<i>Tumor grade</i>	
GX	Grade cannot be assessed
G1	Well differentiated
G2	Moderately differentiated
G3	Poorly differentiated
G4	Poorly differentiated or undifferentiated (four-tiered systems only)
<i>Primary tumor</i>	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor 5 cm or less in greatest dimension
T1a	Superficial location
T1b	Deep tumor
T2	Tumor more than 5 cm in greatest dimension
T2a	Superficial location
T2b	Deep tumor
<i>Regional lymph node involvement</i>	
NX	Regional lymph nodes cannot be assessed
N0	No known metastases to lymph nodes
N1 ^a	Regional lymph node metastasis
<i>Distant metastasis</i>	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
<i>Stage grouping</i>	
Stage IA	Low grade, small (G1–2, T1a or b, N0, M0)
Stage IB	Low grade, large, superficial (G1–2, T2a, N0, M0)
Stage IIA	Low grade, large, deep (G1–2, T2b, N0, M0)
Stage IIB	High grade, small (G3–4, T1b, N0, M0)
Stage IIC	High grade, large, superficial (G3–4, T2a, N0, M0)
Stage III	High grade, large, deep (G3–4, T2b, N0, M0)
Stage IV	Nodal or distant metastases (any G, any T)

^aNote: Presence of positive nodes (N1) is considered Stage IV.

Prognostic Features

Characterization of the heterogeneous group of tumors called sarcomas has been hampered by the relative rarity of each specific subtype. Our understanding of the clinical features and natural history of sarcomas is largely limited to case reports, single-institutional experiences, and a few large-scale surveys of national cancer registries using different methodologies in data collection and reporting. To obtain sufficient numbers of patients with sarcomas, these reports generally combine the data from patients treated over several decades. This practice often results in the inclusion of patients who underwent markedly different treatment regimens, inclusion of bone sar-

comas with soft tissue sarcomas, and inclusion of histologic subtypes that are known to have dramatically different clinical behavior. Despite these limitations, we are able to identify a number of salient features associated with sarcomas that are generally supported by studies involving large, often prospectively collected databases. These reports provide the foundation for current grading systems.

The strongest recognized prognostic factors are tumor grade, size, and depth; these key components of widely used clinical staging systems are discussed next (Table 58.3). Other prognostic factors have variably been identified as statistically significantly associated with either local recurrence or metastasis and survival. Local extension of tumor to involve blood vessels and bone has been shown to be associated with decreased survival, as has microscopic vascular invasion.^{86,87} Some studies have related worse survival and increased local recurrence rates with increasing age.^{88–92} A number of studies have identified that tumor location is of clinical importance.^{86,93–95} LeVay and associates noted that local recurrence was higher in patients with sarcomas of the head and neck, likely reflecting difficulties in obtaining negative surgical margins. They also noted higher rates of metastasis in patients with trunk and head and neck sarcomas when compared with extremity sarcomas. In virtually all major studies, patients with extremity tumors fare better than those with sarcomas arising on the trunk, head, neck, or retroperitoneum. Other prognostic factors associated with adverse outcomes identified by researchers in separate studies include skin involvement, lymph node metastasis, pain at presentation, and postoperative fever following resection.^{90,95–98}

Another area of controversy is the impact of isolated local recurrence on ultimate prognosis. Presentation with local recurrence has been shown to decrease overall survival in a number of studies.^{86,89,92,99} Other studies have indicated a similar outcome for locally recurrent lesions compared to primary sarcomas of the same grade, size, and depth. The available evidence does not clearly support a contention that local recurrence is, in and of itself, an independent negative prognostic factor. Rather, the weight of evidence supports managing most cases of isolated local recurrence of sarcoma in a fashion analogous to the same case presenting for primary treatment.

Histologic grade, widely regarded as the predominant prognostic factor for localized sarcomas, is a subjective determination based on a number of individual microscopic features: these include tumor cellularity, pleomorphism, mitotic rate, degree of differentiation, and the presence or absence of spontaneous necrosis. Some authors have separately evaluated these features and shown them to be independent prognostic factors.^{87,88,93,98,100,101} Newly identified molecular markers will likely play an important role in the future. Several molecular markers, such as c-Kit in gastrointestinal stromal tumors, have demonstrated their clinical utility in the diagnosis and treatment of specific sarcomas. Some molecular markers that have been associated with adverse prognosis are ras, c-myc, Ki-67, murine double minute 2 (MDM2), Rb1, and p53.^{102–113} Further studies involving larger numbers of patients are required before any of these markers can be regarded to have documented independent prognostic significance.

Staging

The importance of staging systems is severalfold. These systems serve as a means to evaluate prognosis, base clinical treatment decisions, and allow comparisons of studies. A staging system needs to be able to discriminate patient outcome in a meaningful and reproducible way. Staging of soft tissue sarcomas remains a work in evolution. Attempts to develop staging systems for soft tissue sarcomas began in earnest in the 1970s. Enneking and colleagues established a staging system for extremity soft tissue sarcomas based on

tumor localization within muscular anatomic compartments, histologic grade and metastasis.¹¹⁴ Subsequent investigators have created new or refined staging systems, each with its strengths and weaknesses.^{85,115} Currently, the most widely used staging system is that of the American Joint Committee on Cancer (AJCC), which modifies the familiar TNM system by the addition of grade (G) as a separate component (see Table 58.2).⁸⁵ Important caveats related to the AJCC staging system are that it does not apply to Kaposi's sarcoma, dermatofibrosarcoma, infantile fibrosarcoma, and angiosarcomas, as these tumors are known to have unique but often poorly

characterized prognostic features. The framers of this staging system also point out that it does not adequately stage sarcomas arising in all anatomic locations. Specifically, sites with unique prognostic features are those sarcomas arising in the dura, brain, parenchymatous organs, gastrointestinal tract, and retroperitoneum. A great deal of evidence forms the basis for the AJCC staging system, but there is also evidence pointing to weaknesses or inadequacies of the current system.

From the studies to date, it is clear that prognosis is inversely proportional to tumor size. The AJCC staging system characterizes size as a dichotomous variable with a breakpoint at 5 cm maximum dimension. Available evidence indicates, however, that size should be considered as a continuous variable. For example, survival with a 6-cm tumor is significantly better than that of a 15-cm sarcoma despite both tumors being staged T2 in the AJCC system. At the very least, it would be appropriate to recognize additional breakpoints (e.g., 10 cm, 15 cm, 20 cm) as defining progressively poorer prognosis categories. Recently, depth was incorporated into the AJCC staging system as a factor secondary in importance to size. Available evidence is inconclusive as to whether depth is truly an independent factor: the apparent prognostic significance of depth may be a reflection of the fact that deeper lesions more often reach larger size (frequently well in excess of the 5-cm cutoff) before diagnosis.

The use of histologic grade as an integral part of the AJCC system is one of the most accepted and time-tested aspects of sarcoma staging, but even this has not been without controversy. Evidence clearly supports that three-part systems (defining low, medium, and high grade) provide additional prognostic information compared to two-part systems.¹¹⁶ The evidence is much less clear that there is additional information conveyed by four-part systems. The AJCC system uses a four-part grading system but collapses this into a two-part system for assignment of the G classification (that is, grade 1 or 2 sarcomas are G1 while grade 3 or 4 sarcomas are G2). Clinically, it is a widely accepted principle that intermediate- and high-grade sarcomas (in three-part systems) are treated similarly. The rationale for collapsing grade 1 and 2 sarcomas into the same category, especially given how most pathologists discriminate grade 1 and 2 lesions, requires further prospective evaluation and perhaps even revision in future iterations of the system.

The relative significance assigned to grade in stage assignment has also been brought into question. Ramanathan and associates observed that AJCC stage III patients in their study in fact had a higher overall survival than stage II patients.¹¹⁷ Other investigators similarly found survival rate discrepancies between stages.^{118–120}

Lymph node metastasis has been identified as a significant negative prognostic finding,^{121,122} as reflected in stage IV assignment in the face of N1 disease, indicating that prognosis for node-positive sarcoma patients is considered similar to those who present with metastatic disease. The frequency of lymph node metastasis has been reported to range from 2% to 13%, with the true incidence likely closer to 5%.^{122–126} Although lymph node metastasis is a rare event in soft tissue sarcomas, higher incidence of lymph node metastasis is observed in synovial cell sarcoma, rhabdomyosarcoma, clear cell sarcoma, and alveolar soft parts sarcoma.¹²⁶ It remains unclear, based on available data, whether nodal metastasis conveys similarly poor prognosis for all these tumor types and

whether the prognosis after nodal metastasis in contemporary series is truly equivalent to metastatic disease beyond the regional nodes.

Validation of the AJCC staging system has been performed through a number of studies. As already discussed, problems with stage discrimination have been identified in several studies. From these reports, it is clear that further modifications will be needed in future iterations. Treatment decisions should incorporate anatomic site, tumor histology, actual tumor size, and, where appropriate, molecular markers rather than restricting decisions to only AJCC stage assignment.

Clinical Evaluation

Extremity Sarcomas

The clinical presentation of patients with soft tissue sarcomas varies by anatomic site. The most common locations for these tumors are shown in Figure 58.1. Patients with soft tissue sarcomas arising in the extremities usually present with a painless mass that is larger than 5 cm (Table 58.4). El-Jabbour et al. reported a median duration of symptoms of 6 months before presentation.¹⁰⁰ In a survey of more than 5,800 sarcoma patients, Lawrence and colleagues reported that about half waited at least 4 months before seeing a physician and 20% experienced delays of 6 months or more *after* seeking treatment before a correct diagnosis was made.¹²⁷ Often sarcoma patients are diagnosed clinically as having a “chronic hematoma” or “pulled muscle” and undergo prolonged observation or treatment for these conditions. In fact, nonathletic adults rarely develop persistent soft tissue masses from either of these causes in the absence of a history of unusually strenuous activity or significant trauma, unless they are on chronic anticoagulant therapy. When a soft tissue mass arises in a patient with no history of trauma or persists more than 6 weeks after local trauma, further evaluation is indicated.

Virtually all soft tissue masses arising in the extremity that are more than 5 cm in diameter and any new, enlarging, or symptomatic lesions should be biopsied. Only small subcutaneous lesions that have persisted unchanged for many years should be considered for observation rather than biopsy.

The best way to avoid undue diagnostic delay during evaluation of a soft tissue mass is for the physician always to remain cognizant of the possibility of malignancy. During the physical examination attention should be given to tumor location, size, mobility, tenderness, vascular exam, skin changes, and inspection of all lymphatic basins. It is also relevant to identify often subtle neurologic changes that can result from the mass. If a deep-seated extremity mass is to be biopsied, we prefer that appropriate imaging studies be performed before biopsy; this ensures no tissue distortion that could complicate the interpretation of the study and may assist in the planning of the biopsy to ensure the highest yield samples.

Retroperitoneal and Visceral Sarcomas

Sarcomas arising in the retroperitoneum and from abdominal viscera most commonly present as an abdominal mass often without other symptoms (Table 58.5). Although the median age is around 50, retroperitoneal sarcomas can occur at any age. These tumors usually do not come to the attention of the patient until they are large. Retroperitoneal sarcomas smaller than 5 cm are rarely seen.^{128,129} When present, symptoms relate to mass effect of the tumor or local invasion. Early satiety, gastrointestinal obstruction or bleeding, lower extremity swelling, or pain can be the first symptoms leading to the discovery of a retroperitoneal sarcoma. The most useful tool in the evaluation of retroperitoneal tumors is a computed tomographic (CT) scan; this allows assessment of tumor location and relationship to adjacent organs, and can identify metastatic lesions in the liver or peritoneal cavity. Once the initial evaluation identifies a retroperitoneal tumor, the clinician must consider a number of clinical entities, including functioning and nonfunctioning adrenal tumors, renal tumors, pancreatic tumors, advanced gastrointestinal carcinomas, germ cell tumors, and soft tissue sarcomas. Detailed history and physical examination can help distinguish many of these entities and prompt further studies. Serum beta-human chorionic gonadotropin (β -hCG), alpha (α -)fetoprotein,

and testicular examination and ultrasonography are indicated in cases of suspected testicular cancer with retroperitoneal metastasis. In patients with lymphadenopathy, either core needle or excisional biopsy of enlarged lymph nodes may be diagnostic for lymphoma. When tumors appear to be arising from the stomach, pancreas, or duodenum, upper gastrointestinal endoscopy with biopsy may be diagnostic. Similarly, colonoscopy with biopsy can be useful in tumors arising from the colon. If these diagnoses are ruled out or low in the differential and sarcoma is the most likely diagnosis, the role of biopsy is controversial.

Pisters and colleagues suggest that surgical exploration is the most appropriate next step for a retroperitoneal mass suspected of being a sarcoma.¹³⁰ We advocate a more-cautious approach, as new treatment options may be considered based on the results of a percutaneous biopsy. Examples include the use of imatinib mesylate (Gleevec) in the treatment of gastrointestinal stromal tumors or primary chemotherapy in germ cell tumors or lymphomas. Often the distinction between these diagnoses can be difficult with nonspecific physical findings and imaging studies. Our approach is to have patients undergo CT-guided biopsy of retroperitoneal tumors before treatment planning if the diagnosis is unable to be established through less-invasive means. It is important to note that nondiagnostic biopsies are not uncommon; in such cases, we proceed to surgery.

Head and Neck Sarcomas

The majority of head and neck cancers are epithelial tumors, followed by lymphomas with sarcomas comprising only 1% to 11% of these malignancies.¹³¹ Sarcomas of the head and neck can occur at any age; however, median ages from series are usually in the fourth and fifth decades (Table 58.6). From several series, we observe that the majority of these tumors are less than 5 cm, and they are less often high grade than sarcomas arising in other sites. Bentz et al. reported a series of 111 head and neck sarcomas, noting that half these patients

presented with a painless enlarging mass; the remainder reported pain or neurologic dysfunction on presentation.¹³² The neck, face, and scalp represent the most frequent subsites for sarcoma formation; however, tumors can arise in the oral cavity, sinuses, orbit, pharynx, and nasopharynx.¹³¹⁻¹⁴³

Imaging

Great advances have occurred during the past two decades through the widespread use of CT and magnetic resonance (MR) scanning. The two modalities have continued to evolve, further refining the quality of these studies. As discussed previously, we strongly encourage imaging of deep soft tissue tumors before any biopsy procedure; this is important in characterizing the lesion before distortion that may accompany the biopsy. Planning the most appropriate biopsy technique, target area, and approach is also facilitated by prebiopsy imaging.

Magnetic resonance images are excellent at delineating tissue planes, neurovascular structures, and characterization of soft tissue tumors without the use of radiation (Figure 58.2). A number of studies have demonstrated the ability of magnetic resonance imaging (MRI) to characterize benign and

malignant soft tissue tumors accurately in a high percentage of cases.¹⁴⁴⁻¹⁴⁷ Totty et al. compared MRI with CT scanning for evaluating soft tissue tumors of the extremities.¹⁴⁴ They noted that T₁-weighted MR images better delineated extension of tumors into surrounding fatty tissue. They found that T₂-weighted and spin-density MR images were superior in detecting tumor extension into muscle. Overall, they found MR to yield superior resolution images to CT scanning in 33% of comparisons and equal results in 67%. In their study, MRI never yielded inferior results compared to CT. The only deficiency they identified was the limited ability of MRI to demonstrate soft tissue calcification and gas. In a study comparing MRI with CT in the evaluation of 27 extremity soft tissue tumors, Weeks and associates found that MRI was able to adequately assess neurovascular involvement in 80% of cases compared with 62% of CT scans.¹⁴⁸ Verstraete and colleagues utilized contrast-enhanced techniques in MRI, demonstrating an improved ability to depict tissue vascularization and perfusion.¹⁴⁷ This advantage is relevant in biopsy planning, where the highest yield specimens are more likely to be obtained from viable, well-perfused areas. When bony involvement or destruction is of concern, CT scanning is better suited than MRI (Figure 58.3).

Imaging of the head and neck can be accomplished through either CT or MRI. We have usually relied on CT as our initial imaging modality and added MRI when further characterization is required. In imaging the chest, trunk and abdomen, CT scanning is the most commonly employed technique (Figure 58.4). Obtaining high-quality MR scans of the chest and abdomen can be difficult, whereas CT is less sensitive to motion artifact.¹⁴⁹ Characterization of fatty tumors, tumor proximity to adjacent organs, and detection of intraabdominal metastasis are all possible with CT scanning of the abdomen. In the pelvis, all these features of CT are relevant, as well as excellent characterization of bony invasion. Granstrom and Unger reviewed the techniques and interpretation of MR in the evaluation of retroperitoneum.¹⁵⁰ They emphasized the importance of axial images in addition to sagittal and coronal views. Although MR has been investigated in the evaluation of specific organs such as pancreas and adrenal glands, large studies comparing MRI of retroperitoneal sarcomas with CT scanning are lacking. At present, we rely primarily on CT scanning in the evaluation of soft tissue tumors arising in the abdomen and pelvis.

Biopsy

The technical details of biopsy in the evaluation and treatment of soft tissue tumors remain the subject of debate, fueled by a surprising lack of high-quality evidence. Concerns surround the technique employed, pathologic interpretation, and treatment implications. Following the initial history and physical examination and appropriate radiologic investigations, the decision regarding biopsy must be carefully considered. Although the technical aspects of the actual performance of the biopsy are not necessarily complex, the decision making can be challenging for even the most experienced surgeon. As Mankin and colleagues pointed out in two similar studies conducted 14 years apart, missteps at this stage can have grave consequences.^{151,152} Their initial report identified a 17% complication rate resulting from the biopsy. More concerning was the finding that, in 18% of patients, the

treatment or outcome was altered because of some difficulty related to the biopsy. Factors implicated included poorly oriented incisions, made without due regard to the subsequent surgical approach required for definitive resection, and wound complications such as infection or hematoma formation. Perhaps the most distressing finding was that nearly 5% of patients went on to have amputations who might otherwise have been candidates for limb-sparing procedures. The authors concluded that the planning of a biopsy, technique employed, incision orientation, and pathologic interpretation could have significant treatment implications. They also found that patients biopsied at outside referring institutions experienced complications with skin, soft tissue, or bone in 31% whereas only 7% of biopsies performed at specialty centers had similar complications. There was an alteration in treatment as a result of the biopsy in 32% of referring institutions who performed these biopsies and 8% in those performed at the specialty centers. When the authors repeated this study, they found very little had changed in these results despite prior warnings. These issues serve to alert us to the significance a biopsy plays in patients presenting with soft tissue tumors.

In lesions of the extremity, a number of methods can be employed to obtain diagnostic tissue, including fine-needle aspiration (FNA) cytology, core needle biopsy, incisional biopsy, and excisional biopsy. Each technique has its advantages and disadvantages and requires expertise in its performance and, equally importantly, in the pathologic interpretation. FNA is the least invasive, associated with a low complication rate, and can be performed in an outpatient setting. Tumors in both superficial and deep locations can be biopsied using this technique. A number of studies have been able to establish the diagnosis of malignancy in more than 90% of cases; in some series, the majority could be assigned to a specific histologic subtype.¹⁵³⁻¹⁵⁷ In a prospective series of 365 consecutive FNA biopsies of soft tissue lesions, Akerman et al. reported correct diagnosis of malignancy in 89% and correct diagnosis of a benign lesion in 96% of lesions.¹⁵⁵ A major concern with the use of FNA remains the occurrence of false-positive diagnoses of malignancy in small numbers of

FIGURE 58.4. Computed tomography of abdominal wall solitary fibrous tumor.

patients in virtually every large series. In Akerman's series, two patients had their care altered as a result of a false diagnosis. The application of ancillary techniques (cytogenetics, immunohistochemistry, flow cytometry, electron microscopy) can achieve a diagnostic accuracy approaching 95% in identifying malignancy.¹⁵⁶ Reported rates of false positives and false negatives range from 1% to 4% with adequate sampling.^{153,156,158,159,160-161} Needle tract seeding following FNA biopsy has been reported; however, it appears to be exceptionally rare.^{155,157,161-163}

It must also be noted that the majority of studies reporting excellent results with FNA are performed in centers with large volumes of soft tissue tumors, expert cytologists, and individuals with expertise and interest in the cytologic evaluation of soft tissue tumors. Whether these results can be reproduced in institutions without dedicated specialized cytopathologists is doubtful. We currently employ FNA in the evaluation of lesions suspicious for recurrence or metastatic disease, where the prior histology is available and can aid in confirmation, but not for primary extremity lesions.

Core needle biopsy has emerged as the most commonly employed biopsy technique in recent years. Several advantages have been identified when using this approach. This procedure can generally be performed in the outpatient setting with local anesthesia. The complication rate is similar to that of FNA, approximately 1% to 2% in several series.¹⁶⁴⁻¹⁶⁶ Core needle biopsy provides a 1 mm × 10 mm tissue sample, preserving tumor architecture to facilitate pathologic diagnosis and the assignment of histologic grade.¹⁶⁶ Ball and associates evaluated 52 consecutive core needle biopsies of soft tissue tumors, reporting accurate diagnosis in 98% of malignant tumors.¹⁶⁵ They reported correct histologic subtype diagnosis in 85% and correct histologic grade assignment in 88% of sarcomas. In a report comparing 570 core needle and open biopsies, Hoerber and colleagues reported sensitivities of 99.4% and 97.4%, respectively.¹⁶⁶ They found a specificity of 98.7% for core needle biopsy and 100% for incisional biopsy. They were able to assign the histologic subtype and grade in 80% of core needle biopsies. Heslin and associates evaluated 164 primary extremity soft tissue tumors comparing first biopsy attempts of core needle biopsy, incisional biopsy, frozen section, and excisional biopsy,¹⁶⁷ finding that 93% of core needle biopsy samples were adequate to establish the diagnosis. Core needle biopsy was able to identify malignancy in 95%, histologic grade in 88%, and subtype in 75% of biopsies. Taken together, these studies support the accuracy, safety, and utility of core needle biopsy in the evaluation of soft tissue tumors. We utilize core needle biopsy for the initial diagnostic study in most patients presenting with soft tissue tumors larger than 5 cm in both superficial and deep locations.

Incisional biopsies play an important role in evaluation of soft tissue tumors, but decisions regarding when and where to employ this technique require significant experience in the treatment of musculoskeletal tumors. As tumor seeding is a concern, excision of the biopsy scar and tract is required if a sarcoma is diagnosed. Poorly planned incisions may result in added morbidity for sarcoma patients when they undergo definitive resection (Figure 58.5).¹⁶⁸⁻¹⁷⁰ Incisions oriented along the long axis of the extremity do not necessarily yield the best cosmetic result, but they minimize future problems in the event a sarcoma is diagnosed. The incision should be

FIGURE 58.5. Poorly oriented biopsy of anterior shoulder with interrupted sutures, hematoma, and infection.

placed directly over the most superficial part of the tumor whenever possible, allowing a surgical approach that avoids crossing through uninvolved compartments to minimize contamination of normal tissues (Figure 58.6).¹⁵⁴ The accuracy in distinguishing benign from malignant tumors is greater than with core needle biopsy; however, risks of hematoma and wound complications are also higher.^{151,152,166} Meticulous hemostasis to avoid hematoma and possible contamination of adjacent muscle compartments is imperative. Because the zone of compressed, reactive tissue around a sarcoma can

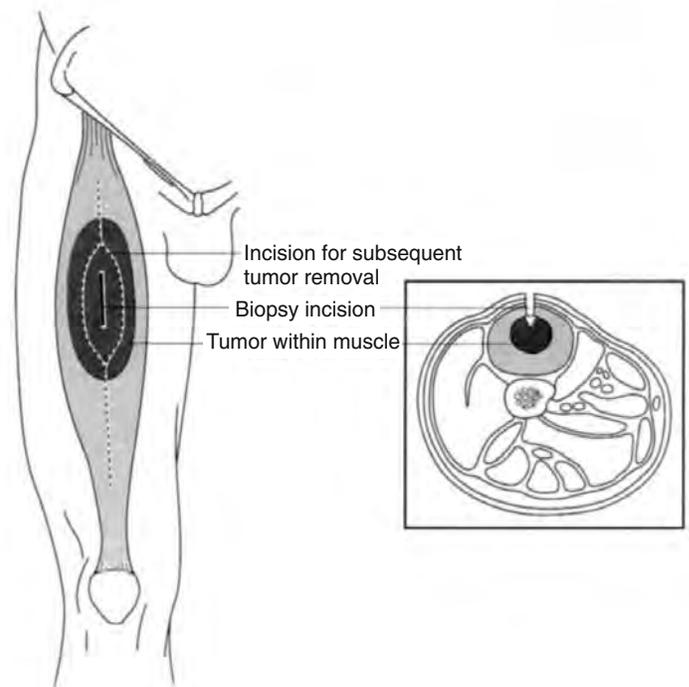

FIGURE 58.6. When making an incision, the incision should be placed directly over the most superficial part of the tumor whenever possible, allowing a surgical approach that avoids crossing through uninvolved compartments to minimize contamination of normal tissues.

look like malignant tumor tissue, we utilize frozen section to ensure adequate tissue for diagnosis has been obtained. The limitations of frozen section histopathology are significant, however, and radical procedures are generally not carried out based on a frozen section diagnosis obtained during incisional biopsy.

Excisional biopsy is reserved for small, superficial lesions. Although most such lesions are benign, the same careful planning is required as described in performing incisional biopsies. The biopsy incision should be oriented in such a way as to allow for uncompromised wide reexcision in the unlikely event of a malignant diagnosis.

When considering biopsy of a large or deep soft tissue tumor, the input of a surgical specialist experienced in the treatment of sarcomas can avoid many of the potential pitfalls reported by Mankin et al.^{151,152} Sarcoma treatment centers continue to see patients who have undergone excisional biopsy for large or deep sarcomas. Unplanned excisional biopsy (the so-called oops phenomenon) carries with it a very high risk of leaving gross or microscopic tumor behind, even when the biopsy surgeon believes a complete excision of all tumor has been carried out. Randall and associates reviewed 104 unplanned resections of soft tissue sarcomas referred to a specialty center and found that 82% of excisional biopsies had positive histologic margins.¹⁷¹ In a retrospective review of 65 patients referred to a specialty care center after unplanned excision of soft tissue sarcomas, Noria and associates documented that 39% of these patients had residual disease when subsequent resection was performed.¹⁷² None of the patients in this series had identifiable disease on physical examination or by imaging. Noria et al. were unable to identify predictive factors to identify those patients who were most likely to have residual disease. When Davis et al. evaluated their experience performing reexcision in 239 patients after soft tissue sarcoma excisional biopsies, they identified residual disease in 35% to 40% of resected specimens.¹⁷³ Other investigators have similarly found a high incidence of residual disease on resection.^{174,175} Increased local recurrence rates have also been associated with excisional biopsy of soft tissue sarcomas in some but by no means all series.^{172,173}

Treatment

Available evidence regarding prognostic and treatment-related factors suggests that treatment decisions for patients with clinically localized soft tissue sarcomas be based on the site and histologic grade of the primary tumor. Traditionally, the mainstay of treatment for soft tissue sarcomas has been surgery.¹⁷⁶⁻¹⁷⁸ Increasingly, it is now recognized that a multidisciplinary, multimodality approach including radiation and at times systemic chemotherapy is associated with improved outcomes for most patients with soft tissue sarcomas. Multimodality therapy in properly selected patients can improve local control rates, decrease the morbidity and quality of life impairment associated with surgery (particularly by decreasing the need for amputation to control extremity sarcomas), and increase the duration of relapse-free survival. Available evidence is insufficient to conclude that multimodality therapy results in increased overall survival durations, but at least some data suggest that it may.

Surgery

The most effective single-modality treatment for localized soft tissue sarcoma in any site is complete resection with histologically negative margins. Because many soft tissue sarcomas manifest a pseudocapsule, "shell out" procedures where tumors are removed from within this apparent capsule are associated with local recurrence rates that approach 100%. Historically, this led to the adoption of extensive radical procedures, frequently in the form of amputations, to ensure adequate local control.

Sarcoma resections are categorized as intracapsular, marginal, wide, or radical.¹⁷⁹ Intracapsular resections are usually a result of "shell out" of an apparently encapsulated tumor when a malignant diagnosis was not anticipated. In a marginal resection, the plane of dissection is outside the pseudocapsule but before or within the surrounding reactive zone. Wide resection consists of resection of surrounding normal tissue outside the reactive zone. In a radical resection, there must exist a natural barrier interposed between the tumor and the margin in all directions. This approach is best illustrated in compartmental resections, where an entire muscle group is resected at its origin and insertion with the fascia intact throughout (Figure 58.7).¹⁷⁹ In this categorization, radical resections are associated with lower local recurrence rates than other procedures when surgery is the sole modality of therapy. In multimodality approaches, however, evidence of the superiority of true radical resections is lacking, and indeed they may be associated with increased complication rates and poorer functional outcomes. For most sarcomas treated with a multimodality approach, wide excisions are the procedure of choice.

The emergence of radiation and systemic chemotherapy as potentially active agents for unresectable sarcomas led to the development of combined modality approaches that could preserve the limb with reasonable function and acceptable local control rates. Rosenberg and associates reported a prospective 2:1 randomized trial of 43 patients comparing limb-sparing surgery (wide excision) and postoperative radiation to amputation; all patients received postoperative systemic chemotherapy.¹⁸⁰ They found that the local recurrence rate was marginally higher in the group undergoing limb-sparing surgery ($P = 0.06$), but a large majority of patients in the limb-sparing surgery group had successful local control of their tumors. There was no statistical difference in overall survival between the two arms, but the study was far too small to reliably detect such a difference. Based on these limited data, multimodality limb-sparing approaches have become the accepted norm for the management of nearly all extremity soft tissue sarcomas. Subsequent studies evaluating limb-sparing surgery in the treatment of soft tissue sarcomas are shown in Table 58.7.

Surprisingly, evidence demonstrating that limb-sparing approaches are associated with measurably improved functional outcomes and/or quality of life compared to amputation is largely nonexistent. Functional outcome comparing patients who had amputation with those who underwent limb-sparing procedures was addressed in a study by Davis et al.,¹⁸¹ who noted a trend toward increased disability in those patients undergoing amputation versus those who had limb-sparing procedures. Conversely, a study by Sugarbaker and associates found that quality of life assessments failed to

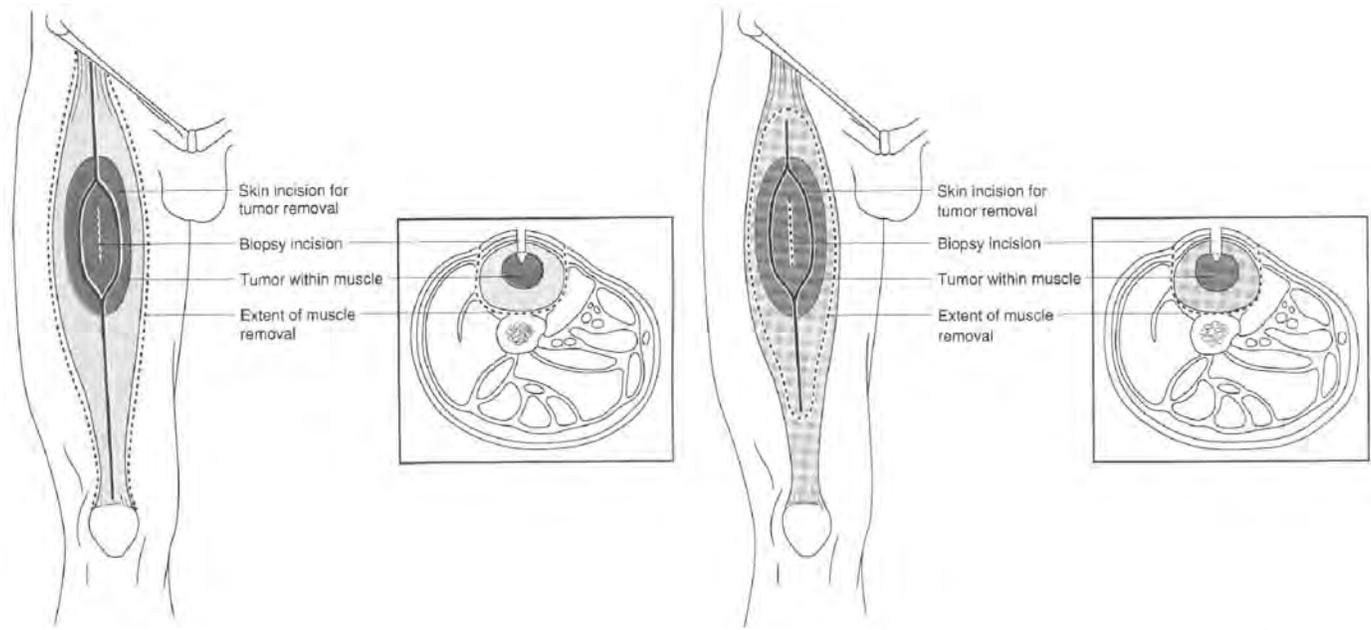

FIGURE 58.7. A compartmental resections is where an entire muscle group is resected at its origin and insertion with the fascia intact throughout.

support a benefit to limb-sparing procedures over amputations.¹⁸² Following radical limb-sparing procedures, many patients have significant functional disability, although most are able to ambulate remarkably well.¹⁸³⁻¹⁸⁵ Stinson and colleagues evaluated acute and long-term effects of limb function following limb sparing therapy,¹⁸³ reporting that 84% of patient were able to ambulate without assist devices with mild or no pain.

Encasement of nerves or blood vessels by soft tissue sarcomas is uncommon but is not in and of itself an indication for amputation. Complete resection of the sciatic nerve results in loss of knee flexion and dorsiflexion of the foot. With aggressive physical therapy and the use of an ankle-foot orthosis, however, these patients can ambulate. Brooks et al. evaluated functional status of patients following resection of the sciatic, peroneal, or tibial nerves.¹⁸⁶ They reported a post-

operative leg function score of 8 of 10 and added that all patients surveyed preferred their status to amputation. A number of reports have documented the feasibility of en bloc resection of arteries and veins with autologous or prosthetic graft reconstructions.^{187,188}

Current multimodality approaches can result in limb preservation with useful function and very high rates of local tumor control. Even though evidence of clear-cut superiority in functional outcome or equivalence in local control and survival when compared to amputation is lacking, sarcoma patients will almost never accept a major amputation if a nonamputative surgery is feasible. This general acceptance of the concept of limb preservation is reflected in the fact that only 5% of patients currently presenting to major centers with primary soft tissue sarcoma of the extremity are treated with amputation.¹²⁷ The weight of current evidence supports the use of limb-sparing surgery as part of the multimodality management of soft tissue sarcoma of the extremities. The optimal techniques for limb-sparing treatment have not been defined, and it is undoubtedly true that multiple effective options exist. Matching the proper combination and sequence of therapies to the needs of the individual patient remains one of the major challenges in the treatment of soft tissue sarcomas and often requires the skills of a dedicated multidisciplinary team of physicians and allied health personnel.

Radiation Therapy

Limb-sparing resection alone, particularly marginal or wide excision, has been associated with local recurrence rates up to 50% to 70%,^{189,190} which sparked an interest in decreasing local recurrence with the application of radiation. Controversy continues regarding the necessity, type, and timing of radiation therapy; as in so many other situations, prospective comparative clinical trials are few, limited in statistical power, and often contradictory.^{118,191,192}

Although most patients with extremity sarcomas do receive some form of radiation along with surgery, available evidence suggests that for some patients, particularly those with small, superficial, or low-grade tumors, wide excision alone is adequate treatment. In a review of 56 patients with extremity sarcoma, Rydholm and associates reported their experience using limb-sparing surgery without radiation.¹⁹² They reported a local recurrence rate of 7%. From their experience, they questioned the necessity of radiation therapy in all extremity sarcoma patients. In contrast, other investigators have demonstrated improved local control rates with the addition of radiation therapy.^{119,193-196} Confounding the impact of radiation therapy is the variability in the timing of radiation, surgical margin status, and use of adjuvant chemotherapy. From the studies to date there appears to be a decrease in local recurrence by adding radiation to resection. Studies have generally supported the omission of radiation for low-grade soft tissue sarcomas when surgical margins are widely free of tumor.^{118,192,196}

It may be the case that aggressive systemic and/or regional chemotherapy can replace the need for radiation in some cases. In a study by Henshaw and associates, 33 patients were treated with preoperative intraarterial cisplatin and systemic doxorubicin.¹⁹¹ Ifosfamide was added in the later part of the study. Included in this study were 18 patients with high-grade soft tissue sarcomas of the extremities and pelvis that were

deemed unresectable, with the remainder of patients having large but potentially resectable high-grade soft tissue sarcomas in the extremities and pelvis. Variability in the definition of unresectability for extremity sarcomas is a major limitation when comparing studies or trying to generalize results to other institutions. In any event, only 2 of the 18 patients who initially were deemed unresectable actually underwent amputation after receiving chemotherapy. All the remaining patients were able to have limb-sparing resections. Twelve of the patients received radiation therapy, which was reserved for those with close surgical margins or limited degrees of chemotherapy-induced necrosis on histologic evaluation of the resected specimen. Two patients had local recurrences; interestingly, these occurred in the higher-risk patients treated with radiation. Disease-free survival in this study was 88% and 80% at 5 and 10 years, respectively. The authors of this study questioned the need for routine use of adjuvant radiation therapy when using aggressive intra-arterial and systemic preoperative chemotherapy.

The timing of radiation relative to surgery has also been investigated in terms of local disease control, effects on wound complications, and long-term morbidity. The use of preoperative external-beam radiation takes advantage of the presence of an intact tumor mass to delineate and limit the field of treatment. A theoretical advantage of preoperative radiation is the treatment (and presumptive sterilization) of tumor cells outside the pseudocapsule, which might otherwise seed the operative site and result in local recurrence.

Potential disadvantages are that it requires delay of the definitive surgery, which can create a psychologic stress for some patients, and that it may result in higher wound complication rates. Postoperative radiation therapy has the advantages of providing the entire tumor specimen to the pathologist for evaluation before deciding on the need for adjuvant therapy, potentially fewer wound complications, and no delay in surgery.

Taken as a whole, studies have failed to demonstrate that preoperative radiation therapy is superior to postoperative radiation. What has been identified is that preoperative radiation therapy is associated with higher wound complications whereas postoperative radiation has been found in some studies to result in increased fibrosis.^{83,197-201} In a prospective randomized trial of 94 patients comparing pre- and postoperative radiation in extremity soft tissue sarcomas, O'Sullivan and colleagues¹⁹⁷ identified wound complications in 35% of the preoperative radiated patients versus 17% of the postoperatively treated patients, a statistically significant difference and strong evidence that wound complication rates are indeed increased after preoperative radiotherapy. No statistically significant difference in local recurrence rates was identified between the two treatment groups. Overall disability was similar between the two groups when assessed one year following therapy. The overwhelming majority of wound complications seen in the preoperatively treated patients occurred in the treatment of lower extremity tumors; wound complication rates were low after preoperative radiation for upper extremity sarcomas. The highest incidence of wound complications (45%) was seen in upper leg tumors treated with preoperative radiation therapy. A confounding element in analyzing wound complications in patients receiving radiation therapy can be the effect of chemotherapy that many patients receive during their treatment. Meric and associates performed a retrospective review of 309 patients and failed to

identify an association between chemotherapy use and wound complications.²⁰²

The optimal method of radiation delivery has not yet been defined. The most commonly used methods are brachytherapy (implanted radiation) and external-beam radiation. Each approach has its advantages and disadvantages. To date there has not been a prospective randomized trial comparing brachytherapy to external-beam radiation. In randomized trials compared to surgery alone, the application of radiation using each technique has been associated with reduction in local recurrences. As such, the primary issues in choosing the best technique is balancing the advantages and disadvantages of each approach for individual patients. Proponents of brachytherapy cite delivery of a high dose of radiation directly to the surgical bed, limited treatment time, limited radiation to surrounding uninvolved tissues, and decreased overall costs.^{203,204} Another advantage lies in its potential for use in treatment of recurrent disease in previously radiated tissues. Limitations of brachytherapy lie in its requirement for dedicated surgical and radiation oncologists with experience with this technique and limitations in the ability to treat extremely large resection beds.¹¹⁹ Because brachytherapy delivers its radiation over a few days instead of many weeks, there is evidence to support the concern that low-grade tumors, with their relatively lower rates of DNA synthesis and cell division, are not well treated by brachytherapy.

With these considerations in mind, the current evidence to date would support preoperative and postoperative external-beam and postoperative brachytherapy radiation as effective methods for local tumor control in large, high-grade soft tissue sarcomas. Our current approach is to tailor therapy to the tumor location, patient ability to complete prescribed therapy, and, most importantly, patient preference.

Adjuvant Systemic Chemotherapy

As with most major issues in the treatment of localized soft tissue sarcomas, the role of chemotherapy remains controversial and the quality of available evidence is variable. Patients with localized soft tissue sarcomas are generally able to achieve local control through surgery and radiation. Unfortunately, roughly 50% will go on to develop distant metastasis, and most of those will die as a direct consequence.¹⁹⁰ Patients with large (more than 5 cm) and high-grade sarcomas are clearly more likely to develop metastatic disease and die than those with smaller or low-grade tumors. Some investigators have observed that local recurrence also places patients at higher risk of distant metastasis, even when all visible disease can be removed by resection or amputations.^{205, 206} This finding suggests but does not prove that lowering local recurrence rates can ultimately enhance relapse-free and overall survival rates. Importantly, adjuvant systemic therapy for osteosarcoma has been shown repeatedly to significantly and markedly improve local control and relapse-free and overall survival rates.

Experience in the treatment of measurable metastatic sarcoma has identified doxorubicin and ifosfamide to have the highest response rates, and the response rates for osteosarcoma and soft tissue sarcoma are relatively similar.^{190,207,208} Extrapolating from experience in osteosarcoma, first-generation clinical trials of adjuvant therapy for soft tissue sarcomas were usually doxorubicin based (often with single-agent

doxorubicin) and used relatively low doses. Factors that often varied between studies were drug doses, tumor histologic subtypes, anatomic sites, methods of delivery, and timing of therapy. These studies gave inconsistent results; however, there appeared to be some evidence of improvement in relapse-free survival. A meta-analysis was performed evaluating 14 trials composed of 1,568 patients with localized resectable soft tissue sarcomas, including both extremity and nonextremity primary sites.²⁰⁹ The analysis revealed a 27% relative reduction in local recurrence in patients treated with chemotherapy, translating to an absolute benefit of 6% fewer local recurrences at 10 years. The relative reduction in distant metastasis-free survival was 30%, with an absolute benefit of 10% at 10 years. Adjuvant chemotherapy resulted in a 25% relative reduction in relapse-free survival, with a resultant 10% absolute benefit at 10 years; this corresponded to an overall improvement in recurrence-free survival from 45% without adjuvant chemotherapy to 55% with its use. Overall survival, however, was not improved significantly by the use of chemotherapy. There was a trend toward improved survival with a potential absolute benefit of 4%, which translated to an overall survival improvement from 50% to 54%.

Several criticisms of this meta-analysis have been raised.^{190,207,210} The first relates to the time frame of these studies compared to contemporary treatment practices: the most recent study included in the meta-analysis completed accrual in 1990. Since that time, higher doses of chemotherapy and more-effective agents such as ifosfamide have become standard for adjuvant therapy. By grouping patients with extremity and nonextremity sarcomas together, the meta-analysis may have been biased against detecting an impact of adjuvant therapy in extremity sarcoma patients, where surgery and radiation eradicate all local tumor in a higher percentage of patients. Nonetheless, as the primary goals of adjuvant chemotherapy are to improve relapse-free and overall survival, the modest absolute relapse-free survival increase of 10% at 10 years and questionable benefit in overall survival are concerning. These findings suggest that 90% of patients treated with chemotherapy would not gain any advantage from adjuvant treatment compared to providing the same or similar chemotherapy upon relapse; this is an important consideration, in that chemotherapy can result in significant toxicities, diminished overall quality of life, and even in rare cases treatment-related deaths.

In the face of the limitations of the meta-analysis, a subsequent trial from Italy has been widely touted as more contemporary support for the use of chemotherapy in the treatment of soft tissue sarcomas. In this prospective randomized trial of 104 patients with large high-grade soft tissue sarcomas of the extremities, Frustaci and associates evaluated the adjuvant use of epirubicin (an anthracycline cytotoxic drug similar in efficacy and toxicity to doxorubicin) and ifosfamide.²¹¹ The study was closed early secondary to an interim analysis revealing a statistically significant improvement in relapse-free survival in the patients in the chemotherapy arm. The median follow-up was 59 months at the time of this interim analysis, which demonstrated a 41% relative reduction in the risk of disease relapse, translating to an absolute benefit of 27% from chemotherapy at 2 years and 13% at 4 years. Local disease-free survival was not found to be statistically significant between the treatment groups, with the treatment arm having 9 local recurrences and 11 in the

control arm ($P = 0.07$). Overall survival favored the treatment arm, with an absolute improvement at 4 years of 19%.

Early termination of a randomized trial due to a highly significant treatment effect requires exceeding a stringent threshold and is the strongest possible evidence of superior efficacy for an investigational therapy. In essence, it means it would be unethical to continue to treat patients on the study with the control regimen (in this case surgery and radiation without systemic adjuvant chemotherapy), and by strong and direct implication, similar patients in the nonprotocol setting as well. Once early termination of a trial takes place, subsequent follow-up of the trial data may be compromised by the smaller than anticipated number of study patients and/or by cross-over of control arm patients to the now recognized superior treatment arm. Indeed, longer-term follow-up of the patients on this study reported at a median of 89 months of follow-up, indicated that the statistically significant survival advantage observed at the interim analysis was no longer present.²¹² Time to disease progression, median survival, and survival at 4 years still favored the treatment arm in the extended analysis, which for the reasons described above cannot be considered to invalidate the interim analysis finding.

What are we to take from this body of literature when considering adjuvant chemotherapy for patients with localized disease? The current evidence supports the contention that doxorubicin and ifosfamide are the most active agents currently available and appear to be most effective at relatively high doses, although there is likely a plateau beyond which further dose escalation is not helpful and may be harmful.^{190,211-218} These high-dose chemotherapy regimens are toxic and frequently require dose reduction and/or hematopoietic growth factor support to complete therapy. From data compiled through meta-analysis and more-contemporary reports, the benefit from the use of adjuvant chemotherapy may be real. However, this benefit will be confined to a minority of treated patients; others will be cured by local therapy alone or relapse despite the addition of chemotherapy. These factors must be considered when weighing the risks and benefits in adjuvant chemotherapy for an individual patient.

At present, the use of adjuvant chemotherapy in the treatment of intermediate- and high-grade soft tissue sarcomas likely confers a small advantage in local control, time to disease progression, and overall survival when high-dose doxorubicin- and ifosfamide-based regimens are used. Our preference is to provide adjuvant chemotherapy treatment of soft tissue sarcomas under strict protocol-based regimens or in the context of prospective clinical trials. Preoperative or neoadjuvant chemotherapy may have practical advantages over postoperative chemotherapy, not the least of which is the ability to monitor response or lack thereof and alter or terminate therapy in patients who do not appear to be deriving any benefit. Preoperative and postoperative chemotherapy have never been directly compared in randomized trials, however.

Regional Chemotherapy

The fact that so many sarcomas arise in the extremities has prompted investigation of cytotoxic chemotherapeutic agents administered intraarterially. This method has the theoretical

advantage of maximizing the dose of drug to the tumor and minimizing the dose delivered systemically to the patient. The relative pharmacologic advantage of intraarterial therapy compared to intravenous administration depends on the degree of "first-pass" extraction of the drug in the perfused tissues. Doxorubicin has a high degree of first-pass extraction in peripheral tissues, conveying a moderate advantage in tumor to systemic drug levels compared to intravenous administration of the same dose. Cisplatin, another drug commonly used for intraarterial therapy of sarcomas, has a much lower degree of first-pass extraction and hence there is relatively little pharmacologic advantage to its intraarterial administration.²¹⁹ Intraarterial administration has significant complexity and risks, requires inpatient hospitalization, and results in limiting the systemic antitumor effects of the drug to the same extent that it augments the regional intratumoral effects. Evidence directly supporting the use of intraarterial chemotherapy in extremity soft tissue sarcomas is minimal, essentially anecdotal. One small, randomized trial (90 patients total) compared intravenous to intraarterial doxorubicin when identical doses were administered as part of a preoperative chemoradiation strategy. This trial was only published in abstract form, but insufficient advantage for intraarterial administration was noted and the authors (hitherto the primary advocates for intraarterial doxorubicin administration) abandoned the technique.²²⁰

Several investigators have attempted to increase the therapeutic advantage of intraarterial drug administration by the use of isolated limb perfusion, a technique commonly applied in the treatment of extremity-confined melanomas. In this technique, surgical isolation of the extremity vasculature and directed circulation of most or all the blood of the extremity through an extracorporeal membrane oxygenator and pump ("heart bypass" machine) minimizes the systemic administration of drug and allows for very high, even otherwise potentially lethal, doses of drug to be circulated intraarterial for a period of time and then extracted in the venous effluent and discarded. Many soft tissue sarcomas present in advanced stages, adjacent to neurovascular structures or with local recurrences where resection may be difficult. From experimental evidence and experiences in the treatment of melanoma patients, most investigators have employed melphalan, tumor necrosis factor- α (TNF- α) or occasionally doxorubicin in the treatment of extremity soft tissue sarcomas.²²¹⁻²³¹ A multi-institutional experience of 186 patients treated with isolated limb perfusion with TNF- α and melphalan (plus gamma interferon in some cases) for primary or recurrent extremity soft tissue sarcomas was reported by Eggermont and colleagues.²³¹ Eighty-two patients had an objective tumor response. At a median follow-up of 2 years, the limb salvage rate was 82%. TNF- α is not available in the United States, and results with melphalan or other drugs in the isolation perfusion of sarcomas have been much less encouraging. Studies evaluating the use of isolated limb perfusion are summarized in Table 58.8.

At present evidence supports a possible role for isolated limb perfusion with TNF- α in carefully selected patients with locally advanced or multifocal soft tissue sarcomas when amputation is the only surgical alternative. Whether limb perfusion is worthwhile for sarcoma patients if only melphalan is available is less clear, but it is still advocated by some.²³²

Treatment of Localized Retroperitoneal Soft Tissue Sarcoma

Surgery

Retroperitoneal soft tissue sarcomas have unique clinical characteristics and pose distinct clinical challenges, which distinguish them from the more-common extremity sarcomas. Patients typically present with very large tumors, often with minimal symptoms. Although the most common site of first recurrence for patients with extremity sarcomas is in the form of distant metastatic disease, patients with retroperitoneal sarcomas are more prone to recur within the abdominal cavity. The overall survival for patients with extremity sarcomas is superior to that of patients with retroperitoneal sarcomas. Local failure is evident in nearly 90% of patients

who die of retroperitoneal sarcomas,²³³ a fact that reflects the large tumor size on presentation, inability to achieve wide surgical margins, and limitations of adjuvant radiation and chemotherapy. Local failure continues to occur beyond 5 and 10 years following resection, leading to some to estimate the overall recurrence rate for resectable retroperitoneal sarcomas exceeds 70%.^{234,235}

As for extremity primaries, surgery is the mainstay of treatment for retroperitoneal sarcomas. Because of the limitations of adjuvant therapy, including the inability to deliver high doses of radiation secondary to limited tolerance of bowel, kidneys, liver, and the spinal cord, surgery is somewhat more likely to be used as the only modality for treatment of these tumors. Reports describing experience in the surgical management of primary retroperitoneal soft tissue sarcomas are summarized in Table 58.9. The data in this table

focus on primary retroperitoneal sarcomas that have no evidence of metastatic disease. These reports have consistently documented the significance of complete resection of all gross disease in improving local control and disease-specific survival. In most reports, complete excision is achieved less than 70% of the time, with local recurrence occurring in approximately half of patients undergoing complete resection. The impact of local recurrence is reflected in diminished overall survival despite attempts at further resections.^{129,236} Results for resection of recurrent retroperitoneal sarcomas are notably worse, in both the percentage of patients who can be resected free of all disease and those who remain recurrence free long term.

With the possible exception of low-grade retroperitoneal liposarcomas, no survival benefit has been observed when incomplete resection is undertaken.^{129,237-240} Major complication rates are identical, however, for partial and complete resections. Thus, patients undergoing incomplete resection procedures are exposed to all the morbidity with none of the potential survival benefit of their counterparts who undergo complete excision. This result emphasizes the need for careful preoperative planning as well as determination of unresectability early in the operative procedure so that incomplete resections are not mandated because the surgeon has passed "the point of no return."

Retroperitoneal liposarcomas represent a distinct situation where a more-aggressive surgical approach, including multiple resections for repeated recurrences and even occasionally incomplete resections, may be justified. Liposarcomas in this location have been observed to have a lower incidence of distant metastases (7%) when compared to 15% to 34% for other histologic subtypes.^{236,239,241} Shibata and associates observed prolongation in survival in patients with partial resection in patients with liposarcomas when compared with those who only had biopsy.²³⁶ Further, they reported effective palliation of symptoms in 75% of symptomatic patients who underwent debulking procedures.

Identification of prognostic factors other than the adequacy of resection has been inconsistent across studies. Tumor size has not been identified as a predictor of survival, with the recognition that virtually all retroperitoneal sarcomas are larger than 5 cm at presentation. Tumor grade has been found to be significant in some studies but not in others, with the weight of evidence supporting shorter recurrence-free and overall survival for patients with high-grade tumors.^{129,233,235,237,239,241-256}

The clinical presentation and imaging evaluation of retroperitoneal sarcomas were discussed previously. Important in the next step is determining resectability from these studies. It is often difficult to determine preoperatively if adjacent vascular structures or organs are involved with tumor. Vascular involvement was noted in 34% of patients undergoing resection in a review by Kilkenny and colleagues.²³⁷ In cases where tumor is near major vessels but routine CT scanning cannot resolve whether the vessels are in fact involved, we have turned to MR angiography or CT angiography. Multivisceral resections are required in the majority of cases (63%–86%), most frequently involving the kidney, colon, small bowel, pancreas, and bladder.^{129,237,239,243,248,254} Our experience and that of others have shown that it can be difficult to determine whether adjacent organs will be attached or freely separable based on preoperative imaging. In planning resection one must be prepared for the high likelihood of exten-

sive en bloc resections to achieve this goal. No surgeon should operate on a retroperitoneal mass unless he or she is prepared for the magnitude of the resection that may be required.

Radiation

Several investigators have explored methods to decrease the incidence of local failure following resection. Extrapolating from evidence supporting improved local disease control with the use of radiation therapy in the trunk and extremities, radiation therapy is widely used as an adjunct to surgery in retroperitoneal sarcomas. There are important differences, however, that make radiation therapy more problematic and call into question its value for patients with retroperitoneal tumors. To date, no randomized trial has documented the value of adjuvant radiation for retroperitoneal sarcomas, so evaluations of its benefit are confined to retrospective analyses.

Proponents of preoperative radiation therapy cite the theoretical advantages of using the tumor bulk to displace uninvolved intrabdominal viscera, thereby decreasing local toxicity and increasing the ability to administer therapeutic doses.^{234,235,257} This approach also allows the target volume to be easily delineated for treatment planning, and treating the tumor before manipulation at the time of surgery could theoretically decrease the likelihood of tumor implantation. Resection is usually performed between 4 to 6 weeks after the completion of radiation. Postoperative external-beam radiation at doses that are most likely to be effective^{258,259} can be associated with significant acute and delayed bowel toxicity.^{233,260} After removal of the large tumor mass that had been displacing adjacent viscera, the bowel tends to fall into the resection bed and often becomes fixed there by postoperative adhesions. However, as in the extremities, postoperative radiation has advantages, including the ability to examine the entire tumor and the excision margins pathologically before deciding on the need for radiation as well as allowing for the completion of healing and recovery from surgery and complications thereof before instituting radiation. The areas of greatest concern for residual tumor and/or the closest surgical margins can be delineated and given focally higher doses of radiation in many cases. Contrary to some reports, we have successfully used postoperative radiation for retroperitoneal sarcomas over nearly two decades with acceptable acute toxicity and very little in the way of severe chronic toxicity. Radiation should not be automatically withheld from patients who have undergone complete resection, especially with close or involved margins, merely because they are postoperative.

That notwithstanding, the limitations of deliverable dose and the large volumes of the abdomen and pelvis that need to be radiated, whether preoperatively or postoperatively, have led many investigators to explore techniques to augment the effectiveness and/or minimize the toxicity of delivered radiation. Cytotoxic chemotherapy may be combined with radiation, but this combination is often poorly tolerated in patients with a large intraabdominal tumor or convalescing from its recent removal. As reviewed by Storm, studies have generally relied on doxorubicin-based regimens and have not demonstrated convincing improvements in disease-free or overall survival.²⁶¹ Nonetheless, a growing body of evidence suggests the combination can be administered to carefully selected patients.²⁶² The current evidence for the use of adju-

vant chemotherapy in the treatment of sarcomas is reviewed in the section on treatment of extremity sarcomas.

Other approaches have also been evaluated. In a Phase I/II trial using preoperative radiation therapy and the radiosensitizer idoxuridine (also known as IUdR or iododeoxyuridine), which does not have direct antitumor effects, in the treatment of retroperitoneal soft tissue sarcomas, Sondak and associates treated 16 patients with alternating weeks of continuous intravenous infusional iododeoxyuridine and twice-daily radiation therapy before surgery. Patients received a total of five cycles of therapy, either entirely preoperatively or split with three cycles before and two afterward.²⁶³ This effort resulted in an overall local control rate of 45% at 24 months; local control was achieved in 5 of the 8 patients who had complete resection with acceptable toxicity. An alternative approach to intensifying the radiation dose to the tumor bed was conducted in a trial by Jones and associates in which 55 patients with resectable primary or recurrent retroperitoneal sarcomas were treated with preoperative external-beam and postoperative brachytherapy.²⁶⁴ Forty-six patients had complete resections, with 41 completing preoperative radiation therapy and 23 having brachytherapy. Preoperative radiation therapy was well tolerated, but those treated with brachytherapy experienced significant toxicity, including 1 death. Sondak et al. reported overall 2-year relapse-free and overall survival of 80 and 88%, respectively.

Another approach that has been investigated is the use of intraoperative radiation. Once an enormously complicated undertaking wherein anesthetized surgical patients needed to be transported to treatment machines in the Radiation Oncology Department with their abdomens open, intraoperative radiation is now practically achieved at a number of centers with specially designed and shielded operating rooms equipped with built-in radiation devices. With this technique, the resection bed can be directly targeted to a high dose while nearby radiosensitive tissues are mechanically retracted out of the treatment field. A summary of studies investigating the use of intraoperative radiation therapy is shown in Table 58.10. Unfortunately, the weight of evidence, including one

small randomized trial,²⁶⁵ suggests that intraoperative radiation increases in-field tumor control but not recurrence-free or overall survival, as patients recur just outside the treatment field, and that it adds significant late toxicity.

Local Recurrence

In the absence of metastatic disease, repeat resection when able to remove all gross disease is the treatment of choice for locally recurrent retroperitoneal sarcomas. Many studies have shown that a significant number of patients experience prolonged disease-free survival when all gross disease can be resected. The addition of chemotherapy or radiation in the treatment of locally recurrent disease remains the subject of debate. Given the extremely high risk of further local and distant recurrence, all patients who have not previously received adjuvant therapy should be considered for it after resection of recurrent disease. Subsequent recurrences have progressively diminishing chances for resection. Evidence for the benefit of third and subsequent resections of retroperitoneal sarcomas is scant and largely limited to studies of patients with low-grade liposarcomas. Such aggressive attempts at disease control should almost always be relegated to centers with significant expertise in the management of retroperitoneal tumors.

Treatment of Gastrointestinal Stromal Tumors

Gastrointestinal stromal tumors (GIST) are uncommon tumors believed to originate from the interstitial cells of Cajal in the alimentary tract. These cells form a smooth muscle cellular network to function as a pacemaker of gut motility.^{266,267} Gastrointestinal stromal tumors are most commonly found in the stomach (39% to 70%), small intestine (20% to 32%), colon and rectum (5% to 15%), and esophagus (less than 5%) (Figure 58.8).^{266–269} The true incidence of these tumors is unclear, because population studies frequently fail to distinguish GIST from gastrointestinal carcinomas.

Traditionally, GIST have been considered to be benign, malignant, or "borderline." The evidentiary basis for this distinction is suspect, but it is clearly difficult to determine if a GIST will metastasize by its light microscopic appearance alone. Studies investigating features most associated with malignant behavior have found tumor size (more than 5 cm), mitotic count (more than 1–5 per 10 high-power fields), tumor necrosis, and most recently immunohistochemical identification of c-Kit (CD117) mutation to be important.^{266–270} In most studies that have attempted to use this type of classification, approximately one-third of GIST are classified as "malignant."²⁷¹ In nearly all studies, however, tumors classified as "benign" or "borderline" manifest unequivocally malignant behavior (i.e., metastasis) in a small percent of cases. Hence, available evidence would suggest that all GIST should be considered to be malignant neoplasms at low, intermediate, or high risk for developing metastatic disease. Whether there is a subset of GIST that are unequivocally benign, with no propensity whatsoever to metastasize, remains to be proven.

Treatment of GIST has traditionally relied on complete resection. Complete resection of GIST has been reported in the range of 48% to 89% of cases; long-term disease-free survival has been reported to be 18% to 35% and overall survival from 28% to 43%.^{271,272} Metastatic GIST are virtually resistant to standard chemotherapeutic agents. Therefore, it is not surprising that the use of adjuvant chemotherapy with cytotoxic agents has been disappointing. In a retrospective review of a multicenter experience in the treatment of GIST with chemotherapy, De Pas and associates found no evident survival benefit from the addition of chemotherapy.²⁷³ The addition of radiation therapy has similarly been limited in its effectiveness in the treatment of GIST.²⁶⁸

Identification of c-Kit mutations in GIST has been the focus of extensive recent attention. The Kit protein is a transmembrane protein receptor that is structurally similar to the macrophage colony-stimulating factor receptor. A gain-of-function mutation of exon 11 of the c-Kit gene in GIST tumors was described by Hirota and colleagues, corresponding to the intracellular juxtamembrane region of the c-Kit protein.²⁷⁴ Additional sites of mutation have been identified

within the c-Kit gene in GIST tumors, with the observation that mutated Kit protein products are constitutively activated in the absence of its stem cell factor ligand.^{267,275} Alternatively, the platelet-derived growth factor receptor (PDGFR)- α has been found to be mutated and activating in a significant percentage of GIST that lack activating mutations in c-Kit.²⁷⁶

Experimental results demonstrated that the use of the tyrosine kinase inhibitor imatinib mesylate (Gleevec) targets the BCR-ABL fusion protein found in chronic myeloid leukemia and is available in an oral formulation.²⁷⁷ Additional studies of imatinib demonstrated activity against other protein tyrosine receptors including PDGFR- α and Kit. With this background, Joensuu and associates treated a patient with rapidly progressive, chemotherapy-resistant metastatic GIST with imatinib.²⁷⁸ This protocol resulted in a dramatic response that was sustained for more than 11 months with minimal toxicity. This observation prompted clinical trials using imatinib in the treatment of GIST.^{279,280} Results of these studies demonstrated an effective initial dose range of 400 to 800 mg per day, which has since been approved by the U.S. Food and Drug Administration for the treatment of metastatic and/or unresectable GIST.²⁸¹ It remains to be determined whether it is better to initiate treatment at the lower end of the effective dose range and increase the dose if necessary because of inadequate efficacy, or to start at the high end of the dose range and decrease the dose in case of toxicity. It is clear, however, that some patients who progress on lower doses of imatinib respond to higher doses, whereas other patients who have prohibitive toxicity at higher doses still derive clinical benefit from doses lower than the usual starting range.

Several investigators have noted that reliance on traditional clinical parameters for measurement of response to imatinib therapy may not be ideal in the treatment of GIST. Benjamin et al. found that time to progression following treatment did not correlate with RECIST criteria of change in size.²⁰⁸ Instead, these investigators were able to correlate time to progression with changes in glucose uptake detected by positron emission tomography (PET) scanning. They found PET achieved a sensitivity of 94% and specificity of 100% in identifying response to treatment, and was more predictive of time to progression, than CT assessment of tumor size. Other investigators have also highlighted the usefulness of PET in evaluating response to imatinib therapy.²⁸² Tumors may manifest little if any change in size on CT scans yet show dramatic decreases in activity on PET scans (Figure 58.9). Unfortunately, even tumors that have shown dramatic responses to imatinib eventually progress in most cases, sometimes after several years. Second-line tyrosine kinase inhibitors are in active clinical investigation; if these prove useful, it would be logical to investigate combination therapy with imatinib in future clinical trials.

Although GIST is a rare tumor, it represents an important model for the use of biologically targeted therapy, where an identified molecular alteration is targeted by a specific therapy with clinically relevant results. Another approach currently under investigation is the use of imatinib in the adjuvant and neoadjuvant setting. Whether adjuvant approaches can decrease recurrence, improve survival, and turn unresectable tumors into those that can be completely resected requires prospective testing in clinical trials.

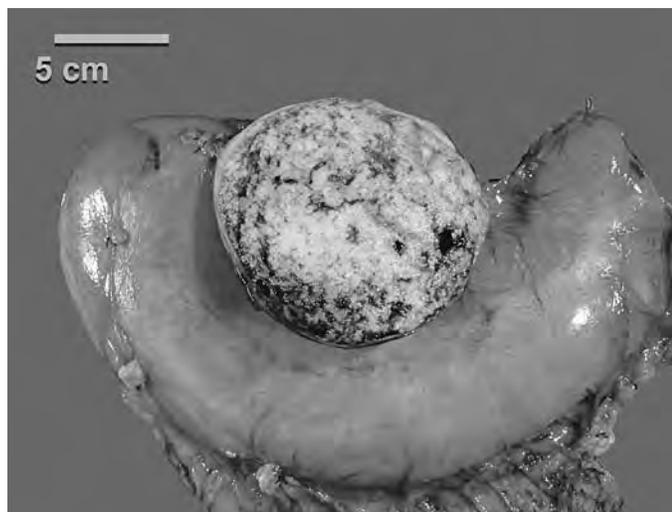

FIGURE 58.8. Bisected gastrointestinal stromal tumor arising from the lesser curvature of the stomach.

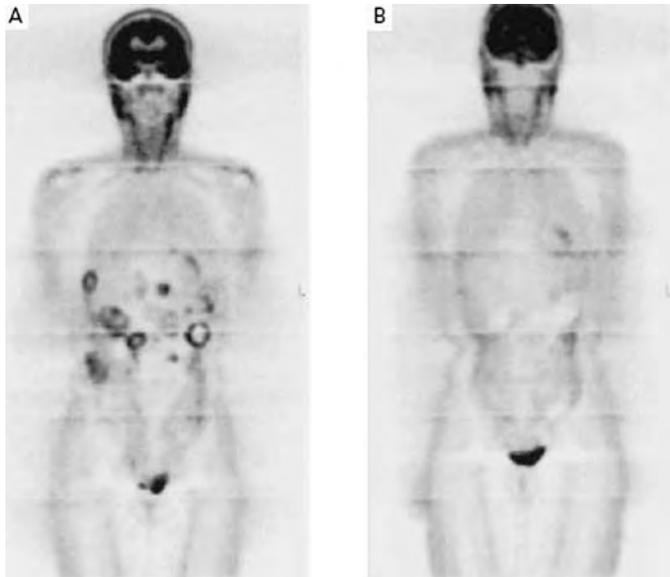

FIGURE 58.9. Positron emission tomography (PET) studies with [^{18}F]fluorodeoxyglucose as the tracer. (A) Before STI571 therapy, multiple metastases are seen in the liver and upper abdomen, with marked retention of [^{18}F]fluorodeoxyglucose in the right renal pelvis and ureter, a finding suggestive of hydronephrosis. (B) After 4 weeks of treatment, no abnormal uptake of tracer is seen in the liver or right kidney.²⁷⁸

Treatment of Localized Soft Tissue Sarcomas of Selected Other Sites

Trunk, Heart, and Great Vessels

Sarcomas arising in the soft tissues of the trunk/body wall have been found to follow a clinical course similar to that observed in the extremities. Sarcomas arising in this location account for approximately 10% to 20% of newly diagnosed sarcomas; they are usually over 5 cm in size and can involve underlying viscera (Figure 58.10). Treatment principles are derived from the experience with extremity sarcomas, with aggressive attempts at wide excision to achieve clear margins and consideration of chemotherapy and radiation for large high-grade tumors. Soft tissue sarcomas arising from chest wall musculature and diaphragm are quite rare. Treatment of these tumors is based on the general principle of wide resection with clear margins. Radiation therapy can be considered for large lesions, particularly when high grade; however, underlying lung tissue may limit the dose that can be delivered.

Sarcomas are the most common primary malignant neoplasm arising in the heart and are usually angiosarcomas.¹⁸⁹ They may arise from the heart or the pericardium and may be asymptomatic. These tumors are usually advanced when identified, and curative resection is difficult. Surgical removal has been the mainstay of therapy.²⁸³ The rarity of these tumors has not allowed the role of adjuvant therapies to be extensively evaluated. Often surgery is aimed at alleviating symptoms rather than cure. Cardiac allotransplantation, alone or with lung transplantation as well, has been performed in anecdotal cases, but seems to be associated with poor results for high-grade tumors.²⁸⁴

The aorta and vena cava are occasionally involved by direct extension of retroperitoneal sarcomas; however,

sarcomas arising de novo from the great vessels are rare. Leiomyosarcomas are the predominant histologic type encountered arising from the vena cava and other named veins. Treatment is again based on complete resection with clear surgical margins.^{285,286} Mingoli and colleagues reported the results of resection of 218 patients compiled from an international registry of inferior vena cava leiomyosarcomas.²⁸⁷ Of 120 patients who underwent radical resection with complete removal of all gross disease and clear microscopic margins, caval wall resection with autologous vein or prosthetic patch repair was performed in 44%, and segmental caval resection was performed in 56%. Of the 67 patients who underwent caval resection, 27 had infrarenal caval ligation and 23 had supracaval ligation. The authors reported 3 post-operative deaths, 21 deep venous thromboses, and 7 major complications. There was a local recurrence rate of 57% (mean follow-up of 32 months). These results support a role for resection to clear margins. We have utilized patch repair following caval wall resection or segmental resection with prosthetic graft placement and avoid ligation of the cava if possible (Figure 58.11). The role of adjuvant therapies in the treatment of tumors in this location remains undefined.

Breast

Primary breast sarcomas comprise less than 5% of all soft tissue sarcomas and can be subdivided into two categories. So-called monophasic or stromal sarcomas are identical to their counterparts arising elsewhere in the body. The most commonly encountered histologic types of these primary breast sarcomas are malignant fibrous histiocytoma, angiosarcoma, and liposarcomas.^{189,288-290} The second category are sarcomas specific to the breast, entitled cystosarcoma phyllodes or, more generically, phyllodes tumors. Because the pathologic and clinical characteristics of phyllodes tumors are quite distinct from other histologic types they are addressed separately.

From retrospective series, primary breast sarcomas have a peak incidence during the fourth and fifth decades and most commonly present as a painless breast mass. These tumors

FIGURE 58.10. Computed tomography of high-grade undifferentiated pleomorphic sarcoma arising from the left abdominal wall musculature.

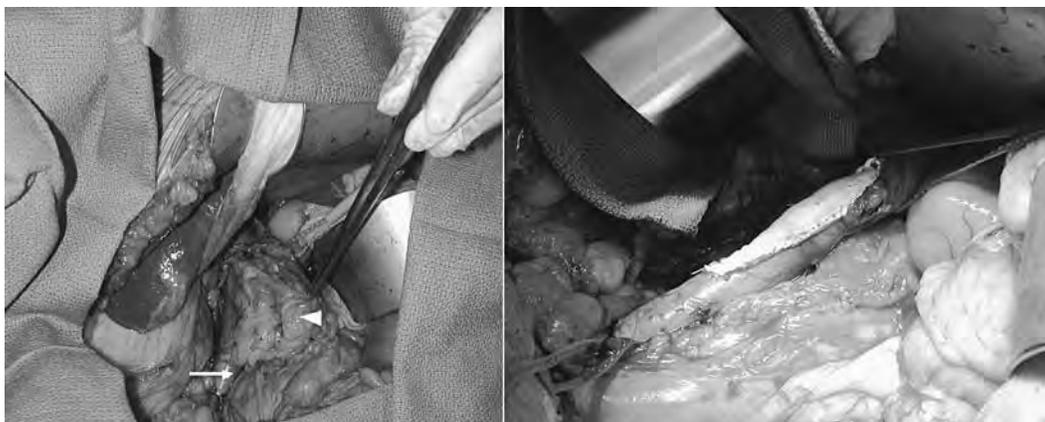

FIGURE 58.11. Left: Leiomyosarcoma (*arrowhead*) arising from the anterior wall of the inferior vena cava (*arrow*). Right: Patch repair of inferior vena cava following resection.

are often mistaken for a fibroadenoma as lymphadenopathy, skin changes, nipple discharge, and other signs typical of breast malignancy are almost always absent. Treatment of primary breast sarcomas is based on experience with extremity and trunk soft tissue sarcomas. Surgical treatment is tailored to breast conservation if the volume of normal breast would be adequate to allow a wide resection of the sarcoma with a 1- to 2-cm circumferential margin. In cases in which breast conservation would not result in a cosmetically acceptable appearance, simple mastectomy is appropriate. Postoperative radiation is often added to decrease local recurrence, particularly if the margin of excision was less than 2 cm (regardless of whether the breast was conserved). Local recurrence, disease-free survival, and overall survival rates following resection are similar to those observed in soft tissue sarcomas arising in other locations. Also, such considerations regarding the addition of adjuvant chemotherapy are the same as discussed in the treatment of extremity sarcomas. As lymph node metastases are exceedingly rare in primary breast sarcomas, axillary dissection is not warranted unless clinically palpable nodes are present.^{189,288,289}

Phyllodes tumors are fibroepithelial or “biphasic” tumors that arise exclusively in breast tissue. They also have a peak incidence during the fourth and fifth decades of life, typically presenting as a painless breast mass. Some patients report a long-standing mass that begins to grow rapidly. Analogous to gastrointestinal stromal tumors, the propensity to metastasize is often difficult to determine histologically. It has been estimated that 25% of cases are “malignant,” but cases deemed to be benign have been associated with the development of distant metastasis. Thus, the evidence would suggest that phyllodes tumors span a spectrum from very low to very high risk of metastasis. Whether any phyllodes tumors can be unequivocally considered to be benign, with no possibility whatsoever of distant metastasis, remains a matter of debate.

Local recurrence of phyllodes tumors is common (16%–22%), so that wide excision with a 1- to 2-cm margin, by mastectomy if necessary, is appropriate therapy.^{189,291,292} Radiation and chemotherapy can be considered for cases deemed at high risk of recurrence or metastasis, but the role of each modality is as yet poorly defined in the treatment of phyllodes tumors.

Treatment of Metastatic Disease

Half of all patients with soft tissue sarcomas ultimately develop metastatic disease. Metastases are present in about 10% of patients at time of initial presentation.^{127,293} The predominant site of first recurrence is in the lung, seen in 52% of patients who developed local or distant disease (70% of patients with extremity primaries). Patients with retroperitoneal sarcomas have a greater tendency for local recurrence and disseminated disease throughout the abdomen. As reported by Potter and colleagues, 80% of recurrences occur within 5 years.²⁹⁴

Approximately 80% of patients with extremity and trunk soft tissue sarcomas who have distant disease have isolated pulmonary metastases.^{2,130} The detection of pulmonary metastatic disease is accomplished by either plain film radiographs or CT scanning of the thorax. CT scans have a greater sensitivity in detecting small (3–10)mm pulmonary nodules than plain film radiographs, which has led many clinicians to use CT rather than plain films when evaluating for pulmonary metastases.¹⁸⁹ On the other hand, this greater sensitivity to small nodules means that many subcentimeter benign nodules are identified on CT scans, especially in older patients. Proving these nodules to be benign can be difficult, and their detection often leads to concern for metastasis for patient and physician alike. PET scans were evaluated by Lucas et al. in comparison with CT scans,²⁹⁵ who reported a sensitivity in detecting pulmonary disease of 87% with a specificity of 100%. Conversely, CT scans had a sensitivity of 100% and a specificity of 96%. PET scanning does poorly at detecting subcentimeter pulmonary nodules and cannot always distinguish malignancy from inflammation or postoperative changes. The available evidence does not support a role for PET in the routine screening for or evaluation of pulmonary metastases, particularly given its limited availability and high cost.

Once detected, pulmonary metastases have associated with median survival rates of 6 to 12 months.^{2,296} Because of the strong predilection for sarcoma to metastasize to the lungs and only to the lungs, resection of even multiple pulmonary metastases (metastasectomies) has been shown in multiple reports to be associated with prolonged relapse-free

survival in a small but significant percentage of patients (probably at least 25%).^{189,293,297-299} Several prognostic features associated with long-term survival in patients undergoing pulmonary metastasectomy have been identified. In an evaluation of soft tissue sarcoma pulmonary metastases, Billingsley and associates observed a more favorable prognosis for those who had complete resection of all metastases, a disease-free interval of more than 12 months or a low-grade primary tumor.²⁹⁸ Adverse findings included histologies of liposarcomas and malignant peripheral nerve sheath tumors as well as age greater than 50. A relationship between outcome and time interval from initial diagnosis to the development of pulmonary metastases has been observed in multiple studies, although this may be largely or entirely a surrogate for histologic grade of the primary tumor.^{189,296-300} Greater numbers of metastatic nodules and rapid tumor doubling times have been associated with diminished survival following resection of soft tissue sarcoma pulmonary metastases.¹⁸⁹ Reported survival rates following complete resection of pulmonary metastases (sometimes with repeated thoracotomies) range from 25% to 39% at 5 years.^{189,293,297,299} From published reports to date, an aggressive approach to resection of pulmonary metastases is warranted.

Resection of soft tissue sarcoma hepatic metastases has also been evaluated. Survival rates following hepatic resection have generally been less than observed in pulmonary resections for metastatic disease. One series of soft tissue sarcoma patients undergoing hepatic resections of metastases reported a 100% recurrence rate.³⁰¹ Despite this, a median survival time of 30 months for resected patients compared with 11 months for unresected patients was found. The inclusion of many patients with what are now recognized to be gastrointestinal stromal tumors in most series describing sarcoma metastatic to the liver makes interpretation of these series more complex.

The role of chemotherapy in the treatment of unresectable metastatic disease has been extensively reviewed.^{190,302} Doxorubicin, ifosfamide, and dacarbazine have all been shown to have significant single-agent activity in the treatment of metastatic soft tissue sarcomas. Although published reports of various combinations of available drugs have suggested them to be superior to single-agent therapy,³⁰³ to date there is little evidence from prospective randomized trials to support that contention. One randomized trial is representative: the addition of ifosfamide to doxorubicin increased response rates at the expense of significantly greater toxicity but did not result in any detectable difference in time to progression or overall survival.³⁰⁴

The influence of drug dose intensity has been studied in numerous retrospective and prospective evaluations. There is considerable evidence to support the contention that the two most active drugs, doxorubicin and ifosfamide, yield better results in terms of response rates and time to progression if given at high doses. The range over which increased dose leads to increased benefit is fairly narrow, however, and not entirely defined. One recent report is sobering: patients randomized to receive doxorubicin plus 6 g/m² ifosfamide actually had slightly superior survival compared to patients randomized to the same dose of doxorubicin plus 12 g/m² ifosfamide.²¹⁸ Reports of even higher doses of chemotherapy along with stem cell rescue have demonstrated the feasibility of this approach; however, its role in the treat-

ment of metastatic soft tissue sarcomas has yet to be determined.³⁰⁵⁻³⁰⁷

There is no consensus whatsoever regarding the ideal second-line chemotherapy regimen for patients with metastatic disease refractory to combination therapy with doxorubicin and ifosfamide. Higher doses of ifosfamide (in the range of 12–14 g/m²) have been associated with objective responses in patients who failed or progressed after chemotherapy with lower doses of ifosfamide, with synovial sarcomas appearing to be particularly responsive to this approach.^{308,309} The toxicity of ifosfamide in this range of doses mandates careful patient selection and excludes many older patients and those with impaired renal function. Recently, the combination of gemcitabine and docetaxel in specific sequence has been associated with high objective response rates, even in patients with prior doxorubicin and ifosfamide chemotherapy. This regimen appears to be particularly effective for patients with leiomyosarcomas,³¹⁰ but responses in other histologies have been seen as well.³¹¹ Low doses of chemotherapy administered more chronically have received some evaluation in sarcoma subtypes. Low-dose paclitaxel has been used for angiosarcomas³¹² and low-dose methotrexate and vinblastine for desmoid tumors.^{313,314} Although substantial data attest to differential sensitivities of various sarcoma subtypes to particular chemotherapy regimens, prospective evaluations of specific regimens for individual subtypes have been limited, and it is likely that hitherto unrecognized patterns of susceptibility and resistance exist. Clinical trials remain a highly appropriate option for patients with metastatic soft tissue sarcomas of all histologic subtypes. Novel approaches to clinical trials design are also worthy of exploration, given the multiple potential interactions of drug type, dose, and schedule with histologic subtype and prior treatment status.³¹⁵

Specialty Centers

Several investigators have highlighted the importance of early referral to centers with specialists with experience in treating soft tissue sarcomas.^{151,152,316,317} Soft tissue masses are common, with benign soft tissue masses exceeding malignant tumors 100 to 200 fold.³¹⁶ As such, physicians frequently treat benign tumor without significant consequence. Unfortunately, malignant soft tissue tumors are more often than not approached with the same lack of concern and are not taken as seriously as masses arising in other locations. In a regional audit of the management of soft tissue sarcomas in England, Clasby and associates found only 21% of patients were investigated adequately and only 60% were treated with wide excision or surgery with radiation.³¹⁸ They reported that in 331 patients who had undergone resections, only 104 had a preoperative biopsy and 26% of patients had not had any form of radiologic investigation. They found junior surgeons initially treated two-thirds of soft tissue sarcoma patients, whereas senior surgeons in 80% of cases performed second operations. In a similar audit conducted in France, Ray-Coquard et al. found only 42% of patients had a preoperative biopsy.³¹⁹ They identified deficiencies in the initial evaluation in 48% of patients where MRI, chest radiographs, and clinical record of tumor size were frequently omitted. No more than 7% of patients in this study had biopsies planned and performed after formal multidisciplinary review. These studies illustrate a number of difficulties associated with the

evaluation and referral of soft tissue tumors. As Clasby and colleagues observed, only 17% of patients were treated with an initial wide margin, with 67% left with an unacceptable margin.³¹⁸ Similarly, Ray-Coquard et al. found 74% with inadequate initial resections. As discussed previously, initial failure to achieve clear surgical margins will result in higher local recurrence rates, with the associated poor prognostic implications associated with local recurrences.³¹⁹

Referral to a specialty center with experience in soft tissue sarcomas should be initiated for subfascial masses of any size, tumors greater than 3 to 5 cm, masses that are noted to be changing in size, or any physical findings worrisome for malignancy. These findings may include proximity to neurovascular structures, painful masses, and tumors that are firm or fixed to underlying structures. When evaluating any soft tissue mass one should always consider these factors to maintain an index of suspicion for such lesions. With better education and early referral, we can expect improved oncologic outcomes with less morbidity associated with surgical treatment.

Surveillance Guidelines

When deciding the appropriate surveillance plan for an individual following treatment for soft tissue sarcoma, several considerations arise. The impact of early detection on therapy and patient outcome varies by anatomic location of the recurrent disease. In cases of local recurrence of extremity soft tissue sarcomas, resection can result in prolonged survival, improved quality of life, and cure in a significant number of patients. The majority (90%) of extremity local recurrences occur during the first 5 years after treatment, of which up to two-thirds are detected during the first 2 years.³⁰⁰ In a retrospective review of surveillance for follow-up of patients with high-grade extremity sarcomas, Whooley and associates evaluated the efficacy and cost-effectiveness of chest radiographs, CT scans of chest, imaging of the affected extremity, and blood tests.³²⁰ Follow-up evaluations were performed every 3 months during the first 2 years, every 4 to 6 months during the third posttreatment year, every 6 months for years 4 to 5, and annually thereafter. Their review found that physical examination was the most common method of detection of local recurrence (97%), with only one recurrence detected solely by surveillance MR (3%). Pulmonary metastasis was

identified in 40% of patients, but only 37% of these patients with pulmonary had symptoms as a basis for detection. Asymptomatic patients had their pulmonary metastasis initially detected with chest radiographs in 83% of cases. In the remainder of patients, pulmonary metastases were detected solely with CT scanning. Metastasectomy was performed on 24 of 36 asymptomatic patients with pulmonary recurrence. Blood tests did not contribute to the detection of any local or distant recurrence.

From their analysis of cost to effectiveness, Whooley et al. concluded that chest radiographs and physical examination were the most useful and cost-effective methods for the detection of local or distant metastasis.³²⁰ They recommended a surveillance program intensified during the early portion of the posttreatment period. They also recommended cross-sectional imaging (CT or MR) every 6 months in cases of deep lesions or in radiated regions where physical examination is difficult.

Similar studies delineating the most useful and cost-effective methods for the detection of local recurrence and distant metastases for other disease sites have not been performed. For soft tissue sarcomas in sites such as head, neck, and trunk, where patterns of failure are similar to those for extremity primaries, it would appear reasonable to follow a similar approach. For intraabdominal and retroperitoneal sarcomas, failure is primarily within the abdomen as in the liver; an additional 20% to 30% of recurrences will occur in the lungs. With this in mind, it would seem appropriate to have the patient undergo physical examination, CT scanning of the abdomen, and chest radiographs as a surveillance strategy. Early detection of local recurrence, metastases to the liver, and pulmonary metastases occasionally results in surgical intervention; it is assumed but not proven that such interventions may prolong survival and improve quality of life.^{129,298,299,301} Time to recurrence for intraabdominal and retroperitoneal sarcomas is also highest in the early posttreatment period, and a similar schedule of evaluation used in extremity sarcomas would seem reasonable. These sarcoma surveillance strategies remain to be proven in prospective trials, but are widely used and almost universally recommended, with some controversy remaining as to the incremental value of chest CT scans over radiographs alone. The current National Comprehensive Cancer Network (NCCN) guidelines for the surveillance of soft tissue sarcomas arising in the extremity and retroperitoneum are summarized in Table 58.11.

TABLE 58.11. Surveillance guidelines for extremity soft tissue sarcomas.

<i>Stage I</i>	<i>Stage II, III</i>
-H&P every 3–6 mo for 2–3 y, then annually	-H&P every 3–4 mo for 3 y, then every 6 mo for next 2 y, then annually
-Consider imaging surgical site with scan annually based on estimated risk of locoregional recurrence	-Imaging of primary site (MRI, CT, consider US)
-Consider baseline imaging after primary therapy	-Chest imaging (plain radiograph or chest CT) every 3–6 mo for 5 y, then annually
-Consider chest X-ray every 6–12 mo	
<i>Surveillance Guidelines for Retroperitoneal Soft Tissue Sarcomas</i>	
<i>Low grade</i>	<i>High grade</i>
Physical exam with imaging (chest/abdomen/pelvis CT) every 3–6 mo for 2–3 y, then annually	Physical exam with imaging (chest/abdomen/pelvis CT) every 3–4 mo for 3 y, then every 6 mo for next 2 y, then annually

MRI, magnetic resonance imaging; CT, computed tomography; mo, months; y, years.

The use of PET scanning in the evaluation and surveillance of GIST is currently under investigation. At present, guidelines do not incorporate PET scans for the routine surveillance of GIST; however, this may change due to the advent of effective therapy (imatinib). To date, there are no compelling data to suggest that PET scanning has a routine role in the initial management or posttreatment surveillance of soft tissue sarcomas other than GIST.

Conclusion

The evaluation and treatment of soft tissue sarcomas remains challenging. Advances in pathology and molecular biology have greatly improved our understanding of this complex and heterogeneous group of tumors. Since the 1980s, aggressive treatment approaches by experienced multidisciplinary teams have improved the outlook for these patients. The widespread acceptance of limb-sparing procedures, the identification of active chemotherapy regimens, and improvements in local disease control from the use of radiation therapy are all examples of the strides that have been made in the treatment of patients with soft tissue sarcoma. Despite these advances, areas of concern remain. Most distressing is the fact that approximately half of patients diagnosed with soft tissue sarcomas will succumb to their disease. Local recurrence remains a difficult problem, with increased associated morbidity and psychologic stress for affected patients. Through improved education, we hope that early biopsy and referral of soft tissue sarcomas will become the norm, and that patients will derive the benefits of multidisciplinary evaluation and treatment of their disease.

Cutaneous Melanoma

Mark R. Albertini, B. Jack Longley,
Paul M. Harari, and Douglas Reintgen

Epidemiology

The incidence of melanoma has increased dramatically during the past several decades among Caucasian populations.¹ Mortality rates continue to rise overall, but in some populations, such as females, the mortality rate has plateaued or even fallen. The reasons for these trends are not altogether obvious, but may involve changes in attitudes and behaviors with regard to sun exposure or an increased public awareness to the early signs of melanoma diagnosis.

Incidence rates vary from a low of 0.2 (females and males) in China to 34.9 per 100,000 among females in New Zealand and 40.5 per 100,000 among males in Australia.¹ There were 23.1 new cases per 100,000 population in the United States (incidence rate adjusted to the 2000 United States population). Approximately 59,580 new cases of malignant melanoma and 7,770 deaths due to melanoma are predicted for the United States in 2005.² Over the past 30 years, the incidence rate has tripled, particularly in the Caucasian male population. Recent data would suggest that the largest proportion contributing to the increased incidence are "thin" melanomas. People born before 1950 show an increased risk of developing melanoma whereas those whose birthdays are after 1950 show stable or declining rates.¹

Melanoma is a tumor that occurs in the relatively young, with the mean age of diagnosis being 50 years of age, 10 to 15 years before the mean age of diagnosis of some of the more-common cancers such as breast, lung, and colon. In the United States, there has been an increase in the diagnosis of thin melanomas in the young and an increase in the diagnosis of thick lesions in men over the age of 65.¹

Dermatopathology of Melanoma

The classification of cutaneous melanomas depends on an interaction between the clinical and pathologic features. The commonly recognized melanomas include (1) lentigo maligna melanoma, (2) superficial spreading melanoma, (3) nodular melanoma, and (4) acral lentiginous melanoma. We begin with a discussion of precursors of melanoma followed by a description of the histopathologic features of the various types of melanoma.

Precursors of Malignant Melanoma

It is widely accepted that many if not most melanomas of the superficial spreading type arise in preexisting junctional or

compound melanocytic nevi, and benign melanocytic nevi are therefore a risk factor for malignant melanoma.³ Determining the exact percentage of melanomas arising in nevi is problematic because many melanomas are probably not detected until they have overrun small precursor nevi and because the terminology for early melanoma (in situ) arising in nevi is not standardized (please see following discussion of "dysplastic" nevi). However, most studies that are based on histologic features alone report finding remnants of a preexisting nevus in about 22% of melanomas of the superficial spreading type.^{4,5} Studies that include clinical as well as histopathologic criteria report precursors in as many as 39.5% of melanomas.⁶

Several subgroups of precursor nevi have been identified including preexisting congenital nevi, sporadic acquired nevi, and nevi associated with the familial melanoma syndrome. It is commonly accepted that melanomas may arise in large congenital nevi, but a separate study that specifically addressed the size of congenital precursor lesions established that a significant percentage of melanomas may also arise in small congenital nevi less than 1.5 cm in diameter.⁴ A representative histologic study found that 59% of the precursor nevi showed features of acquired nevi, 39% showed features of congenital nevi, and the remaining few nevi were not further categorized.⁵ Of all these nevi, 54% also showed histologic features of so-called dysplastic nevi, a designation that is controversial.

"Dysplastic nevi" were originally described as a cutaneous marker of familial melanoma.⁷ The term "dysplastic nevus" has since been used to describe syndromes of multiple atypical nevi occurring in association with either familial melanomas or sporadic melanomas, and the term has also been used to describe individual atypical nevi occurring in patients without a personal or familial history of melanoma. Several studies have shown a lack of inter-observer reproducibility in the histologic diagnosis of dysplastic nevi, and it is now widely accepted that there is a continuum from ordinary benign (banal) nevi through nevi with moderate and severe dysplasia, to nevi with developing melanoma in situ.⁸ Furthermore, the NIH consensus conference recommended excising nevi with histologic features of a dysplastic nevus and moderate to severe cytologic atypia with the 0.5 cm margins, the same margins that they recommended for treatment of melanoma in situ, because developing melanoma in situ may show overlapping histologic characteristics with these nevi.

Types of Malignant Melanoma

LENTIGO MALIGNA AND LENTIGO MALIGNA MELANOMA

Lentigo maligna is by definition the in situ phase of lentigo maligna melanoma (LMM). Lentigo maligna occurs in chronically sun-exposed skin, usually of the head and neck but occasionally in other sun-exposed areas. Lentigo maligna typically evolves over many years as an unevenly pigmented macular lesion that expands peripherally and that eventually may measure several centimeters in diameter. The histopathologic features in lentigo maligna may be subtle, and partial biopsies may not be diagnostic. Early lentigo maligna may show only epidermal hyperpigmentation and a subtle increase in the number of melanocytes, features that are not easily distinguishable from changes seen in chronically sun-damaged skin. Helpful histologic features include extension of atypical melanocytes down follicular epithelium and spread of melanocytes above the dermal epidermal junction, so-called pagetoid spread of melanocytes.⁹⁻¹¹

When the dermis is invaded, the lesion is called lentigo maligna melanoma. Dermal invasion is a focal process and may be difficult to recognize. Invasive cells of lentigo maligna melanoma usually have abundant cytoplasm and are epithelioid or spindle shaped in character but may rarely appear as small round cells. Occasionally, lentigo maligna melanoma invades as cells that have spindle-shaped nuclei and relatively little cytoplasm, and induces a fibrotic or “desmoplastic” response in the underlying stroma. This variant, called *desmoplastic malignant melanoma*, may also show neurotropism and may be very difficult to recognize, requiring a high degree of suspicion and the use of immunoperoxidase studies to establish the diagnosis.¹² This morphologic variant of lentigo malignant melanoma is important because it may be difficult to recognize, but it is not associated with a difference in prognosis, compared to other primary melanomas, when adjusted for tumor thickness.¹³

SUPERFICIAL SPREADING MELANOMA

Superficial spreading melanomas (SSM) often arise in melanocytic nevi and must be distinguished histologically from normal or atypical nevi. Architecturally, normal nevi are usually symmetric and show relatively uniform nests of cytologically typical melanocytes occurring at the tips and sides of rete ridges. Criteria for a diagnosis for superficial spreading melanoma include both architectural and cytologic features. Architectural features favoring a diagnosis of melanoma include asymmetric growth, a lack of circumscription, and large size. A major criterion for the diagnosis of melanoma is the spread of melanocytes throughout the epidermis as individual cells or nests of cells. Poorly circumscribed lesions also show individual cells at their edges, which are irregularly distributed at and above the dermal epidermal junction.^{10,11}

With early invasion, atypical melanocytes extend from the epidermis into the most superficial (papillary) dermis as individual cells, where they start to form nests. Melanoma cells are typically round or polygonal in shape. The dermal component of benign melanocytic nevi is typically composed of melanocytes arranged in nests that are larger in the upper dermis and that gradually decrease in size in the deeper por-

tions of the dermis. Melanocytes of benign nevi may also be arranged in single file, splayed between dermal collagen bundles, and arranged around neurovascular or adnexal structures. In contrast, invasive melanoma cells usually do not decrease in size in the deeper portions of the dermis, a characteristic that distinguishes them from the cells of benign melanocytic nevi. Invasive melanoma more typically grows as irregularly sized and shaped nests of cytologically atypical cells, as irregularly distributed single cells, or as sheets of atypical cells.

ACRAL LENTIGINOUS MELANOMA

The term *acral lentiginous melanoma* (ALM) refers mainly to melanomas occurring in the hairless skin of the palms and soles but also includes those arising in the nail unit and the surrounding periungual areas.^{10,11} They are called lentiginous because their early pattern of growth consists of a proliferation of individual cells along the dermal-epidermal junction, a pattern that resembles melanocytic growth in benign lentiginous. Features that distinguish ALM from lentiginous include the presence of cytologically atypical cells that tend to confluence and the formation of irregularly distributed junctional nests without a benign dermal component. Cytologically, cells in early ALM may be relatively bland and it may be very difficult to establish the diagnosis, particularly if the specimen is a partial biopsy from the edge of a lesion that may show only an increase in pigment and a subtle increase in the number of melanocytes. Invasive ALM usually grows as epithelioid or spindle-shaped cells, or as smaller melanoma cells with less cytoplasm. As with LMM, ALM may show a desmoplastic growth pattern and may preferentially invade and grow along nerves.

NODULAR MELANOMA

The histologic features of a nodular melanoma (NM) are those of expansile dermal growth with relatively little involvement of the epidermis.^{10,11} The epidermal component is often described as spreading no more than three rete ridges beyond the dermal component of the tumor, so whereas the overall architecture of SSM is horizontally oriented as the tumor cells spread within the epidermis and invade the papillary dermis, the orientation of nodular melanoma is vertical and NM typically appear deeper than they do wide. The dermal nests and masses of nodular melanoma cells should be larger than any of the nests present within the epidermis. NM often grow in sheets and may show marked focal differences in pigmentation and cell morphology in different parts of the tumor. Cytologically, the cells of NM are often epithelioid or spindle shaped, but may also be small with a high nuclear to cytoplasmic ratio.

Histologic Features of Prognosis in Cutaneous Melanomas

The only histologic features of primary melanomas that have been consistently shown to be correlated with prognosis in multivariate (Cox regression and Tree structured survival) analyses have been tumor thickness, micrometastases, ulceration, mitotic activity, and incomplete removal of the original lesion with the presence of melanoma on the margins of

the primary resection specimen.¹³⁻¹⁷ These histologic features are of prognostic significance independent of the age of the patient, the type of the melanoma, or the anatomic location, and it is therefore recommended that these features be specifically mentioned in pathology reports.¹⁸

TUMOR THICKNESS AND LEVEL

The concept that the depth of invasion of a melanoma into the dermis and subcutaneous fat could be related to prognosis was first suggested by Allen and Spitz,¹⁹ and was modified by Clark et al.,²⁰ who proposed descriptive levels including an in situ level, and levels of invasion involving the papillary dermis, the reticular dermis, and the subcutaneous fat. These studies clearly established the concept that the depth of the tumor was more significant prognostically than its diameter, but these methods resulted in a stepwise classification and were not highly reproducible. In 1970, Alexander Breslow proposed determining the thickness of primary cutaneous melanomas by measuring from the top of the granular layer of the epidermis to the greatest depth of the invasion into the dermis, using an eyepiece micrometer.¹⁵ The resultant continuous variable, usually reported to the hundredth of a millimeter, is variously referred to as the Breslow depth or Breslow thickness, and has been found to be a reproducible and statistically significant prognostic variable in the evaluation of primary cutaneous melanoma.¹⁵

VASCULAR INVASION AND MICROMETASTASES

The presence of invasion of tumor cells within blood or lymphatic vessels has been shown to be associated with a poor prognosis^{21,22} and is generally accepted as a poor prognostic feature. Similarly, micrometastases, defined as discrete masses of tumor cells measuring greater than 0.05 mm in diameter and located in the reticular dermis or subcutaneous fat, separated from the main tumor mass by normal tissue, has been identified as a histologic prognostic feature, and is also generally accepted as an indicator of a poor prognosis.

ULCERATION AND OTHER TISSUE REACTION PATTERNS

Spontaneous ulceration of the epidermis has been identified as an independent indicator of poor prognosis in a number of studies.^{14,16,17} A second tissue reaction pattern that has been described is the presence or absence of tumor-infiltrating lymphocytes (TILs), which are lymphocytes that infiltrate between the individual melanocytes making up nests and clusters of melanoma cells invading the dermis.²³ Histologic identification of TILs requires interpretation, and the usefulness of this feature has not been as widely validated as have tumor thickness, ulceration, mitoses and margins. A third commonly studied variable is the presence of regression. The histologic feature of partial regression of a primary melanoma are usually observed in the papillary dermis, where there is fibrosis characterized by delicate collagen bundles in the papillary dermis, usually associated with melanophages and lymphocytes, and with melanoma present in the overlying epidermis and/or adjacent papillary dermis. There is also frequently flattening of the overlying epidermis. However, the histologic diagnosis of regression in thin melanomas requires

interpretation, and various proposals have been made for the prognostic significance of certain patterns of regression or for stratifying regression based on the percentage of the melanoma that appears to be affected. However, regression of a primary melanoma does not appear to be a robust indicator of clinical outcome.²⁴

MITOSES AND PROLIFERATIVE INDICES

The presence of mitosis in the invasive component of a melanoma, usually reported as the mitotic rate per millimeter squared (mm²) or the number of mitoses per 10 high-power fields, has consistently shown to be an independent variable for predicting prognosis.¹⁶ Mitoses are obviously an expression of the proliferative rate of the tumor, and the proliferative capacity has also been estimated by immunohistochemical staining for Ki-67, also known as proliferating nuclear antigen (PNAC).^{25,26} Conversely, the level of cyclin A, a cell-cycle regulator, has been reported to be positively associated with disease-free survival.²⁵

Melanoma Genetics

Familial Melanoma Syndromes

Two general types of genetic abnormalities are observed in families whose members are at increased risk for melanoma. In one type of abnormality, seen in the multiple primary melanoma syndrome, family members carry an abnormal CDKN2A tumor suppressor gene. This gene, which is located on 9p21, encodes the cell-cycle progression regulator p16, which is part of the cyclin D1/CDK 4/p16/pRb signaling pathway. This cyclin signaling pathway controls proliferation in many cell types,²⁷⁻³⁰ and loss of function of genes in this pathway affects individual cells, placing them at increased risk for transformation. In contrast, the mechanism of the second type of familial melanoma susceptibility functions on the level of the whole organism by affecting the ability of pigmented keratinocytes to protect epidermal melanocytes from transformation by ultraviolet irradiation. In this second type of susceptibility, variation in the melanocortin I receptor (MCI R) has been identified as the probable basis for high-risk phenotypes such as pale (type 1) skin, the lack of ability to tan in response to ultraviolet (UV) exposure, and red hair.³¹ Thus, these mutations work at the level of the entire organism by decreasing the natural protection afforded by normal epidermal melanin and increasing the risk of damage to melanocytes when the individual is exposed to ultraviolet light.

Genetic Abnormalities in Sporadic Melanoma

In general, sporadic human melanomas show genetic instability, characterized by multiple chromosomal gains and losses, when examined by comparative genomic hybridization,³²⁻³⁵ but no specific individual gene changes have been associated with the development of sporadic melanomas, other than those directly affecting the cyclin pathway. In sporadic melanomas, loss of the tumor suppressor genes INK 4a/ARF, which are also components of the cyclin pathway, is

frequently found.³⁶ Overexpression of HDM2 is found in 56% of invasive primary and in metastatic melanomas, 27% of melanomas in situ, and in only 6% of "dysplastic nevi," a finding that suggests that this gene may play a role in progression of individual melanomas.³⁷ Although in vivo animal models of melanoma have been developed by overexpressing HRAS, mutations and increases in copy number of this gene have been found in humans only in Spitz nevi and not in melanomas.

Risk Factors and Prevention

Risk Factors

The identification of risk factors and high-risk populations for melanoma provides opportunities for both primary prevention and early diagnosis. A greatly elevated melanoma risk is present for a changing nevus as well as for dysplastic nevi in the setting of familial melanoma.^{38,39} Individuals with a familial melanoma syndrome, as discussed in the previous section on melanoma genetics, are high-risk individuals. An individual with a personal history of melanoma has a lifetime risk of at least 3% of having another primary melanoma.^{39,40} Individuals with precursor lesions such as atypical or dysplastic nevi, giant congenital nevi, or numerous common nevi have an increased melanoma risk.^{38,39} An elevated risk is also present for patients receiving immunosuppression.⁴¹

There are numerous studies that suggest the importance of ultraviolet radiation (UVR) on the development of melanoma.^{39,42} Geographic location near the equator, especially for individuals with a fair complexion, is associated with an increased risk of melanoma. The phenotype of the typical melanoma patient (fair complexion, tendency to sunburn rather than tan, blond or red hair color, blue or green eyes) is well described.³⁹ Blistering sunburns, especially in childhood and adolescence, is an identified risk factor. Outdoor recreational habits that include intermittent high ultraviolet radiation (UVR) exposure are associated with an increased melanoma risk. Individuals with the genetic disorder xeroderma pigmentosum, a condition with defective cellular DNA repair mechanisms following UVR, have a significantly increased risk for melanoma compared with age-matched controls.⁴³

Prevention

Strategies to prevent melanoma have primarily emphasized primary prevention strategies that target high-risk individuals.^{44,45} Because UVR is considered an important modifiable risk factor, efforts have focused on avoidance of excessive sun exposure. The wearing of protective clothing, avoiding blistering sunburns, minimizing peak hours of sun exposure, avoiding tanning parlors, and use of sunscreen with a sun protection factor (SPF) of 15 or higher, are all examples of this sun protective behavior. The topic of sunscreens and melanoma risk remains controversial.^{46,47} Several factors confound interpretation of studies evaluating use of sunscreens and melanoma risk. Individuals with a fair complexion and at increased risk for problems with UVR may be more likely to use sunscreens. Sunscreen use may be higher in individu-

als with a prior history of sunburns. In addition, individuals using sunscreens may allow themselves to have increased UVR. A meta-analysis of 18 case-controlled studies recently addressed this topic, and no association was seen between melanoma and sunscreen use.⁴⁸ Direct proof that sunscreens reduce the risk for melanoma is lacking. However, significant indirect evidence supports the recommendations by the American Academy of Dermatology that includes regular use of a broad-spectrum high-SPF sunscreen along with protective clothing and avoiding midday sun as measures to reduce melanoma risk. A prospective randomized study to determine the efficacy of sunscreens would be informative, but this study is unlikely to be performed.

Strategies aimed at chemoprevention of melanoma in individuals with high-risk lesions are also being developed.⁴⁹ The possible molecular mechanisms for UV melanogenesis, as well as preliminary data from clinical and preclinical studies, were recently reviewed.⁴⁹ Molecular and histologic markers are being identified as surrogate endpoints for melanoma chemoprevention studies. Agents currently receiving clinical testing include retinoids, lovastatin, nonsteroidal antiinflammatory agents, and vitamin E. Many other agents including green tea, perilyl alcohol, COX-2 inhibitors, selenium, and others are receiving preclinical testing. The results of these studies are eagerly awaited, and additional clinical testing is anticipated for melanoma chemoprevention of high-risk precancerous lesions.

Melanoma and Pregnancy or Exogenous Hormone Administration

Melanoma and Pregnancy

A number of clinical observations suggest that pregnancy might have an effect on melanocytes.⁵⁰⁻⁵² Increased pigmentation is often associated with pregnancy. An increase in levels of melanocytic-stimulating hormone has also been measured in some pregnant women, and receptors that bind the female hormone estrogen can be found on some melanomas. These observations have raised the possibility that the hormonal and other physiologic changes associated with pregnancy may influence the development and course of melanoma. Thus, several investigators utilized available prognostic factors to study women diagnosed with melanoma during their pregnancy as well as evaluate the effect pregnancy might have on women who have previously been diagnosed with melanoma. When patients who are pregnant are compared with patients who are not pregnant and the known prognostic factors are comparable, the outcome of the patients are very similar.⁵⁰⁻⁵² In addition, the majority of available evidence indicates that women who became pregnant after being previously treated for melanoma do not have a worse outcome or an earlier reactivation of previously diagnosed melanoma.⁵²

Melanoma and Exogenous Hormone Administration

The estrogen receptor has been identified in approximately one of five melanomas, which has led some to speculate that

the presence of estrogens might influence the course of the disease.⁵¹ However, current studies have not demonstrated any convincing association, either favorable or unfavorable, between the use of oral contraceptives before the diagnosis of melanoma and survival.⁵¹ There are no large, well-conducted studies that have addressed the issue of birth control pills or hormone replacement therapy following the diagnosis of melanoma. Therefore, recommendations are usually made on the basis of clinical need and with the understanding that no evidence currently requires that oral contraceptives or hormone replacement therapy be withheld from these patients.

Classification and Staging: The 2002 AJCC Staging System

The American Joint Committee on Cancer (AJCC) melanoma task force first published the most recent revisions to the melanoma staging system and companion validation prognostic factor analyses in 2001.^{53,54} This updated melanoma staging system represents a significant change from the previous system (Table 59.1). These changes are based on a better understanding of the melanoma-associated prognostic factors, derived from an extensive body of literature as well as from the largest melanoma prognostic factor analysis ever conducted, involving complete raw data from 17,600 patients.⁵⁴

The most important criteria for T classification are tumor thickness followed by tumor ulceration (Table 59.2). Analyses of large prospective databases confirmed the importance of tumor thickness as a prognostic factor and found that Clark

level of invasion was significant only for melanoma lesions 1 mm thick or less.⁵⁴

In the revised melanoma staging system, four criteria were established as significant prognostic factors for survival in patients with regional metastases: (1) the number of lymph nodes harboring metastatic disease, (2) microscopic versus macroscopic tumor burden in the lymph nodes, (3) the presence of satellite or in-transit metastases, and (4) the presence of ulceration in the primary lesion. These criteria require pathologic confirmation of nodal or regional metastatic disease (see Table 59.2).

Within the M classification there is only one group, M1, because no breakpoints in this classification stratify patients into groups with survival differences sufficient to warrant further subgroupings. Within the M1 group, however, there are three subcategories, “a,” “b,” and “c,” reflecting survival differences that have been reported in other studies or were apparent in 1-year analyses, although not on longer-term analyses, in the AJCC prognostic factors study (see Table 59.2). M1a includes distant skin, subcutaneous, or lymph node metastases; these manifestations of distant disease have been associated with a better prognosis than distant metastases in other anatomic locations.⁵⁴ Lung metastases are included in a separate category, M1b, because of the survival advantage at 1 year in the AJCC analysis for patients with lung metastases compared to patients with other visceral metastases (57% versus 41%, *P* less than 0.0001). Finally, M1c includes all other visceral metastases and cases with any distant metastases and an elevated serum lactate dehydrogenase level. Serum lactate dehydrogenase level is included in the M1c category because it has been identified as one of the

TABLE 59.1. Differences between the previous (1997) version and the present (2002) version of the melanoma staging system.

Factor	Old system	New system	Comments
Thickness	Secondary prognosis factor; thresholds of 0.75, 1.50, 4.0mm	Primary determinant of T staging; thresholds of 1.0, 2.0, 4.0mm	Correlation of metastatic risk is a continuous variable
Level of invasion	Primary determinant of T staging	Used only for defining T1 melanomas	Correlation only significant for thin lesions; variability in interpretation
Ulceration	Not included	Included as a second determinant of T and N staging	Signifies a locally advanced lesion; dominant prognostic factor for grouping stages I, II, and III
Satellite metastases	In T category	In N category	Merged with in-transit lesions
Thick melanomas (>4.0mm)	Stage III	Stage IIC	Stage III defined as regional metastases
Dimensions of nodal metastases	Dominant determinant of N staging	Not used	No evidence of significant prognostic correlation
Number of nodal metastases	Not included	Primary determinant of N staging	Thresholds of 1 vs. 2–3 vs. ≥4 nodes
Metastatic tumor burden	Not included	Included as a second determinant of N staging	Clinically occult (“microscopic”) vs. clinically apparent (“macroscopic”) nodal volume
Lung metastases	Merged with all other visceral metastases	Separate category as M1b	Has a somewhat better prognosis than other visceral metastases
Elevated serum lactate dehydrogenase (LDH)	Not included	Included as a second determinant of M staging	
Clinical vs. pathologic staging	Did not account for sentinel node technology	Sentinel node results incorporated into definition of pathologic staging	Large variability in outcome between clinical and pathologic staging; pathologic staging encouraged before entry into clinical trials

most important predictors of poor prognosis in patients with metastatic disease.⁵⁴

The clinical and pathologic stage groupings for the current staging system are shown in Table 59.3. Stage I includes thin primary lesions with low associated melanoma-specific mortality. The 10-year survival rates for patients with stage IA and IB disease are 88% and 81%, respectively.⁵³ Stage II includes lesions associated with an intermediate and somewhat higher risk of metastatic disease and melanoma-specific

mortality. The 10-year survival rates for patients with stage IIA, IIB, and IIC disease are 64%, 52%, and 32%, respectively.⁵³ Because of the significant heterogeneity of prognoses in patients with stage III disease, three substages were defined: IIIA, IIIB, and IIIC. The 5-year survival rates for patients with stage IIIA, IIIB, and IIIC disease are 67%, 53%, and 26%, respectively.⁵³ For patients with stage IV disease, the 1-year survival rates in the M1a, M1b, and M1c groups are 59%, 57%, and 41%, respectively.⁵³

TABLE 59.2. Definition of TNM in the 2002 American Joint Committee on Cancer staging system for cutaneous melanoma.

<i>Primary tumor (T)</i>	
TX	Primary tumor cannot be assessed (e.g., shave biopsy or regressed melanoma)
T0	No evidence of primary tumor
Tis	Melanoma in situ
T1	Melanoma ≤1.0mm in thickness with or without ulceration
T1a	Melanoma ≤1.0mm in thickness and level II or III, no ulceration
T1b	Melanoma ≤1.0mm in thickness and level IV or V or with ulceration
T2	Melanoma 1.01–2mm in thickness with or without ulceration
T2a	Melanoma 1.01–2.0mm in thickness, no ulceration
T2b	Melanoma 1.01–2.0mm in thickness, with ulceration
T3	Melanoma 2.01–4mm in thickness with or without ulceration
T3a	Melanoma 2.01–4.0mm in thickness, no ulceration
T3b	Melanoma 2.01–4.0mm in thickness, with ulceration
T4	Melanoma >4.0mm in thickness with or without ulceration
T4a	Melanoma >4.0mm in thickness, no ulceration
T4b	Melanoma >4.0mm in thickness, with ulceration
<i>Regional lymph nodes (N)</i>	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in one lymph node
N1a	Clinically occult (microscopic) metastasis
N1b	Clinically apparent (macroscopic) metastasis
N2	Metastasis in two to three regional nodes or intralymphatic regional metastasis without nodal metastases
N2a	Clinically occult (microscopic) metastasis
N2b	Clinically apparent (macroscopic) metastasis
N2c	Satellite or in-transit metastasis <i>without</i> nodal metastasis
N3	Metastasis in four or more regional nodes, or matted metastatic nodes, or in-transit metastasis or satellite(s) <i>with</i> metastasis in regional node(s)
<i>Distant metastasis (M)</i>	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
M1a	Metastasis to skin, subcutaneous tissues, or distant lymph nodes
M1b	Metastasis to lung
M1c	Metastasis to all other visceral sites or distant metastasis at any site associated with an elevated serum lactic dehydrogenase (LDH)

^aClinical staging includes microstaging of the primary melanoma and clinical/radiological evaluation for metastases. By convention, it should be used after complete excision of the primary melanoma with clinical assessment for regional and distant metastases.

^bPathologic staging includes microstaging of the primary melanoma and pathologic information about the regional lymph nodes after partial or complete lymphadenectomy. Pathologic stage 0 or stage IA patients are the exception; they do not require pathologic evaluation of their lymph nodes.

Surgical Considerations

All lesions with characteristics that are concerning for melanoma should be biopsied. An "ABCD" rule is available to help identify pigmented lesions at risk for melanoma: Asymmetry, Border irregularity, Color inhomogeneity, and diameter greater than 6 mm (the size of a pencil eraser).⁵⁵ Any pigmented lesion that demonstrates a change in size, color, or shape should be considered clinically suspicious. Although the majority of lesions needing biopsy can be identified by careful visual inspection, additional tools are available to assist in the evaluation of pigmented skin lesions. Serial photography can be used to help follow individuals with a large number of atypical appearing nevi. The use of digital photography especially allows for careful sequential assessment of individual pigmented lesions.^{56,57} Lesions that change over time can be identified for diagnostic biopsy. Epiluminescence, or surface microscopy, can be used to examine individual pigmented lesions for features suggestive of malignancy.^{56,58,59} Any pigmented lesion with changes or features suggestive of melanoma should be biopsied expeditiously.

Biopsy Techniques

The most powerful predictor of survival for primary melanoma is tumor thickness. There is almost a linear relationship between increasing tumor thickness and decreasing

survival. The corollary to this is that it is important to biopsy the suspicious pigmented lesion with the proper technique. Shave biopsies should not be performed when a melanoma is suspected because of the risk of cutting through the depth of the lesion and having a positive deep margin. If this occurs, a true tumor thickness cannot be ascertained and prognosis and treatment decisions are hampered; this is particularly pertinent when a shave biopsy straddles the tumor thickness of 0.76–1.0 mm. Patients with melanomas less than 0.76 mm in thickness have "thin" melanomas and have a high likelihood of cure with simple surgical techniques [1.0-cm-wide local excision (WLE)]. Patients with melanomas thicker than this have a defined rate of nodal and systemic metastases and are candidates for a wide local excision and nodal staging with the new lymphatic mapping techniques. Patients are done a disservice if a true tumor thickness cannot be ascertained. The proper biopsy technique for suspicious pigmented lesions is an excisional biopsy with a 1.0-mm margin. For larger lesions that cannot be completely excised, a 6.0-mm punch or incisional biopsy of the most nodular-appearing area that reaches into the subcutaneous fat beneath the lesion is indicated to make the diagnosis.

Surgical Treatment of the Primary Melanoma

Local management of primary melanoma necessitates wide excision of the lesion with a margin of normal-appearing skin.

TABLE 59.4. Completed prospective randomized trials evaluating surgical excision margins.

<i>Trial</i>	<i>No. of patients</i>	<i>Tumor thickness (mm)</i>	<i>Excision margins</i>	<i>Overall local recurrence</i>	<i>Overall survival</i>	<i>Comments</i>
French Cooperative Group ⁶⁴	362	≤2	2 cm vs. 5 cm	NSD ^a	NSD	Margins of 2 cm are safe for melanomas ≤2 mm
World Health Organization, Melanoma Program, trial 10 ⁶⁵⁻⁶⁷	612	≤2	1 cm vs. 3 cm	NSD ^b	NSD	Margins of 1 cm are safe for melanomas ≤1 mm Follow-up for local failures is ongoing for 1- to 2-mm melanomas
Swedish Melanoma Group ^{68,69}	989	≤2	2 cm vs. 5 cm	NSD	NSD	Margins of 2 cm are safe for melanomas ≤2 mm
Intergroup Melanoma Surgical Trial ^{70,71}	486	1-4	2 cm vs. 4 cm	NSD	NSD	Margins of 2 cm are safe for melanomas 1-4 mm
U.K. Melanoma Study Group ^{72,73}	900	>2	1 cm vs. 3 cm	NSD ^c	NSD	A percentage of nodal or other local/regional events may be reduced by margins >1 cm for melanomas >2 mm

^aNo significant difference.

^bTrend toward an increase in the absolute number of local recurrences in the narrow excision group for patients in the 1-2 mm subset.

^cThe patients who received a 3-cm excision had an improved relapse-free survival when all local and regional events were grouped together.

Previously, the surgical standard of care was a 3- to 5-cm-wide local excision (WLE) and a split-thickness skin graft. Increasingly, it has become evident that the risk of local recurrence coincides more with the thickness of the lesion and whether it is ulcerated rather than the extent of the surgical margins.⁶⁰⁻⁶² It may seem more rational, then, to use surgical margins that vary with the ulceration and thickness of the lesion, as these factors seem to correlate best with the risk for local recurrence.

The least advanced form of the disease is melanoma in situ. Although the natural history of this noninvasive melanoma is not completely understood, failure to reexcise the biopsy site may result in a local recurrence as either an invasive melanoma or an in situ lesion.⁶³ Therefore, it is recommended that the biopsy site of an in situ melanoma be reexcised with at least a 0.5- to 1-cm margin of skin. For "thin" melanomas (less than 1.00 mm in thickness), only a minimum local recurrence rate has been reported in observed patient series,⁶⁰⁻⁶² despite varying surgical margins. In other words, survival is not influenced by the size of the resection margins. At the present time, a wide excision consisting of no less than 1 cm minimum margin of skin is recommended by many melanoma surgeons.⁶¹ This procedure may be performed as a generous elliptical excision and a primary skin closure. Results from five completed prospective randomized studies, summarized in Table 59.4, have established guidelines for excisional margins for invasive melanomas less than 4.0 mm in thickness.⁶⁴⁻⁷³ Current recommendations are for 1-cm margins for melanomas up to 1 mm, 1- or 2-cm margins for melanomas between 1 and 2 cm, and 2-cm margins for melanomas between 2 and 4 mm.⁶¹ The risk of local recurrence may exceed 10% to 20% for those melanomas more than 4 mm in thickness.^{60-62,73} Thus, at least 2-cm margins are recommended for these deep primary melanomas.

Intraoperative Lymphatic Mapping and Sentinel Node Biopsy

A new procedure has been developed to assess the status of the regional lymph nodes more accurately and decrease the morbidity and expense of a complete elective lymph node dissection (ELND). The technique, termed intraoperative lymphatic mapping and selective lymphadenectomy, relies on the concept that regions of the skin have specific patterns of lymphatic drainage, not only to the regional lymphatic basin but also to a specific lymph node (sentinel lymph node, SLN) in the basin.⁷⁴ Morton et al. initially proposed the technique^{75,76} using a vital blue dye method and showed, in animals and initial human trials, that the SLN is the first node in the lymphatic basin into which the primary site drains. They showed that the SLN histology reflected the histology of the remainder of the nodal basin, so that complete nodal staging could be obtained with a SLN biopsy.⁷⁴

These data have been confirmed by many other institutions, including the Lakeland Regional Cancer Center (LRCC) and Moffitt Cancer Center (MCC),⁷⁷ M.D. Anderson Cancer Center,⁷⁸ and the Sidney Melanoma Unit.⁷⁹ These studies have demonstrated an orderly progression of melanoma nodal metastases. Preoperative lymphoscintigraphy is performed to provide a roadmap for the surgeon as to what basins are at risk for metastatic disease. This nuclear medicine study involves the injection of technetium sulfur colloid into the skin around the melanoma and imaging the patient to ascertain the direction of cutaneous lymphatic flow (Figure 59.1). Two mapping agents are then routinely used intraoperatively, a vital blue dye and a radiocolloid that has the right particle size to be taken up by the cutaneous lymphatics to migrate to the SLN. Upon exposing the lymph nodes in the basin, the SLN will be stained blue and will become "hot" compared to

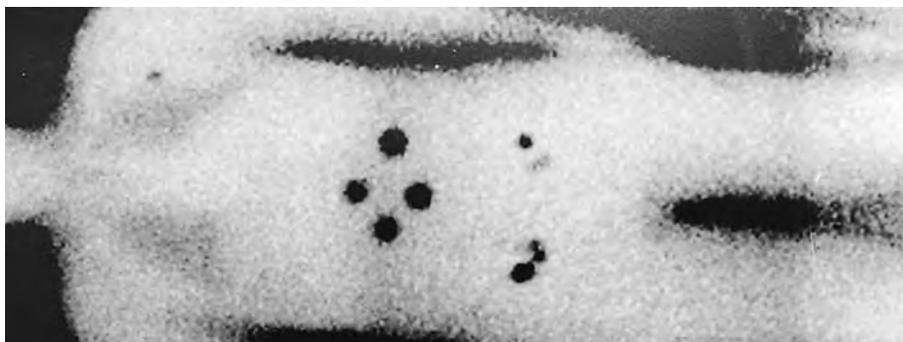

FIGURE 59.1. Preoperative lymphoscintigraphy in a patient with an intermediate-thickness melanoma around the umbilicus. This region of the skin is a watershed area of the body that can show multidirectional lymphatic flow with more than one basin at risk for metastases. This particular primary melanoma drains to both superficial groins as well as the left axilla.

surrounding neighboring non-SLNs and other tissue in the basin. These hot spots can then be used to direct the dissection with a hand-held gamma probe to the SLN.

This SLN concept was demonstrated in a study involving patients with a primary melanoma tumor thickness greater than 0.76mm and who were considered candidates for an elective lymph node dissection.⁷⁶ The SLN was harvested and submitted separately to pathology, followed by a complete node dissection. In this study, 42 patients met the criteria for SLN biopsy based on prognostic factors of their primary melanoma.⁷⁶ Thirty-four patients had histologically negative SLNs, with the rest of the nodes in the basin also being negative. Thus, there were no “skip” metastases documented. Eight patients had positive SLNs, with 7 of the 8 having the SLN as the only site of disease. Nodal involvement was compared between the SLN and non-SLN groups based on the binomial distribution. Under the null hypothesis of equality in distribution of nodal metastases, the probability that all seven unpaired observations would demonstrate involvement of the SLN was 0.008. The data presented demonstrates that nodal metastases from cutaneous melanoma are not random events. The SLNs in the lymphatic basins can be mapped and individually identified, and they have been shown to contain the first evidence of melanoma metastases. These findings demonstrate effective pathologic staging, no decrease in standards of care, and a reduction of morbidity with a less-aggressive, rational surgical approach and lower costs for the healthcare system.⁷⁴

Several prospective national trials are in progress to assess whether this surgical strategy provides a survival benefit for patients. In addition, the Florida Melanoma Trial, with the central office and laboratory located at the Lakeland Regional Cancer Center, is a regional industry-sponsored trial that will examine whether all patients with a positive SLN need to undergo a complete lymph node dissection of the affected basin. The results of these ongoing trials will help determine the final role of radioguided surgery in patients with malignant melanoma.

Surgical Management of Regional Metastases

ELECTIVE LYMPH NODE DISSECTION

Results from four completed prospective randomized studies are available to assess potential survival benefit for patients with clinically negative lymph nodes who receive elective lymph node dissection (ELND) as part of their primary tumor management (Table 59.5).⁸⁰⁻⁸⁶ These studies clearly demonstrate no overall survival benefit for all patients receiving ELND.⁸⁷ However, findings from prospectively stratified subgroups of patients suggest that patients with intermediate-thickness melanomas (1–4 mm) that are not ulcerated appear to have a survival advantage with ELND.⁸⁴⁻⁸⁷ Although surgical management of these patients has been largely replaced with SLN evaluation, these results suggest the potential cura-

TABLE 59.5. Completed prospective randomized trials evaluating elective lymph node dissection (ELND).

<i>Trial</i>	<i>No. of patients</i>	<i>Sites</i>	<i>Tumor thickness (mm)</i>	<i>Overall group survival benefit</i>	<i>Subset survival benefit</i>	<i>Comments</i>
World Health Organization Melanoma Program Trial 1 ^{80,81}	553	Extremities	All thicknesses	NSD ^a	No ^b	All melanoma patients do not benefit from ELND
Mayo Clinic Surgical Trial ^{82,83}	171	Extremities	All thicknesses	NSD	No ^b	All melanoma patients do not benefit from ELND
Intergroup Melanoma Surgical Trial ^{84,85}	737	All	1–4	NSD	Yes ^c	Defined subsets may benefit from ELND ^c
World Health Organization Melanoma Program Trial 14 ⁸⁶	227	Trunk	≥1.5	NSD	Yes ^d	Defined subsets may benefit from ELND ^d

^aNo significant difference.

^bProspective stratified subgroup analysis was not performed.

^cAmong the prospectively stratified subgroups of patients, 10-year survival rates were improved in patients who received ELND and had the following characteristics: nonulcerated melanomas, tumor thickness of 1–2 mm, extremity melanomas.

^dAmong the prospectively stratified subgroups of patients, overall survival was improved in patients with a tumor thickness of 1.5–4.0 mm.

tive potential of surgery for defined subsets of patients with regionally metastatic disease.⁸⁷

THERAPEUTIC LYMPH NODE DISSECTION

In patients with gross nodal metastases, the standard of care is to perform a complete lymph node dissection. The 5-year survival of patients with a nonulcerated melanoma and one, microscopically involved lymph node in the regional basin is approximately 75%. For patients with resected gross nodal disease in the regional basin, the 5-year survival rate drops to 25%. Thus, even in the face of gross nodal disease, surgery in and of itself in the nodal basin can cure approximately 25% of the patients.^{53,54}

ISOLATED LIMB PERFUSION

Isolated limb perfusion (ILP) refers to the regional intravascular delivery of chemotherapeutic agents to an extremity that has had involvement with melanoma.⁸⁸ The concept behind ILP is that administration of high drug concentrations is possible with ILP, and the goal with this approach is to improve treatment outcome while limiting systemic toxicities. Major toxicities with ILP have included systemic toxicities related to the infused agent as well as regional toxicities including skin toxicity, limb edema, myopathy, peripheral neuropathy, and vascular toxicity, including arterial embolic events and deep venous thrombosis.⁸⁸

The application of ILP for extremity melanoma has included both adjuvant ILP as well as ILP for established metastatic disease. Unfortunately, most of the literature describing ILP involves nonrandomized single-institution studies that often use a variety of treatment regimens as well as include heterogeneous patient populations.⁸⁸ A randomized trial involving 852 patients was performed by an intergroup including the European Organization for Research and Treatment of Cancer (EORTC), World Health Organization (WHO), and the North American Perfusion Group (NAPG) to evaluate the benefit of prophylactic ILP with melphalan for patients with high-risk extremity melanoma.⁸⁹ Study results published with a median follow-up of more than 6 years demonstrate an improvement related to disease-free survival, with a decrease in both in-transit metastases (6.6% to 3.3%) as well as a decrease or delay in regional lymph node metastases in the ILP-treated patients.⁸⁹ Unfortunately, no benefit in decreasing distant metastases or improving survival was identified. Thus, routine use of adjuvant ILP cannot be recommended for patients with resected high-risk extremity melanoma.

ILP with melphalan has also been administered at normothermic or hyperthermic (HILP) temperatures to melanoma patients who have disease consisting of established in-transit metastases, either with or without additional regional lymph node disease.⁸⁸ Results from a number of uncontrolled studies report complete responses ranging from 7% to 82% and overall response rates that range from 48% to 100%.⁸⁸ To improve these results, tumor necrosis factor (TNF) alone or with interferon-gamma has been added to melphalan.^{88,90,91} Initial results have demonstrated high response rates, and a multiinstitutional Phase III study by the American College of Surgeons Oncology Group (ACSOG) is now in progress to compare ILP using melphalan plus TNF with ILP using melphalan alone.⁸⁸ The use of ILP is a treatment of choice for some highly selected patients with in-transit metas-

tases involving an extremity. The optimal treatment agent, treatment time, and limb temperature have not been clearly identified. Palliation can be a goal of this therapy for patients with bulky, symptomatic melanoma of the extremity.

Surgery for Stage IV Melanoma Patients

Patients with systemic metastases (AJCC stage IV) have poor prognoses.⁵³ Selection of surgery as a treatment option should take into account the general medical condition of the patient, the potential for prevention or relief of symptoms, and improvement in the quality of life. Surgery may be an effective palliative treatment for isolated metastases, especially because melanoma often metastasizes sequentially and effective chemotherapy is not presently available. Surgical excision of metastatic melanoma may give the patient the best, quickest, and longest lasting palliation. On some occasions, the palliative effect can last for 5 to 10 years.^{92,93} The obvious limitation of surgery is that it is a local form of treatment, and the patient will very likely die of metastatic disease in another location. Careful patient selection is therefore important.

Mucosal Melanoma

Primary melanomas arising from the mucosal epithelia lining the respiratory, alimentary, and genitourinary tracts are rare, accounting for 3% to 4% of all melanomas diagnosed annually. The lack of large numbers of cases is responsible for the lack of insight into the pathogenesis, natural history, and treatment of mucosal melanomas. Mucosal melanomas are considered to be more aggressive with a worse prognosis than melanomas of the skin, and there are no microstaging data applicable for prognosis for patients with mucosal melanomas. The anatomic sites at which these melanomas originate are the head and neck, followed by vulvar and vaginal mucosa, followed by the anorectum.^{94,95} Similar to the primary melanomas that originate in the skin, mucosal melanomas are more common in the Caucasian population and are diagnosed in an older age group. The presence of melanocytes in the mucous membranes is well established, and thus the mucosal melanomas are considered true primary lesions and not metastases. The characteristic growth pattern of cutaneous melanoma is probably not applicable to mucosal melanoma, which is characterized by a rapid vertical growth phase and metastases. Mucosal melanomas act more like the thick, ulcerated cutaneous melanomas. For this reason, the treatment of the primary melanoma should be as conservative as possible, with total excision obtaining clear margins, but avoiding radical resections. For instance, patients with rectal melanoma should be treated with local excisions obtaining clear margins if possible instead of the more radical abdominoperineal resection.⁹⁴ A focus in these patients should be on systemic therapy, because many will have systemic metastases at the time of diagnosis. Five-year survival for patients with mucosal melanoma is uncommon regardless of primary site.⁹⁵

Radiation Therapy Considerations

There are several clinical settings in which radiation can provide important benefits for patients with melanoma, the most common involving the palliation of symptomatic

regional and distant metastases. Palliative settings frequently include patients with painful bony or soft tissue metastases, as well as patients with metastases to the brain and spinal axis. Furthermore, there are several adjuvant therapy settings for which the role of radiation remains of potential value in an effort to diminish locoregional disease recurrence.

Radiotherapy for Symptomatic Treatment

Focal radiation generally provides excellent pain palliation for patients with metastatic melanoma.^{96,97} High rates of palliative pain response for bone metastases have been routinely identified as exemplified by a randomized trial comparing fractionation regimens of 9 Gy \times 3 fractions versus 5 Gy \times 8 fractions delivered in a twice-weekly schedule. An overall response rate greater than 90% was identified without significant difference between the two arms.⁹⁸ Similarly, patients with metastatic melanoma will often have painful soft tissue or in-transit metastases that contribute directly to a reduced quality of life. Symptomatic lesions often can be successfully palliated with small-field electron beam or shallow photon tangent beams for pain relief. In addition, there is a rich literature regarding the use of hyperthermia as an adjuvant to radiation therapy in the treatment of malignant melanoma.^{99,100} These reports include studies employing focal hyperthermia with microwave, ultrasound, and interstitial heating devices. Both retrospective and prospective studies suggest an advantage in clinical response for some patients treated with combined hyperthermia and radiation compared with patients treated with radiation alone.¹⁰⁰

Patients with central nervous system metastases involving the brain or spinal cord present special circumstances for which the emergent use of radiation therapy is often warranted. The heterogeneity of melanoma responsiveness to radiation means that selected patients will have prompt regression of brain metastases following palliative radiotherapy, whereas others will not demonstrate clear response. The combination of high-dose corticosteroids with whole-brain radiation therapy provides effective symptom palliation in one-half to two-thirds of patients as measured by transient improvement in performance status and small extensions in median survival.¹⁰¹ Despite several studies, no clear benefit of altered fractionation regimens has been clarified, and a convention of 3 Gy \times 10 fractions or 4 Gy \times 5 fractions is common throughout much of North America. There are emerging reports regarding the potential additional value of stereotactic radiosurgery for patients with one to three melanoma brain metastases, particularly those with lesions of less than 3 cm and no active disease progression in other systemic sites.¹⁰²

Role of Adjuvant Radiotherapy

There are selected circumstances in which locoregional radiotherapy in the adjuvant setting appears particularly promising.^{96,103,104} The best described data set examining the use of adjuvant radiotherapy for localized melanoma involves patients with intermediate to thick tumors of the head and neck, with or without regional nodal spread.^{96,103} Prospective nonrandomized trials suggest a marked reduction in locoregional disease recurrence in comparison with historic controls treated at the same institution.^{103,105} A similar approach has been advocated for melanoma patients with axillary nodal

disease, specifically including those patients with extracapsular disease, multiple metastatic nodes, or recurrent disease in a previously dissected axilla. Reports from the M.D. Anderson Cancer Center with more than 5-year median follow-up suggest that the addition of axillary radiation in these high-risk settings can substantially reduce the likelihood of subsequent axillary failure over historical outcome at the same institution.¹⁰⁶

Adjuvant Interferon Therapy

The only U.S. Food and Drug Administration (FDA)-approved adjuvant therapy following resection of high-risk melanoma remains interferon alpha-2b (IFN- α -2b).¹⁰⁷ Vaccines remain experimental for melanoma patients, and vaccine considerations are presented in a later section of this chapter. Interleukin-2 has been evaluated alone and with other biologic response modifiers and/or chemotherapy in numerous advanced-disease studies (see following sections). Unfortunately, there remains no established adjuvant therapy benefit for high-risk melanoma patients following interleukin-2-based therapy. Although historically controlled studies have suggested benefit for adjuvant therapy with granulocyte-macrophage colony-stimulating factor (GM-CSF),¹⁰⁸ this benefit remains unproven and is now receiving prospective randomized clinical trial testing. Numerous other adjuvant therapies including bacillus Calmette-Guérin (BCG), *Corynebacterium parvum*, dacarbazine, levamisole, megestrol acetate, and interferon-gamma have been evaluated and shown to have limited or no benefit in both randomized and nonrandomized adjuvant therapy trials for melanoma patients.¹⁰⁹⁻¹¹¹

Although high-dose therapy with IFN- α -2b is the only FDA-approved adjuvant treatment for patients with resected high-risk melanoma, significant debate and controversy continue regarding interpretation of the completed interferon adjuvant studies.¹¹²⁻¹¹⁵ The results of studies evaluating high-dose IFN- α -2b are summarized in Table 59.6. In E1684, the 5-year overall survival rate of patients randomized to observation was 37% and the 5-year overall survival rate of patients randomized to receive IFN- α -2b was 46%.¹⁰⁷ This difference was statistically significant and resulted in FDA approval of high-dose adjuvant IFN- α -2b for melanoma patients following resection of high-risk (stage IIB and III) melanoma. The intergroup trial E1690 was performed to confirm results from E1684, as well as to concurrently compare high-dose IFN- α -2b and low dose IFN- α -2b with observation following resection of high-risk melanoma.¹¹⁶ Regional lymph node evaluation was not required for patients with T4N0 disease. The 5-year relapse-free survival rate for high-dose IFN- α -2b was 44%, the relapse-free survival rate for low-dose IFN- α -2b was 40%, and the relapse-free survival rate for observation was 35%. However, no significant improvement in overall survival was achieved by either high-dose or low-dose IFN- α -2b in comparison with observation.¹¹⁶

The E1694 study compared high-dose IFN- α -2b with a GM2 vaccine based on earlier data suggesting benefit in stage III melanoma patients having GM2 antibodies following vaccination with a GM2 ganglioside vaccine.¹¹⁷ An independent data monitoring committee evaluated results from the E1694

TABLE 59.6. Completed randomized trials evaluating high-dose interferon alpha-2b (IFN- α -2b) as adjuvant therapy of melanoma.

Trial	No. of patients	Eligibility	Treatment regimens	HDI overall survival benefit	HDI relapse-free survival benefit	Comments
E1684 ¹⁰⁷	287	T4 N1-3	HDI vs. observation	Yes	Yes	IFN- α -2b prolonged median survival from 2.8 to 3.8 years compared to observation
E1690 ¹¹⁶	642	T4 N1-3	HDI vs. LDI ^b vs. observation	No	Yes	There was no difference in the estimated 5-year overall survival rates of 52%, 53%, and 55% for HDI, LDI, and observation, respectively
E1694 ¹¹⁸	851	T4 N1-3	HDI vs. GMK vaccine ^c	Yes	Yes	IFN- α -2b is superior to GMK vaccine

^aHigh-dose interferon- α -2b (HDI) given at 20MU/m²/day IV 5 days per week for 4 weeks, then 3 times weekly at 10MU/m²/day subcutaneously for 48 weeks.

^bLow dose interferon- α -2b (LDI) given 3 times weekly at 3MU subcutaneously for 2 years.

^cGMK vaccine (modified GM₂ ganglioside vaccine [Progenics, Inc., Tarrytown, NY]) given subcutaneously on a weekly basis for 4 weeks, then every 12 weeks for the next 84 weeks.

study following 16 months of median follow-up. Results from that analysis demonstrated that treatment results had crossed the stopping boundaries specified by the study. The estimated 1- and 2-year relapse-free survival rates for the IFN- α -2b-treated patients were 71% and 62%, and the GM2-KLH/QS21-treated group had 1- and 2-year relapse-free survival rates of 62% and 49%.¹¹⁸ These results resulted in the recommendation for discontinuation of GM2-KLH/QS21 for patients still receiving it, as it was determined to be inferior to interferon.¹¹⁸

The clinical toxicity and economic cost of adjuvant therapy with this high-dose IFN- α -2b regimen are significant. Although the clinical toxicity of high-dose IFN- α -2b is substantial, overall clinical benefit from this treatment has been reported following quality of life adjusted survival analysis.¹¹⁹ In addition, several investigators are attempting to identify strategies to decrease some of the interferon-associated toxicities.¹²⁰ Consensus is not present regarding the "standard" use of this treatment for patients with resected high-risk melanoma.^{112,121}

Systemic Chemotherapy

The success of various chemotherapy strategies for patients with metastatic melanoma has been very limited.^{110,122-125} Although some patients have certainly benefited from current treatments, additional improvements are critically needed.

Single Agents

The use of single-agent dacarbazine (dimethyl-triazanoimidazol carboxamide, DTIC) has been a "standard" treatment and remains the only FDA-approved cytotoxic drug for metastatic melanoma patients. However, the modest response rate of 15% to 20%, with most of the responses being of brief duration, certainly leaves ample room for improvement.^{63,126} The median response duration is only 4 to 6 months, and the likelihood of a complete response is less than 5%. Many other drugs have been evaluated for single-agent activity against melanoma. Overall response rates complete response (CR) + partial response (PR) between 13% and 24% have been reported in single-agent chemotherapy studies utilizing a variety of doses and schedules for temozolomide,^{127,128} cisplatin,¹²⁹ carboplatin,¹³⁰ paclitaxel,¹³¹ docetaxel,¹³² carmustine (BCNU),¹³³ lomustine (CCNU),¹³⁴

fotemustine (FTMU),¹³⁵ vindesine,¹³⁶ vinblastine,¹³⁶ and the dihydrofolate-reductase inhibitor piritrexim.¹³⁷ Most of these responses are partial, and median response duration is usually measured in units of a few months. Although results from several single-agent Phase II chemotherapy studies appear better than single-agent DTIC, none have been confirmed as superior in a prospective randomized Phase III study.^{122,123,128} Thus, combination treatments and novel agents with new mechanisms of action are being actively investigated.

Combination Chemotherapy or Chemohormonal Therapy

Combination chemotherapy regimens have attempted to either combine agents with distinct single-agent activity and/or add tamoxifen as a means to enhance activity of the treatment regimen. A randomized Italian study evaluated treatment with DTIC, either alone or in combination with tamoxifen, for patients with metastatic melanoma.¹³⁸ This study reported an improved response rate (28% versus 12%; $P = 0.03$) and an improved median survival (48 weeks versus 29 weeks; $P = 0.02$) in patients receiving DTIC combined with tamoxifen compared with patients receiving DTIC alone (Table 59.7). However, a more-recent study from the Eastern Cooperative Oncology Group (ECOG) randomized 258 eligible patients with metastatic melanoma to receive treatment with dacarbazine either alone or combined with tamoxifen, IFN- α -2b or both tamoxifen and IFN- α -2b. There was no difference between time to treatment failure (median, 2.6 months) or overall survival (median, 8.9 months) between any of the four treatment groups.¹³⁹ Thus, neither tamoxifen, IFN- α -2b, nor the combination of tamoxifen and IFN- α -2b was able to improve response rate, time to treatment failure, or survival of melanoma patients when these treatments were added to single-agent therapy with dacarbazine (see Table 59.7). Several studies have reported promising results of tamoxifen in combination with cytotoxic agents including cisplatin,¹⁴⁰ navelbine,¹⁴¹ and others.¹²⁵ Subsequent Phase III testing to determine impact of tamoxifen on the combination treatment either has been negative or has not been performed.¹²⁵ Although tamoxifen is still being administered as part of published Phase II protocols, existing data do not demonstrate improved therapeutic outcome with addition of tamoxifen to cytotoxic regimens for melanoma patients.

The three-drug combinations of cisplatin, vinblastine, and DTIC or cisplatin, vindesine, and DTIC achieved response

TABLE 59.7. Randomized Phase III trials comparing chemohormonal or combination chemotherapy with DTIC for patients with advanced melanoma.

rates between 35% and 40% in Phase II testing. Unfortunately, no benefit in response duration or overall survival was seen in subsequent randomized comparison with DTIC (see Table 59.7).¹⁴² The treatment combination of cisplatin, dacarbazine, carmustine, and tamoxifen (CDBT; also known as the Dartmouth regimen) has been suggested for many years to have significant activity for patients with metastatic melanoma. Many of these studies reported response rates up to 30% to 50%, and some of these responses seemed to be durable.¹⁴³⁻¹⁴⁵ However, a more recently completed prospective randomized trial compared CDBT with single-agent therapy with DTIC and found no difference in overall survival with either of these treatments (Table 59.7).¹⁴⁶ Although several phase II studies have suggested potential benefit for combination chemotherapy over single agent chemotherapy, results from subsequent phase III testing have been disappointing.

Additional agents are also receiving investigation in combination with standard cytotoxic agents. Thalidomide is an orally bioavailable agent that has both antiangiogenic as well as some immunomodulatory properties. Use of thalidomide as single-agent therapy in melanoma has had limited activity.¹⁴⁷ The combination of thalidomide and temozolomide was tested for patients with metastatic melanoma, as melanoma is a highly vascular tumor that could benefit from this combined approach.^{148,149} Current results demonstrate this treatment to be well tolerated and to have some antitumor activity. Overall response rates in small Phase II studies have ranged from 15% to 32%, and durable responses have been reported.^{148,149} Further study is needed to determine if this combination regimen offers improved outcome over either single agent alone. Other approaches being tested clinically include the combination of chemotherapy with the anti-sense BCL2 oligonucleotide to inhibit antiapoptotic pathways as well as the combination of chemotherapy with novel agents such as Raf kinase inhibitors. It is anticipated that increased understanding of the many pathways involved in melanoma tumorigenesis will provide new opportunities for melanoma treatment strategies.¹⁵⁰

Cytokines and Other Immune Activators

Many cytokines and other immune activators are being actively evaluated as therapy for patients with metastatic melanoma.¹⁵¹ Treatment with high-dose bolus IL-2 is

approved by the FDA for the treatment of metastatic melanoma, and many studies are in progress to improve efficacy and/or decrease toxicity of cytokine-based regimens for advanced melanoma patients.

Interferons

As outlined earlier, treatment with IFN-α-2b has received extensive testing as adjuvant therapy for patients with resected stage III melanoma. In addition, measurable responses have been seen with IFN therapy for melanoma patients with advanced metastatic disease.¹⁵¹ Although the dose and schedule of IFN utilized in the metastatic setting have been quite varied, about 15% of patients have had tumor regression and 5% have been CRs. Although most of these responses last for only a few months, some can be more durable.

Interleukin 2

When peripheral blood mononuclear cells are cultured together with high concentrations of IL-2, a striking proliferation of natural killer (NK) cells and some T cells is observed, with induction of dramatically augmented cytolytic function.¹⁵² This IL-2-induced cytolytic function allows destruction of most cultured tumor cell lines and most populations of fresh tumor cell suspensions. For at least some patients with melanoma, measurable shrinkage of grossly evident tumor metastases can be induced by IL-2 treatment.^{153,154} Approximately 6% of these patients achieved complete remission and 10% of patients achieved partial remission in numerous Phase II studies using high-dose bolus IL-2.^{151,154,155} These clinical data supported the approval by the FDA of high-dose bolus IL-2 as a treatment for patients with metastatic melanoma.

IL-2 treatment induces NK cell activation, the release of cytokines, and a cytokine syndrome that is associated with capillary leak. This IL-2 therapy has a dose-dependent toxicity profile and has significant toxicity when administered in the approved high-dose bolus regimen.¹⁵⁶ The approved regimen is for administration of IL-2 at 600,000 to 720,000 IU/kg every 8 hours, up to a maximum of 15 doses, on days 1 through 5 and 15 through 19 of a treatment course. Data supporting approval and use of high-dose bolus IL-2 are based on nonrandomized Phase II data.¹⁵⁵ In addition, protocols

using lower-dose outpatient regimens of IL-2 have generally had lower response rates as well as few long-term survivors.^{151,154} However, the limitations of decision making based on Phase II data for advanced melanoma patients were emphasized with the recently reported results of the randomized Phase III study of combination chemotherapy and biochemotherapy.¹⁵⁷ Thus, use of high-dose bolus IL-2 as a single agent has been primarily at specialized centers with experience in administration of this treatment. Studies involving administration of lymphokine-activated killer (LAK) cells as well as tumor-infiltrating lymphocytes (TILs) together with IL-2 did not demonstrate sufficient additional activity to support noninvestigational use of these approaches.¹⁵¹ More-recent studies are investigating use of nonmyeloablative chemotherapy before adoptive transfer of cloned T cells and high-dose IL-2 therapy.¹⁵⁸ These studies, as well as integration of vaccine-based approaches given together with IL-2, will receive intense investigation in upcoming years.

Biochemotherapy

Several nonrandomized, single-institution Phase II studies have evaluated combination chemotherapy given together with IL-2 and IFN- α as biochemotherapy for patients with metastatic melanoma. Both inpatient and outpatient regimens have been evaluated, and response rates of 40% to 60% have been reported.¹⁵⁹⁻¹⁶² In addition to the high response rates reported, up to 10% of these patients have achieved a durable complete response. The frequent finding of high response rates in separate Phase II studies, as well as the consistent reporting of durable complete responses in a minority of responders, led to high expectations as well as great enthusiasm for this approach. The potential benefit of IL-2/cisplatin-based biochemotherapy has been investigated in at least six randomized trials (Table 59.8).^{157,163-167} The recent intergroup

Phase III randomized study was conducted to determine in a definitive fashion whether biotherapy (IL-2, IFN- α 2b, and G-CSF) added to the results of chemotherapy consisting of dacarbazine, cisplatin, and vinblastine when administered in a concurrent fashion. A total of 416 patients without prior treatment for metastatic melanoma were enrolled into the study, and results demonstrated increased toxicity without additional clinical benefit following treatment with the concurrent biochemotherapy regimen (see Table 59.8).¹⁵⁷ It remains unknown whether clinical benefit over chemotherapy alone can be achieved with other biochemotherapy regimens, such as use of some of the sequential biochemotherapy regimens. However, the disappointing result of this carefully performed intergroup study emphasizes the need for Phase III testing of promising approaches before accepting them as standard therapy.

Vaccine Therapy

Numerous advances in molecular biology and immunology provide opportunities for the design and analysis of vaccine-based therapies for melanoma patients.¹⁶⁸⁻¹⁷¹ Although melanomas contain antigens that can stimulate T-cell responses, the antigen(s) that can stimulate effective *in vivo* T-cell activation and an antitumor response are not known. Potential sources for antigens to use in melanoma vaccines, listed in Table 59.9, include whole melanoma cells as well as defined melanoma antigens or genes for defined melanoma antigens.

The use of melanoma cellular vaccines has included both autologous as well as allogeneic melanoma cells.¹⁷²⁻¹⁷⁵ Dr. Berd and colleagues have been investigating strategies to enhance the immunogenicity of autologous melanoma cell vaccines.¹⁷⁶ A recent update of this nonrandomized experience described 214 clinical stage III (N2 and N3) patients treated adjuvantly with an autologous tumor cell vaccine

modified with the hapten dinitrophenol (DNP).¹⁷⁷ The 5-year overall survival rate of 44% was better than expected from historical controls, and the 47% of patients with an induced delayed-type hypersensitivity (DTH) to unmodified autologous melanoma had an overall survival that was twice that of the DTH-negative patients (59.3% versus 29.3%; *P* less than 0.001). Additional approaches designed to augment the immunogenicity of autologous melanoma cells include the use of oncolysates of melanoma cells with vaccinia virus and the use of irradiated gene modified melanoma cells as a melanoma vaccine.^{173,178-180}

Other investigators are utilizing vaccines based on allogeneic cell lines, as this strategy offers many practical advantages over the use of autologous cells as a cancer vaccine.¹⁷³⁻¹⁷⁵ An allogeneic melanoma cell lysate vaccine (Melacine) was compared with combination chemotherapy with the Dartmouth regimen in a randomized clinical trial for patients with metastatic melanoma.¹⁸¹ Although both treatments had low but similar median survivals (7.2 months for the Dartmouth regimen compared with 6.8 months for Melacine), the improved toxicity profile for Melacine resulted in its approval in Canada. In addition, Melacine was investigated as adjuvant therapy for patients with intermediate-thickness, node-negative melanoma.¹⁸² Although no overall survival benefit for this vaccine was seen in all treated patients, the patient subset with a specific histocompatibility leukocyte antigen (HLA) expression (HLA-A2 and/or HLA-C3) had improved relapse-free and overall survival compared to control patients.¹⁸³ Another allogeneic cellular vaccine with promising results in adjuvant studies as well as some antitumor activity in metastatic disease is CancerVax.¹⁸⁴ This vaccine is currently receiving expanded testing in a Phase III adjuvant study comparing CancerVax (with BCG) versus BCG alone for patients with resected stage III melanoma.

Several gangliosides on melanoma cells have been characterized, and these gangliosides provide a target for an antibody response to melanoma.¹¹⁷ Unfortunately, the GM2-KLH/QS-21 vaccine was inferior to interferon when evaluated in a prospective randomized trial as adjuvant therapy for patients with resected high-risk melanoma.¹¹⁸ Another approach to stimulate an antibody response to melanoma uses an antiidiotypic antibody as an immunogen. Clinical trials are in progress, and some patients have been shown to develop an antiidiotypic antibody following vaccination with an antiidiotypic antibody.¹⁸⁵

Several clinical studies are now in progress either utilizing immunodominant peptides for melanoma-associated antigens or using DNA-encoding proteins containing melanoma-associated antigens.¹⁸⁶⁻¹⁸⁹ Additional studies are

combining these defined vaccines with cytokines or other immune activators. Rosenberg and colleagues reported antitumor activity in HLA-A2-positive melanoma patients receiving GP-100 peptide in combination with IL-2,¹⁹⁰ and Nestle and colleagues reported antitumor activity and antigen-specific T-cell immunity in melanoma patients treated with peptide or tumor lysate pulsed dendritic cells.¹⁹¹ Thus, ongoing clinical studies will determine the immunogenicity and antitumor activity of defined antigen vaccines given alone or with other immunotherapies. Initial Phase I and Phase II studies will determine promising approaches, but prospective, randomized Phase III studies will be needed to determine clinical benefit.

Imaging and Follow-Up of Melanoma Patients

The use of intensive follow-up of melanoma patients receiving definitive surgical management of primary melanoma is without demonstrated benefit.¹⁹²⁻¹⁹⁴ The majority of recurrences for patients with resected melanoma occur in the skin, soft tissues, or lymph nodes. Thus, careful physical examination remains of primary importance in the follow-up of these patients. In addition, the majority of recurrences amenable to surgical resection will be in these regions. Because most recurrences occur in the first 2 years following surgery, the frequency of follow-up is typically greater during the first 2 years following definitive surgery. Typical intervals are every 6 months for patients with melanomas less than 1 mm in thickness and every 3 to 4 months for patients with deeper primary melanomas and/or regional lymph node involvement. Addition of chest X-rays and laboratory studies typically does not take place for patients with melanomas less than 1 mm, but often are obtained at intervals from 3 to 6 months for patients with deeper primary melanomas and/or regional lymph node involvement. Follow-up intervals then become gradually longer between years 3 and 5, and yearly follow-up typically takes places after year 5. Because recurrences can take place more than 10 years from initial resection, some ongoing follow-up is appropriate for these patients.

The use of molecular tumor markers in the blood as early predictors of melanoma recurrence or disease outcome for melanoma patients is also receiving intense investigation.^{195,196} The strategy receiving the most intensive investigation involves use of a multiple-marker reverse transcription polymerase chain reaction (RT-PCR) to predict disease outcome. The markers being evaluated include the presence of melanoma-associated mRNA for tyrosinase, melanoma antigen recognized by T cells (MART-1), and the melanoma antigen MAGE. Although preliminary studies suggest potential benefit for this technology, additional evaluation and validation of assay characteristics are needed before incorporation into routine clinical monitoring.

Nonmelanoma Cutaneous Malignancies

Montgomery Gillard, Timothy S. Wang,
and Timothy M. Johnson

Facts and Figures

The nonmelanoma skin cancers (NMSC) are the most common human cancer type. More than half of all cancers diagnosed in the United States are NMSC. In the year 2003, more than 1.3 million new cases of NMSC will be diagnosed.¹ One in 5 Americans born in 2003 will be diagnosed with skin cancer in their lifetime. Recent publications and articles in the lay press have labeled nonmelanoma NMSC as "today's epidemic."² The incidence of NMSC has been rising since the 1960s at 4% to 8% per year.³ Basal cell carcinoma (BCC) and squamous cell carcinoma (SCC) account for 96% of new cases of NMSC. The remaining 4% consists of many other types of NMSC, but given their low incidence, discussion of these lesions is beyond the scope of this chapter.

Approximately 80% of skin cancers are BCC and 16% are SCC. Melanoma accounts for 4% of skin cancer diagnoses, but accounts for 75% of skin cancer deaths.¹ NMSC has an excellent prognosis: 90% to 99% of patients are curable following therapy and less than 1% of cases result in death. The number of deaths due to NMSC has been estimated at 2,000 to 2,500 year with three-fourths of these deaths attributed to SCC.⁴ However, these tumors are associated with significant morbidity in terms of significant local destruction and disfigurement and medical costs. The annual cost of treating NMSC has been estimated to be more than \$500 million.⁴ A recent publication described skin cancer among the most costly of all cancers to treat for the Medicare population.⁵ Despite the tremendous impact of NMSC on the U.S. population, a limited quality of evidence-based research exists.

Demographics

Increased risk for NMSC is associated with a number of host and environmental risk factors (Table 60.1). Exposure to sunlight is the principal cause of both BCC and SCC. The risk of NMSC varies according to race and ethnic group, with whites of Celtic ancestry having the highest incidence rates.⁶ The increased risk phenotype includes fair skin that tans poorly and sunburns easily, extensive freckling, blue or light-colored eyes, and red, blond, or light brown hair. NMSC is uncommon in African Americans, Asians, and Hispanics.⁷ As with most malignancies, incidence increases with increasing age. Residence in areas with high levels of ambient ultraviolet B

(UVB) radiation (i.e., lower latitudes) is associated with a higher incidence of NMSC.⁸ Most NMSC occur on sun-exposed sites, and 80% of lesions arise on the face, head, or neck.⁷ Although NMSC usually occurs on sun-exposed sites, these tumors can rarely occur in sun-protected sites such as the anogenital area, mucous membranes, palms, and soles.^{9,10}

Genodermatoses and Other Medical Conditions

A number of genetic syndromes are associated with an increased risk of NMSC.¹¹ Albinism is primarily an autosomal recessive disorder characterized by partial or complete failure to produce ocular and cutaneous protective melanin. Nevoid BCC nevus syndrome (Gorlin's syndrome) is an autosomal dominant or mosaic disorder associated with multiple BCC, jaw cysts, palmoplantar pits, abnormal ribs and vertebrae, and hypertelorism. Xeroderma pigmentosum is an autosomal recessive disorder characterized by hypersensitivity to UV light and high incidence of skin cancer, including melanoma, due to defects in DNA repair. Other less-common genetic syndromes associated with NMSC include epidermodysplasia verruciformis, epidermolysis bullosa, and dyskeratosis congenita. Other conditions associated with an NMSC include burn and vaccination scars, chronic inflammatory processes and ulcers, radiation, photodamaged skin, immunosuppression, and a history of previous NMSC.^{12,13}

Environmental Factors

Ultraviolet radiation, particularly UVB (290–320 nm), induces skin cancer as demonstrated in epidemiologic and experimental data.^{7,14} Depletion of the earth's ozone layer increases the levels of UVB radiation and the incidence of NMSC by 2% to 4% for each 1% reduction of the ozone layer.^{15,16} Ultraviolet B radiation induces NMSC by a variety of mechanism including direct DNA damage, damage to DNA repair systems, and alteration of the local cutaneous immune system.¹⁷ Other environmental/exposure factors associated with NMSC, primarily SCC, include a variety of chemicals: these include hydrocarbons found in coal tars, soot, asphalt, and cutting oils. Chronic exposure to arsenic has been associated with NMSC on both sun-exposed and covered sites.¹⁸ Psoralens used in combination with UVA (PUVA) used for the treatment of psoriasis and other inflammatory dermatoses produce dose-dependent increase in SCC.¹⁹ Cigarette smoking

has been linked to causing SCC of the lip and mouth.²⁰ Human papillomavirus has been associated with cutaneous SCC.²¹ The carcinogenic effect of ionizing radiation inducing NMSC is documented in human and animal models.²²

Basic Science

Basal Cell Carcinoma

BCC can develop in both a hereditary and sporadic fashion. Mutations in the PTCH gene have been identified as the cause of nevoid BCC syndrome and in sporadic BCC.^{23–26} PTCH is a cell membrane receptor for a family of proteins called Hedgehog (Hh).²⁷ The PTCH protein binds and inhibits a transmembrane protein smoothed (SMO). Mutations in either PTCH or SMO lead to increased smoothed signaling and growth promotion with subsequent cancer formation. The activation of the smoothed pathway leads to induction of a number of proteins via the Gli1 transcription factor, including transforming growth factor-beta (TGF-β), platelet-derived growth factor receptor-α, PTCH, and Gli1, and are relevant to cancer development.²⁸

Mutations that inactivate the tumor suppressor gene p53, also known as the guardian of the genome, are one of the most frequently found defects in all tumors.²⁹ The function of p53 is to sense DNA damage and arrest cell division to allow for DNA repairs or induce an apoptotic response to eliminate defective and potentially malignant cells. Fifty percent to 100% of BCC contain p53 mutations.^{30,31} Despite the frequency of p53 mutations in BCC, a causal role for these mutations in BCC development or progression has not been demonstrated. Patients with Li-Fraumeni syndrome, characterized by an inherited mutation in the p53 gene, are susceptible to an increased incidence of a number of malignancies, but an increase in NMSC has not been reported.²⁸

Squamous Cell Carcinoma

Squamous cell carcinoma can develop in a hereditary and sporadic fashion. There are several rare syndromes that can predispose individuals to SCC, but there are no monogenic disorders that feature SCC exclusively.³² Ultraviolet radiation generates specific mutations, thymidine dimers, in p53. The most frequent alteration is the CC→TT mutation, which is a UV signature mutation. Keratinocytes with one mutation in p53 after UV exposure undergo apoptosis. In contrast, keratinocytes with dysfunctional p53 and an additional p53 mutation as a result of UV irradiation cannot undergo apoptosis and instead undergo clonal expansion, which is manifested clinically as the development of an actinic keratosis, a known precursor lesion to SCC. Uncontrolled proliferation of these abnormal keratinocytes eventually leads to SCC in situ and invasive SCC.³³ Brash et al. found that 58% of invasive SCCs of the skin contain mutations in p53.³⁴ Mutations in other tumor suppressor genes such as RAS and p16/CDKN2A have also been reported.^{35,36}

Clinical Presentation

Basal Cell Carcinoma

BCC originate de novo presumably in the bulge area and have no precursor lesion. The presentations of BCC are as varied as the tumor is common. Approximately 80% of BCCs are found on the head and neck.⁷ Basal cell carcinoma can be classified into subtypes by their clinical morphology and histopathology. Clinical subtypes vary in appearance and clinical course and include the following more common variants: nodular, superficial, aggressive (infiltrating and morpheiform), and pigmented.^{37–39}

The nodular or nodular ulcerative variant is the “classic” BCC. Clinically, this appears as a translucent, flesh-colored or pink, pearly papule with prominent telangiectasias (Figure 60.1). Nodular BCC may ulcerate, forming what was once

FIGURE 60.1. Nodular pattern basal cell carcinoma of the left nasal ala.

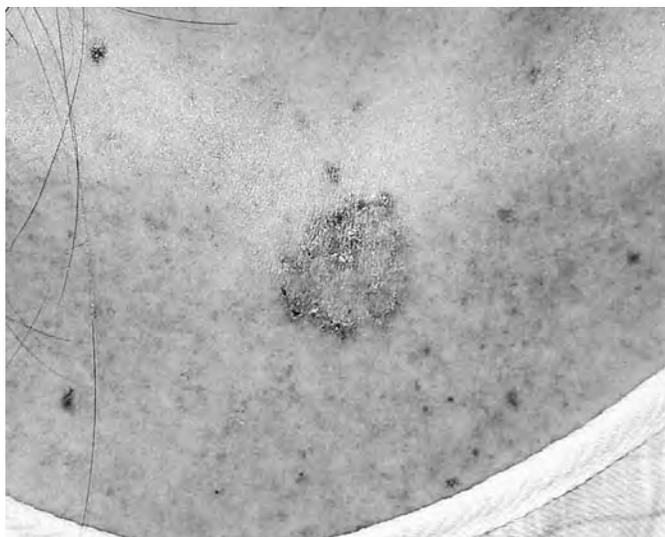

FIGURE 60.2. Superficial pattern basal cell carcinoma on the chest, clinically resembles nummular eczema.

FIGURE 60.3. Locally destructive, recurrent, aggressive growth pattern basal cell carcinoma previously treated with surgical excision and radiation therapy, 9 and 6 years, respectively.

termed a rodent ulcer because of its resemblance to a rat bite. Most lesions are small (less than 1 cm) papules; however, patients do present with very large, disfiguring lesions that have been neglected for many years. Superficial BCC usually presents as a red, scaly macule with a thready translucent border, often with areas of hypopigmentation, atrophy, or scarring. They commonly occur on the trunk and extremities, are sometimes confused with inflammatory skin conditions such as psoriasis and eczema, and may closely resemble Bowen's disease and actinic keratoses (Figure 60.2). The aggressive subtype of BCC usually presents as a flat, indurated, pale, white-to-yellow papule or plaque with indistinct clinical borders and a "scarlike" appearance. As these lesions grow, they often become firm. They are also known as infiltrating, morpheaform, sclerosing, sclerotic, and fibrotic BCC. These lesions often extend well beyond (more than 1 cm) their clinically apparent margins and may ulcerate later in the clinical course (Figure 60.3). Pigmentation within BCC can be variable and can be seen in a variety of subtypes. Some lesions are heavily pigmented, and are categorized as a pigmented BCC and can bear striking resemblance to malignant melanoma or pigmented seborrheic keratoses. Neglected BCC or those with high risk factors described later may result in extensive local tissue destruction and very high morbidity (Figure 60.4).

Squamous Cell Carcinoma

Several precursor lesions to invasive SCC exist, including actinic keratoses, arsenical keratoses, thermal keratoses, radiation keratoses, chronic cicatrix keratoses, Bowen's disease (SCC in situ), and erythroplasia of Queyrat.⁴⁰ Actinic keratoses (AK) are both precursors of cutaneous SCC and markers of increased risk for NMSC. Clinically they arise as rough, scaly patches, on average 4 to 10 mm in diameter, on sun-exposed areas. They can be skin colored, erythematous, pink, or brown, and often they are more easily felt than seen.

Actinic keratoses occur most commonly on the head and neck and extensor arms and hands. The annual rate of progression of AKs to SCC is unknown and controversial, with estimates of conversion ranging from 0.025% to 20%; the

FIGURE 60.4. Multiply recurrent, neglected, basal cell carcinoma involving the eye. Although rarely lethal, tumors with high-risk factors may be associated with local tissue destruction and high morbidity, and even metastasis and death.

FIGURE 60.5. Squamous cell carcinoma of the left ear, a known high-risk location.

cumulative risk depends on the number or lesions and the length of time they persist.^{41–43} Among patients with multiple AKs, the cumulative lifetime risk of having at least one invasive SCC is believed to be 6% to 10%.⁴⁴ Clinically, there are two main types of SCC in situ, which include Bowen's disease and erythroplasia of Queyrat. Bowen's disease often presents as a slow-growing, poorly defined, scaly pink patch on sun-exposed sites.⁴⁵ Erythroplasia of Queyrat occurs as SCC in situ on the glans penis, often as a smooth, erythematous, plaque. SCC in situ lesions progress to invasive SCC.²¹

Invasive SCC most commonly occurs on the sun-exposed areas of the body. Approximately 80% develop on chronically sun-exposed areas on the head and neck and extremities, followed by the trunk.²¹ They vary in their presentation and often appear as 0.5 to 1.5 cm, firm, hyperkeratotic pink papules, nodules, or plaques, sometimes with pain (Figure 60.5). Ulceration is a common finding, and the lesions tend

to bleed easily following minor trauma. In darker-skinned patients, SCC may present in nonsun-exposed areas, are often hyperpigmented, and are most commonly associated with chronic inflammatory or scarring processes. Keratoacanthoma (KA) is a well-differentiated subtype of SCC that tends to grow rapidly to form a crateriform nodule.⁴⁶ Keratoacanthoma metastasis has been reported.⁴⁷

Histopathology

Basal Cell Carcinoma

The histologic patterns of BCC are as diverse as its clinical appearance. Classic histologic features include presence of multiple basaloid tumor cells islands, cords, or nests with peripheral palisading of nuclei and focal areas of separation or retraction artifact between tumor nodules and mucinous stroma. Many histologic subtypes and classification schemes exist. Nevertheless, there are four major architectural patterns that are useful to identify because of their clinical and prognostic implications. These patterns include superficial, nodular, micronodular, and aggressive-growth (infiltrative and morpheiform) (Table 60.2). Multiple patterns may be found in up to 35% to 50% of lesions, with the most aggressive pattern correlating with biologic behavior.

Numerous, multifocal small buds of basaloid tumor cells that arise in the epidermis and extend into the superficial dermis and down hair follicles characterize superficial BCC. Nodular BCC, also known as solid or well circumscribed, is the most common histologic pattern.⁴⁸ It is composed of variable-sized tumor lobules in the dermis that are well circumscribed. Larger lesions that ulcerate are termed nodulocystic BCC and are characterized by centrilobular necrosis or cystic degeneration within the center of the tumor lobules. Smaller tumor islands, approximately the same size as hair bulbs, characterize micronodular BCC.

The aggressive-growth BCC classification merges the histologic pattern with the biologic and clinical behavior. The

TABLE 60.2. Histopathologic features of basal cell carcinoma (BCC) and squamous cell carcinoma (SCC).

Basal cell carcinoma	
Superficial pattern	Numerous, multifocal small buds of basaloid tumor cells that arise in the epidermis and extend into superficial dermis or down hair follicles
Nodular pattern	Well-circumscribed tumor lobules of varying size in dermis
Micronodular pattern	Smaller tumor islands, approximately the size of hair bulbs
Aggressive growth pattern	Narrow linear strands and cords of basaloid tumor cells embedded in a sclerotic stroma
Squamous cell carcinoma	
Conventional type	Malignant proliferation of keratinocytes that extend into dermis with varying degrees of keratinization and anaplasia
Adenoid/acantholytic type	Endophytic invasive lesion with acantholysis of tumor cells leading to a pseudoglandular appearance
Bowenoid type	Full-thickness architectural disorder with loss of polarity and absence of orderly keratinocyte maturation with invasion into the dermis
Spindle cell/pleomorphic type	Broad fusiform sheets of atypical spindle cells with rare foci of squamous differentiation
Small cell type	Small round neuroendocrine-like malignant cells, usually associated with overlying SCC in situ lesion
Verrucous type	Well differentiated with little atypia and with pseudoepitheliomatous hyperplasia that "bulldozes" into dermis
Keratoacanthoma type	Well-circumscribed, keratin-filled invaginations, composed of well-differentiated squamous cells with "glassy" eosinophilic cytoplasm
Squamous cell carcinoma in situ type (Bowen's disease)	Full-thickness epidermal dysplasia without invasion into dermis, disordered maturation with "windblown" appearance

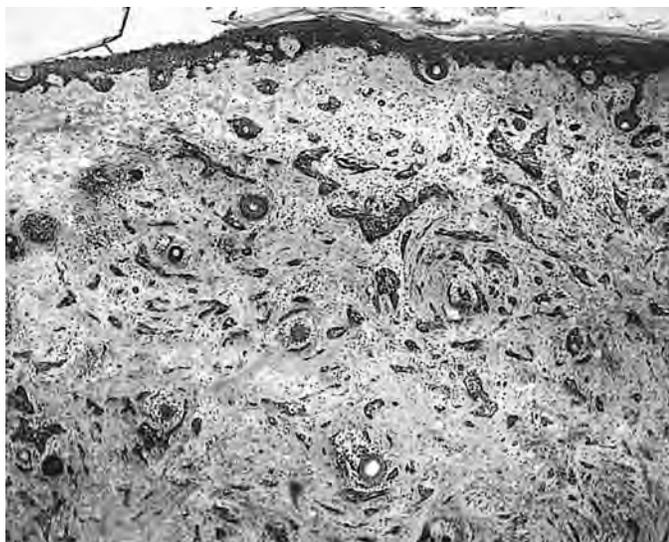

FIGURE 60.6. Mohs' surgery: frozen-section histologic slide of an aggressive growth pattern basal cell carcinoma with numerous tumor cells, often only one cell layer thick, arranged in elongated strands embedded in a dense fibrous stroma. The strands of tumor cells often extend a considerable distance from the clinical lesion and deeply invade the deep dermis and subcutis.

histologic features include small islands and narrow linear strands and cords of basaloid tumor cells embedded in a dense, fibrous to sclerotic stroma. The narrow strands resemble "finger-like" or "spiky" projections; peripheral palisading and stromal retraction are often inconspicuous or absent.⁴⁹ It is important for the pathologist to convey to the clinician the growth pattern of all BCC, but it is paramount for aggressive-growth BCC. The aggressive-growth BCC is an infiltrating lesion with extensive subclinical invasion into deep dermis, subcutis, and muscle (Figure 60.6). Aggressive-growth BCC often shelve and skate along muscle and fascial planes, cartilage, and bone. Perineural invasion is also more common.⁵⁰ Micronodular BCC similarly often has significant subclinical extension through the dermis or subcutis.⁵¹

Squamous Cell Carcinoma

There are several histologic subtypes of SCC with the conventional subtype, otherwise known as generic or simplex, being the most common. Other subtypes include adenoid/acantholytic, bowenoid, spindle/pleomorphic, small cell, verrucous, keratoacanthoma, SCC in situ, and microinvasive SCC. The conventional subtype is characterized by lobules and cords of atypical keratinocytes originating from the epidermis and invading the dermis. Cellular features include enlarged, hyperchromatic, variably pleomorphic nuclei with often prominent mitotic activity. Many lesions produce larger amounts of keratin, resulting in keratin-pearl formation, and intercellular bridges are usually easily seen.⁵² Perineural invasion occurs in 2.4% to 14% of SCC and is even more frequent in recurrences.⁵³ The conventional type of SCC may be further subclassified by the degree of differentiation. The Broders system of histologic grading of SCC is based on the degree of cellular differentiation in the neoplasm.⁵⁴ Grade I is well differentiated with more than 75% keratinization and grade IV with less than 25% keratinization. More commonly, lesions are referred to as "well differentiated versus poorly differentiated." The underlying trend is that as tumors become

less differentiated they behave in a more clinically aggressive mode.

Bowenoid SCC is characterized by architectural disorder of the full thickness of epidermis, with loss of polarity and absence of orderly keratinocyte maturation. The atypical keratinocytes may extend downward along the follicular epithelium to the level of the sebaceous glands. Evidence of invasion into the dermis differentiates bowenoid SCC from Bowen's disease (SCC in situ). Adenoid or acantholytic tumors exhibit a conventional SCC pattern with acantholysis leading to a pseudoglandular appearance. The spindle-cell/pleomorphic variant is composed of intertwining fascicles, and bundles of atypical keratinocytes are surrounded by a myxoid or storiform stroma.⁵⁵ Immunohistochemistry is often required to differentiate these neoplasms from spindle cell melanoma and atypical fibroxanthoma. Spindle cell SCC demonstrates positive staining with cytokeratins.⁵⁶ The small cell variant of SCC resembles a Merkel cell carcinoma or metastatic small cell neuroendocrine carcinoma.

Prognostic Factors and Risk Status

The majority of NMSC are, fortunately, low-risk lesions that can be treated with relatively high cure rates. "Higher-risk" NMSC lesions are associated with higher incidence of recurrence and/or metastasis. Numerous clinical high-risk factors exist in regard to NMSC. These risk factors include the following: size, location, primary versus recurrent, ill-defined clinical borders, occurrence in immunosuppressed individuals, histologic pattern subtype and depth, perineural invasion, and tumors developing in areas of previous irradiation.

Basal Cell Carcinoma

Most primary BCC are cured by appropriate initial treatment. Recurrent tumors are often locally destructive and more difficult to treat.⁵⁷ Several prognostic factors of primary BCC are known to influence whether the tumor will recur after treatment; these include size, anatomic location, histologic subtype, clinically poorly defined tumor borders, perineural invasion, immunosuppression, tumors developing in sites of prior radiotherapy, and recurrent lesions (Table 60.3). BCC located on the head and neck is more likely to recur than

TABLE 60.3. Basal cell carcinoma (BCC) risk factors.

• Anatomic location
■ High risk: mask areas of face, genitalia, hands and feet
■ Medium risk: cheeks, forehead, scalp, and neck
■ Low risk: trunk, extremities
• Size
■ Lesions ≥ 6 mm on high-risk area: mask areas of face, genitalia, hands and feet
■ Lesions ≥ 10 mm on medium-risk area: cheeks, forehead, scalp, and neck
■ Lesions ≥ 20 mm on low-risk area: trunk and extremities
• Histologic subtype patterns
■ Aggressive growth
■ Micronodular
• Poorly defined clinical borders
• Perineural invasion
• Development in sites of prior radiation
• Immunosuppression
• Recurrent tumors

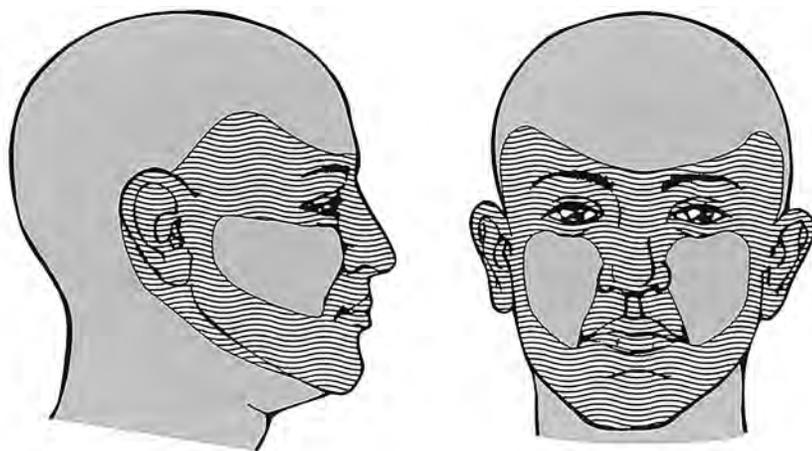

FIGURE 60.7. Lesions located in the high-risk “mask area” of the face (*horizontal lines*) are at increased risk for tumor recurrence. The genitalia, hands, and feet are also high-risk locations. Medium-risk areas of the head and neck shown by *gray shading*.

lesions developing on the trunk and extremities. The high-risk “mask areas” of the face (central face, eyelids, eyebrows, periorbital, nose, lips, chin, mandible, preauricular and postauricular areas, temple and ears) and the genitalia, hands, and feet are at increased risk for tumor recurrence (Figure 60.7). Medium-risk locations include the cheeks, forehead, scalp, and neck, and low-risk sites include the trunk and extremities. The data for size and location are based upon a large 27-year retrospective review from the skin cancer unit at New York University (NYU) published in 1991 and 1992 by Silverman et al.^{58–61} The combination of size and location affects recurrence rates. Recurrences in the NYU study were significantly more common when tumors in high-risk locations were 6 mm or more in size, in medium-risk areas 10 mm or more in diameter, and in low-risk areas, 20 mm or more.

An increased risk of tumor recurrence is associated with two histologic subtypes, the aggressive growth (sclerosing, morpheiform, fibrosing, desmoplastic, scirrhous, infiltrative), and micronodular patterns.⁶² Poorly defined clinical borders result in higher recurrent rates.⁵⁷ Perineural invasion poses a significantly increased risk of recurrence and subclinical invasion, and occurs in up to 3% of all BCC.⁶³ The incidence of BCC is reportedly increased by a factor of 10 in immunosuppressed transplant recipients.⁶⁴ BCC in immunosuppressed patients should be viewed as potentially high-risk tumors. BCC developing in skin previously treated with radiation are at higher risk for significant subclinical invasion and are considered high-risk lesions.⁶⁵ Recurrent BCC have rerecurrence rates reported as high as 33% to 50%, regardless of anatomic location or treatment modality used.⁶⁶

Metastatic BCC is a rare event (0.03%).⁶⁷ Metastatic spread is most often to the regional lymph nodes, followed by the lungs, bones, and skin.⁶⁸ The 5-year survival rate for patients with metastatic disease is poor, and patients with distant disease have a median survival of only between 10 and 14 months.

Squamous Cell Carcinoma

Invasive SCC is the more serious form of NMSC because of its greater potential to metastasize. The majority of SCC are low-risk lesions that are treated with relatively high cure rates. Several variables have been identified as determining risk of local recurrence, metastasis, and survival rates. In 1992, Rowe et al. reviewed the literature since 1940 to identify the

most important prognostic factors.⁶⁹ Nine variables of cutaneous SCC have been identified as “high-risk” factors for increased likelihood of recurrence, metastasis, and death: size, depth of invasion, histologic differentiation, rapid growth, etiology (scar, radiation, chronic ulcer or inflammatory process, and sinus tract), anatomic site, immunosuppression, perineural invasion, and recurrent lesions (Table 60.4).

SCC is the most common skin cancer in immunosuppressed transplant recipients, occurring 65 to 250 times as frequently as in the general population.⁷⁰ Immunosuppression-associated SCC are biologically aggressive and associated with higher risk of rapid growth, local recurrence, regional and distant spread, and mortality.^{12,69}

The most common sites of spread are the regional lymph nodes, which occurs in 85% of metastatic cases. Approximately 15% of metastases involve distant sites such as the lungs, liver, brain, bone, and skin.^{21,71} Prognosis for patients with metastatic SCC is poor; 10-year survival rates are less than 20% for patients with regional lymph node involvement and less than 10% for patients with distant metastases.

Treatment: Evidence-Based Medicine

Numerous treatment modalities are used for NMSC, both surgical and nonsurgical. Despite the enormous amount of literature involved in the treatment of NMSC, there has been relatively little good-quality research on the efficacy of the treatment modalities used. Rare systematic reviews of treatment modalities and meta-analyses have been reported. This type of analysis may generate misleading results by ignoring the meaningful heterogeneity among studies, fortifying the biases in individual studies, and introducing further biases through the process of finding studies and selecting the results that are pooled.⁷² Most of the reported literature is retrospective and not randomized and suffers from selection bias; that is, treatment modality used was influenced by whether the lesion was low or high risk. The selection of therapy is based upon the clinical and histologic risk factors described previously. Randomization is the only way to avoid tumor selection bias, and to date there have been fewer than 30 randomized controlled trials examining treatment modalities in NMSC. Similarly, recurrence rates for different therapies are difficult to compare because of lack of uniformity in methods of reporting. Most of the (short-term) studies report a recurrence rate based on the total number of patients with recurrent NMSC divided by the total number of patients with initial tumors (raw recurrence rate = all recurrences / all tumors treated). This method artificially lowers the recurrence rate because it ignores patients unavailable for follow-up, which is not uncommon for elderly populations who may die of other causes and be unavailable for follow-up.⁷³ In contrast, most long-term studies report a recurrence rate based on the total number of patients with recurrent NMSC divided by the total number of patients who were observed for at least 5 years (strict 5-year recurrence rate = all recurrences / all nonrecurrent tumors followed up for 5 years + all tumors recurring within 5 years). This method excludes nonrecurrent patients who were observed for less than 5 years and thereby artificially raises the recurrence rate.⁷³ From a statistical point of view, recurrence rates are the result of calculating several types of survival curves, such as the Kaplan–Meier survival curve and the life table survival curve according to Cutler and Ederer. The modified life table recurrence rate would be intermediate between the raw and strict recurrence rate in most instances because it uses all available data and gives weighted credit for tumor-free follow-up of less than 5 years.

In this section, the treatment modalities for NMSC are described and the best clinical evidence that currently exists outlines the effectiveness of the therapy described. The Cochrane Collaboration performed a comprehensive evidence-based review of interventions utilized for the treatment of primary BCC in 2003.⁷⁴ To be included in their analysis, studies had to meet their strict criteria: adult patients with histologically proven primary BCC, and excluded recurrent lesions or patients with genodermatoses. Primary outcome was recurrence at 3 to 5 years measured clinically (to simulate what happens in clinical practice). Secondary outcomes looked at early treatment failure within 6 months, measured histologically, and esthetic considerations and discomfort to patients. *Clinical Evidence*, an annually updated evidence-based medicine periodical, recently outlined an evidence-based review of squamous cell carcinoma of the skin.⁷⁵

Electrodesiccation and Curettage

Electrodesiccation and curettage (ED&C) is a common treatment modality used primarily by dermatologists and is highly operator dependent. ED&C is a procedure causing local tissue destruction performed under local anesthesia. NMSC have a soft feel that can be differentiated from uninvolved normal surrounding tissue, which feels smooth and firm. First, a larger curette is used to debulk the majority of the soft tumor; this is followed by electrodesiccation of the periphery and base of the wound to destroy residual tumor cells. This process is repeated with both large and small curettes and electrodesiccation for a total of 2 to 4 cycles depending upon the size and feel of the lesion. The experienced operator may provide similar high cure rates with curettage alone, omitting electrodesiccation. The resulting wound heals by secondary intention as a hypopigmented, atrophic scar. If the curette extends into the subcutis or a sclerotic “feel” is noted, excision of the site should be performed. A disadvantage of ED&C is the lack of a surgical specimen in which to examine margins for completeness of tumor removal or to obtain data on histologic depth of invasion.

CLINICAL EVIDENCE

To date there have been no randomized controlled trials (RCT) comparing ED&C of NMSC with other modalities. Rowe et al. performed a meta-analysis on all the literature from 1947 to the present and reported cure rates for the treatment of primary BCC. They found that the short-term (less than 5 years) recurrence rates for primary BCC in all locations treated with ED&C was 4.7% and the long-term (more than 5 years) recurrence rate was 7.7%.⁵⁷ Their findings underscore the fact that short-term follow up (less than 5 years) artificially lowers the recurrence rate and emphasizes the need for standardization of follow up for studying recurrence rates in NMSC. In fact, 18% of recurrences occur after 5 years.⁵⁷ Kopf et al. reported on recurrence rates of primary BCC treated with ED&C and noted cumulative 5-year recurrence rates for all lesions ranging from 5.7% to 18.8%.⁷⁶ An interesting distinction was that residents in training had higher recurrence rates (18.8%) compared with attending physicians (5.7%); this raises yet another variable in determining tumor recurrence, the degree of experience of the treating physician.

The study by Silverman et al. examined recurrence rate for 2,314 primary BCC treated with ED&C and further examined the role of size and location in recurrence.⁵⁹ They found that tumors located in low-risk areas (neck, trunk, extremities) of all sizes responded well to ED&C with a 5-year recurrence rate of 3.5%, whereas tumors located at high-risk locations had a recurrence rate of 4.5% if they were less than 6 mm in size and a 17.6% recurrence rate if they were larger.⁵⁹ ED&C has been documented as an effective primary treatment modality for the treatment of low-risk primary BCC. For recurrent BCC, rerecurrence rates with ED&C were 33.3% at 5 years and 40% at more than 5 years.⁵⁷

The treatment of SCC with ED&C is less well documented. In the meta-analysis by Rowe, recurrence rates for primary SCC treated with ED&C was 3.7%.⁶⁹ However, these data suffer from the small sample size (82 patients) and treatment bias in selecting for smaller lesions. ED&C of primary SCC is limited to small, low-risk, minimally invasive or in situ lesions in low-risk or nonhair-bearing locations.

In summary, ED&C is an effective primary treatment for primary low-risk BCC and small in situ or minimally invasive SCC in low-risk locations. The technique is operator dependent and the degree of experience with the procedure affects the results. The procedure is easily performed in an office setting with little morbidity.

Cryosurgery

Cryosurgery uses liquid nitrogen delivered by a spray apparatus or cryoprobe that allows for deep-freezing to -50 to -60°C to achieve local destruction and necrosis of tissues. Typically, two freeze-thaw cycles are used. The resulting wound heals by secondary intention. The most common side effects are transient edema, pain, and erythema. Chondritis and cartilage necrosis may occur. Cosmetic results are similar to ED&C. The procedure is performed in an office but requires experience and additional equipment. It is an effective treatment for low-risk BCC as well as for some SCC.^{77,78}

CLINICAL EVIDENCE

A total of four randomized controlled trials (RCTs) have been performed in regard to the use of cryosurgery to treat primary BCC (Table 60.5). One study is omitted from this review because it did not histologically confirm the diagnosis of BCC.⁷⁹ One of the studies examined cryosurgery compared to radiotherapy (RT) for 93 patients with primary BCC, excluding lesions on the nose or pinna. Recurrence rates were recorded at only 1 year and not 3 to 5 years.⁸⁰ This limitation should be a red flag, and conclusions should be approached with caution because nearly two-thirds of all lesions recur within the first 3 years but may occur at 5 to 10 years. Cryosurgery showed a high recurrence rate (39%) compared with radiotherapy (4%). Cosmetic and discomfort levels were equivalent. Another study of 96 patients compared cryosurgery with surgical excision for superficial and nodular primary BCC of the head and neck.⁸¹ The recurrence rate was 3 in 48 for the cryosurgery group and 0 in 48 for the excision group. The primary outcome was final cosmetic result, and the outcome was better in the excision group. Ninety percent of the cryosurgery group complained of moderate to severe swelling and exudative drainage.

A final study of 88 primary BCC compared cryosurgery with photodynamic therapy (PDT).⁸² Lesions were located on the head, neck, and extremities, and the follow-up was 1 year. The recurrence rate at 1-year follow-up was 15% for the cryosurgery group and 25% for the PDT group. This was the only trial to confirm recurrence histologically.

Thissen et al. in 1999 performed a systematic review of noncontrolled prospective studies of primary BCC treated with cryosurgery followed for at least 5 years.⁷³ They found a cumulative 5-year recurrence rate ranging from 3.5% to 16.5%. A large retrospective study of 3,869 primary BCC, less than 2 cm on all anatomic locations and treated with cryosurgery, were noted to have a 3% to 4% recurrence rate during a follow up period of 1 to 10 years.⁸³

No RCT have been performed regarding cryosurgery for the treatment of SCC. Kuflik and Gage reported a series of 3,540 primary skin cancers in 2,220 patients treated over 18 years, of which 188 were SCC.⁸⁴ The overall cure rate was 98.4%. Graham and Clarke reported a cure rate of 97.3% for 563 primary SCC; however, the majority of lesions were low risk, ranging in size from 0.5 to 1.2 cm.⁸⁵

In sum, cryosurgery is an effective method to treat small low-risk BCC. However, there is no good direct evidence to show that it is better than other modalities. The cure rates for cryosurgery are less than for surgical excision or radiation therapy. There is even less evidence to recommend cryosurgery as a first-line treatment for SCC. The National Cancer Comprehensive Network (NCCN) does not include cryosurgery as a primary treatment modality in their guidelines for treating NMSC.⁸⁶

Surgical Excision

Surgical excision is an effective treatment modality for all types of NMSC. Recommended margins for excision of NMSC published in the literature range from 2 to 10 mm. A prospective study of 117 patients determined that a surgical excision margin of 4 mm of normal-appearing skin was adequate 95% of the time to clear primary BCC that were less than 2 cm.⁸⁷ Similarly, Brodland and Zitelli reported that to achieve clear surgical margins for low-risk SCC (less than 2 cm, Broders histologic grade I, and low-risk location) the minimum surgical margin was 4 mm.⁸⁸ Furthermore, a 6-mm margin was needed for higher-risk SCC (Broders histologic grade more than I, more than 2 cm in diameter in a low-risk site and more than 1 cm in a high-risk anatomic site) to obtain a 96% clearance rate. Surgical excision is advantageous because it provides a specimen for histologic margin evaluation, heals rapidly, and is often cosmetically acceptable. The disadvantage of surgical excision is difficulty in estimating the surgical margin need, and the possibility of positive surgical margins following excision. Higher-risk lesions are often associated with significant, asymmetric subclinical extension. Some authors advocate monitoring incompletely

excised NMSC rather than reexcising them or performing Mohs' surgery.⁸⁹ We and the NCCN believe that this is not appropriate therapy. Recent reviews have further supported the need to treat incompletely excised NMSC.^{90,91}

CLINICAL EVIDENCE

One RCT by Avril et al. of 347 patients compared surgical excision with frozen section margin control versus radiotherapy in primary BCC.⁹² Lesions were less than 40mm in diameter, located on the face, and the growth pattern histology was nodular, ulcerated, superficial, and aggressive. The main outcome measure was histologically confirmed persistent tumor or recurrent tumor at 4 years. A second outcome measure was final cosmetic result. The results demonstrate that there were significantly more persistent or recurrent tumors (11 in 173) at 4 years in the radiotherapy group as compared to the surgery group (1 in 174). This finding equates to an odds ratio of 0.09 [95% confidence interval (CI), 0.01–0.67] in favor of surgery. Cosmetic outcome at 4 years was better in the surgery group. Patients assessed their cosmetic results as good in 87% of the cases following surgery and in 69% after radiotherapy (Table 60.6).

A retrospective review of 588 primary BCC treated with surgical excision demonstrated that BCC less than 6mm in diameter on the head had recurrence rates of 3.2%, whereas larger tumors had recurrence rates of 5% to 9%.⁶⁰ Tumors of any size excised from the ear, nasolabial groove, scalp, or forehead had much greater recurrence rates, 42.9%, 20.2%, 14.7%, and 8.4%, respectively.⁶⁰ Surgical excision of recurrent BCC is less effective than excision of primary BCC. In the systematic review by Rowe et al., the average 5-year recurrence rate for excision of recurrent tumors was 17.4%.⁵⁷

There has been no RCT assessing the role of surgical excision of cutaneous SCC. The prospective study by Brodland and Zitelli found a 95% clearance rate for SCC less than 2cm in diameter with a margin of 4mm of normal skin and a 96% clearance rate of tumors more than 2cm with a margin of 6mm.⁸⁸ The systematic review by Rowe et al. demonstrated that the recurrence rate after excision of low-risk lesions ranges from 5% to 8%.⁶⁹ High-risk lesions larger than 2cm had a recurrence rate of 15.7% after excision, and the recurrence rate for tumors less than 2cm in size was 5.8%. Poorly differentiated lesions recurred at a rate of 25% after excision, compared with well-differentiated lesions that recur at a rate of 11.8%.⁶⁹

Mohs' Micrographic Surgery

Histopathologic processing via bread loafing of standard surgical excision specimens examines less than 1% of the true surgical margin; this is problematic in higher-risk NMSC

given its high incidence of subclinical extension, which may also be highly asymmetric. Mohs' micrographic surgery (MMS) is an effective procedure in the treatment of NMSC. The tumor is excised with narrow margins and processed using horizontal frozen sectioning, with total (theoretical 100%) margin control. The procedure is named after its inventor, Dr. Frederic E. Mohs. Originally, a zinc chloride chemical paste was applied to the skin to "fix" the tissue in situ. Dr. Mohs and Dr. Theodore Tromovitch modified the technique in the 1970s to its current "fresh tissue" technique. The term chemosurgery is no longer used because of the advent of the fresh tissue technique. The American College of Mohs Micrographic Surgery and Cutaneous Oncology is the "gold standard" body of the field, and certification requires completion of an approved 1- to 2-year fellowship following residency. By definition, the Mohs surgeon functions as both the operative surgeon and pathologist, and through fellowship training the Mohs surgeon becomes adept at microscopic interpretation of horizontally cut frozen sections as well as local flap and graft soft tissue reconstruction techniques.

Mohs' surgery is performed under local anesthesia in an outpatient setting. Briefly, the clinically evident tumor is outlined and anesthetized, and then all gross tumor is removed. Next, a disk of tissue in the shape of a saucer is excised with 1- to 3-mm-deep and peripheral margins. The skin edges are beveled at 45° to assist in tissue processing of the peripheral edges. The specimen is then divided, color-coded, and a schematic map is made for precise anatomic orientation. The specimen is then flipped over and flattened so that the beveled skin edge is placed in the same horizontal plane as the deep margin. The Mohs histotechnician cuts horizontal frozen sections that incorporate the entire undersurface and epidermal skin margin for histologic interpretation. The slides are processed, stained, and reviewed by the Mohs surgeon, who acts as both the surgeon and the pathologist. If residual tumor is noted, the patient returns to the operative suite and the exact area of positivity is again excised, mapped, color-coded, and sent to the Mohs histotechnician for horizontal frozen sectioning. This process is repeated until all margins are free of tumor. In this manner, maximal normal tissue is conserved, and 100% of the margin is examined. Reconstruction can be performed immediately after margins are free (Figure 60.8).

Mohs' surgery is a labor-intensive technique and requires an experienced team. Good-quality Mohs' frozen sections are essential and require additional histotechnician training and experience. Mohs' surgery often requires a multidisciplinary approach for difficult tumors. Collaboration with surgeons from other specialties such as plastic, oculoplastic, and head and neck is important for complex tumors and reconstructions.

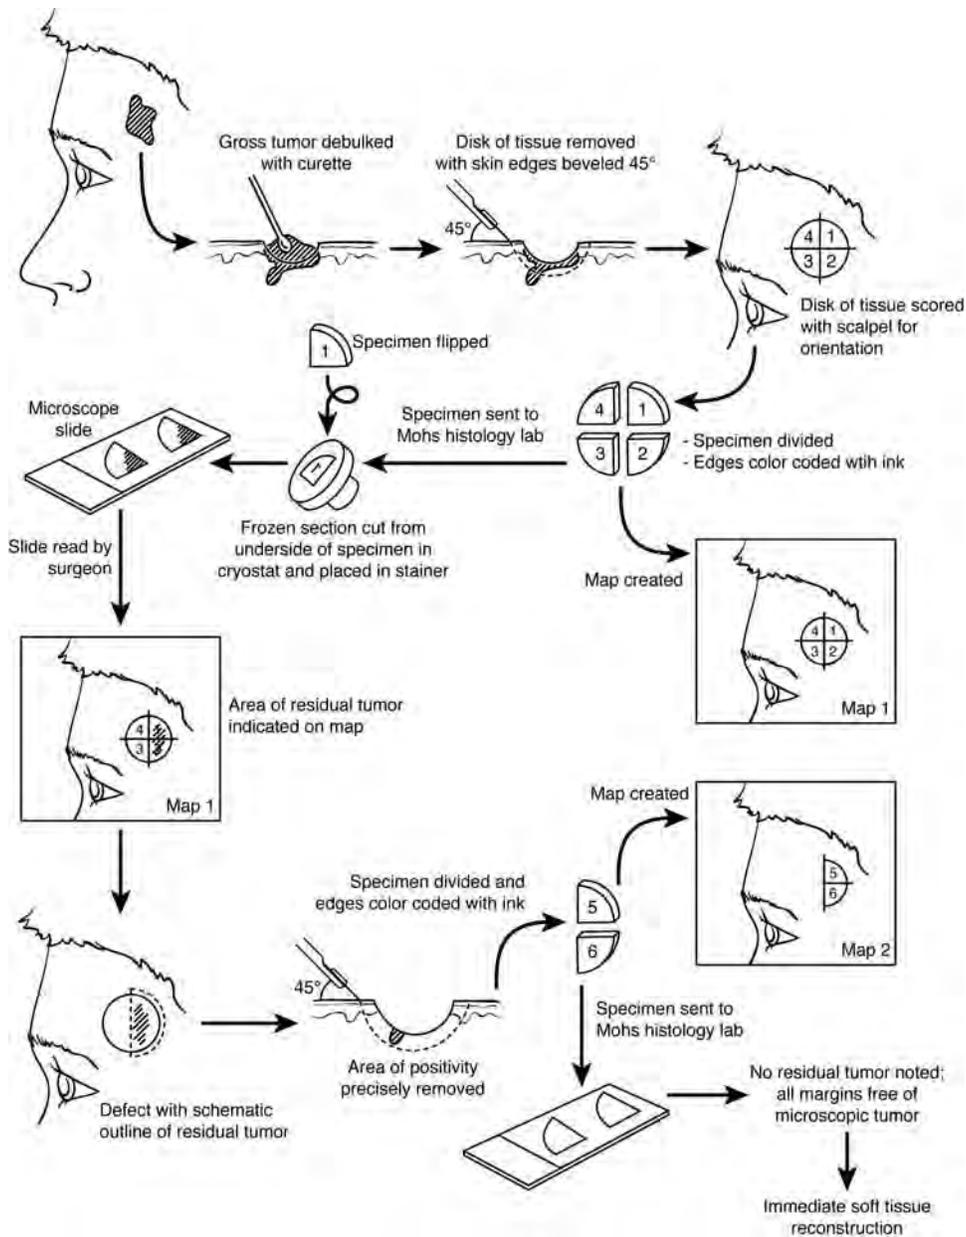

FIGURE 60.8. Schematic diagram of Mohs' surgery technique for the treatment of nonmelanoma cutaneous malignancy (NMSC). Residual tumor is noted in stage I; the area of positivity is deli-

neated and excised in stage II. Once margins are tumor free, reconstruction may occur.

CLINICAL EVIDENCE

There have been no RCT comparing MMS with other treatment modalities for treatment of NMSC. A systematic review by Rowe et al. analyzed all studies since 1950 that reported recurrence rates for primary BCC.⁵⁷ The 5-year cure rate for primary BCC treated with MMS was 99% (based on 7,670 tumors). For recurrent BCC, the 5-year cure rate for MMS was 94%. A study of 145 patients with primary BCC treated with MMS and followed for 5 years demonstrated a raw recurrence rate of 0.7% (1 in 145) and a strict recurrence rate of 0.8% (1 in 117).⁹³ Mohs et al. reported on the efficacy on MMS for the treatment of primary BCC located on high-risk sites such as

the ear and eyelid. A study of 1,032 patients with primary BCC located on the ear, a known high-risk site for recurrence, treated with MMS demonstrated a raw recurrence rate of 1.3% (13 in 1,032) and a strict recurrence rate of 1.7% (13 in 748).⁹⁴ A similar study of 1,483 patients with primary BCC of the eyelid, another high-risk site, showed a raw recurrence rate of 0.5% (7 in 1,483) and a strict recurrence rate of 0.6% (7 in 1,124).⁹⁵

An extensive review of all studies since 1940 reported the local recurrence rate for MMS, and standard surgical excision documented a local recurrence rate of 3% for MMS compared with 8% for primary surgical excision of cutaneous SCC.⁶⁹ For primary SCC located on the lip, the recurrence rate was

3.1% compared with 10.9% for non-MMS. For SCC located on the ear, the recurrence rate was 5.3% for MMS compared with 18.7% for non-MMS modalities.

In sum, MMS is a highly effective treatment modality for treatment of NMSC. Although there have been no RCT, MMS offers exceptionally high cure rates with maximal preservation of normal tissue. Despite the lack of RCT, the profound benefit of the procedure has been proven and documented in the literature. The NCCN Non-Melanoma skin cancer panel has recognized the benefit of MMS, and it is a primary treatment modality for high-risk and recurrent lesions.

Radiation Therapy

Fractionated radiation therapy (RT) is an effective therapy for NMSC and with proper tumor and patient selection can obtain a cure rate greater than 90% with excellent cosmetic results. Favorable lesion characteristics include low- to medium-risk tumors. Patient characteristics that would favor RT include patients who are poor surgical candidates. Radiation therapy is a primary treatment modality endorsed by the NCCN guidelines. Experience and a clinical understanding of NMSC are vitally important. Contraindications for RT include genodermatoses predisposing to skin cancer (nevroid BCC syndrome and xeroderma pigmentosum) and connective tissue disease (lupus and scleroderma).

CLINICAL EVIDENCE

Two RCTs have been conducted comparing RT with cryosurgery and surgical excision and have already been described (see Tables 60.5, 60.6).^{80,92} Both trials demonstrated low recurrence rates, ranging from 2% to 6%, and excellent cosmetic results for the treatment of primary BCC. RT was superior to cryosurgery but not surgical excision.

A large review of 2,314 patients with primary BCC treated with RT showed a cumulative recurrence rate of 13.2%.⁶¹ Fischbach et al. reviewed 231 patients with BCC and 67 patients with SCC and found 2-year recurrence rates of 7.8% and 14.9%, respectively.⁹⁶ Petrovich et al. examined 447 primary BCC treated with RT and noted a 10-year recurrence rate of 2%.⁹⁷ In that same study, 115 patients with SCC were treated with RT and had a 10-year recurrence rate of 12%. This study showed a definite relationship in both BCC and SCC between local control at 5 years and tumor size. Local control at 5 years was 99% for lesions less than 2 cm, 92% for tumors 2 to 5 cm, and 60% for tumors more than 5 cm.

Lasers and Photodynamic Therapy

Laser therapy and photodynamic therapy (PDT) have been reported for treating NMSC. Both are new technologies and are considered experimental by the NCCN consensus committee. Zeitouni et al. performed a recent review of the literature, which consists primarily of case reports and small series.⁹⁸ Most of these cases involve low-risk, superficial lesions that are easily treated by a variety of modalities. The primary laser used to treat NMSC is the carbon dioxide (CO₂) laser. The CO₂ is essentially a destructive modality similar to ED&C. Photodynamic therapy involves the administration of a photosensitizing drug (either systemic or topical) and its subsequent activation by light (laser or nonlaser light) to produce activated oxygen species that selectively destroy target cells. Light sources include the diode laser and nonlaser light such as filtered halogen or xenon arc lamps, blue light fluorescent tubes, and light-emitting diode (LED) arrays.

CLINICAL EVIDENCE

There has been no RCT comparing treatment of NMSC by CO₂ laser to other modalities. Early reports concerning the effectiveness of CO₂ laser therapy for primary BCC documented a 50% recurrence rate.⁹⁹ However, a more-recent study of 370 superficial BCC demonstrated no recurrences with 20 months of follow up.¹⁰⁰ In this study, however, curettage was also used along with the CO₂ laser. The use of CO₂ laser for the treatment of SCC in situ has been reported.¹⁰¹ The high recurrence rate is most likely due to follicular extension of the SCC in situ lesions, which is deeper than the depth treated with the CO₂ laser. In certain locations, such as the penis and distal digit, CO₂ laser has been reported to be successful and preserve function and good cosmesis.^{102,103} The best indication for CO₂ laser is in the treatment of the precancerous condition actinic cheilitis. CO₂ laser treatment of actinic cheilitis by means of superficial vermilionectomy has been extensively studied and is the treatment of choice.¹⁰

A RCT comparing PDT with cryosurgery for the treatment of primary BCC was described previously (Table 60.7). The study involved 88 primary BCC and compared cryosurgery with topical photodynamic therapy (PDT) for lesions located on the head, neck, and extremities; the follow up was 1 year.⁸² The recurrence rate at 1-year follow-up confirmed histologically was 15% for the cryosurgery group and 25% for the PDT group. The photosensitizer was topically applied 5-aminolevulinic acid (ALA). A systematic review of

TABLE 60.7. Clinical trials for topical photodynamic therapy (ALA-PDT) for treatment of primary NMSC.

Study	Year	Tumor type	Randomization	No. of patients (number of lesions)	Follow-up	Recurrence rate (%)	Clearance rate (%)
Wang et al. ⁸²	2001	BCC	PDT vs. Cryo	47 PDT 41 Cryo	1 year	25% PDT 15% Cryo	
Morton et al. ¹⁰⁶	1996	Bowen's	PDT vs. Cryo	20 PDT 20 Cryo	1 year		75% PDT (1 Tx) 50% Cryo (1 Tx)
Salim et al. ¹⁰⁷	2000	Bowen's	PDT vs. 5-FU	20 PDT (33 lesions) 20 5-FU (33 lesions)	1 year		82% PDT (27/33) 48% 5-FU (16/33)
Morton et al. ¹⁰⁸	2000	Bowen's	Red light vs. green light	32 red 29 green	1 year		94% red (30/32) 72% green (21/29)

Cryo, cryosurgery; PDT, topical ALA-photodynamic therapy; 5-FU, topical 5% 5-fluorouracil; Tx, treatment; BCC, basal cell carcinoma; Bowen's, squamous cell carcinoma in situ.

12 studies by Peng et al. demonstrated a weighted average complete clearance rate of 87% for 826 superficial BCC treated with PDT and a rate of 53% for 208 nodular BCC for a short follow up period of 3 to 36 months.¹⁰⁴ Nodular and aggressive-growth pattern BCC respond poorly.

PDT has been documented to treat Bowen's disease; 13 cases and 3 RCTs have been reported. A single ALA-PDT treatment cleared 86% (6 studies, 71 of 83 patients); this number rose to 93% when one or two treatments were performed (9 studies, 239 of 257 patients).¹⁰⁵ The recurrence rate ranged from 0% to 40% (average, 12%) during a follow-up period of 3 to 36 months, and most lesions were small. A RCT comparing PDT with cryotherapy for the treatment of 40 small Bowen's disease lesions demonstrated the PDT was at least as effective as cryotherapy. PDT displayed a higher rate of clearance, 75% after a single treatment compared with 50% for the cryotherapy group.¹⁰⁶ A RCT comparing ALA-PDT with topical 5-fluorouracil (5-FU) showed a complete clinical response of 82% (27 of 33 lesions) for the ALA-PDT group compared to 48% clearing (16 of 33 lesions) for the 5-FU group at 12 months follow-up.¹⁰⁷ Although these were RCTs, the evidence they provide is suspect because of the short follow-up period and response rates much lower than with standard treatment modalities such as surgery, ED&C, or RT. A RCT comparing different wavelengths of light used as the light source for ALA-PDT demonstrated that the more-penetrating red light (630 ± 15 nm) had a significantly higher clearance rate than green light (540 ± 15 nm).¹⁰⁸

The use of ALA-PDT for primary treatment of invasive SCC is controversial. ALA-PDT has also been reported in the treatment of SCC but is noted to have high recurrence rates (up to 69%) and, in light of the metastatic potential, even strong advocates of ALA-PDT do not recommend it for SCC.¹⁰⁵

In sum, the current evidence does not support the use of laser therapy as a primary treatment modality for NMSC. Similarly, current efficacy data do not support the introduction of PDT for the treatment of BCC, SCC in situ, and invasive SCC without further studies. Currently, there are no 5-year follow-up data, and therefore no direct comparison of ALA-PDT can be made with conventional therapies. However, considerably higher failure rates were associated with PDT when compared to failure rates for surgery, radiotherapy, and cryosurgery described in other studies.

Medical Treatments

Alternatives to surgical treatment of NMSC exist and may be used in certain circumstances, such as debilitated patients or extensive or multifocal lesions. Medical therapy of NMSC includes the biologic response modifiers such as intralesional interferon and topical 5% imiquimod cream, as well as topical chemotherapeutic agents such as topical 5-fluorouracil.

Clinical Evidence

INTRALESIONAL INTERFERON

Three randomized controlled trials have been performed in regard to intralesional interferon (IFN) and BCC (Table 60.8). The first trial, of 165 patients with either nodular or superficial BCC on the head, neck, face, trunk, and extremities, compared interferon-alpha-2b (IFN- α -2a) at 1.5 million units three times weekly for 3 weeks with placebo vehicle in a 3:1 ratio of interferon-treated to placebo-treated patients.¹⁰⁹ Early treatment failure at 20 weeks confirmed by punch biopsy was 14% (17 of 120) in the interferon (IFN) group and 71% (30 of 42) in the placebo group. A second trial of 45 patients with BCC was randomized to receive IFN- α -2a, IFN- β -2a, or a combination.¹¹⁰ IFN- α -2a is a related cytokine with similar mechanism of action that differs from IFN- α -2b by only one amino acid. Increased effectiveness was not shown with combination therapy. In the third RCT of 65 patients, a single dose of 10 million IU of a sustained-release IFN- β -2a was compared with the same dose weekly for 3 weeks.¹¹¹ The early treatment failure measured histologically at 16 weeks was 48% (16 of 33) in the single-injection group and 20% (6 of 30) for the three-times-weekly injection.

The use of intralesional interferon as primary treatment for SCC has been reported; however, no RCT exist. A trial of 28 invasive SCC and 8 SCC in situ were treated with intralesional IFN- α -2b. Lesions ranged in size from 0.5 to 2.0 cm.¹¹¹ Each patient was injected with 1.5 million IU intralesionally, three times per week. At 18 weeks, treatment sites were excised and examined histologically for tumor persistence. Thirty-three (97.1%) of 34 lesions revealed an absence of SCC histologically after therapy, although three biopsy specimens

(8.8%) obtained after treatment showed actinic keratoses, for an overall complete response rate of 88.2%. The lesion not eliminated after treatment was an invasive squamous cell carcinoma.

In sum, the evidence does not support the use of intralesional IFN as a primary treatment modality for BCC or SCC. Intralesional IFN has a high percentage of early failure rates and does not compare with current standards of surgical or radiotherapy cures.

IMIQUIMOD

A total of 8 RCT were found regarding the use of topical imiquimod 5% cream for primary BCC (Table 60.9). Beutner et al. examined the efficacy and safety of imiquimod in the treatment of superficial and nodular BCC located on the trunk, ranging in size from 0.5 to 2 cm².¹¹² A total of 35 patients were selected, with 24 receiving imiquimod and 11 receiving vehicle in one of five dosing regimens for up to 16 weeks. Treatment failures from the different dosing regimens were combined and compared with the vehicle; there was a significant reduction in early treatment failures with imiquimod as compared to the vehicle [odds ratio (OR) 0.02;

95% confidence interval (CI), 0.00–0.02]. Geisse et al. compared regimens of twice-daily, once-daily, 5 days per week, or 3 days per week versus vehicle for superficial BCC.¹¹³ Lesions ranged in size from 0.5 to 2 cm². Early treatment failures were 0% (0 of 10), 13% (4 of 31), 11% (5 of 26), and 48% (14 of 29), respectively; vehicle failure rate was 26 of 32 (81%).

Robinson et al. evaluated imiquimod for nodular BCC using the same four regimens as Geisse for a period of 12 weeks.¹¹⁴ Early treatment failures were 25% (1 of 4), 24% (5 of 21), 30% (7 of 23), and 40% (8 of 20), respectively; vehicle early treatment failure rate was 78% (21 of 24). Marks et al. examined imiquimod applied for 6 weeks in 99 patients with superficial BCC.¹¹⁵ Lesions ranged in size from 0.5 to 2.0 cm². Posttreatment biopsy clearance rates were reported as 100% (3 of 3), 88% (29 of 33), 73% (22 of 30), and 70% (23 of 33) for twice-daily, once-daily, 5 days per week, and 3 days per week regimens, respectively. There was a trend toward higher doses of imiquimod having fewer treatment failures as compared to lower doses. Another trial of 99 patients evaluated treatment of nodular BCC with imiquimod using various dosing schemes.¹¹⁵ Results demonstrate a trend toward fewer treatment failures using higher doses of imiquimod compared with lower doses (OR, 95% CI, 0.18–1.01). Another study of

92 patients with nodular BCC treated with once-daily, 5 days per week, or 3 days per week imiquimod was compared with vehicle.¹¹⁶ Early treatment failure rates were 24%, 30%, 40%, and 87%, respectively.

Two studies examined the role of occlusion and found no significant difference in early treatment failure rates.¹¹⁷ Sterry et al. reported 90 patients with nodular BCC with regimens of 3 days per week with and without occlusion and 2 days per week with and without occlusion, respectively.¹¹⁷ Early treatment failure rates were 35% (8 of 23), 50% (12 of 24), 50% (11 of 22), and 43% (9 of 21), respectively, and there was no significant difference in early treatment failure when occlusion was used (OR 1.20; 95% CI, 0.29–1.52).

Imiquimod has been reported to treat SCC in situ. A Phase II open labeled study examined the use of imiquimod once daily for 16 weeks in 16 patients.¹¹⁸ Almost all lesions were located on the legs (15 of 16), and lesions ranged in size from 0.7 to 21.6 cm². Posttreatment biopsies at 6 weeks revealed no residual tumor in 14 of 15 patients, corresponding to an early treatment failure of 7% (1 of 15). One patient died of an unrelated illness before a biopsy could be obtained. Several case reports have documented the efficacy of imiquimod in treating SCC in situ on the penis.^{119,120} Recently, 2 cases of SCC were reported treated with imiquimod.¹²¹

Side effects and potential drawbacks for topical imiquimod 5% cream include a high rate of significant local skin reaction, such as erythema, pain, edema, vesicles, erosion, and ulceration. In all studies local reactions were common, and some patients were unable to finish studies secondary to moderate to severe local reactions.

No long-term study (3–5 years) of the efficacy of imiquimod in the treatment of NMSC has been performed. As stated previously, 1-year or shorter-duration follow-up periods are inadequate and can falsely improve treatment success rates. No RCT has compared imiquimod with standard treatment modalities such as ED&C, surgery, or radiation.

5-FLUOROURACIL

Two RCTs were identified in the use of topical 5-fluorouracil (5-FU) for the treatment of BCC (Table 60.10). The first trial compared 5% 5-FU cream in phosphatidyl choline (PC)

vehicle with 5% 5-FU in petrolatum for nonsuperficial BCC at least 0.7 cm in greatest diameter, not located on the face.¹²² Early treatment failure measured histologically at 16 weeks was 10% for the phosphatidyl choline cream compared with 43% for the petrolatum preparation. The second trial of 122 patients tested the efficacy of six treatment regimens using 5-FU/epinephrine gel.¹²³ Overall, the six regimens had an average early treatment failure of 9% documented histologically at 3 months after treatment. Side effects included local irritation, erythema, and ulceration.

One RCT comparing 5-FU with PDT has been described previously.¹⁰⁷ The complete clearance rate of the 5-FU group was 48% compared with 82% for the PDT group. Numerous case reports and small series have reported successful treatment of SCC in situ and invasive SCC following treatment with 5-FU. Most of these studies had small numbers of patients with short follow-up periods. Current evidence does not support the use of topical 5-FU as a primary treatment for BCC, SCC in situ, or invasive SCC.

Prevention and Follow-Up

Sun protective measures such as avoiding the sun during the middle of the day, sun protective clothing and shade seeking, and sunscreens are effective for NMSC prevention. A RCT found significantly fewer new actinic keratoses with daily sunscreen use versus placebo.¹²⁴ Another RCT found a 40% relative reduction in the incidence of SCC with daily application of sunscreen to the head, neck, arms, and hands compared with discretionary application.¹²⁵

Patients who have been diagnosed with NMSC need continued follow up to facilitate early detection of new tumors or tumor recurrence. Marcil and Stern performed a meta-analysis of the risk of developing a subsequent NMSC in patients with a history of NMSC in 2000.¹²⁶ They found an overall 3-year cumulative risk of a subsequent BCC after an index BCC was 44%, which was at least a 10-fold increase in incidence over baseline. Similarly, for SCC, the overall 3-year cumulative risk was 18%, which was also a 10-fold increase in incidence. All patients should be instructed on how to perform self-skin examinations, and these should be performed monthly. Additionally, patients with high-risk SCC should be instructed to palpate the regional lymph nodes monthly to detect for regional metastasis.

TABLE 60.10. Medical therapy: clinical trials of topical 5-fluorouracil for treatment of primary NMSC.

Study	Year	Tumor type	No. of patients (number of lesions)	Randomization	Early treatment failure (%)	Conclusions
Romagosa et al. ¹²²	2000	BCC	13 (17 lesions)	10 5-FU/PC 7 5-FU/PL	10% 5-FU/PC 43% 5-FU/PL	Increased short-term clearance with 5-FU/PC over 5-FU/PL
Miller et al. ¹²³	1997	BCC	122	6 different treatment regimens using 5-FU/epi gel	Overall 9%	No statistically significant differences between regimens
Salim et al. ¹⁰⁷	2000	SCC in situ	40 (66 lesions)	20 5-FU (33 lesions) 20 PDT (33 lesions)	52% 18%	5-FU less effective for short-term eradication compared to PDT

5-FU, 5% 5-fluorouracil; 5-FU/PC, = 5% 5-fluorouracil cream in phosphatidyl choline vehicle; 5-FU/PL, 5% 5-fluorouracil in petrolatum; 5-FU/epi gel, 5% 5-fluorouracil/epinephrine gel; PDT, topical ALA-photodynamic therapy.

Cancer of Unknown Primary Site

F. Anthony Greco and John D. Hainsworth

In the United States, unknown primary cancers represented about 2% of all cancer diagnoses reported between 1973 and 1987.¹ Registries from seven other countries have listed incidences from 2.3% to 7.8%.² These patients are heterogeneous with several clinical presentations and histologic tumor types. Most have metastatic carcinoma of unknown primary site, while others have equivocal pathologic diagnoses with tumors difficult to classify by light microscopic examination. Specialized pathologic studies are essential in diagnosing the type of neoplasm present in many of these patients.

The nature or biology of the primary tumor in patients with unknown primary cancers is enigmatic. The clinical and biologic information suggest that some of these patients represent a distinct entity. Some of these patients have occult primaries found occasionally during the course of their disease, and more commonly at autopsy. Several other possible explanations for the apparent absence of a primary cancer can be contemplated. First, some patients have an unrecognized primary neoplasm (not an unknown primary cancer) inadvertently believed to represent a metastatic lesion. Extragonadal germ cell tumor, lymphoma, melanoma, or sarcoma are examples that arise from these lineages anywhere in the body. Second, primary cancers may inexplicably involute or regress entirely after metastasis has occurred. This notion is supported by the scarring seen occasionally in the testicle of patients with metastatic germ cell neoplasms. Third, tumors may have arisen from embryonic "rest cells" failing to complete their appropriate migration in utero to their appropriate tissue/organ. Extragonadal germ cell tumors with primaries in the mediastinum or undescended testicular cancer are examples of this phenomenon. Fourth, the pathogenesis of these carcinomas may result from a specific genetic lesion present in all cells, and these tumors arise from a second mutation or carcinogenetic event. This mechanism is suggested by the unusual occurrence of metastatic adenocarcinoma of unknown primary site in monozygotic twin brothers with primary immunodeficiency disorder (X-linked hyper IgM syndrome).³ Finally, some of these cancers may arise from adult stem cells exhibiting plasticity.^{4,5} Hematopoietic stem cells are able to transform into several cell types including liver, muscle, gastrointestinal, skin, and brain.⁴ Some unknown primary tumors might continue to reflect such a transformation of adult stem cells and may in fact be "tumors of adult stem cells." Seemingly metastatic adenocarcinoma in lymph node, liver, bone, or elsewhere may, in fact, have arisen from an adult stem cell with the

capacity to transform into any cell and subsequently develop as a "primary" neoplasm in any of these tissues.⁵ Unknown primary tumors all possess a metastatic phenotype. When a primary is clinically undetectable, the natural history may in some patients vary from known primary cancers.

Karyotypic analysis of metastatic carcinoma of unknown primary site usually demonstrates diverse multiple complex random abnormalities not yet helpful in most instances for diagnosis or classification but is more representative of advanced neoplasms of many types.⁶ No direct evidence exists to support a common/nonrandom genetic profile for even a portion of unknown primary tumors. Recently, however, gene expression profiles of known primary tumors suggest that the metastatic potential of tumors is encoded in most of the primary tumor, rather than rare cells within the primary tumor.⁷ About 10% of poorly differentiated carcinomas of unknown primary strongly express Her-2-neu,⁸ and these patients may be reasonable candidates for a trial of anti-Her-2-neu antibody therapy (trastuzumab). The vascular endothelial growth factor (VEGF)^{9,10} and the epidermal growth factor receptor (EGFR) are also commonly expressed in several epithelial neoplasms, including unknown primary carcinoma, and therapy with EGFR and VEGF inhibitors is being explored. A much better understanding of unknown primary cancer is likely to arise from the development and study of gene expression profiling of these and other neoplasms.

Several important issues have changed over the past 20 years in oncology. Combination chemotherapy, often used with surgery or radiation therapy, has proved to be potentially curative for some patients with several metastatic tumors. Palliation and prolongation of survival has been possible for some patients with many other tumor types following systemic therapy. Therapy is evolving. Several new and useful biologic targeted agents such as rituximab, trastuzumab, imatinib, and gefitinib are now available. Improving therapies for several known solid tumors is relevant for patients with unknown primary cancer because several of these patients are also likely to respond to these therapies.

Electron microscopy and immunohistochemistry and more recently molecular genetics are responsible for more accurate and precise diagnosis of neoplasms. Several clinical syndromes and features are also being recognized and are helping physicians to better manage these patients.

Patient management requires an understanding of clinicopathologic features that help to identify several subsets of patients with more-responsive tumors. A patient with cancer

of unknown primary site usually develops symptoms or signs at a metastatic site, and the diagnosis is made by biopsy of a metastatic lesion. History, physical examination, and other evaluation of the patient fail to identify the primary site. Routine light microscopic histology establishes the neoplastic process and provides a useful classification system on which to further evaluate and manage these patients. There are four major light microscopic diagnoses: (1) poorly differentiated neoplasm, (2) poorly differentiated carcinoma (with or without features of adenocarcinoma), (3) well-differentiated and moderately well differentiated adenocarcinoma, and (4) squamous cell carcinoma.

Poorly Differentiated Neoplasms of Unknown Primary Site

In these patients, the pathologic diagnosis of a neoplasm is clear, but the lineage (e.g., carcinoma, lymphoma, melanoma, sarcoma) is not established. A precise diagnosis is essential for these patients because many have responsive tumors. About 5% of all patients with cancers of unknown primary site present with this diagnosis by initial light microscopic appearance, but most are diagnosed by specialized pathologic study. Thirty-five percent to 65% of poorly differentiated neoplasms have large cell lymphomas after further pathologic study.¹¹⁻¹⁴ Most of the remaining tumors are carcinomas, with melanoma and sarcoma accounting for less than 15%.

Immunoperoxidase tumor staining, electron microscopy, and genetic analysis are helpful in the diagnosis. An adequate biopsy is essential, and frequently a more-definitive diagnosis can be made by obtaining a larger biopsy. Special tissue processing may be necessary for some pathologic studies. Rarely tumors remain unclassifiable after additional specialized pathologic study.

Specialized Pathology

Immunoperoxidase staining is the most common and widely available specialized pathologic technique for the classification of cancers. Examples of some immunoperoxidase staining patterns that are useful in the differential diagnosis of various neoplasms are listed in Table 61.1.

Many important issues can usually be answered by immunoperoxidase staining. The common leukocyte antigen (CLA) stain is used to make the important distinction between lymphoma and carcinoma.^{15,16} Staining for chromogranin and synaptophysin suggests a neuroendocrine carcinoma. Prostate-specific antigen (PSA) staining highly suggests prostate carcinoma.^{17,18} Some stains in appropriate clinical situations suggest breast carcinoma (e.g., estrogen or progesterone receptors, gross cystic fluid protein),¹⁵ sarcoma (e.g., positive staining for desmin, vimentin, factor VIII antigen, c-kit-CD117 stain),¹⁹⁻²⁴ amelanotic melanoma (e.g., positive staining for S-100 protein, vimentin, HMB-45) or germ cell tumor [positive for the human chorionic gonadotropin (HCG)].^{25,26}

Poorly differentiated neoplasms identified as lymphoma by positive CLA staining respond well to the combination chemotherapy used for non-Hodgkin's lymphoma.¹¹ Their survival was similar to a group of concurrently treated patients who had typical non-Hodgkin's lymphomas.

TABLE 61.1. Useful immunoperoxidase tumor staining patterns in the differential diagnosis of neoplasms.

<i>Immunoperoxidase staining</i>	<i>Tumor type</i>
Epithelial stains (e.g., CK 7, 20 variable)	Carcinoma
EMA (+) CLA, S-100, vimentin (-)	Lung carcinoma
TTF-1 (+)	Adenocarcinoma
CK 7 (+), CK 20 (-)	Other non-small cell carcinoma
TTF-1 (-)	
TTF-1 (+), chromogranin (+)	Small cell carcinoma
NSE (+)	
CK 7 (-); CK 20 (+)	Colorectal carcinoma
ER, PR (+)	Breast carcinoma
Her-2-neu (+)	
CK 7 (+), CK 20 (-)	
Gross cystic fluid protein 15 (+)	
Epithelial stains (+)	
NSE, chromogranin, synaptophysin (+)	Neuroendocrine carcinoma
Epithelial stains (+)	
HCG, AFP (+)	Germ cell tumor
Placental alkaline phosphatase (+)	
Epithelial stains (+)	
PSA (+), rare false (-) and (+)	Prostate carcinoma
Epithelial stains (+)	
CK 7 (-), CK 20 (-)	Thyroid carcinoma
Thyroglobulin (+), TTF-1 (+)	Follicular/papillary
Calcitonin (+)	Medullary Sarcoma
Vimentin (+)	Mesenchymal
Epithelial stains usually (-)	
Desmin (+)	Rhabdomyosarcoma
Factor VIII antigen (+)	Angiosarcoma
CD117 (C-kit) (+)	Gastrointestinal stromal tumor
S-100, vimentin, HMB-45 (+)	Melanoma
NSE often (+)	
Synaptophysin (-)	
Epithelial stains (-)	
CLA (+), rare false (-)	Lymphoma
EMA occasionally (+)	
All other stains (-)	

+, positive result; -, negative result; AFP, alpha-fetoprotein; CK, cytokeratin; CLA, common leukocyte antigen; EMA, epithelial membrane antigen; ER, estrogen receptor; HCG, human chorionic gonadotropin; NSE, neuron-specific enolase; PR, progesterone receptor; PSA, prostate-specific antigen; TTF-1, thyroid transcription factor-1.

Electron microscopy can be useful in some poorly differentiated neoplasms, although it is not widely available, requires special tissue fixation, and is relatively expensive. If the lineage of a tumor is unclear after routine light microscopy and immunoperoxidase staining, electron microscopy should be done. Electron microscopy is also reliable in differentiating lymphoma from carcinoma. It may be superior to immunoperoxidase staining for diagnosis of poorly differentiated sarcoma. Subcellular structures such as neurosecretory granules (neuroendocrine tumors) or preme-lanosomes (melanoma) can suggest the tumor.

Genetic analysis (identification of chromosomal abnormalities and specific genetic changes) is becoming important. Tumor-specific chromosomal abnormalities in diagnosis is still limited but will likely become more important in the future.

The majority of B-cell non-Hodgkin's lymphomas are associated with tumor-specific immunoglobulin gene rearrangements, and specific chromosomal changes have been identified in some B-cell and T-cell lymphomas and in Hodgkin's disease.^{27,28} If the diagnosis of lymphoma cannot be definitively established with either immunoperoxidase staining or electron microscopy, detection of chromosomal translocations t(14:18); t(8:14); t(11:14) and others or the presence of an immunoglobulin gene rearrangement can be diagnostic.

Other nonrandom chromosomal rearrangements associated with nonlymphoid tumors have been identified but are unusual. Translocation of 11:22 (t11:22) has been found in peripheral neuroepitheliomas, desmoplastic small round cell tumors and in Ewing's tumor.²⁹⁻³¹ An isochromosome of the short arm of chromosome 12 (i12p) and other chromosome 12 abnormalities are frequently found in germ cell tumors.³²⁻³⁴ Other nonrandom cytogenetic abnormalities found in tumors include t(2:13) in alveolar rhabdomyosarcoma; 3p deletion in small cell lung cancer; 1p deletion in neuroblastoma; t(X:18) in synovial sarcoma; and 11p deletion in Wilm's tumor. Epstein-Barr viral genome found in tumor cells of patients with cervical lymph node metastases of unknown primary site suggests nasopharyngeal primaries.^{35,36}

DNA microarrays are being evaluated in several neoplasms³⁷ and hold promise as a method to classify neoplasms based upon gene expression profiling, perhaps identifying specific genetic patterns independent of previous histologic and biologic knowledge. This technique and others may eventually identify more specific tumor lineages or primary tumor types. Molecular classification of unknown primary carcinoma by gene expression is ongoing and is likely to provide more useful diagnostic and therapeutic information in unknown primary cancers.

Poorly Differentiated Carcinoma, with or Without Features of Adenocarcinoma, of Unknown Primary Site

Various subsets of patients with poorly differentiated carcinoma have been identified in the past 15 years. Specialized pathology has continued to improve and when used with clinical features has resulted in the recognition of several favorable subsets of patients with specific therapeutic implications. Poorly differentiated carcinoma account for about 30% of carcinoma of unknown primary sites, and about 33% have some features of adenocarcinomatous differentiation (poorly differentiated adenocarcinoma). Some patients have extremely responsive neoplasms, and therefore careful clinical and pathologic evaluation is necessary in patients with poorly differentiated carcinoma.

Clinical Characteristics

The clinical characteristics of these patients appear to differ with considerable overlap from the characteristics of patients

with well-differentiated adenocarcinoma. When considering the whole group as compared to well-differentiated adenocarcinoma (see subsequent section), the median age is younger and the symptom interval is shorter. Metastasis predominantly involve peripheral lymph nodes, mediastinum, and retroperitoneum.

Pathologic Evaluation

Chemotherapy-responsive tumors cannot be identified by light microscopic features. Immunoperoxidase staining is essential, and for selected tumors electron microscopy and genetic analysis is indicated. Rarely, lymphoma is diagnosed, even though the light microscopic features are more typical of carcinoma. Immunoperoxidase staining is helpful in the routine evaluation of metastatic poorly differentiated carcinoma. Occasionally, it may suggest the lineage of the tumor and have specific therapeutic implications.³⁸⁻⁴⁰

Electron microscopy can also be useful for a minority of these carcinomas. Electron microscopy should be done for those tumors not diagnosed by immunoperoxidase stains. Lymphoma can be diagnosed reliably, and sarcoma, melanoma, mesothelioma, and neuroendocrine tumors occasionally are defined by subcellular features.

Chromosomal or genetic analysis is continuing to evolve as an important diagnostic method. Several neoplasms have specific abnormalities. Motzer and associates performed genetic analysis on tumors in 40 poorly differentiated carcinoma patients with the extragonadal germ cell syndrome or "midline carcinomas of uncertain histogenesis."⁴¹ In 12 of the 40 patients, abnormalities of chromosome 12 (e.g., i[12p]; del [12p]; multiple copies of 12p) were diagnostic of germ cell tumor. Other abnormalities diagnostic of melanoma (2 patients), lymphoma (1 patient), peripheral neuroepithelioma (1 patient), and desmoplastic small cell tumor (1 patient) were also seen. Of the germinal neoplasms diagnosed on the basis of genetic analysis, 5 achieved a complete response to cisplatin-based chemotherapy. These data confirmed our previously formulated hypothesis that some of these patients have histologically atypical germ cell tumors.^{42,43} Additional specific genetic abnormalities or gene expression profiling in solid tumors almost certainly will improve our ability to establish tumor lineage or biology and perhaps also identify specific targets to improve therapy.

In the limited necropsy data available that we have accumulated, it appears that primary sites are found in only a minority of these patients (about 40%). These observations are contrary to those for well-differentiated adenocarcinoma of unknown primary site, in which an occult primary site is found in most patients (about 75%) at autopsy.^{44,45}

Diagnostic Evaluation

A history, physical examination, and routine laboratory testing, including a chest radiograph, should be done in each patient. Any abnormalities are followed with appropriate diagnostic testing. Computed tomography (CT) scans of the chest and abdomen should be performed because of the frequency of mediastinal and retroperitoneal involvement. Serum levels of HCG and alpha fetoprotein (AFP) should be measured. Elevations of these markers suggest the diagnosis of germ cell tumor. Serum tumor markers, such as carci-

noembryonic antigen (CEA), CA 125, CA 19-9, and CA 15-3 can help in monitoring response to chemotherapy but are not specific enough to be useful in diagnosis. Positron emission tomography (PET) scanning appears to have a role in suggesting the primary cancer in about 20% to 30% of patients.⁴⁶⁻⁵⁴

Treatment

Appropriate therapy can be given when additional pathologic studies identify a specific neoplasm (e.g., lymphoma, sarcoma). Patients with clinical features highly suggestive of extragonadal germ cell tumor (e.g., mediastinal or retroperitoneal mass and elevated serum levels of HCG or AFP) should be treated with chemotherapy effective for germ cell tumors. Despite specialized pathologic study, most patients have multiple metastases and are left with the nonspecific diagnoses of poorly differentiated carcinoma or poorly differentiated adenocarcinoma. A small subset of these patients have highly responsive tumors.^{43,55-57} These patients were usually young men with mediastinal tumors; serum levels of HCG or AFP were frequently elevated. These patients were thought to have histologically atypical extragonadal germ cell tumors. Other tumor types have also subsequently been identified in some of these patients (i.e., thymoma, neuroendocrine tumors, sarcomas, lymphomas), but many others have not been precisely classified. Further evidence for the responsiveness of many other tumors in patients with poorly differentiated carcinoma of unknown primary site has accumulated since 1978.^{38,29,42,58-60}

An update of our initial prospective study in 220 of patients treated with cisplatin-based chemotherapy shows the following: 12% of the entire group have remained alive and free of tumor at a minimum follow-up of 6 years with a range of 6-17 years; the median survival for all patients was 20 months (3 years for complete responders); of the 58 complete responders, 22 patients remain relapse free (38%), representing 10% of the entire group. These results supported the notion that some of this poorly differentiated histology represents more sensitive tumors than well-differentiated adenocarcinoma, and prolongation of life was possible for some of these patients with the expectation of cure for a small minority. In those relatively rare patients with features of an extragonadal germ cell tumor, a standard regimen for the treatment of testicular or extragonadal germ cell tumors should be administered.

We now know that a large number of the 220 patients in the initial study had favorable subsets, each with a relatively good prognosis: these included (a) patients with poorly differentiated neoplasms otherwise not specified; (b) patients with the extragonadal germ cell syndrome; (c) patients with anaplastic lymphoma diagnosed as carcinoma; (d) patients with primary peritoneal carcinoma; (e) patients with poorly differentiated neuroendocrine carcinoma; and (f) patients with predominant sites of tumor involving the retroperitoneum, mediastinum, and peripheral lymph nodes. The nature of many of the other carcinomas remains obscure. Others have also reported the responsiveness of selected poorly differentiated carcinomas.⁶¹⁻⁶⁶ Complete responses were seen in 10% to 20% of these patients, and 5% to 10% were long-term disease-free survivors. These results were usually seen with platinum-based chemotherapy.

Our more-recent experience has excluded or stratified these more-favorable subsets of patients in our clinical trials, with the remaining patients having more unfavorable features and poor prognoses. These patients with unfavorable features have a similar prognosis to the large majority of the well-differentiated adenocarcinoma group (discussed later), and thus we now include all these patients in new clinical trials.

The Minnie Pearl Cancer Research Network has treated 396 patients since 1995 on five sequential prospective Phase II clinical trials incorporating several newer drugs (paclitaxel, docetaxel, gemcitabine, irinotecan). Patients with favorable prognostic features were excluded from these trials. As discussed later, the long-term survival seen in these patients suggests a major improvement in survival with these newer therapies.

Neuroendocrine Carcinoma of Unknown Primary Site

These neoplasms have been more readily recognized in recent years with the development of improved pathologic techniques. Well-differentiated or low-grade neuroendocrine tumors such as typical carcinoid or islet cell tumors occasionally present with metastases, without a clinically detectable primary site. These tumors usually have an indolent natural history. Carcinoid tumors of unknown primary have been appreciated for years.¹ There are also two groups of neuroendocrine tumors that are poorly differentiated by light microscopy. The first group of tumors have neuroendocrine light microscopic features (typical small cell, atypical carcinoid, or poorly differentiated neuroendocrine carcinoma) and act aggressively. The second group of neuroendocrine tumors, recently recognized, has high-grade biology and usually no neuroendocrine features by light microscopy. In this group, the diagnosis by light microscopy is poorly differentiated carcinoma, and neuroendocrine features are only recognized when immunoperoxidase staining or electron microscopy is performed.

Low-Grade Neuroendocrine Carcinoma

In these tumors, the metastatic sites usually involves the liver and/or bone, and these are sometimes associated with clinical syndromes produced by the secretion of bioactive substances (e.g., carcinoid syndrome, insulin production, glucagonoma syndrome, vipomas [vasointestinal peptide producing tumors], Zollinger-Ellison syndrome). Primary sites should be sought in the small intestine (particularly the ileum), rectum, pancreas, or bronchus.

These tumors usually exhibit an indolent biology, and slow progression over years is typical. These patients should be managed the same as those with metastatic carcinoid or islet cell tumors from known primary sites. Intensive systemic chemotherapy with cisplatin-based chemotherapy is not useful for most patients as the response rates are low.⁶⁷ Appropriate management may include local therapy (resection of isolated metastasis, hepatic artery ligation/embolization, cryotherapy, radiofrequency ablation), treatment with somatostatin analogues, streptozocin, doxorubicin, 5-fluorouracil-based systemic therapy, or symptomatic management.

Small Cell Carcinoma

A lung primary should be suspected, but when no primary is identified, patients with small cell carcinoma should be treated with combination chemotherapy as recommended for small cell lung cancer. Paclitaxel, carboplatin, and oral etoposide is a very active therapy for these patients, and we have continued to evaluate this regimen. Most of these tumors are initially very sensitive to chemotherapy, and major palliative benefit can be derived from treatment. Some patients will enjoy long-term benefit. Rarely these tumors present as a single metastatic site, and the addition of radiation therapy and/or resection to combination chemotherapy should be considered.

Poorly Differentiated Neuroendocrine Carcinoma

In a small minority of poorly differentiated carcinomas, electron microscopy reveals neurosecretory granules, a finding diagnostic of neuroendocrine carcinoma. In the past, these tumors have been called: poorly differentiated neuroendocrine tumors, atypical carcinoids, or primitive neuroectodermal tumors. Electron microscopy is the most definitive diagnostic technique, but most of the tumors also have typical immunoperoxidase staining patterns with positive staining for neuron-specific enolase, chromogranin, or synaptophysin.

We reported 29 patients with poorly differentiated neuroendocrine tumors of unknown primary site⁵⁸ and later updated our experience to include a total 51 of patients.⁶⁸ These patients had clinical evidence of high-grade tumor, and the majority had metastases in multiple sites; 77% of these patients responded to chemotherapy with a cisplatin-based combination regimen, 13 patients (26%) had complete responses, and 8 patients have remained continuously disease free.

Currently, we are evaluating the combination of paclitaxel, carboplatin, and oral etoposide in patients with poorly differentiated neuroendocrine tumors of unknown primary site.⁶⁹ Since 2000, 32 patients have been treated. The majority of these patients had several sites of metastasis, with predominant tumor in the liver (18 patients), nodes (6 patients), and mediastinum (2 patients). These patients also responded well, with 4 complete responders and 12 partial responders. Ten patients remain alive from 12 to 35 months later, and 4 remain progression free.

The origin(s) of these poorly differentiated neuroendocrine tumors remain obscure. Genetic studies may be helpful if an 11:22 translocation (peripheral neuroepithelioma, soft tissue Ewing's sarcoma, or desmoplastic small round cell tumor) or i(12p) abnormality (germ cell tumor) is identified. All these patients without a specific diagnosis should be treated with a trial of combination chemotherapy. Patients with a single site of tumor involvement may be curable with local treatment modalities alone; however, adjuvant chemotherapy should also be administered in these patients if clinically feasible.

Adenocarcinoma of Unknown Primary Site

Clinical Characteristics

Well-differentiated and moderately well differentiated adenocarcinoma represent the most frequent light microscopic

diagnoses (60% of patients). Many physicians associate these patients with the entity of unknown primary cancer. The majority are elderly and have metastatic tumors at multiple sites. The sites of tumor often determine the clinical presentation. Common metastatic sites include liver, lung, bone, and lymph nodes.

The primary tumor surfaces in only 15% to 20% of patients during life.⁷⁰ However, at autopsy an occult primary site is detected in about 70% to 80% of patients. The most common primaries identified at necropsy are the pancreas and lung (about 40%).⁴⁴ Adenocarcinomas from a wide variety of other primary sites are also encountered, but infrequently. An unexpected metastatic pattern is also observed for several of these tumors. Occult pancreatic primaries more frequently involve bone rather than liver, and occult lung and prostate cancer less often involve bone. The clinical course and response to various therapies of occult primary cancers may also differ from that of known primaries.

Patients with metastatic adenocarcinoma of unknown primary site have had a very poor prognosis, with a median survival of only 3 to 4 months. Several patients have widespread metastases and poor performance status at the time of diagnosis. However, within this large group are subsets of patients with more-favorable prognoses, as discussed later. Furthermore, chemotherapy has improved in the past few years, and many patients now are candidates for chemotherapy with an expectation of clinical benefit and improved survival.

Pathology

The light microscopic diagnosis of well-differentiated or moderately well differentiated adenocarcinoma is based on the recognition of glandular structures formed by neoplastic cells. The site of the primary tumor cannot be determined by histologic examination. Certain histologic features typically are associated with some carcinomas, such as signet-ring cells with gastric cancer and papillary features with ovarian cancer, but are not specific enough to be diagnostic. Immunoperoxidase stains and electron microscopy are not helpful in providing additional information in most well-differentiated or moderately well differentiated adenocarcinomas. Prostate-specific antigen stain (PSA) is an exception as it is relatively specific for prostate cancer. Positive immunostaining for estrogen or progesterone receptors, gross cystic fluid protein 15, or Her-2-neu suggests metastatic breast cancer. Neuroendocrine stains [e.g., neuron-specific enolase (NSE), chromogranin, synaptophysin] can occasionally identify an unsuspected neuroendocrine neoplasm. Several other stains or batteries of stains have been evaluated⁷¹⁻⁷⁶ and may suggest the primary (see Table 61.1), but none are specific enough to reliably diagnose the primary site. The diagnosis of poorly differentiated adenocarcinoma should be viewed the same as poorly differentiated carcinoma (see previous section).

Diagnostic Evaluation

These patients should be evaluated similarly to that described for patients with poorly differentiated carcinoma. An exhaustive search for the primary site should not be done. Suspicious clinical symptoms or signs and the extent of metastatic disease should be evaluated. A thorough history and physical

examination, standard laboratory screening tests (i.e., complete blood count, liver function tests, serum creatinine, urinalysis), and chest radiography are indicated. All women should undergo mammography and all men should have a serum PSA determination. CT scans of the abdomen can identify a primary site in about 20% of patients and frequently are useful in identifying additional sites of metastatic disease.^{77,78} Other symptoms, signs, or abnormal physical and laboratory findings should be investigated with appropriate diagnostic studies. An exhaustive evaluation looking for the primary site is rarely useful, is expensive, and often results in false-positive results. A consideration of gastrointestinal endoscopy is appropriate because several of these primary tumor types are now more treatable than before.

PET scanning is an important addition for the evaluation of potential primary sites. Various tumor markers (CEA, CA 15-3, CA 19-9, CA 125, B-HCG, AFP) have not proven to be useful (except in rare instances) for diagnosis or prognosis but can be used to follow the response to therapy.^{79,80}

Treatment

This group of patients contains several clinically defined subsets for which useful specific therapy is indicated. Most tumors within these clinically defined subgroups are well- or moderately differentiated adenocarcinomas, but a minority are poorly differentiated carcinomas. Chemotherapy can now be considered, with expectations for good palliation and improved survival for the other patients (discussed later) who do not fit into any of the subsets listed below.

PERITONEAL CARCINOMATOSIS IN WOMEN

Diffuse peritoneal carcinomatosis is typical of ovarian carcinoma, although carcinomas from the gastrointestinal tract, lung, or breast can occasionally produce this clinical picture. It is now accepted that many of these women have a primary peritoneal carcinoma. Anecdotal case reports from the 1980s documented excellent responses to cisplatin-based chemotherapy in women with this syndrome.⁸¹⁻⁸⁴ Similar to ovarian carcinoma, the incidence of primary peritoneal carcinoma is increased in women with BRCA1 mutations.⁸⁵

The clinical features are similar to ovarian carcinoma. Most patients have elevated serum levels of CA-125 antigen. An occasional patient presents with pleural effusion only, but metastases outside the peritoneal cavity are not common. The histologic features are usually similar to ovarian carcinoma. Most of these patients should undergo laparotomy with surgical cytoreduction followed by combination chemotherapy. These patients are now treated as in ovarian cancer and are considered clinically and biologically similar. The overall results from therapy are similar to ovarian cancer. Carboplatin plus paclitaxel or similar regimens considered optimal for the treatment of advanced ovarian cancer would seem a reasonable choice for initial chemotherapy.

Papillary peritoneal carcinomatosis or primary peritoneal carcinoma has also been seen in men.⁸⁶ It is difficult to confirm the precise biology, and some of these tumors may be metastatic from an occult primary from elsewhere. The study of gene expression patterns in these patients may solve this dilemma in the future. A trial of chemotherapy should be administered in good performance status patients regardless of gender.

WOMEN WITH AXILLARY LYMPH NODE METASTASES

Axillary adenocarcinoma should be considered as arising from an occult primary breast cancer in women. The histology is occasionally poorly differentiated carcinoma. Men with occult breast cancer are very rare. The presence of estrogen and/or progesterone receptors highly suggests the diagnosis of breast cancer.⁸⁷ These patients may have stage II breast cancer with an occult primary, which is potentially curable with appropriate therapy. Magnetic resonance imaging (MRI) and PET are superior to mammography in identifying a breast primary.⁸⁸⁻⁹⁰ In the past, modified radical mastectomy was recommended. A clinically occult breast primary has been identified after mastectomy in about 60% of patients.⁹¹⁻⁹³ Prognosis is similar to that of other patients with stage II breast cancer.⁹¹⁻⁹⁵ Primary radiotherapy to the breast after axillary lymph node dissection is a reasonable alternative therapy. Either neoadjuvant or adjuvant chemotherapy should be administered in this setting, similar to standard therapy for stage II breast cancer.

Women who present with multiple metastatic sites including the axillary lymph nodes may have metastatic breast cancer. They should be considered for therapy for metastatic breast cancer, particularly if serum levels of CA 15-3 or CA 27-29 are elevated and/or estrogen and progesterone receptor and/or Her-2-neu is positive in their tumor.

PROSTATE CARCINOMA

Prostate-specific antigen levels should be measured in men with adenocarcinoma of unknown primary site. In some patients the clinical features (i.e., metastatic pattern) do not suggest prostate cancer, but a positive prostate-specific antigen (serum or tumor stain) is reason for a trial of hormonal therapy.^{96,97}

Squamous Carcinoma of Unknown Primary Site

Squamous Carcinoma Involving Cervical and Supraclavicular Lymph Nodes

Cervical lymph nodes are involved more often. These patients are often elderly, and frequently they have abused alcohol or tobacco. When the middle or upper cervical lymph nodes are involved, a primary tumor in the head and neck region should be suspected. These patients should have an examination of the oropharynx, hypopharynx, nasopharynx, larynx, and upper esophagus by direct endoscopy, with biopsy of any suspicious areas. CT of the neck and PET are indicated as these may also identify primary sites.^{50-54,98} Epstein-Barr virus genome detected in the tumor tissue suggests a nasopharyngeal primary site.^{35,36} When the lower supraclavicular or cervical lymph nodes are involved, lung cancer should be suspected. Fiberoptic bronchoscopy should be performed, because a lung primary is frequently found.⁹⁹

Local treatment should be given to the involved neck when no primary is found. Results in more than 1,400 patients using a variety of treatment modalities have been reviewed.¹⁰⁰⁻¹²² About 30% to 40% of patients achieved long-term disease-free survival after local treatment modalities. The results obtained using high-dose radiation therapy, radical neck dissection, or a combination of these therapies

have been similar. When resection alone is used in these patients, a primary tumor in the head and neck eventually becomes apparent in 20% to 40%. Radiation therapy techniques should be similar to those used in patients with primary head and neck cancer,¹¹¹ and the nasopharynx, oropharynx, and hypopharynx may be included in the irradiated field. Patients with involvement of supraclavicular nodes and low cervical nodes do not do as well (10%–15% long-term survival rates), probably because lung cancer is a frequent occult primary site. Chemotherapy should also be considered, but its role remains controversial, even though it is now clear that combined chemotherapy and radiotherapy are superior to radiotherapy alone in most locally advanced head and neck squamous cancer.

Squamous Carcinoma Involving Inguinal Lymph Nodes

Primary sites in the genital or anorectal areas should be sought. Identification of a primary site is important because curative therapy is available for carcinomas of the vulva, vagina, cervix, and anus, even after spread to regional lymph nodes. About one-half of these patients with inguinal presentations have poorly differentiated carcinoma. In those without identified primary tumors, surgical resection with or without radiation therapy to the inguinal area sometimes results in long-term survival. Neoadjuvant or adjuvant chemotherapy should also be considered.

Squamous Carcinoma Metastatic to Other Sites

Metastatic squamous carcinoma in other areas usually represents metastasis from an occult primary lung cancer, and an appropriate evaluation is indicated. In good performance status patients, chemotherapy with regimens employed in the treatment of non-small cell lung cancer may be considered. Other rare presentations include primaries from the head and neck, esophagus, anus, and skin.

Poorly differentiated squamous carcinoma should be evaluated carefully. Occasionally, breast carcinoma undergo squamous differentiation at metastatic sites. As is the case with poorly differentiated adenocarcinoma, the diagnosis of poorly differentiated squamous cell carcinoma is sometimes based on minimal histologic findings. Specialized pathologic evalu-

ation with immunoperoxidase stains, electron microscopy, and molecular studies should be considered. If the diagnosis remains unclear, these patients should be considered for a trial of therapy for poorly differentiated carcinoma (see previous section).

Chemotherapy for Metastatic Carcinoma of Unknown Primary Site

Most patients with well-differentiated or moderately differentiated adenocarcinoma and poorly differentiated carcinoma do not fit in one of the several favorable prognostic clinical subgroups. Chemotherapy of various types, in the past, has produced low response rates, very few complete responses, and very few long-term survivals.^{2,68,122,123} The results of chemotherapy in several reported prospective clinical trial series in 1,515 patients from 1964–2002 have been reviewed.^{2,68} The overall response rates from these prospective clinical studies varied from 8% to 39% (mean, 20%); complete responders were less than 1%, median survival 4–15 months (mean, 6 months), survival beyond 2 years was rarely reported, and disease-free survival beyond 3 years was not reported.

We have also reviewed several retrospective reports of survival for 31,419 patients with unknown primary cancer^{1,124–131} (Table 61.2) to better define the natural history of this syndrome. Treatment was variable, and some patients received no systemic therapy. These series contained patients now known to fit into specific treatable or favorable subsets. The median survival was 5 months with a 1-year survival of 22% and 5-year survival of 5%. Survival at 1 year and beyond is likely represented by subsets of patients with a more-favorable prognosis who received local therapy (squamous cell carcinoma) or those with very indolent tumors (such as carcinoids). Data in Table 61.3 support this assertion. Squamous (epidermoid) carcinoma and well-differentiated neuroendocrine carcinoma (carcinoid, islet cell type histology) reported in 2,971 patients from some of these series had median, 1-year, and 5-year survival rates of 20 months and 66% and 30%, respectively. All the other patients in these series (total of 26,029 patients) had median, 1-year, and 5-year survival rates of 6 months and 20%, and 5%, respectively.

These historical control data need to be viewed with several factors in mind. Some of the prospective series

are small, and large randomized comparisons are lacking. In addition, patients with all histologic types were included in these series. The patients were not standardly evaluated or compared in reference to sites of metastasis (nodal versus visceral), performance status, sex, age, or other known prognostic factors.

The chemotherapy for patients with adenocarcinoma and poorly differentiated carcinoma who do not fit or conform to a specific "treatable" or favorable subset has recently improved. Several new drugs have been introduced into clinical practice (taxanes, gemcitabine, vinorelbine, and topotecan) with a rather broad spectrum of activity and are changing

the standard treatment for patients with several common epithelial cancers.

The Minnie Pearl Cancer Research Network has completed five sequential prospective Phase II trials since 1995 in 396 patients incorporating paclitaxel,^{132,133} docetaxel,^{133,134} gemcitabine,¹³⁵ and irinotecan¹³⁶ into first-line therapy. Except for a few exceptions (8 patients in the first two trials), all these patients were considered to have poor prognostic features (i.e., patients with known favorable prognostic features were excluded). The chemotherapy regimens, patient characteristics, response rates, and survivals are summarized in Tables 61.4 and 61.5. The total response rate in the five clin-

ical trials was 30% (107 of 353 evaluable patients), with 85 (94%) partial responders and 22 (6%) complete responders. The median survival is 9.1 months, and the 1-, 2-, 3-, 5-, and 8-year survivals are 38%, 19%, 12%, 8%, and 6%, respectively (minimum follow-up, 1 year, maximum 8 years). The median progression-free survival is 5 months, and the 1-, 2-, 3-, 5-, and 8-year progression-free survivals are 17%, 7%, 5%, 4%, and 3%, respectively. There have been no significant differences in survival when comparing the survival curves of all five Phase II studies. There was moderate toxicity, primarily myelosuppression, and 8 (2%) treatment-related deaths.

Trials recently reported by others^{2,62,137–140} have confirmed the activity of the newer cytotoxic agents, but long-term follow-up has not yet been reported. The standard therapy for good performance status patients with carcinoma of unknown primary site is with one of the newer cytotoxic combinations as reported in the 396 patients in this chapter, or as reported by others.^{137–140}

The more-common patients with unknown primary adenocarcinoma or poorly differentiated carcinoma who do not fit or conform to any previously defined “treatable” or favorable subsets now have the opportunity to attain clinical benefit from the new cytotoxic drug combinations. Randomized trials of treatment versus no treatment have not been done, but the median survival as well as 1-, 2-, 3-, and 5-year survival results are superior to the survivals recorded from the past. The survival for patients with unknown primary carcinoma is now similar to the survival of several other groups of advanced carcinoma patients receiving various types of chemotherapy, such as advanced-stage non-small cell lung cancer.

The Changing Role of Prognostic Factors

The prognoses of the various subsets of patients with poorly differentiated neoplasm (otherwise not classified), poorly differentiated carcinoma, well-differentiated adenocarcinoma, squamous cell carcinoma, neuroendocrine carcinoma, and those with a single small site of metastasis are relatively good. Some other patients with poorly differentiated carcinoma have chemotherapy-responsive tumors, and complete responses and long-term survival have been documented for a minority of these patients. Subsets of patients with a more-favorable prognosis or other “favorable” prognostic factors have been recognized. Many of these patients are managed

with specific therapies and have a better prognosis than the group as a whole. Others have features associated with a better prognosis when treated with chemotherapy. Both pathologic and clinical factors can now define several patients with a better prognosis (Table 61.6). For the most part, the larger group of patients with well differentiated adenocarcinoma have had relatively resistant tumors, with virtually no complete responses to chemotherapy, and no long-term survivals in the past. This situation is now changing, as discussed previously.

Most patients who do not fit into a favorable subset have a poor prognosis, regardless of their initial light microscopic diagnosis (well-differentiated adenocarcinoma or poorly differentiated carcinoma). Recently, these patients have been treated with several of the newer cytotoxic combinations (taxanes, gemcitabine, and irinotecan), and modest improvements in the response rate (with some complete responses) and survival have been documented. In addition, the newer cytotoxic combinations appear more effective with less toxicity than cisplatin-based chemotherapy, even for those patients within favorable prognostic subsets who otherwise require chemotherapy. For those rare patients with the extragonadal germ cell syndrome, cisplatin-based therapy remains

TABLE 61.6. Favorable prognostic factors in cancer of unknown primary site.

1. Poorly differentiated malignant neoplasm (otherwise not classified) (60% = lymphomas)
2. Extragonadal germ cell syndrome (PDA or PDC)
3. Retroperitoneal, mediastinal, and/or peripheral lymph node involvement (PDA, PDC, WDA)
4. Squamous cell carcinomas (head/neck or inguinal area)
5. Isolated axillary adenopathy: women, rare in men (WDA, PDC, PDA)
6. Peritoneal carcinoma: women, rare in men (WDA, PDC, PDA)
7. Blastic bone metastases or increased PSA in serum or tumor: men (WDA, PDA, PDC)
8. Neuroendocrine carcinoma: high-grade or poorly differentiated (small cell and others)
9. Neuroendocrine carcinoma: low-grade or well-differentiated (carcinoid/islet cell type)
10. Single site of metastasis (WDA, PDC, PDA)
11. Performance status 0, 1 (with otherwise favorable features)
12. Normal serum LDH (with otherwise favorable features)

PDC, poorly differentiated carcinoma; PDA, poorly differentiated adenocarcinoma; WDA, well-differentiated adenocarcinoma; LDH, lactic dehydrogenase.

^bMay also present with poorly differentiated carcinoma and management and outcome is similar.

the treatment of choice. Additional study of the patients with poor prognoses is important to build on the progress seen with newer cytotoxic agent-based combination chemotherapies.

Conclusion

The recognition of subsets of patients with more treatable cancers within the large heterogeneous population of cancers of unknown primary site represents an improvement in the management of these patients. These patients with more-responsive tumors can often be identified by clinical and pathologic evaluation (Table 61.7). The outcome for patients with cancers of unknown primary site is likely to improve as the therapy for various other cancers improves. Several combination chemotherapy regimens using newer agents have recently found to be useful in previously "unresponsive" patients (i.e., non-small cell lung cancer, colorectal cancer). Recent data, as reported here, also support the benefit of chemotherapy for many unknown primary cancer patients. Improved therapy will likely be developed after a more thorough understanding of the basic biology of these and other cancers is appreciated. Until then, empiric approaches to better manage and treat these patients should continue.

Solid Tumors of Childhood

Crawford J. Strunk and Sarah W. Alexander

Cancer in children, as compared with adults, is rare. From 1993 to 2000, the incidence of cancer in children and adolescents aged 0 to 19 years was approximately 160 cases per 1 million.¹ Despite the relative rarity of the disease and the progress made in therapy, cancer remains the leading cause of disease-related death in children ages 1 to 19 years² (Figure 62.1).

The most common forms of cancer are the acute leukemias and central nervous system tumors. As a group, solid tumors make up approximately one-third of all cancer diagnoses in children. The incidence and types of solid tumors vary by age¹ (Figure 62.2). In general, African-Americans and Asian/Pacific Islanders are less likely to develop cancer than children who are Caucasian.¹ Boys have a higher incidence of cancer than do girls and also have slightly lower overall cure rates.¹

Screening and Family History

The childhood cancer that has undergone significant study regarding utility of screening is neuroblastoma. Despite extensive efforts, these screening programs have not been shown to decrease disease-related mortality.³⁻⁶ There are, however, children who are at increased risk of developing cancer for whom screening is indicated.⁷ For example, patients with Beckwith-Wiedemann syndrome benefit from routine surveillance for Wilm's tumor.⁸

For most children with cancer the disease is a sporadic event; however, for a small fraction the disease is related to a familial cancer syndrome. Certain clinical features should make the clinician consider a familial cancer syndrome, including cancer occurring at an unusually young age (compared with the usual age of presentation for the type of cancer), multifocal development of cancer in a single organ or bilateral development of cancer in paired organs, development of more than one primary tumor of any type in a single individual, family history of cancer of the same type in a close relative, high rate of cancer within a family, and occurrence of cancer in an individual or a family exhibiting congenital anomalies or birth defects.⁷

Environmental Factors

Environmental factors contribute to an increased risk of cancer in children. Exposure to ionizing radiation increases the risk of leukemia, thyroid cancer, and osteosarcoma.⁹⁻¹²

The risk of ionizing radiation associated with radiographic procedures such as repeated X-rays and computed tomography (CT) has led to considerations of more judicious use of imaging studies in children.¹³ There is no measurable increased risk associated with exposure to electromagnetic pulses associated with underground transformers or high-energy electrical stations.¹⁴

There are an increasing number of childhood cancer survivors who are at risk for secondary malignancies related to the therapy of their primary cancer, such as chemotherapy-related malignancies, most notably topoisomerase and alkylator-related leukemia, and radiation-related secondary neoplasms, including sarcomas, skin cancers, and brain tumors.^{15,16}

Clinical Presentation

Persistent low-grade fevers, weight loss, and night sweats are frequent presenting symptoms. Bony tumors often are diagnosed weeks to months after treatment of relatively minor trauma whose symptoms fail to resolve.¹⁷ Most often, however, a lump or mass, with or without pain, first noted by either the parent or the child is usually the first presenting symptom in the child with a solid tumor.¹⁷

Principles of Therapy

Treatment of solid tumors in pediatrics involves the combination of chemotherapy, surgery, and radiation. In general, children tolerate more intensive therapy than their adult counterparts. Special considerations in children include appropriate dosing of drugs (often based on limited pharmaceutical data); ability to comply with prescribed therapy (for example, the need for anesthesia for radiation), and special concerns for long-term toxicities of therapy.

Late Effects of Therapy

One in 900 adults are survivors of childhood cancer.¹⁸ These individuals are at risk for significant long-term sequelae, including growth impairment, infertility, endocrinopathies, cardiac and pulmonary disease, hearing and visual deficiencies, and orthopedic problems as well as secondary malignancies.

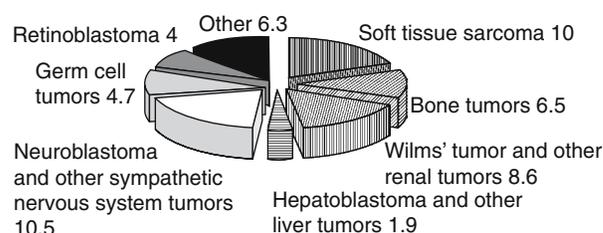

FIGURE 62.2. Incidence rates of solid tumors in children less than 15 years of age.

nancies.¹⁹ In addition, issues of school function and the psychosocial impact of therapy often remain significant years after the completion of therapy. Awareness and surveillance of late effects has improved, and long-term follow-up guidelines for the care of patients who are survivors of childhood cancer have been developed.²⁰

Neuroblastoma

Epidemiology

Neuroblastoma (NB) is the most common extracranial solid tumor in children, with a reported incidence of 8 per 1 million children ages 0 to 19 years, which equates to approximately 600 new cases of NB diagnosed in the United States every year.¹ The peak age of incidence is in the 1- to 3-year-old age group. Most cases of NB are considered sporadic; however, approximately 1% to 2% of all cases are familial.²¹

Biology and Histology

Neuroblastoma cells are derived from primitive sympathetic chain cells, and a portion of these tumors have amplification of the *n-myc* oncogene, which resides on the distal end of the short arm of chromosome 2.²² Some tumors have double minute chromatid bodies in which the region containing the *n-myc* oncogene has become amplified as an extrachromosomal component.²³ Transgenic mice that have targeted expression of *n-myc* develop neuroblastoma-like tumors.²⁴ Other genetic abnormalities associated with neuroblastoma cells include the chromosome 1p deletions, gain of 17q, and abnormal expression of *Trk-A*, a member of the neurotrophin receptor family important in the regulation of cell survival and growth.²⁵⁻²⁷ Histologically, neuroblastomas are small uniformly sized cells with associated neuropil. The presence of Homer Wright pseudorosettes is a common diagnostic feature.

Clinical Presentation

Children with localized neuroblastoma may present only with a painless mass that may be found incidentally by imaging done for unrelated reasons.¹⁷ An advanced disease may present with persistent fevers, bone pain, signs of spinal cord compression, or "raccoon eyes" with disease metastatic to the orbits.²⁸ Children can present with catecholamine-

mediated signs or symptoms, such as hypertension or, rarely, vasoactive intestinal polypeptide (VIP)-induced diarrhea,²⁸ and rarely paraneoplastic symptoms, including opsoclonus myoclonus.

Diagnosis and Staging

Any patient suspected of having neuroblastoma requires complete staging evaluation including CT of the chest, abdomen, and pelvis, bilateral bone marrow aspirates and biopsies, bone scan and metaiodobenzylguanidine (MIBG) scan, and urine specimens for catecholamines and homovanillic acid (HVA) and vanillylmandelic acid (VMA).²⁹ Fluorodeoxyglucose-positron emission tomography (FDG-PET) scanning of patients with neuroblastoma is evolving for staging and treatment response.³⁰⁻³² Diagnosis is usually by light microscopic evaluation of a biopsy, although some patients with widely disseminated disease are diagnosed by bone marrow evidence of disease and elevated urine catecholamines.

Anatomic staging of neuroblastoma is based on the International Neuroblastoma Staging System (Table 62.1).²⁹ Special consideration must be made with regard to stage 4S, or "special" disease. Patients with 4S disease are those under 1 year of age who present with tumor that may be metastatic but is limited only to liver, skin, and bone marrow (with less than 10% involvement).³³

Prognostic Factors

Age (with younger children having a better outcomes) and stage of disease remain critical prognostic determinants. Biological factors that have been validated to be associated with a

TABLE 62.1. International neuroblastoma staging system.

Stage	Definition
1	Localized tumor with gross total resection
2a	Localized tumor with incomplete resection
2b	Localized tumor with or without incomplete resection with ipsilateral positive nodes
3	Tumor that has spread across midline by either direct extension or by lymph node metastasis
4	Disseminated disease with distant metastasis
4s	See text for full description of this stage

less-favorable prognosis include amplification of the *n-myc* oncogene, hypodiploid cells, and 1p LOH (loss of heterozygosity).^{34–38} The staging system developed by Shimada, which includes data regarding patient age, stage, and histopathologic information, has been shown to be a valid prognostic tool.³⁹

Current Principles of Therapy

Surgery, radiation, and chemotherapy are all important tools in the therapy of children with neuroblastoma. The Children's Oncology Group (COG) neuroblastoma trial used a risk-based treatment plan (Table 62.2). Age of the patient, stage of the disease, *n-myc* status, Shimada histology of

the tumor, and DNA index determine these risk groups. Patients with low-risk disease have an excellent event-free survival and overall survival rate with tumor resection alone, including those who do not have a gross total resection (Table 62.3). In addition, those patients who do relapse are highly likely to be cured with salvage surgery and chemotherapy.^{40,41}

Patients with intermediate-risk neuroblastoma also have a very good prognosis, although they require significantly more intensive therapy (see Table 62.3). They are treated with multiagent chemotherapy, most often including cyclophosphamide, doxorubicin, cisplatin, or carboplatin and etoposide. Surgery is often done after initial induction

chemotherapy. Radiation therapy is used to treat postsurgical residual disease.

Improvement of therapy for patients with high-risk neuroblastomas has been modest, with an overall survival of 30% or less.⁴² Treatment usually involves multiagent induction chemotherapy, surgical resection of the primary site of disease, and radiation of residual disease followed by autologous stem cell transplantation (Table 62.4). Autologous stem cell transplant has been shown to have a measurable impact on overall survival.^{42–47} In addition, in this high-risk group the use of isotretinoin posttransplantation, which is thought to induce differentiation of neuroblastoma cells, has been shown to be of benefit.⁴²

Unique to neuroblastoma is the therapy of stage 4s disease. Despite widely disseminated disease, so long as the biology of the tumor is favorable, infants treated with surgery of the primary tumor site and little if any subsequent chemotherapy have an excellent prognosis (Table 62.5).^{48,49}

Late Effects of Therapy

Late effects of treatment for neuroblastoma are dependent on the therapy required. Patients with high-risk disease are at greatest risk of significant long-term morbidity, including cardiac and renal dysfunction, short stature, hearing loss, and secondary malignancies.^{50,51}

Wilms' Tumor and Other Renal Tumors

Epidemiology

Wilms' tumor is the most common renal cancer in children, with an incidence of 7.6 per million children less than 15 years of age per year.¹ The mean age of presentation is 3 years for unilateral disease and 2 years for bilateral disease.⁵²

Wilms' tumor is associated with several congenital syndromes, including WAGR (Wilms' tumor, aniridia, genitourinary malformations, and mental retardation), Beckwith–Wiedeman, sporadic hemihypertrophy, and Denys–Drash syndromes.^{53,54} These patients often present at younger ages and have a higher incidence of bilateral disease but have excellent prognosis with modern treatment regimens.^{55,56}

Biology and Histology

Wilms' tumor is associated with the loss of function of certain tumor suppressor genes, including Wilms' tumor suppressor genes 1 and 2 (WT1 and WT2), as well as the familial loci FWT1 and FWT2.⁵⁷ In addition, the loss of heterozygosity of 16q as well as 1p is found in Wilms' tumor patients and may be associated with poor outcome.⁵⁸ The histology of Wilms' tumor classically includes three distinct cell types: the blastema, stromal, and epithelial. Anaplasia in Wilms' tumor is described as the presence of cells within the tumor sample with very enlarged polyploid nuclei.⁵⁹

Clinical Presentation

Wilms' tumors most commonly present with parent-detected abdominal distension or an abdominal mass or abdominal pain, gross hematuria, or hypertension.⁶⁰

Diagnosis and Staging

The initial evaluation of a child suspected of having Wilms' tumor should include CT of the chest, abdomen, and pelvis and a renal ultrasound (with evaluation for intravascular tumor spread). Rare perioperative sudden death has been reported from pulmonary emboli from intravascular tumors.⁶¹ Primary nephrectomy is the initial therapy for most children treated in North America, and therefore initial biopsy for diagnosis is usually not undertaken. Patients with clear cell sarcoma and rhabdoid tumors of the kidney should also have radionuclide bone imaging in addition to magnetic resonance imaging (MRI) evaluation of the brain. The National Wilms Tumor Study Group (NWTSG) has long-standing staging criteria that are used for all pediatric renal tumors, irrespective of histology (Table 62.6).⁶²

Prognostic Factors

Tumor stage is an important factor in prognosis, along with tumor histology, with those with anaplastic disease having worse outcomes than others.^{59,63} Biologic factors that are associated with worse outcomes include loss of heterozygosity at arms 16q and 1p.⁵⁸

TABLE 62.6. Staging system for renal tumors according to the National Wilms Tumor Study Group.

Stage	Description
I	Tumor confined to the kidney and completely resected.
II	Tumor extends beyond the kidney but is completely resected. Includes at least one of the following: penetration of the renal capsule, invasion of the renal sinus vessels, biopsy of the tumor prior to removal, local tumor spill.
III	Gross or residual microscopic tumor postoperatively, including inoperable tumor, positive surgical margins, tumor spillage involving peritoneal surfaces, regional lymph node metastases, or transected tumor thrombus.
IV	Hematogenous or lymphatic metastasis outside the abdomen (e.g., lung, liver, bone, brain)
V	Bilateral renal tumors at onset

Current Principles of Therapy

Patients with stage I favorable histology (FH) (no anaplasia) WT have an excellent prognosis with primary nephrectomy and short-duration chemotherapy with vincristine and actinomycin and possibly with vincristine alone.^{64–67} Small tumors (less than 550g) and age less than 24 months at diagnosis have been shown to be favorable prognostic factors,⁶⁸ prompting the evaluation of nephrectomy alone in this population. This strategy was evaluated in the NWTSG-V study. The study was closed when the strict stopping rules were met with excess relapse rate in the group who did not receive adjuvant therapy; however, the overall survival (OS) at 2 years in both groups remains 100%.⁶⁹

Patients with stage II or III favorable histology Wilms' tumor have an OS between 80% and 90%.⁷⁰ The recent group studies have focused on minimizing long-term risks of therapy, primarily the risks of cardiomyopathy from adriamycin and the risks of second malignant neoplasms and effects on growth and fertility from radiation therapy. For patients with stage II FH WT, neither the addition of adriamycin to actinomycin and vincristine nor the addition of abdominal radiation improved OS.^{66,67} For patients with stage III disease, the addition of adriamycin and abdominal radiation both lead to statistically significant although modest improvements in OS, with some protocols using neoadjuvant chemotherapy.^{67,71,72}

Patients with stage IV Wilms' tumor (WT) metastatic to lung also have a very good OS of approximately 80%. In NWTSG-3, patients received vincristine, actinomycin, and adriamycin in addition to whole-lung irradiation, with abdominal radiation only for those with stage III abdominal disease.^{67,70} In an attempt to avoid the acute and chronic toxicities of pulmonary radiation, the International Society of Paediatric Oncology (SIOP) investigated the use of pre-nephrectomy chemotherapy. Those who obtained a complete response (CR) in terms of their pulmonary disease after 6 weeks of therapy did not receive pulmonary radiation therapy, with a relapse-free survival (RFS) and OS of 83%.⁷³

Patients with stage V disease (bilateral disease) provide unique challenges in terms of providing effective cancer therapy while at the same time allowing for the preservation of adequate renal function. For those patients with favorable histology, the use of "nephron-sparing" surgery, with resec-

tion of tumor masses, as opposed to nephrectomy in addition to neoadjuvant chemotherapy, has led to overall survival rates approaching 70%, with 80% of survivors having normal renal function in long-term follow-up.^{74,75}

The Use of Neoadjuvant Therapy

The use of pre-nephrectomy chemotherapy has been a source of much controversy, with North American institutions traditionally not pursuing neoadjuvant therapy whereas it is the standard of care in many European centers.⁷⁶ A series of studies done by SIOP has investigated various durations of preoperative chemotherapy with the goal of decreasing the need for abdominal irradiation by making more tumors amenable to complete surgical removal and decreasing the rate of intraoperative tumor rupture or spill.^{77,78} This strategy has not been followed by the NWTSG because of concerns of misdiagnosis by reliance on initial biopsy alone, difficulty in interpreting histologic information in pretreated tumors, and loss of upfront staging information.⁷⁰

Therapy for Relapsed Disease

Patients with recurrent Wilms' tumor who have not previously received doxorubicin, who have an abdominal recurrence only and did not receive prior abdominal radiation therapy, and those who relapse more than 12 months after completions of primary therapy have a relatively favorable prognosis.⁷⁹ Chemotherapeutic agents used in this group include carboplatinum, etoposide, ifosfamide, and cyclophosphamide. The use of stem cell transplant for patients with less-favorable characteristics has been explored, but there are no data to date that reveal superiority of this modality.^{80,81}

Late Effects of Therapy

Renal failure posttherapy for Wilms' tumor is relatively rare (less than 1%) and is most often caused by either bilateral nephrectomy done as therapy of bilateral disease, secondary to underlying renal disease (Denys-Drash syndrome), or by radiation nephritis.⁸² Other significant late effects include risk of cardiac dysfunction (primarily related to adriamycin), pulmonary disease and infertility (primarily related to radiation), and second malignant neoplasms.⁸³⁻⁸⁵

Other Renal Tumors

Clear Cell Sarcoma of the Kidney

Clear cell sarcoma of the kidney is the second most common renal neoplasm in children. Mean age of diagnosis is 36 months with a 2:1 male to female preponderance.⁸⁶ These tumors metastasize to bone in addition to lung, brain, and other soft tissues.⁸⁷ The outcome of patients with clear cell sarcoma is inferior to that for those with a favorable histology Wilms' tumor. Use of doxorubicin in the therapy for patients with clear cell sarcoma appears to be important.⁸⁶

Rhabdoid Tumor

Rhabdoid tumor of the kidney is an extremely aggressive renal neoplasm that usually presents in infancy. The tumor

is extremely rare in those over the age of 5 years, with 85% of patients presenting before the age of 2 years.⁸⁸ The clinical presentation of children with rhabdoid tumor differs somewhat from those with Wilms' tumor in that they are more likely to have gross or microscopic hematuria, fever, and hypercalcemia.⁸⁹

Rhabdoid tumors, whose cellular origin is unknown, were initially described as a distinct entity in 1978⁹⁰ and contain a unique deletion of 22 q11-12, localized to the *hSNF5/INI1* gene, which occasionally is a germ-line mutation.⁹¹

Patients with rhabdoid tumors (majority in stage III or IV) have a dismal prognosis, with 80% of children dead of progressive disease within 1 year of diagnosis^{88,92} despite aggressive chemotherapy, surgery, and radiation therapy.⁹³ A unique association with rhabdoid tumor is the finding of associated brain tumors that may be either from metastatic disease or from synchronous tumors in a susceptible host. Staging at the time of diagnosis must include an MRI of the brain.

Renal Cell Carcinoma

Renal cell carcinoma is extremely rare in children. When it does occur, evaluation and therapy are based on data from adult studies. There are two unique forms of renal cell carcinoma that rarely occur in children. The first is associated with a translocation of Xp11.2.^{94,95} The second is renal medullary carcinoma, primarily associated with individuals with sickle cell trait.⁹⁶

Osteosarcoma

Epidemiology

Osteosarcoma is the most common primary bone tumor of children, with an incidence of 5 per 1 million children, with an increased incidence in late adolescence.¹ Osteosarcomas have been reported in patients as old as the sixth decade, but the peak age of incidence is in the second and third decades of life.⁹⁷ Boys and African-Americans have a higher predilection for development of osteosarcoma. Ionizing radiation has been associated with an increased risk of developing osteosarcoma.⁹⁸ In addition, germ-line defects in the *RB1* gene and those patients with Li-Fraumeni syndrome have an increased incidence of osteosarcoma.⁷

Biology and Histology

Osteosarcomas arise from primitive mesenchymal stem cells. Histologically, osteosarcoma, unlike chondrosarcomas and fibrosarcomas, appears as a malignant sarcomatous stroma with evidence of production of osteoid.

The underlying biology of osteosarcoma is not well understood. There is an association with hereditary retinoblastoma syndrome and Li-Fraumeni syndrome. Cytogenetic analysis has shown not only loss of heterozygosity (LOH) at the 13q region (*RB* gene) and 17p region (*p53*), but also at the 3q and 18q regions, areas that may harbor additional tumor suppressor genes.^{99,100} In approximately 20% of osteosarcomas, the 12q13-14 region, the area that codes for *MDM2*, is amplified,¹⁰¹ suggesting increased activity of *MDM2* in

osteosarcoma. MDM2 is an intracellular protein that interacts with, and renders inactive, the p53 tumor suppressor gene.⁹⁷

Clinical Presentation

Osteosarcoma generally presents as pain or swelling of a bone or joint with or without a soft tissue mass. The usual time from onset of symptoms to time of diagnosis often is prolonged, ranging from 3 to 6 months or longer.¹⁷ Often a sports-related injury is recalled with the initial onset of symptoms. Relatively rarely, osteosarcoma can present secondary to a pathologic fracture. Signs of systemic disease such as weight loss and fevers are rarely noted. The most common site of presentation is in the metaphyses of long bones. The most frequent sites are the distal femur, proximal tibia, and proximal humerus.¹⁰²

Diagnosis and Staging

Plain film examination of the affected area provides clues to the diagnosis. Some osteosarcomas are most often lytic lesions, with a *starburst pattern*, that may have characteristic findings including Codman's triangle. MRI and CT are used to further define the anatomy of the primary site of disease.

Approximately 15% to 20% of patients with osteosarcoma are noted to have metastases at diagnosis.¹⁰² About 80% of those with metastases have pulmonary metastases.^{102,103} The majority of the remaining 20% of metastases are bone lesions.^{102,103} Because metastatic disease at diagnosis affects not only therapy but also prognosis, all patients should undergo staging evaluation before beginning therapy, including CT of the chest and radionuclide bone scan. Diagnosis of osteosarcoma is made based on histopathologic review of biopsy of the primary lesion.

Prognostic Factors

The single most significant prognostic factor in patients with osteosarcoma remains extent of disease at presentation, with those with metastatic disease at diagnosis continuing to have a poor overall survival.¹⁰⁴ Tumors of the axial skeleton are more difficult to eradicate than those of the extremities, partly related to feasibility of complete surgical resection.¹⁰⁵ Large tumors and those occurring in children less than 10

years old are also associated with poorer outcomes. Biologic factors that may predispose to worse outcomes include LOH of the RB gene locus, overexpression of HER-2, and hyperdiploidy.¹⁰⁶⁻¹⁰⁸ Last, response to neoadjuvant chemotherapy is a powerful prognostic factor with those individuals with less than 10% of residual tumor visible in the resection specimen faring better than those with a larger percentage of viable disease.^{109,110}

Current Principles of Therapy

Before 1970, patients with osteosarcoma had a very poor prognosis, with a 5-year event-free survival (EFS) of only 20%.¹¹¹ Historically, most patients died of relapsed disease after amputation of the primary tumor. Current principles of therapy include neoadjuvant chemotherapy, surgery for local control, and postsurgical adjuvant chemotherapy; approximately 70% of all patients with nonmetastatic disease at diagnosis can be cured.¹⁰² Radiotherapy remains part of local control measures when tumors are located in sites not amenable to surgery.¹¹²

Three drugs, methotrexate, cisplatin, and doxorubicin, are the backbone to chemotherapeutic treatment of osteosarcoma (Table 62.7).¹¹³ Somewhat more recently the addition of ifosfamide and etoposide as a combination regimen has been shown to have therapeutic utility.^{114,115} Local control surgery is most commonly performed after 2 to 3 months of neoadjuvant chemotherapy. A recent Pediatric Oncology group study reported no difference in EFS for patients given presurgical chemotherapy for 12 weeks compared to those who underwent primary resection at the time of diagnosis followed by chemotherapy.¹¹⁶ Advantages to neoadjuvant chemotherapy include tumor shrinkage, facilitating possible limb salvage procedures, and prognostic information based on the histologic response of the excised tumor. Risks of neoadjuvant chemotherapy include progression of disease before surgery.

Patients with metastatic lesions at diagnosis fare poorly, with an overall survival of 21% to 30%.^{117,118} Within the group of patients with metastatic disease, favorable characteristics include the site of metastatic disease (with lung only being more favorable than metastatic disease to bone) and completeness of surgical resection of all tumor sites.¹⁰⁴ To date efforts to improve outcomes with intensified chemotherapy have not shown substantial benefit (Table 62.8).¹¹⁹

Surgical Management

Historically, amputation was the preferred surgical approach¹¹¹; however, during the 1980s limb-sparing surgical techniques were developed in conjunction with improved diagnostic imaging.¹²⁰ By the late 1990s, studies suggested patients with limb salvage surgery had no more local recurrences than those who underwent amputation if surgical margins were adequate, including those initially presenting with pathologic fracture.¹²¹⁻¹²⁴

Therapy of Recurrent Disease

Patients who have recurrent disease generally have a grave prognosis.^{125,126} Lungs are the most common site of recurrence, although recurrence can occur locally and at distant bony sites.¹²⁷ Prognostic factors that may influence long-term survival in these patients include the relapse-free interval, sites of recurrent disease, number of pulmonary nodules, and feasibility of complete surgical resection.^{126,128}

Late Effects of Therapy

Despite surgical advances, orthopedic issues related to amputation or limb salvage procedures can give rise to lifelong impairments. In addition, cardiomyopathy related to anthracycline therapy and hearing deficits related to cisplatin are common among survivors.¹²⁹

Ewing's Sarcoma Family of Tumors

Epidemiology

Ewing's sarcoma is the second most common primary malignancy of bone in childhood. It is primarily a tumor of bony origin but can also arise from soft tissues. Included in the Ewing's sarcoma family of tumors (ESFT) is the peripheral primitive neuroectodermal tumor (PPNET).

The majority of individuals diagnosed with Ewing's sarcoma are between the ages of 10 and 20 years.¹³⁰ Ewing's sarcoma is not associated with any known familial cancer syndromes, nor are there known environmental causes.¹³¹ The disease is significantly more common in Caucasians than in African-Americans and shows a slight male preponderance.¹³²

Biology and Histology

The cellular origin of Ewing's sarcoma cells has been controversial over the years, but more recently evidence has revealed that it is most likely derived from primitive neural crest cells. The Ewing's sarcoma family of tumors shares a unique pattern on cytogenetic and molecular characteristics. Ninety percent to 95% of tumors have the EWS-FLI1 (t(11;22)(q24;q12)) translocation.¹³³ This translocation can be identified as type 1 (65%), type 2 (20%), and others (15%). The second most common translocation, occurring in the remaining 5% to 10% of ESFT, is EWS-ERG, which has several known specific fusion types. Histologically the Ewing's family of tumors represents a spectrum from undifferentiated Ewing's sarcoma to the more-differentiated PPNET.

Clinical Presentation

Typical presenting symptoms in patients with Ewing's sarcoma include pain, palpable mass, fevers, and occasionally pathologic fracture. Many individuals ascribe their pain to a "strain" or recent traumatic event.¹³⁴ Some patients present with symptoms related to metastatic sites of disease, including cough from pulmonary disease or multifocal bone pain from extensive bone or bone marrow involvement. The mean time from initial symptoms to diagnosis of Ewing's sarcoma is frequently months, with those individuals with a palpable mass having the shortest interval.¹³⁴

The primary site of disease is axial in approximately 50% of patients and involves the extremities in the other 50%.¹³⁵ At the time of diagnosis, approximately 25% of children have metastatic disease, most commonly to lung followed by other bony sites and bone marrow.¹³⁶

Diagnosis and Staging

Early involvement of an orthopedic surgeon skilled in the care of pediatric bone tumors is imperative. Initial biopsy techniques are not only important in providing needed diagnostic material but may have an impact on subsequent local control measures including the possibility of limb salvage surgery.

The complete evaluation of a new patient with Ewing's sarcoma includes a detailed radiographic evaluation of the primary site of disease, assessment for metastatic disease, and a baseline assessment of organ function in anticipation of intensive therapy. The evaluation of the primary site often

begins with plain radiographs, followed by MRI and CT, depending on site of disease. The metastatic evaluation needs to include CT scan of the chest, bilateral bone marrow aspirates and biopsies, and radionuclide bone scan.

Prognostic Factors

The most significant prognostic variable for patients with Ewing's sarcoma is whether the disease is localized or metastatic at the time of diagnosis.¹³⁷ Those with localized disease have a 70% chance of disease-free survival (DFS) whereas those with metastatic disease have a DFS of 20% to 30%. Individuals with pulmonary disease as their only site of metastatic disease do more favorably than those with bony or bone marrow involvement.¹³⁸ Approximately 20% to 30% of patients with localized disease with morphologically normal bone marrow examination will have detectable disease in the bone marrow when assayed by polymerase chain reaction (PCR), which is associated with a worse prognosis.¹³⁹

Traditionally, both site of primary disease (axial and pelvic tumors being worse than extremity tumors) and size of the primary tumor (tumors greater than 8 cm in longest dimension or greater than 200 cm³) have been important prognostic factors.¹⁴⁰⁻¹⁴² However, in several more recent cooperative group studies these factors were no longer found to be significant, potentially related to both more-aggressive adjuvant chemotherapy and improved local control measures.^{143,144} More recently, histologic response to neoadjuvant chemotherapy has been shown to be an important prognostic tool, with those with less viable disease after neoadjuvant chemotherapy having better outcomes.¹⁴⁵⁻¹⁴⁷

Last, type of ESFT translocation has been shown to have some prognostic implications. Individuals with EWS-FLI1 type 1 have been shown to have a decreased risk of developing metastatic disease compared to those with other EWS-FLI1 type translocations.¹³³

Current Principles of Therapy

The therapy of Ewing's sarcoma has been developed through the investigations performed by several large cooperative groups, beginning in the 1970s (Table 62.9). In most current protocols, multiagent neoadjuvant chemotherapy (most often including adriamycin, vincristine, cyclophosphamide, etopo-

side, and ifosfamide) is given for 10 to 12 weeks, followed by local control with either surgery, radiation, or a combination of the two modalities followed by further chemotherapy. Early on the addition of doxorubicin was found to be important,¹⁴⁸ whereas more recently the addition of etoposide and ifosfamide to the backbone of vincristine, doxorubicin, and cyclophosphamide was shown to improve outcome.¹⁴³

Dose intensification, either by higher-dose chemotherapy per cycle or by "interval compression," with more frequent chemotherapy cycles, has been investigated. Both methods utilized granulocyte colony-stimulating factor (G-CSF) support. Both methods have been shown to be feasible but without improvement in outcome for those treated with the more-intensive regimens.^{149,150}

Historically, surgery was considered superior to radiation therapy for local control therapy in Ewing's sarcoma.^{151,152} With advances both in systemic therapy and in radiation planning and surgical techniques, the rates of local recurrence have declined and the difference between surgical and radiation therapy outcomes has become nonsignificant.^{153,154} Some studies continue to show somewhat more favorable results with surgery, but this may be biased by risks associated with worse outcomes for those with very large tumors that are not approachable surgically.¹⁵⁵

Recent attempts to improve outcome in individuals with metastatic disease have largely focused on dose-intensifying chemotherapy, including the evaluation of "megatherapy" with stem cell support.¹⁵⁶ There have been multiple single-institution and cooperative group studies with various conditioning regimens, including the use of total body irradiation (TBI) and tandem transplantation (Table 62.10). One component of stem cell transplant for metastatic Ewing's that may contribute to failure of this modality is evidence of the presence of tumor cells in the stem cell harvests.¹⁵⁷ There continues to be some interest in the use of intensified therapy for subgroups of high-risk patients in whom intensified therapy may prove to have some moderate benefit.

Therapy for Relapsed Disease

Patients with recurrent disease after aggressive primary therapy have a poor prognosis, with EFS at 5 years of 15% to 20%.¹⁵⁸ Those with localized recurrence and those whose

recurrence occurs more than 2 years after initial diagnosis have a somewhat better outlook.^{158,159} The combination of cyclophosphamide and topotecan has been shown to have significant activity in patients with relapsed Ewing's sarcoma¹⁶⁰ and is often used as part of a reinduction regimen. The use of high-dose therapy and stem cell transplant for this group of patients has not yet shown significant improvement in overall survival.

Late Effects of Therapy

The therapy for Ewing's sarcoma involves intensive use of both alkylators and topoisomerase II inhibitors (etoposide). The intensive use of these agents has been associated with a significant risk of therapy-related acute myelogenous leukemia and myelodysplastic syndromes (t-AML/MDS),^{150,161} which may limit any potential additive efficacy of dose-intensified regimens.

Other long-term sequelae for patients treated for Ewing's sarcoma include secondary malignancies related to radiation therapy, orthopedic problems related to local control surgeries, and infertility or early menopause, renal dysfunction, or cardiac dysfunction as sequelae of chemotherapy.¹⁶²

Rhabdomyosarcoma and Undifferentiated Sarcomas

Epidemiology

Rhabdomyosarcoma (RMS) is the third most common extracranial solid tumor in children (Surveillance, Epidemiology, and End Results; SEERS). The median age of diagnosis is 5 years, with the majority presenting by age 10. This tumor arises in virtually all parts of the body; however, certain groupings by age, location, and histology are common. For example, botriod rhabdomyosarcoma tumors of the vagina occur almost exclusively in infants, whereas head and neck tumors with embryonal histology are more common in those under 8 years of age and extremity tumors with alveolar histology are more common in adolescents. Most cases of RMS are sporadic; however, there is an association with neurofibromatosis and with the Li-Fraumeni syndrome.¹⁶³⁻¹⁶⁵

Biology and Histology

Rhabdomyosarcoma is thought to arise from primitive muscle cells. Undifferentiated sarcomas are those of mesenchymal origin that cannot be ascribed to any specific lineage. The two most common histologic types of RMS are alveolar (ARMS) and embryonal (ERMS), which have unique

genetic patterns. ARMS has a characteristic translocation of t(2:13)(q35;q14), which juxtaposes PAX 3, a transcription regulator gene, to FKHR, a member of the forkhead family of transcription factors.¹⁶⁶ ERMS is associated with LOH at 11p15.¹⁶⁷ Botriod rhabdomyosarcoma is considered a histologic subtype of ERMS.

Clinical Presentation

The presentation of patients with RMS is variable given that the tumor can involve almost any part of the body. Most often RMS is diagnosed because of the patient presenting with a mass (with or without a history of trauma) or with organ dysfunction related to anatomic disruption from an undetected mass. In the Intergroup Rhabdomyosarcoma Studies (IRS) I, II and III, 35% of the patients had disease involving the head and neck (including parameningeal and orbital), 22% had genitourinary sites of primary disease, 18% had extremity tumors, and the remaining 25% had tumors originating at numerous other sites.¹⁶⁸⁻¹⁷⁰

Diagnosis and Staging

The evaluation of a child with RMS, not unlike that of other solid tumors, includes radiographic evaluation of the primary site of disease, assessment of possible sites of metastatic disease, and testing for organ function in anticipation of further therapy. The site of local disease is imaged with CT and/or MRI. Evaluation of sites of metastatic disease should include a chest CT, bilateral bone marrow aspirates and biopsies, and technetium-99 bone scan.

Staging of patients with RMS often involves the use of a combination of two systems: the TNM staging systems and the clinical grouping (Tables 62.11, 62.12). Careful and com-

TABLE 62.11. Clinical group staging of rhabdomyosarcoma as defined by Intergroup Rhabdomyosarcoma Studies (IRS) V.

Clinical group	Extent of disease
I	A. Completely resected localized disease confined to the muscle or organ of origin B. Completely resected localized disease with infiltration outside the muscle or organ of origin
II	A. Gross total resection with microscopic residual B. Regional disease with involved nodes, with gross total resection and no microscopic residual C. Regional disease with involved nodes, with gross total resection with microscopic residual
III	A. Incomplete resection after biopsy only B. Incomplete resection after major resection
IV	Distant metastatic disease

TABLE 62.12. TNM staging for rhabdomyosarcoma as used for IRS IV.

Stage	Site	Invasiveness of tumor (T)	Size of tumor (T)	Nodes (N)	Metastasis (M)
1	Orbit Head and neck Genitourinary	T1 or T2	A or B	N0 or N1 or Nx	M0
2	Bladder/prostate Extremity Parameningeal Other	T1 or T2	A	N0 or Nx	M0
3	Bladder/prostate Extremity Parameningeal Other	T1 or T2 T1 or T2	A B	N1 N0 or N1 or Nx	M0
4	All	T1 or T2	A or B	N0 or N1 or Nx	M1

T (tumor): T1, confined to anatomic site of origin; T2, extension; A, less than 5 cm in diameter; B, more than 5 cm in diameter; N (regional nodes): N0, not clinically involved; N1, clinically involved; Nx, unknown; M (metastases): M0, no distant metastases; M1, distant metastases present.

plete staging evaluations are critical in that they determine appropriate risk-adapted therapeutic plans.

Prognostic Factors

Several important factors have been identified as useful tools in predicting outcome in patients with RMS: site of primary disease (with the orbit being the most favorable site), surgical resectability (clinical group), extent of disease spread (clinical stage), histology (with embryonal histology associated with a better prognosis than alveolar), and patient age.¹⁷⁰⁻¹⁷² In the IRS-V study, these factors are used to allocate patients into risk categories with risk-adapted therapy.

Current Principles of Therapy

SURGERY

Primary surgical resection with regional nodal sampling, when appropriate, is a critical component of the therapy of RMS. Complete initial surgical resection has been shown in multiple studies to be associated with improved outcome.¹⁶⁸⁻¹⁷⁰ For certain disease sites, such as the bladder, the orbit, or biliary tract, aggressive surgical therapy is not reasonable, and biopsy done only to confirm diagnosis is the appropriate surgical approach. Several clinical trials have evaluated the utility of "second-look surgery" following adjuvant chemotherapy for patients with incomplete resections after initial surgery.^{168-170,173} The data supporting this approach are mixed, and the question is again being evaluated in IRS-V. In addition, the use of biopsy only at disease outset followed by chemotherapy with no further local control for those with a radiographic complete response was evaluated in an International Society of Pediatric Oncology protocol and was shown to be associated with a higher rate of local disease relapse.¹⁷⁴

RADIATION THERAPY

Radiation therapy is an important tool in the therapy of children with RMS. Doses of 50.4 to 54.0 Gy for gross disease and 41.4 to 45.0 Gy for microscopic residual disease are usually

employed. There is clear evidence that the use of radiation in patients with alveolar histology, even with complete resection, provides improvement in local control. The timing of radiation therapy in the multimodality therapy of patients with RMS has varied over time but most often occurs 9 to 12 weeks after the initiation of adjuvant chemotherapy, except for those with invasive parameningeal tumors, for whom therapy usually begins immediately. For young children, the long-term sequelae of radiation therapy, particularly the potential for morbid growth deformities, can make treatment decision difficult.

CHEMOTHERAPY

Pioneering studies by Wilbur et al. were the first to show benefit of multiagent chemotherapy in patients with RMS.¹⁷⁵ Many agents have been shown to have activity in treating RMS, including vincristine, actinomycin, cyclophosphamide, doxorubicin, ifosfamide, etoposide, and cisplatin. More recently, the camptothecin analogues topotecan and irinotecan have shown activity in this disease.^{176,177}

Formed in 1972, the Intergroup Rhabdomyosarcoma Studies Group (IRSG) has allowed for well-designed studies of this rare pediatric cancer. The results of IRS studies I-V are summarized in Table 62.13. Despite the improvement in outcomes in each sequential IRS study, progress in treating those with metastatic disease has been marginal, with survival of approximately 30%.^{170,178} Patients with embryonal histology who are less than 10 years of age and have pulmonary metastatic disease only are a unique group with a more-favorable prognosis.^{170,178} The use of autologous transplant in attempts to intensify therapy and improve outcome in those with clinical group IV disease has not been shown to provide clinical benefit to date.¹⁷⁹⁻¹⁸¹

THERAPY FOR RELAPSED DISEASE

The therapy for patients with relapsed RMS is problematic and the outcome poor; 95% of all relapses of RMS occur within 3 years of diagnosis.¹⁸² The median survival time from first relapse is 0.8 years, with 20% of the patients alive at 5 years. Adverse prognostic factors include rapidity of relapse and extent of disease at the time of relapse. Patients with

ERMS with localized recurrence have a more-favorable prognosis, with a 5-year OS of 50% with aggressive multimodal-ity therapy.¹⁸²

LATE EFFECTS OF THERAPY

Chemotherapy-related long-term sequelae include infertility or early menopause, renal tubular dysfunction, and secondary leukemias. The increasing role of risk-adapted therapy in RMS is an important strategy in attempting to minimize late effects of therapy.

Hepatoblastoma and Other Liver Tumors

Epidemiology

Primary malignant tumors of the liver in pediatrics are uncommon. According to the SEER program of the National Cancer Institute, liver cancers account for approximately 1% of all pediatric cancers, with hepatoblastoma accounting for 79% of that total, resulting in about 100 new cases of hepatoblastoma per year.¹ The incidence is highest in infants, with most cases occurring before age 5 and males being more commonly affected than females. The incidence of hepatoblastoma has increased during the past 30 years, with incidence in the United States increasing from 0.6 per million (1973–1977) to 1.2 per million (1993–1997).¹⁸³

The incidence of hepatoblastoma is higher in individuals with Beckwith–Wiedemann syndrome (BWS), hemihypertro-

phy (HH), and familial adenomatous polyposis (FAP). Three percent of patients with BWS or HH develop hepatoblastoma.^{184,185} In this group of patients, screening with serial abdominal ultrasounds and alpha fetoprotein (AFP) measurements has been shown to be of benefit.¹⁸⁶

Recent analysis of the cancer registry in Japan indicates that the incidence of hepatoblastoma is increasing in patients with very low birth weight.¹⁸⁷ Recent analysis of data from both SEER and state registries as well as the unexpectedly high percentage of very low birth weight infants diagnosed with hepatoblastoma on a Children’s Cancer Group (CCG) trial appear to confirm those results.^{188,189} Of note, the increase in survival of very low birth weight infants has occurred over the same length of time, leading some investigators to conclude that the overall increased incidence of hepatoblastoma is not simply by chance.^{190,191}

Biology and Histology

Cytogenetic studies of hepatoblastoma have revealed extra copies of chromosomes 1q, 2q, 7q, 8, 17q, and 20.¹⁹² In addition, loss of heterozygosity (LOH) at the 11p15 site has been observed in one-third of patients with hepatoblastoma.¹⁹³ Genes thought to be potentially significant genes on 11p15 include insulin-like growth factor (IGF)-2 and the tumor suppressor genes p57 (KIP2) and H19.¹⁹⁴ The histology of hepatoblastoma ranges from undifferentiated small cells to cells resembling those during embryonal and fetal development. Most tumors have a mixed histologic pattern.

Clinical Presentation

Most patients present with an enlarging abdominal mass, often brought to medical attention by the child's parents' concern over a protuberant or firm abdomen. Systemic symptoms such as weight loss or anorexia are rarely seen. Some boys can present with precocious puberty.¹⁹⁵

Diagnosis and Staging

On detection of any intraabdominal mass, abdominal ultrasound should be performed to characterize the location and approximate size of the lesion. Doppler flow during ultrasonography can aid in determining the proximity of the tumor to the portal vein. CT scan of the abdomen and pelvis or MRI scan should be undertaken to delineate more accurately the size of the tumor, location, and proximity to the portal vein and inferior vena cava (IVC). The right lobe of the liver is more often involved than the left lobe.¹⁸⁸ The lungs are the most common site of metastatic disease, present in approximately 10% of patients at diagnosis¹⁸⁸; therefore, CT scan of the chest should also be performed. Serum AFP levels should be obtained as well as these are elevated in 90% of cases.¹⁹⁶ There is a correlation between AFP level and extent of disease in all stages.¹⁹⁷

Prognostic Factors

The single most significant prognostic factor for children with hepatoblastoma is feasibility of complete surgical resection. Biologic features that have prognostic implications include histologic subtype (with fetal histology having better outcome than embryonal) and degree of mitotic activity.¹⁹⁸ Patients whose tumors become resectable after neoadjuvant

chemotherapy and those whose AFP levels fall quickly have also been shown to have more-favorable outcomes.¹⁹⁹

Current Principles of Therapy

Historically, surgery was the only curative therapy for hepatoblastoma; however, only about 30% of tumors are considered resectable at diagnosis.^{200,201} The staging system commonly employed is based on the surgical removal of the tumor, such that stage I is complete resection, stage II is microscopic disease after surgery, stage III is unresectable disease or macroscopic disease after surgery, and stage IV is metastatic disease.¹⁸⁸ However, there is no universally accepted staging system for hepatoblastoma.²⁰²

The utility of chemotherapy in the treatment of hepatoblastoma was first realized in the 1970s.¹⁸⁸ Results of recent group studies are summarized in Table 62.14. Chemotherapy has been shown to increase the overall survival of patients with hepatoblastoma as well as to increase the number of patients with resectable tumors.²⁰³ Early studies documented the benefit of adjuvant therapy with cisplatin and doxorubicin.^{204,205} More recently it has been shown that the use of cisplatin, 5-fluorouracil, and vincristine was equally effective but less toxic than cisplatin and doxorubicin.²⁰⁶ Other chemotherapeutic agents that have been shown to be of utility include carboplatin, ifosfamide, and etoposide.²⁰⁷⁻²⁰⁹

THERAPY OF PATIENTS WITH UNRESECTABLE DISEASE

Orthotopic liver transplantation for patients with unresectable hepatoblastoma has been shown to be an effective therapeutic modality in multiple case series (Table 62.15).²¹⁰⁻²¹² In these studies, presurgical chemotherapy was

given to reduce the size of the primary tumor. Postoperative chemotherapy or radiotherapy was also performed to consolidate local control. Patients with disease documented to be more responsive to neoadjuvant chemotherapy have a superior overall survival.

THERAPY OF PATIENTS WITH METASTATIC OR RECURRENT DISEASE

The therapy for children with metastatic disease or recurrent disease remains challenging. Intensification of the chemotherapeutic regimen with high-dose cisplatin and etoposide has shown to be of potential benefit,^{207,213} as has surgical removal of isolated pulmonary metastases.^{214,215} Several case reports and small case series have reported successful use of high-dose therapy and autologous stem cell rescue for poor-risk patients.^{213,216}

Hepatocellular Carcinoma

Although rare, primary liver tumors in children over 3 years of age are more likely to be hepatocellular carcinoma (HCC) than hepatoblastoma.¹⁸³ Risk factors for HCC in children include Byler's disease, Wilson's disease, and hepatorenal tyrosinemia.¹⁸³ Because of the rarity of this disease in children, studies evaluating the therapy of HCC in pediatric patients have been limited, and most children are treated according to adult therapeutic guidelines. As for adult patients, the primary therapy is surgery, with chemotherapy having limited efficacy.^{217,218}

Retinoblastoma

Epidemiology

Retinoblastoma, the most common intraocular tumor in children, is a tumor of developing retinal cells. This tumor has an annual incidence of 11 new cases per million population less than 5 years of age.¹ It occurs as a sporadic and familial tumor, with the former the more common presentation. The majority of children with retinoblastoma present by the age of 2 years, and 95% of cases occur by age 5.²¹⁹ Approximately one-quarter of retinoblastomas are bilateral¹; these are all almost all hereditary, associated with germ-line mutations in the RB1 gene. Another 15% of retinoblastomas are unilateral but hereditary. The remaining 60% are unilateral and nonfamilial.²²⁰ A small number of children present with bilateral

retinoblastomas in addition to a pineal blastoma, a combination known as trilateral retinoblastoma.²²¹

Biology and Histology

Forty percent of retinoblastomas are hereditary and associated with a germ-line mutation. The epidemiology of the disease prompted the development of the "two hit hypothesis."²²² The specific gene involved is now known as RB1, a tumor suppressor gene located on chromosome 13q14.²²³ The defective RB protein leads to a lack of control over cell-cycle regulation.

Histologically, retinoblastoma appears as basophilic cells with scant cytoplasm and having a high mitotic index.²²⁴ Flexner-Winstersteiner rosettes are characteristic, representing a specific orientation of photoreceptor cells.²²⁵

Clinical Presentation

Children with retinoblastoma most often present with leukokoria. The second most common presentation is strabismus.^{226,227} Less-common presentations include decreased vision, ocular inflammation, and family history of the disease.²²⁶

Diagnosis and Staging

Diagnosis of retinoblastoma is based on direct ophthalmoscopic evaluation. The characteristic finding of the tumor is a chalky, whitish-gray retinal mass with soft, friable consistency.²²⁸ CT scan of the head and orbits may demonstrate a solid intraocular tumor with intratumoral calcifications.²²⁹ Differential diagnosis includes persistent hyperplastic primary vitreous, Coats' disease, and ocular toxoplasmosis.²³⁰

Staging of retinoblastoma is based most commonly on the Reese-Ellsworth (RE) classification system developed in the 1960s. With more-modern treatment techniques, this system is not clearly prognostic for the ability to save either vision or life; however, it remains the most common staging system in use worldwide. Other staging systems have been developed.^{231,232} Metastatic retinoblastoma at the time of initial tumor diagnosis is relatively rare. When metastasis does occur, the disease can spread by direct extension (through the optic nerve or by choroidal invasion), by contamination of the subarachnoid space and dissemination through the cerebrospinal fluid, by hematogenous spread (most commonly to lung, bone, bone marrow, and brain), or by lymphatic spread

to the conjunctivae and lids.²²⁸ When metastases are suspected, formal staging evaluation, including bone marrow aspirate and biopsy, lumbar puncture, and radionuclide bone scan should be done.

Prognostic Factors

Prognosis for children with retinoblastoma has improved dramatically over the past decades, with approximately 90% of all children diagnosed being cured of their disease. Patients with overt metastatic disease at the time of diagnosis continue to have a very poor prognosis. Risk factors for development of metastatic disease include extension of the tumor in the optic nerve beyond the lamina cribosa and extrascleral extension into the orbit.^{233,234}

Current Principles of Therapy

Traditionally, retinoblastoma was treated with enucleation or with external-beam radiation (EBRT). Recent treatment regimens have tried both to avoid enucleation in attempts to save vision as well as to avoid using external-beam radiation because of the risk of secondary cancers, endocrinopathies, and facial hypoplasia.²³⁵ Low-stage tumors can often be managed with local therapy alone. Local treatment modalities that avoid the need for enucleation include cryotherapy, laser photocoagulation, plaque radiotherapy, and thermotherapy.

Retinoblastoma is a chemotherapy-sensitive tumor, with the active agents currently employed including vincristine, carboplatinum, etoposide, adriamycin, and cyclophosphamide.²³⁶⁻²⁴³ The use of systemic chemotherapy in conjunction with local therapy, without enucleation or EBRT, in the treatment of patients with lower-stage disease has been successful.^{237,239,244}

For patients who have RE stage V disease at diagnosis, enucleation remains the standard of care.^{237-239,243,245,246} The role of adjuvant chemotherapy for those with poor prognostic features to prevent metastatic disease is generally recommended, although this idea has not undergone rigorous randomized controlled study.²⁴⁶ There currently are no specific criteria for which patients with intraocular retinoblastoma with extraretinal extension should receive chemotherapy.

Patients with metastatic disease have a grim prognosis, with an average survival of 6 months.²⁴⁷ For individuals with disseminated disease, the use of myeloablative therapy and autologous stem cell rescue may have some role.²⁴⁷⁻²⁵⁰ Patients with trilateral retinoblastoma also fare extremely poorly despite aggressive therapy. Interestingly, those patients with bilateral retinoblastoma who have received neoadjuvant chemotherapy may be protected from developing pineal blastoma.²⁵¹

Late Effects of Therapy

The long-term sequelae of therapy for retinoblastoma include blindness or impaired vision related to extent of initial disease and local control therapies employed. Radiation therapy of the orbit in young children is associated with significant morbidity, including orbital growth abnormalities, endocrinopathies, and risks of secondary tumors. With the

increasing use of adjuvant chemotherapy in high-risk patients with retinoblastoma, long-term sequelae of these medications will also become problematic.

Patients with germ-line mutations in the RB1 gene are at increased risk of developing second primary tumors.^{223,252,253} Over the course of 50 years after their initial diagnosis, the risk of second primary tumors in those patients with heritable forms of retinoblastoma is 50%.²⁵⁴ Most commonly, the second tumor is osteogenic sarcoma, followed by other soft tissue sarcomas and malignant melanoma.^{223,252,253}

Germ Cell Tumors

Epidemiology

Germ cell tumors (GCT) represent approximately 3% of pediatric malignancies, equaling about 250 new cases per year in the United States.¹ GCT can occur in both gonadal and extragonadal sites. Extragonadal tumors occur more frequently in patients younger than 3 years of age; gonadal tumors occur more often during and after puberty.²⁵⁵

Phenotypically, female patients with part or all of the Y chromosome (such as those with gonadal dysgenesis, androgen resistance syndromes, or some patients with Turner's syndrome) are at increased risk of developing gonadoblastoma, a benign germ cell tumor found in dysgenetic gonads.^{256,257} In addition, males with undescended testes have an increased risk of developing GCTs, with the risk lessened but still elevated in those who undergo orchiopexy.²⁵⁸⁻²⁶⁰

Biology and Histology

Germ cell tumors include a diverse group of neoplasms with a presumed common cell of origin, the primordial germ cell. Extragonadal tumors are thought to arise from aberrancy from the complex migration pattern of germ cells during embryogenesis.

Cytogenetic findings in children with GCTs vary by site, age, and sex of the patient. Abnormalities in 1(12p) are very common in adolescent boys with testicular tumors, less common in girls with malignant ovarian GCTs, and rare in younger children with extragonadal GCTs.²⁶¹

The histology of GCTs is diverse and complex and includes teratomas and gonadoblastomas, which most often are benign and malignant GCTs, including yolk sac tumors, germinomas, embryonal carcinomas, and choriocarcinomas.²⁶²

Clinical Presentation

The clinical presentation of children with germ cell tumors varies by age, sex, and site of the tumor. Boys with testicular tumors most often present with a palpable or visible mass. Girls with ovarian tumors often present with abdominal pain, sometimes mimicking an acute abdomen. The clinical signs associated with extragonadal tumors vary with site of disease, with the most common sites involved including the sacrococcygeal area, the mediastinum, the central nervous system, or the retroperitoneum. Infants with sacrococcygeal tumors are often diagnosed prenatally by routine ultrasonography.

Diagnosis and Staging

Staging evaluation for malignant GCT should include abdominal, pelvic, and chest CT, bone scan, and measurements of beta-human chorionic gonadotropin (β -HCG) and AFP.²⁶³ In the evaluation of infants with GCTs, normative values for AFP must be taken into consideration, with baseline levels falling to adult levels by 8 months of age.²⁶⁴

Prognostic Factors

Overall outcomes for children with GCTs are very favorable. In two sequential Intergroup studies that included 515 patients, including 79 with immature teratomas and 436 with malignant CGTs, the OS at 8 years was 92%.²⁶⁵⁻²⁶⁷ Adverse prognostic factors include AFP greater than 10,000 kU/L, higher-stage disease, and extragonadal sites.

Current Principles of Therapy

Surgery is the therapy of choice for benign GCTs. For malignant GCTs, surgical resection remains important; however, given the effectiveness of chemotherapy, aggressive primary surgeries are not necessarily warranted. Chemotherapeutic agents known to be active in the therapy of GCTs include actinomycin, bleomycin, doxorubicin, cisplatin, carboplatin, and etoposide. The use of combination regimens has been shown to increase the chance of cure. The most common regimen currently employed, developed initially in adults and studied subsequently in children, includes bleomycin, etoposide, and cisplatin.^{268,269}

Recent Children's Cancer Group-Pediatric Oncology Group (CCG-POG) studies have used a risk-based approach to therapeutic decisions. In these studies, patients with stage I testicular malignant tumors and those with immature teratomas are considered low-risk and are treated initially with surgery alone. With this strategy, those with stage I testicular disease had an EFS of 79% and an OS of 100%²⁷⁰; those with immature teratomas had an EFS of 95% and OS of 98.7%.^{265,266}

Intermediate-risk patients have been defined as those with stage II testicular or stage I or II ovarian malignant GCTs. These patients were treated with surgery and four or six cycles of a modified Einhorn regimen. Patients with stage I ovarian tumors had an EFS and OS of 95% and those with stage II ovarian tumors had EFS and OS of 87% and 93%, respectively; those with stage II testicular tumors had an EFS and OS of 100%.^{265,266} Given the data regarding favorable outcome of patients with stage I ovarian tumors treated with surgery, only these patients will be considered low risk in future studies.²⁷¹⁻²⁷³

High-risk patients have been those with stage III or IV gonadal tumors and all stages of extragonadal extracranial malignant GCTs.²⁵⁵ These patients have been treated with surgery followed by four or six cycles of cisplatin, etoposide, and bleomycin. The use of higher-dose cisplatin improves EFS but does not improve OS and is associated with significant toxicity.²⁶⁷ In addition, the data suggested that those patients with stage III-IV testicular, stage III ovarian, and stage I-II extragonadal GCTs had excellent responses, with EFS 83% to 100% for the various subgroups.²⁶⁷ In future Intergroup studies, only those with stage IV ovarian and

stages III and IV extragonadal GCTs will be considered high risk.

Late Effects of Therapy

The chemotherapy for GCTs is associated with long-term risks of pulmonary toxicity, secondary leukemias, and hearing loss. Risk stratification done in an attempt to minimize exposure to individuals with lower-risk disease with these agents, while preserving excellent cure rates, remains an important focus of the management of children with GCTs.

Acute Myeloid Leukemia and the Myelodysplastic Syndromes

Jonathan E. Kolitz

Epidemiology and Etiology of Acute Myeloid Leukemia

The incidence of acute myeloid leukemia (AML) in the United States is about 2.5 per 100,000, with a strong association with increasing age.¹ Males are predominantly affected. There is a predilection for Caucasians in North America and Australasia.² The incidence of acute promyelocytic leukemia (APL) is increased in Hispanics and may be associated with a breakpoint in the PML-RAR α gene pathognomonic of that disease.³

The etiology of most cases of AML is unknown. The Hiroshima and Nagasaki atomic bombings⁴ and the Chernobyl nuclear plant disaster⁵ have been directly linked with causing AML. Therapeutic radiation alone has been shown to cause a fivefold-increased risk of AML in patients treated for ankylosing spondylitis⁶ and has been implicated in causing AML with favorable karyotypes.⁷

Cigarette smoking contributes to inducing AML, especially acute erythroleukemia.⁸ Pharmacogenomic studies have associated mutations in enzymes involved in the detoxification of tobacco-derived carcinogens with leukemia risk.^{9,10}

Leukemia in identical twins may have a shared clonal derivation, with leukemic progenitors migrating hematogenously within a monozygotic placenta from one twin to the other.¹¹ Genetic predispositions to developing AML have been documented in hereditary and sporadic diseases associated with numerical abnormalities in chromosome number, instabilities in DNA and chromatin structure, and defects in DNA repair mechanisms.¹²⁻¹⁴ Down syndrome has been linked to the development of acute megakaryoblastic leukemia.¹² AML can arise as an end stage in multiple myeloma¹⁵ and myeloproliferative disorders.

Treatment with alkylating agents and topoisomerase II inhibitors can cause AML.¹⁶⁻¹⁹ Among the antimetabolites, hydroxyurea induces AML, often harboring 17p mutations, in 3.5% of patients with essential thrombocythemia,²⁰ whereas methotrexate is probably not leukemogenic in patients treated for rheumatoid arthritis.²¹

Combining radiotherapy and chemotherapy markedly increases the risk of leukemia. The MOPP regimen (mechlorethamine, vincristine, procarbazine, and prednisone) plus radiotherapy for treating Hodgkin's disease is associated with a 2.3% to 13% risk of secondary leukemia at 15 years depending on the extent of the radiation.²²

Myeloablative treatments have been linked to development of myelodysplastic syndrome (MDS) and AML. A 5% to 10% incidence of secondary MDS/AML has been observed following autologous transplantation for non-Hodgkin's lymphoma.^{23,24}

Major differences exist between therapy-related AML due to alkylating agents and those induced by inhibitors of topoisomerase II (anthracyclines, epipodophyllotoxins). Alkylating agent-induced AML often has a myelodysplastic phase, a latency period of 3 to 9 years, a strong association with chromosomal deletions, particularly involving chromosomes 5 and/or 7, and a tendency to be chemotherapy resistant. Topoisomerase II-related AML, which was initially observed as a therapy-related complication of childhood ALL,²⁵ usually presents without a myelodysplastic phase, tends not to display dysplastic changes in the diagnostic marrow, has a short latency period (usually less than 3 years), is often associated with balanced chromosomal translocations involving 11q23, and displays variable chemosensitivity.²⁶

Poor-risk secondary AML caused by alkylating agents is associated with deletions of chromosomes 5 and 7.^{27,28} Chromosome 5 abnormalities related to alkylating agent exposure are often associated with loss of heterozygosity for the tumor suppressor gene p53.²⁹ The balanced translocations that occur following exposure to topoisomerase II inhibitors frequently involve the MLL gene in chromosome 11q23³⁰ and multiple partner chromosomes.³¹

Balanced translocations can create fusion proteins that lead to impaired gene transcription and cellular differentiation; these have been categorized as class II mutations, distinct from class I mutations, which lead to the synthesis of proteins able to stimulate proliferation and/or impede cell death.³² Figure 63.1 illustrates these two major mutation categories. Class II mutations occur in favorable risk cases of

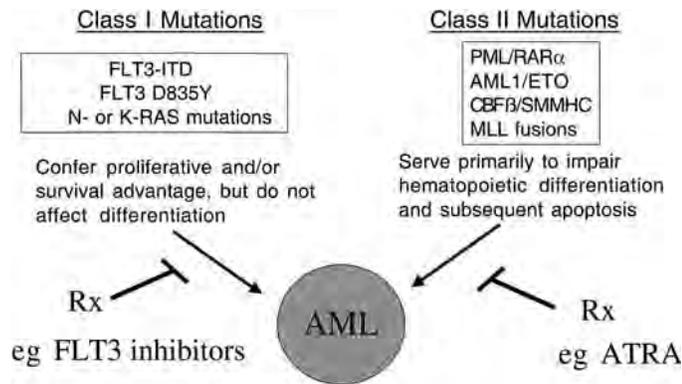

FIGURE 63.1. Class I and II mutations and the origin of acute myeloid leukemia (AML). Class I mutations induce proliferation and enhance survival of leukemic cells whereas class II mutations impede differentiation. Both may be needed to induce acute leukemia. (From Gilliland DG, Griffin JD. *Blood* 2002;100:1532–1542.)

AML, including APL and the core-binding factor (CBF) leukemias marked by t(8;21), inv(16), or t(16;16).

An internal tandem duplication and activation loop mutations in FLT3 (fms-like tyrosine kinase 3) are class I mutations that occur in up to 30% of patients with AML and are often associated with normal cytogenetics and inferior outcomes.³² Absence of the wild-type FLT3 allele particularly correlates with poor response to therapy.³³ Activating class I mutations also occur in the Ras family of oncoproteins, which transmit downstream signals stimulating cell proliferation after undergoing farnesylation.³⁴ Ras mutations have a high prevalence (20%–40%) in AML and may strongly contribute to the expansion and myeloid differentiation of early progenitor cells.³⁵ The Ras pathway has been shown to be stimulated by mutations in SHP-2, a cytoplasmic tyrosine phosphatase.³⁶ An important common pathway leading to cell proliferation, differentiation, and survival involves signal transducer and activator of transcription (STAT) factors.³⁷ Mutated FLT3 and other tyrosine kinases can directly phosphorylate and activate STAT molecules.

Survival signals that inhibit programmed cell death, or apoptosis, also contribute to the growth advantage of myeloid leukemia cells.³⁸ Activation of caspases, enzymes that are final common mediators of cell death following stimulation by proapoptotic signals, is commonly impaired in myeloid leukemic cells, with the degree of dysregulation also correlating with clinical outcomes.³⁹ NF-kappa B is an antiapoptotic and proliferative stimulus present in leukemic progenitors but not in quiescent, normal pluripotent stem cells.⁴⁰ Among proapoptotic mediators, mutations in p53 occur in a minority of patients with AML, most often in the setting of 17p deletions,⁴¹ whereas mutations in the retinoblastoma 1 gene occur in 19% to 55% of cases of AML.⁴² p53 mutations have an adverse prognostic impact⁴³ whereas the clinical impact of Rb-1 mutations is unclear.⁴²

Diagnosis and Classification

The use of molecular techniques has helped reclassify the myeloid leukemias using prognostically important clinical and cytogenetic findings. Unlike the French-American-

British classification of AML,⁴⁴ which depends on morphology and histochemistry, the World Health Organization (WHO) classification (Table 63.1)⁴⁵ establishes categories of AML with distinct cytogenetics and more uniform clinical behavior.

The presence of 20% or more marrow blasts is required to diagnose AML because the FAB category of refractory anemia with excess blasts in transformation, which includes 20% to 29% blasts, behaves in a fashion identical to frank AML.⁴⁶ Frequently, therapy-related AML presents with dysplastic features reminiscent of RAEB-t, whereas AML with MLD will arise as a de novo disease with similar morphologic features. Of note, AML with MLD and therapy-related AML frequently share similar cytogenetic abnormalities, particularly, deletions of chromosomes 5 and 7 associated with alkylating agent exposure. Such dysplastic features affect prognosis.⁴⁷ The analysis of blast populations in bone marrow and peripheral blood smears and marrow biopsies continues to rely on immunohistochemical and flow cytometric techniques.⁴⁸ Specific antigen staining patterns characterize erythroleukemia⁴⁹ and megakaryoblastic leukemia.⁵⁰ Immunophenotyping, rather than morphologic and histochemical findings, is needed to diagnose AML with minimal differentiation (M0).⁵¹ Fluorescence in situ hybridization (FISH)⁵² and reverse transcriptase polymerase chain reaction (RT-PCR)⁵³ are occasionally helpful in identifying distinct subtypes of AML missed by cytogenetics. Spectral karyotyping permits simultaneous visualization of all chromosomes and can also complement classic cytogenetics.⁵⁴

Response criteria for the treatment of AML have been updated to recognize the methodologies available to identify

TABLE 63.1. The World Health Organization (WHO) classification of acute myeloid leukemia.

- I. Acute myeloid leukemia with recurrent genetic abnormalities
 - i. Acute myeloid leukemia with t(8;21)(q22;q22), (*AML1/ETO*)
 - ii. Acute myeloid leukemia with abnormal bone marrow eosinophils and inv(16)(p13q22) or t(16;16)(p13;q22), (*CBF β /MYH11*)
 - iii. Acute promyelocytic leukemia with t(15;17)(q22;q12), (*PML/RAR α*) and variants
 - iv. Acute myeloid leukemia with 11q23 (*MLL*) abnormalities
- II. Acute myeloid leukemia and myelodysplastic syndromes, therapy related
 - i. Following myelodysplastic syndrome or MDS/MPD
 - ii. Without antecedent myelodysplastic syndrome or MDS/MPD, but with dysplasia in at least 50% of cells in two or more myeloid lineages
 - iii. Alkylating agent/radiation-related type

MRD.⁵⁵ In addition to morphologic CR, cytogenetic and molecular CRs are also recognized. Detection of blast populations with the same immunophenotype as the presenting myeloid leukemia puts a patient's remission status in doubt. Persistence of pretreatment cytogenetic abnormalities in an otherwise remission marrow portends very poorly for disease-free survival (DFS).⁵⁶ Note is also made of the category of CRi, that is, CR with incomplete peripheral blood count recovery.

Prognostic Factors in AML

Advanced age correlates negatively with outcomes in AML because of the decreased ability of the elderly to withstand intensive chemotherapy and because of an increased prevalence of poor-risk cytogenetics. Furthermore, AML in the elderly has increased expression of multidrug resistance proteins, such as p-glycoprotein (Pgp).⁵⁷

The major factor predictive of CR, disease-free survival, and overall survival in AML, is the cytogenetics at time of diagnosis.⁵⁸⁻⁶⁰ Analysis of 1,213 patients treated on Cancer and Leukemia Group B (CALGB) trials segregates patients into favorable (CBF leukemias), adverse (including complex karyotypes with three or more abnormalities), and intermediate [normal, t(9;11), among others] risk groups.⁶⁰ The cumulative incidence of relapse observed in that analysis is shown in Figure 63.2.

The poor outcomes associated with therapy-related AML are due largely to adverse cytogenetics, with 76% of patients in one large series having abnormalities of chromosomes 5 and/or 7.¹⁸ Secondary AML displaying favorable karyotypes, such as inv(16) and t(15;17) have outcomes similar to de novo AML.⁷

Different series have found that isolated trisomies of chromosomes 8 and 21 have poor⁶¹ and intermediate⁵⁸ outcomes in de novo AML. Abnormalities of 3q have inferior responses to induction therapy and poor survival.^{58,60} Additional cytogenetic abnormalities, even those that are regarded as prognostically negative, do not alter the favorable risk associated

with CBF and APL karyotypes.^{58,60} Cytogenetic abnormalities involving 11q23 have been associated with monocytic leukemias and very poor outcomes.³¹ An exception may be t(9;11) when treated with intensive postremission therapy.⁶²

Partial tandem duplication (PTD) of the MLL gene occurs in up to 11% of patients with AML and normal cytogenetics and is associated with inferior DFS.^{63,64} MLL PTD is generally not present in patients with CBF leukemias.⁶⁴

FLT3 is the most frequently constitutively activated kinase in human leukemia.⁶⁵ Most such mutations occur in patients with normal karyotypes: they occur in 30% or more of patients with APL without prognostic impact⁶⁶⁻⁶⁸ and in less than 10% of patients with CBF leukemias.^{67,69}

Higher levels of Wilms' tumor 1 (WT1) protein gene expression correlate with inferior outcomes among patients with normal or good-risk cytogenetics.⁷⁰ Expression of mRNA for c-mpl, the thrombopoietin receptor, predicts for poor outcomes despite intensive chemotherapy.⁷¹ An example of a loss-of-function mutation associated with improved outcomes occurs in the myeloid transcription factor CCAAT/enhancer binding protein alpha-(C/EBP α).⁷²

The in vitro growth of leukemic cells in the absence of exogenous growth factors has prognostic import. Three-year survival was 39% in patients with blasts with a low proliferative capacity, as contrasted with a 3% survival in patients with blasts with the highest proliferative rate.⁷³

The presence of dysplastic changes in the presenting bone marrow has no additional negative implications beyond those related to the diagnostic karyotype.⁷⁴ Also significantly affecting overall survival (OS) is the presence of residual blasts in bone marrow early after induction chemotherapy,⁷⁵ the time taken to attain CR,⁷⁶ and persistent cytogenetic abnormalities following treatment.⁵⁶

Once remission is achieved, detection and quantitation of MRD has prognostic significance. Detection by RT-PCR of the PML-RAR α transcript associated with the t(15;17) of APL generally presages clinical relapse.⁷⁷ On the other hand, prolonged clinical DFS has been seen in patients with AML and t(8;21) despite the presence of the associated AML1-ETO transcript.⁷⁸ Studies using real-time RT-PCR for CBF α /MYH11 suggest that there are thresholds above and below which relapse and continued DFS occur in patients with AML and inv(16). Similarly, increased copies of mRNA for WT1 correlates with increasing risk of relapse.⁷⁰

Ultimately, unique gene expression profiles as measured using microarrays may provide more powerful prognostic findings. Early data show that patients with favorable cytogenetics have unique gene expression profiles.⁷⁹

Therapy of AML

The treatment of AML is usually initiated with an induction phase, aimed at eradicating the leukemic population with cytotoxic agents, with or without the use of myeloid growth factors. Once remission is achieved, treatment is directed at eradicating MRD, using moderate- to high-intensity consolidation chemotherapy. Increasing use of myeloablative regimens is occurring in suitable younger patients, while the role of postremission chemotherapy in older patients is unclear.

The Role of Anthracyclines in Induction Therapy of AML

The establishment of the importance of anthracycline-based induction chemotherapy for AML dates back more than 20 years.⁸⁰ Doxorubicin caused excess gastrointestinal toxicity as compared with daunorubicin, leading to its abandonment as part of most remission induction therapies.⁸¹

Multiple agents with similar structural and pharmacodynamic (intracellular topoisomerase II inhibition) properties, but distinct pharmacokinetic and toxicity profiles, are available and have been tested in Phase III trials. As outlined in Table 63.2, several large Phase III trials have pitted newer anthracyclines against daunorubicin in induction regimens for patients with untreated AML. All tested regimens incorporate a course of ara-c given by c.i.v. (continuous IV) for 7 days. Although trends favoring idarubicin have been noted with respect to CR incidence, only one trial has shown a survival advantage.⁸² None of these studies took into account a possible dose–response effect attributable to each anthracycline, nor were attempts made to establish comparable dose-limiting toxicities.

High-Dose Cytarabine Therapy

Attempts to overcome drug resistance in blast populations by giving higher than conventional doses of ara-c (high-dose cytarabine, HiDAC) have been evaluated in induction and postremission regimens. With respect to conventional ara-c dosing regimens, a Phase III comparison of two c.i.v. doses showed little difference in outcomes, except in patients less than 60 years of age, where a survival advantage was suggested for patients receiving the higher ara-c dose.⁸³ A Phase II trial in which 3 days of HiDAC were added to a 7 and 3 induction led to a high (89%) CR incidence and an OS of 55% at 5 years.⁸⁴ Patients were consolidated with an autologous or allogeneic transplant. Phase III trials of HiDAC have not shown major improvements in CR rates in patients with de novo AML. A Southwest Oncology Group (SWOG) randomized trial of daunorubicin plus HiDAC, or standard cytarabine and more conventional postremission therapy, showed no dif-

ference in CR rates or in OS, although a trend favoring HiDAC with respect to prolongation of DFS was noted.⁸⁵ Adding HiDAC to etoposide and daunorubicin led to a modest increase in OS and a far more striking increase in DFS in patients 15 to 60 years of age as compared with conventional doses of cytarabine.⁸⁶

HiDAC given during induction can be toxic and impede the timely delivery of postremission therapy, as seen in the SWOG trial in which more than twice as many patients were unable to receive postremission therapy after a HiDAC induction as compared with a standard dose ara-c induction.⁸⁵ HiDAC can cause significant neurotoxicity, especially irreversible cerebellar ataxia, the risk of which is considerably increased by patient age, and adverse renal and hepatic function,⁸⁷ as well as cumulative ara-c dose.⁸⁸

Hematopoietic Growth Factors During Induction Therapy

Table 63.3 summarizes results of the major Phase III trials that have evaluated the effect of myeloid growth factors following completion of induction chemotherapy. Modest benefits have been observed, mostly with respect to time in hospital and duration of neutropenia. Although trends favoring growth factor use have been variably noted, only one large Phase III trial showed a strongly significant impact on CR incidence in patients receiving granulocyte colony-stimulating factor (G-CSF).⁸⁹ One trial that evaluated marrow response status before starting growth factor also demonstrated an improvement in therapy-related mortality.⁹⁰ That trial also described a favorable impact on medical costs using granulocyte-macrophage colony stimulating factor (GM-CSF),⁹¹ while another study showed no such benefit.⁹² It can be concluded that use of myeloid growth factors following induction chemotherapy may cause modest reductions in febrile complications and length of hospitalization without stimulating regrowth of leukemic cells.

Two large European studies have shown that reduced probabilities of relapse and increased OS occurs when myeloid growth factors are used concurrently with induction

TABLE 63.3. Phase III trials of myeloid growth factors after induction chemotherapy.

Reference	N	Year	Age (years)	Induction therapy ^a	Growth factor	CR ^b	Comment
256	388	1995	≥60	7 + 3	GM-CSF Placebo	51% 54%	↓ days of neutropenia (15 vs. 17) with GM-CSF ($P = 0.02$); no effect on TRM. Nonglycosylated GM-CSF used. No marrow done before starting GM-CSF.
90	124	1995	55–70	7 + 3	GM-CSF Placebo	60% 44%	Doubling of median survival with GM-CSF ($P = 0.048$), with significant ↓ TRM. Glycosylated GM-CSF used. Marrow examined before GM-CSF started.
89	233	1995	≥65	7 + 4	G-CSF Placebo	70% 47%	Glycosylated G-CSF (lenograstim) used. No effect on OS or TRM. ↓ duration of neutropenia with G-CSF ($P < 0.001$).
257	521	1997	≥16	5 + 3 + etoposide	G-CSF Placebo	69% 68%	No difference in DFS or OS. ↓ days of neutropenia, hospitalization, antibiotics (all $P \leq 0.0001$) and number of patients needing antifungal therapy ($P = 0.04$) with G-CSF.
258	234	1998	≥55	7 + 3	G-CSF Placebo	50% 41%	Incidence of infection, time in hospital, overall survival same. 15% ↓ in time to neutrophil recovery ($P = 0.014$) and duration of infection with G-CSF.

^aInduction regimens consisted of 5–7 days of cytarabine 100–200mg/m² c.i.v. + daunorubicin 45mg/m² i.v. × 3 or 4 days, as indicated. Etoposide 100mg/m² i.v. × 5 was given concurrently in Ref. 257.

^bCR differences did not reach $P \leq 0.05$ except in Ref. 89 ($P = 0.002$). A trend favoring GM-CSF was noted in Ref. 90 ($P = 0.08$).

chemotherapy.^{93,94} Such “priming” studies aim at increasing the susceptibility of blast cells to cytotoxic agents by increasing the percentage of blast cells in S phase. A U.S. Phase III trial showed no benefit for priming.⁹⁵

Postremission Therapy

An important refinement in the use of postremission therapy has been the recognition that outcomes may differ greatly as a function of the cytogenetics detected in the diagnostic bone marrow. An important example is the susceptibility of the CBF leukemias to HiDAC-based regimens.

There appears to be less therapy-related toxicity when HiDAC is used during postremission as compared with induction therapy, partly because patients enter such therapy with intact cellular barriers against infection and bleeding, and partly because post-CR HiDAC therapy has often been given alone, without an anthracycline. In a three-arm Phase III trial comparing standard (100mg/m²), intermediate (400mg/m²) ara-c and HiDAC as postremission therapy for patients with de novo AML, patients treated with HiDAC had a 4-year DFS of 44%, versus 29% and 24% for patients treated with intermediate and standard ara-c doses, respectively ($P = 0.002$).⁹⁶ Analysis according to cytogenetic risk indicated that patients with the CBF leukemias especially benefited from HiDAC therapy, with a cure fraction well in excess of 50%.⁹⁷ Furthermore, the number of courses of HiDAC given during remission correlates with DFS among patients with t(8;21).⁹⁸ The large French experience with 271 patients with CBF leukemia suggests that outcomes using diverse postremission therapies, including HiDAC, IDAC, or myeloablative approaches, may be significantly affected by age in patients with inv(16) and t(16;16)⁹⁹ and the WBC count among patients with t(8;21).¹⁰⁰

Among patients not stratified by cytogenetic risk, a randomized comparison of four versus eight courses of intensive consolidation therapy showed no benefit for the more prolonged treatment arm.¹⁰¹ On the other hand, a large randomized trial concluded that intensive induction and consolidation chemotherapy incorporating daunorubicin,

mitoxantrone, conventional dose, and HiDAC, followed by either dose-reduced monthly maintenance or an additional course of intensive consolidation, led to a DFS advantage in patients with poor-risk prognostic features and an overall trend toward improved survival.¹⁰²

Whether the use of sequential, putatively noncross-resistant, significantly myelosuppressive chemotherapy regimens improves outcomes following attainment of CR was evaluated in an early Phase II trial in which HiDAC/asparaginase and amsacrine/etoposide were intercalated between three courses of conventional daunorubicin/cytarabine.¹⁰³ Although DFS may have exceeded that seen in historical controls at that time, an 18% incidence of therapy-related mortality in patients in CR proved prohibitive. The EORTC and CALGB have also evaluated noncross-resistant chemotherapy regimens following CR without demonstrating improvements in outcome.^{104,105}

The Role of Transplantation in Acute Myeloid Leukemia

Whether transplants using autologous or allogeneic marrow or peripheral blood stem cells (PSC) improve outcomes in AML in first CR continues to be debated even after the completion of several large Phase III trials. A meta-analysis of published trials evaluating autologous transplantation for AML in first CR concluded that DFS is significantly prolonged ($P = 0.006$) but not OS.¹⁰⁶ Such analyses do not weigh variables such as cytogenetic risk, time to transplant, use of marrow rather than PSC, and the chemotherapy used before stem cell harvesting. Studies using an intent-to-treat analysis evaluating transplantation versus chemotherapy have not fully addressed the different risks of relapse among distinct cytogenetic risk groups after initial CR is achieved. Allogeneic transplantation is not easily amenable to randomized analysis: our understanding of the relative benefits of allogeneic transplantation relies on retrospective analyses of outcomes among patients undergoing “genetic randomization” who are assigned allografts if they had a matched sibling donor.

TABLE 63.4. Phase III trials of autotransplantation versus chemotherapy in AML in first CR.

Reference	Year	N	Induction CR, %	Received post-CR therapy	Received autotransplantation ^a	DFS		OS	
						Auto	Chemo	Auto	Chemo

109	1998	1966	77%	89%	11% ^e	53 ^f	40	57	45
107	1998	808	70%	67%	54%	35	35	43	52 ^g

^aOf all CR patients, excluding those assigned to allografts.

^bEstimate based on 623 patients in CR, 168 assigned to allograft, leaving 455 patients in CR who could have been randomized to autologous transplant vs. chemotherapy: 95 underwent autotransplants.

^c $P = 0.05$.

^dEstimate based on 367 CRs minus 73 allografts = 294 patients potentially eligible to be randomized to autograft of whom 75 were autografted patients.

^eAn additional 7% elected to undergo autotransplant and were not randomized.

^f $P = 0.04$, 381 patients randomized among 1,131 eligible.

^g $P = 0.05$.

Outcomes from the four large Phase III trials that have compared autologous and allogeneic transplantation and non-myeloablative chemotherapy are summarized in Tables 63.4 and 63.5. Important differences between the studies include the number and intensity of post-CR consolidation regimens before randomization between chemotherapy and transplant, the length of time between achieving CR and randomization, the transplant conditioning regimens, and therapy-related mortality. Only one study utilized ex vivo purged autologous marrow.¹⁰⁷ Two trials showed a DFS advantage favoring autologous transplant, which did not translate into improved OS because of effective salvage therapies.^{108,109} When analyzed according to cytogenetic risk, a DFS and OS benefit was noted in patients with intermediate-risk cytogenetics.¹¹⁰ The DFS associated with chemotherapy alone was unusually low in one of the trials.¹⁰⁸ On the other hand, therapy-related mortality significantly affected transplant outcome in another trial in which patients who were randomized to receive chemotherapy had significantly improved OS.¹⁰⁷

In the absence of readily available and reliable methodologies to purge leukemic cells ex vivo, increasing emphasis has been placed on the concept of in vivo purging, for example, utilizing either repeated courses or higher doses of chemotherapy to effect a reduction in the leukemia cell burden below a critical threshold that may result in fewer relapses.

Multiple, sequential courses of moderately intensive therapy were used in the MRC AML 10 trial, leading to a sig-

nificant improvement in DFS in the relatively small number of patients who completed three courses of postremission therapy before transplant.¹⁰⁹ A single, highly myelosuppressive regimen of HiDAC and high-dose infusional etoposide has been used in patients in first CR for in vivo purging and stem cell mobilization and collection in a Phase II trial.¹¹¹ Following an etoposide and busulfan autotransplant, 55% of 128 patients reached 5 years disease free. Whether such brief duration, high-intensity approaches will improve outcomes in a larger cohort of patients uniformly categorized according to cytogenetic risk is undergoing evaluation by the CALGB.

A direct comparison between allogeneic and autologous transplantation in patients 45 years of age or younger in first CR showed that patients with donors had improved DFS and reduced RR, with the benefit confined to patients with adverse risk cytogenetics.¹¹² These findings are in keeping with disappointing results of high-dose in vivo purging in patients with poor-risk cytogenetics.¹¹¹ Data from an intergroup trial show that favorable risk cytogenetics patients benefit from autologous and allogeneic transplantation more so than chemotherapy, whereas poor-risk karyotypes respond best to allografting.¹¹³ Whether outcomes for autotransplant can be improved upon if the approach is limited to patients with minimal tumor burdens remains unclear. DFS has been shown to be inversely related to levels of MRD before autotransplant.¹¹⁴

Not surprisingly, tumor burden before allogeneic transplantation is less critical, largely in part of the graft-versus-

TABLE 63.5. Phase III trials of “genetic randomization” comparing allogeneic transplant versus chemotherapy in previously untreated AML.

Reference	Year	DFS		OS		Comment

leukemia effect exerted by the allograft.¹¹⁵ Outcomes following allogeneic transplant performed in patients in early relapse are comparable to those seen in patients in first CR.¹¹⁶ Furthermore, results following allografts in patients in CR are not improved by administering one course of HiDAC before transplant.¹¹⁷

Nonmyeloablative or reduced-intensity (RI) allografts exploit the graft-versus-leukemia effect mediated by donor lymphocytes that occurs after the achievement of partial or full engraftment.¹¹⁸ Cytotoxic agents are used mainly to inhibit host immune responses before infusion of donor stem cells rather than to exert an antileukemic effect. Immunosuppressive regimens are critically important to modulate what can be severe graft-versus-host disease (GVHD). The degree to which chimerism develops correlates both with antileukemic effects and morbidity and mortality, which may be substantial, from GVHD.¹¹⁹ Because the antileukemic effect mediated by the graft may be aborted by rapidly progressive disease, outcomes are likely to be improved if patients are transplanted in remission.¹²⁰ Older patients who may not be candidates for a full allograft could be considered for RI transplantation.

Induction Regimens for Relapsed and Refractory Acute Myeloid Leukemia

HiDAC-Based Regimens

As is the case in untreated AML, cytogenetic abnormalities are predictive of outcome following salvage therapy of patients in relapse or with refractory disease.^{121,122} An additional important prognostic factor is the duration of first CR: multivariate analyses point to a 6-month cutoff as being significant,^{122,123} whereas a univariate analysis suggests that cytogenetics are particularly important when the CR duration is less than 1 year.¹²¹ Patients who have initial remissions lasting beyond 2 years may have an outlook comparable to that of previously untreated patients.¹²¹ Other prognostic markers include the WBC, blast percentage in blood and/or marrow, serum lactate dehydrogenase (LDH), and bilirubin levels.

HiDAC-containing regimens were first evaluated in relapsed and refractory AML, where CR incidences between 40% and 60% have been reported when given alone or in combination with an anthracycline or etoposide. Representative studies are outlined in Table 63.6.

Multiple salvage regimens for relapsed and refractory AML have been published using intermediate (IDAC) to high doses of cytarabine. Examples include the FLAG and FLAG-Ida regimens,¹²⁴⁻¹²⁶ and the MEC regimen, which consists of mitoxantrone, etoposide, and IDAC.¹²⁷ High-dose mitoxantrone and HiDAC attempts to exploit the potential for a dose response associated with single high doses of mitoxantrone (80 mg/m²).¹²⁸ Topotecan has been combined with IDAC and studied with¹²⁹ and without^{130,131} cyclophosphamide. A liposomal preparation of daunorubicin (DaunoXome) has gone through a dose-escalation evaluation in combination with IDAC.¹³² Although remissions can be achieved with any of these regimens, durable responses occur only for patients undergoing stem cell transplantation. The FLAG and topotecan/cytarabine regimens can occasionally be helpful in older patients who either cannot receive an investigational agent or are precluded from receiving an anthracycline-based reinduction because of comorbidities.

A critical consideration is the lack of tabulation of many earlier trials treating relapsed/refractory AML according to cytogenetic risk. Extrapolating from outcomes seen in previously untreated patients with RAEB, and what is now described as AML with MLD, and poor-risk cytogenetics treated with FLAG or FLAG-Ida,⁴⁶ brief remissions and adverse karyotypes are the strongest predictors of poor outcome to conventional salvage regimens. Ideally, therefore, patients with such adverse findings at relapse should be considered for investigational therapies.

Non-HiDAC-Containing Salvage Therapies

Multiple Phase I and II trials have explored the use of alternative induction regimens that do not include HiDAC or, in some instance, dispense with ara-c entirely. Examples of such regimens are outlined in Table 63.7. Regimens using single agents have generally been associated with poor outcomes. Demonstration of antileukemic effects, including achievement of transient marrow aplasia, using these agents may justify further evaluation in combination regimens and in less heavily pretreated patients. Liposomal daunorubicin appears to have single-agent activity and has been combined with IDAC with moderate efficacy in a Phase I-II dose-escalation study.¹³² A larger Phase II or III evaluation using the recommended dose of DaunoXome (135 mg/m² q d × 3 days) has yet to be performed.

TABLE 63.6. Trials of high-dose cytarabine (HiDAC)-containing regimens in relapsed/refractory AML.

Treatment of Acute Myeloid Leukemia in the Elderly

Because the median age of AML in the United States is 63 years, a major proportion of clinical decision making involves a patient population with frequently significant comorbidities. Furthermore, older patients are more likely than younger patients to present with adverse prognostic features, especially unfavorable cytogenetics, antecedent myelodysplastic syndrome, AML with multilineage dysplasia,¹³³ and Pgp expression.⁵⁷

Multiple trials have compared the option of best supportive care with that of induction chemotherapy for older patients with AML. A retrospective multivariate analysis of conventional chemotherapy versus best supportive care indicated that chemotherapy administration and LDH less than 400 were significantly associated with prolonged survival.¹³⁴ Prospective studies, all nonrandomized, show trends toward better OS with therapy as compared with best supportive care.¹³⁵ The very elderly (age 80 or more), on the other hand, may not benefit from chemotherapy as compared with patients who are just 10 years younger.¹³⁶

Once a decision is made to treat an elderly patient with AML, scant evidence exists pointing to the superiority of one regimen over another. Among randomized studies, SWOG has shown that using mitoxantrone and etoposide instead of standard daunorubicin and cytarabine in untreated elderly patients offers no meaningful advantages and may be inferior with respect to OS.¹³⁷ The MRC randomized 1,314 older patients between three anthracycline- and cytarabine-containing regimens and showed a significantly higher CR rate for daunorubicin + 6-thioguanine (DAT) but no effect on OS.¹³⁸ A small Phase III trial comparing high-dose versus standard-dose mitoxantrone, each in combination with cytarabine, showed no differences with respect to CR incidence, DFS, and OS.¹³⁹ Among nonanthracycline-containing regimens, FLAG has been used extensively by hematologists

in older patients with untreated and relapsed AML. A Phase III trial that compared Ara-C and G-CSF with and without fludarabine showed that although Ara-CTP incorporation into the DNA of leukemic blast cells is enhanced by fludarabine, no significant differences in CR incidence, DFS, and OS were noted.¹⁴⁰

Attempts at reversing multidrug resistance using drugs that inhibit Pgp are reviewed above. Gemtuzumab ozogamicin has been used with and without interleukin (IL)-11 in this patient population, with retrospective data indicating that outcomes cannot justify using the regimen in place of conventional idarubicin and cytarabine.¹⁴¹ The CALGB is planning to study the effect of the bcl-2 antisense inhibitor G3139¹⁴² when combined with daunorubicin and cytarabine in a Phase III trial in untreated elderly patients.

Whether elderly patients in CR should receive postremission therapy is unsettled. Unmaintained remissions of 6 to 9 months have been noted following standard- or high-dose mitoxantrone plus cytarabine induction regimens, results comparable to those seen when postremission therapy is given.¹³⁹ The EORTC and ECOG demonstrated a trend toward improved DFS but not OS using courses of low-dose SC ara-c as compared with observation in older patients in CR.^{143,144} More intensive consolidations using mitoxantrone and an IDAC variant¹⁴⁵ or HiDAC^{96,146} have not improved outcomes in this patient population.

Acute Promyelocytic Leukemia

Acute promyelocytic leukemia (APL) is the most curable of AML subtypes. It is characterized by a pathognomonic translocation, t(15;17), and an associated fusion protein (PML-RAR α) that underlies the disease's pathogenesis. PML-RAR α promotes histone deacetylation, thereby inhibiting gene transcription, an effect that is reversed by all-*trans* retinoic acid (ATRA).¹⁴⁷

The efficacy of oral administration of ATRA in inducing CR in APL when used as a single agent is well established.¹⁴⁸ Among large Phase III trials comparing ATRA monotherapy and combination chemotherapy inductions, the North American Intergroup study showed that ATRA improved DFS but not CR incidence whether given before or after chemotherapy.¹⁴⁹ That study also suggested a dose response on the part of APL to anthracycline therapy, a finding consistent with the fact that APL has low expression of p-glycoprotein.¹⁵⁰ Phase II data exist supporting the efficacy of an ATRA and idarubicin induction regimen for APL that omits cytarabine,¹⁵¹ as well as an ATRA plus arsenic trioxide (ATO) regimen, which dispenses with chemotherapy altogether.¹⁵²

Current practice generally involves concurrent administration of ATRA with anthracycline-based induction therapy on the basis of Phase III trials that have found a superior DFS when ATRA and chemotherapy are given concurrently. A significant improvement in CR incidence (87% versus 70%) for concurrent versus sequential ATRA plus chemotherapy has been seen,¹⁵³ whereas a second trial in which a formal ATRA monotherapy induction was followed by chemotherapy and compared with concurrent ATRA/chemotherapy noted no difference in CR rates but found that EFS survival was significantly improved at 2 years (86% versus 75%).¹⁵⁴ The incidence of the ATRA syndrome, a major, potentially lethal complication of ATRA therapy,¹⁵⁵ has been markedly reduced when chemotherapy and ATRA are given together.¹⁵⁶

In relapsed APL, ATO induced CR in 84% of 41 patients,¹⁵⁷ and the humanized anti-CD33 monoclonal antibody Hum195 effected molecular CR in 11 of 22 relapsed patients reinduced into clinical CR with ATRA.¹⁵⁸ More than 80% of patients attained undetectable levels of the PMR-RAR α transcript by RT-PCR following ATO induction and consolidation therapy.¹⁵⁷ The current North American Intergroup study is assessing the effect of ATO consolidation therapy in APL patients in first CR when given before consolidation chemotherapy.

Another question being addressed in the North American Phase III trial is the relative benefit of two forms of maintenance chemotherapy: ATRA given intermittently for 1 year with or without concurrent daily low-dose oral chemotherapy with daily purinethol and weekly methotrexate. The possible benefit of ATRA maintenance has been previously described when given alone¹⁵⁹ and in combination with low-dose chemotherapy.¹⁵⁴

The studies cited previously indicate that long-term DFS in 80% or so of patients with untreated APL is being realized. In event of relapse, encouraging data demonstrate that autologous transplantation in patients with APL in second remission, who have achieved molecular eradication of the PML-RAR α transcript, an outcome often achievable with ATO-based salvage treatment, enjoy prolonged second remissions.¹⁶⁰

New Agents for the Treatment of Acute Myelogenous Leukemia

Immunotherapy of AML

Monoclonal antibodies can be used to potentiate the effects of combination chemotherapy in the treatment of bulk leukemia, or can serve as a means of eradicating MRD.

Although, in principle, unlabeled antibodies can be combined with chemotherapy with little additive toxicity, only one large Phase III has been conducted: patients with relapsed AML over age 60 were randomized to receive salvage chemotherapy with or without Hum195, a humanized anti-CD33 antibody.¹⁶¹ No definite advantage was seen in the antibody-containing arm.

M195, whether labeled or unlabeled, can cause at least transient antileukemic effects with acceptable toxicity. The replacement of β -emitting radiolabels, such as yttrium and iodine-131 with the pure α -emitter bismuth-214, allows for the retention of significant antileukemic effects with a reduced incidence of myelosuppression.¹⁶²

Gemtuzumab ozogamicin (GO) is a murine anti-CD33 antibody construct that is linked to calicheamicin. Modest single-agent activity for this antibody has been documented in Phase II trials, with the largest overview of its efficacy being a report of 157 older patients in first relapse.¹⁶³ Relapsed patients whose first CR lasted more than 1 year had a 35% CR rate, with the probability of CR falling to 9% in patients with first CR durations less than 6 months. In general, the incidence of febrile complications following GO therapy is comparable to that seen with cytotoxic therapy, whereas the incidence of mucositis appears lower and that of hepatotoxicity, including a low but troublesome incidence of venoocclusive disease (VOD), is higher. The likelihood of developing VOD is increased substantially in patients who receive allogeneic transplants within 4 months of treatment with GO.¹⁶⁴

A Phase II study of GO with or without the thrombopoietic agent interleukin 11 led to CR incidences and remission durations in poor-risk AML and MDS patients that were inferior to those achieved at the same institution using conventional chemotherapy with idarubicin and cytarabine.¹⁴¹

GO has been combined with several chemotherapy regimens for treating relapsed and refractory^{165,166} as well as previously untreated AML.^{167,168} To date, these early data have only demonstrated the feasibility of such combination therapies.

Other monoclonal radiolabeled antibodies which have been used for treating AML, either as salvage therapy or as part of a myeloablative transplantation regimen, include ¹³¹I¹⁶⁹ and ²¹⁴Bi¹⁶² conjugates of M195, ¹³¹I-anti CD45,¹⁷⁰ and ¹⁸⁸Re-anti CD66.¹⁷¹

Interleukin 2 (IL-2), which can induce immune responses on the part of cytotoxic T cells and NK (natural killer) cells against autologous blasts in vitro, and that has exerted antileukemic effects in poor-risk patients, has shown an acceptable safety profile when used as a postremission therapy.^{172,173} Evaluations of the effectiveness of IL-2 as a postremission adjuvant therapy for AML are ongoing. A construct of GM-CSF linked to diphtheria toxin has shown modest activity in heavily pretreated, chemotherapy-refractory patients.¹⁷⁴ A noteworthy development has been the observation of significant anti-AML effects following vaccination of AML patients with an HLA-A2-restricted peptide.¹⁷⁵

Multidrug Resistance (MDR) Modulation

Chemotherapy resistance is partly mediated by P-glycoprotein (Pgp), a cell membrane drug efflux pump encoded by the *MDR1* gene. Significant expression of Pgp is age related, with Pgp positivity noted in close to three-quarters of patients over

TABLE 63.8. New agents for the treatment of AML.

Reference	Agent	Target	Toxicity	Results	Comment
243, 274, 275	R11577 (Tipifarnib, Zarnestra)	Farnesyl transferase	DLT = neurotoxicity in phase I; minimal toxicity in phase II	About 20% CR in untreated patients; very low CR in previously treated patients	Response associated with inhibition of farnesylation in vivo
276	CEP-701	FLT3	DLT not identified	Transient blast clearance documented in PB and BM	Response correlates with inhibition of FLT3 autophosphorylation
277	SU11248	FLT3	50 mg po qd well tolerated; grade 4 cardiac, fatigue, hypertension at 75 mg po qd	4/4 brief PR in mutated FLT3; 2/10 in wild type	In vivo inhibition of phosphorylation of tyrosine kinases (c-kit, FLT3, VEGF)
278	PKC412	FLT3	75 mg po tid well tolerated; 2 fatal pulmonary events of unclear etiology	7/20 > 2 log reduction in blasts; median 13 weeks	FLT3 autophosphorylation inhibited in vivo
234	SU5416	VEGF-R 1, 2	Grade 3/4 in 7%–14%: headaches, infusion-related reactions, dyspnea, thrombotic episodes	3/33 refractory/relapsed AML PR	Marked apoptosis and necrosis in marrows of some patients with AML between days 7 and 14 after beginning therapy
279	Bortezomib (PS-341, Velcade)	Proteasome	DLT \geq 3 syncope, orthostatic hypotension, edema, noncardiac chest pain	Transient decreases in blasts noted	44%–63% nonsustained proteasome inhibition documented
142	Oblimersen (G3139, Genasense)	BCL-2	Combined with FLAG; no clear DLT	5/17 CR	75% had BCL-2 mRNA downregulated in vivo

age 55.⁵⁷ Multivariate analyses have shown that only Pgp expression and cytogenetics are independent predictors of complete remission (CR) and overall survival (OS) in de novo AML.^{176–178}

Favorable effects on CR incidence occurred in patients receiving quinine, a Pgp inhibitor, with idarubicin and ara-c induction therapy who also demonstrated in vitro efflux of the Pgp substrate rhodamine-123.¹⁷⁹ No overall survival advantage was seen, however. Attempts to pharmacologically reverse Pgp activity have centered on the use of cyclosporin A (CsA) and its nonimmunosuppressive analogue, PSC-833 (Valspodar; Novartis). Both drugs competitively inhibit Pgp function and diminish drug efflux in vitro.^{180–183} Promising results favoring the use of CsA as a Pgp modulator with infusional daunorubicin and HiDAC in a Phase III trial in poor-risk AML conducted by the Southwest Oncology Group¹⁸⁴ have yet to be duplicated using PSC-833. Three Phase III studies evaluating PSC-833 have been terminated, however. Toxicity concerns halted a trial in older patients with de novo AML,¹⁸⁵ whereas a Phase II trial in relapsed/refractory patients ended because of lack of benefit in the experimental arm.¹⁸⁶ A recent Phase III trial in untreated AML in patients more than 60 years of age conducted by the Medical Research Council (MRC) demonstrated early excess mortality from PSC-833-containing daunorubicin, cytarabine, and 6-thioguanine induction therapy, which became inapparent with further follow-up.¹⁸⁷ On the other hand, nonrandomized Phase I/II data in patients less than 60 years of age with untreated AML suggest a favorable effect on DFS and OS, particularly in patients less than 45 years of age.¹⁸⁸

New Cytotoxics and Signal Transduction Inhibitors

Among new nucleoside analogues, Clofarabine exerts significant antileukemic effects when used as a single agent in relapsed AML, with toxicity consisting of moderate liver function abnormalities.¹⁸⁹ The 1-nucleoside analogue troxa-

citabine has in vitro antileukemic activity that is complementary to that mediated by ara-c.¹⁹⁰ Disappointingly, troxacitabine when combined with ara-c or with idarubicin, was found highly likely to be inferior to idarubicin and ara-c in the treatment of older patients with AML and poor-risk karyotypes.¹⁹¹ These studies have shown that the major non-hematologic toxicities of troxacitabine are mucositis and hand-foot syndrome.

A host of interesting new agents that target protein kinases, mediators of angiogenesis, farnesyl transferase, DNA methylation, histone acetylation, and the proteasome are undergoing clinical investigation for the treatment of AML. A representative listing of these agents is found in Table 63.8, along with their targets and early clinical findings. Of great interest will be the determination of optimal means of using these agents and how best to sequence or combine them with chemotherapy.¹⁹²

The Myelodysplastic Syndromes

The myelodysplastic syndromes (MDS) encompass diseases marked by variable abnormalities in hematopoiesis, involving one or more lineages, usually accompanied by dysplastic marrow morphology involving two or three lineages. Marrow cellularity can vary markedly in these diseases, with an important overlap noted between some forms of hypocellular MDS, aplastic anemia, and paroxysmal nocturnal hemoglobinuria.¹⁹³ Increasing evidence supports the likelihood that many cases of MDS arise from a mutated hematopoietic stem cell.¹⁹⁴

MDS is predominantly a disease of the elderly, with 80% of patients diagnosed over age 60 years. Although the etiology of MDS is unknown in most cases, prior chemotherapy is a well-recognized cause. Factors involved in the pathobiology of MDS include abnormalities in apoptotic and growth signals, interactions with bone marrow stromal and vascular

TABLE 63.9. The World Health Organization classification of the myelodysplastic syndromes.

<i>Disease</i>	<i>Blood findings</i>	<i>Bone marrow findings</i>
Refractory anemia (RA)	Anemia No or rare blasts	Erythroid dysplasia only <5% blasts <15% blasts
Refractory anemia with ringed sideroblasts (RARS)	Anemia No blasts	>15% ringed sideroblasts Erythroid dysplasia only <5% blasts
Refractory cytopenia with multilineage dysplasia (RCMD)	Bi- or pancytopenias No or rare blasts No Auer rods <1 × 10 ⁹ /L monocytes	Dysplasia in ≥10% of cells of >2 lineages <5% blasts No Auer rods <15% ringed sideroblasts
Refractory cytopenia with multilineage dysplasia and ringed sideroblasts (RCMD-RS)	Bi- or pancytopenias No or rare blasts No Auer rods <1 × 10 ⁹ /L monocytes	Dysplasia in ≥10% of cells of ≥2 lineages <5% blasts No Auer rods ≥15% ringed sideroblasts
Refractory anemia with excess blasts 1 (RAEB-1)	Cytopenias <5% blasts No Auer rods <1 × 10 ⁹ /L monocytes	≥1 lineage dysplasia 5%–9% blasts No Auer rods
Refractory anemia with excess blasts 2 (RAEB-2)	Cytopenias 5%–19% blasts Auer rods ± <1 × 10 ⁹ /L monocytes	≥1 lineage dysplasia 10%–19% blasts Auer rods ±
Myelodysplastic syndrome—unclassified (MDS-U)	Cytopenias No or rare blasts No Auer rods	Unilineage dysplasia <5% blasts No Auer rods
MDS associated with isolated del(5q)	Anemia Usually normal or increased platelet counts <5% blasts	Normal to increased megakaryocytes with hypolobulated nuclei <5% blasts Isolated del(5q) No Auer rods

endothelial cells, and, in some cases, T- and NK cell-mediated autoimmune mechanisms. Strategies aimed at interruption of such mechanisms are reviewed next.

Table 63.9 depicts the WHO classification of MDS. Chronic myelomonocytic leukemia (CMML), which shares characteristics of MDS and myeloproliferative diseases and has a variable clinical course,¹⁹⁵ has been placed in a separate category of myelodysplastic/myeloproliferative disorders. To improve the analysis of outcomes following treatment in each of these diseases, the International Prognostic Scoring System (IPSS) has gained acceptance because of its reliance on readily available clinical parameters and reasonable correspondence with prognosis.¹⁹⁶ The IPSS segregates patients into low, intermediate-1 and -2 (INT-1 and INT-2), and high-risk groups (Table 63.10). Figure 63.3 depicts the relationship between the IPSS categories, survival and probability of development of AML observed in 816 patients with MDS.

Standardized response criteria to be used to assess clinical trials in MDS patients have been agreed upon.¹⁹⁷ These criteria emphasize the importance of stratifying patients

according to the IPSS and looking at endpoints such as progression-free and disease-free survival.

Role of Hematopoietic Growth Factors in MDS

Erythropoietin (epo) has been shown to benefit a significant minority of patients with MDS. Patients with low marrow blast percentages and serum erythropoietin levels, and without red cell transfusion dependence, are more likely to respond to treatment with epo.¹⁹⁸ Prolonged administration of epo may be needed to effect a response.¹⁹⁹ Of interest is the observation that erythroid progenitors that have normal karyotypes by FISH analysis preferentially undergo expansion in response to epo.²⁰⁰

Several studies have utilized G- or GM-CSF in combination with epo, attempting to exploit a possible synergy between these agents with respect to stimulating erythropoiesis while also aiming to expand neutrophil numbers in neutropenic patients. Although not conclusive, the data suggest that the combination of G-CSF and epo may be more

TABLE 63.10. International prognostic scoring system for myelodysplastic syndromes.

<i>Prognostic variable</i>	<i>Score value</i>				
	<i>0</i>	<i>0.5</i>	<i>1.0</i>	<i>1.5</i>	<i>2.0</i>
BM blasts (%)	<5	5–10	—	11–20	≥21
Karyotype ^a	Good	Intermediate	Poor	—	—
Cytopenias	0–1	2–3	—	—	—

Scores for risk groups: low, 0; INT-1, 0.5–1.0; INT-2, 1.5–2.0; high, ≥2.5.

^a Good: normal, -Y, del(5q), del(20q); poor: complex (≥3 abnormalities) or chromosome 7 anomalies; intermediate: other abnormalities.

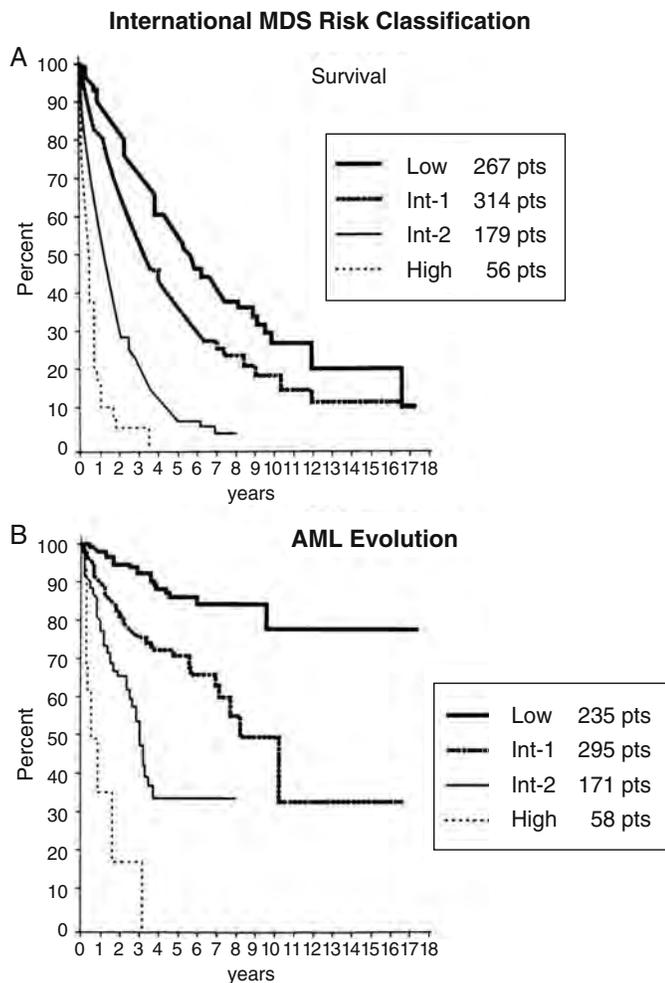

FIGURE 63.3. Probability of survival and evolution into AML according to International Prognostic Scoring System (IPSS) categories. (From Greenberg et al.,¹⁹⁶ by permission of *Blood*.)

effective than epo alone in stimulating erythropoiesis, particularly in patients in more favorable risk groups.^{201,202} Transfusion-dependent patients unresponsive to epo do not benefit from the addition of myeloid growth factors.²⁰³ With respect to neutrophil stimulation, one trial has shown that GM-CSF, with or without epo, can increase neutrophil counts by a median of fourfold without inducing an excess risk of conversion to acute leukemia.²⁰⁴

Attempts to stimulate thrombopoiesis in MDS and AML have included the use of IL-11, which appears to have modest platelet-stimulating properties,²⁰⁵ and thrombopoietin, which has not been shown to enhance platelet recovery following induction chemotherapy of AML and about which concerns have been raised regarding potential adverse effects on the biology of myeloid malignancies.²⁰⁶

Chemotherapy for High-Risk MDS

Selected patients with MDS with adverse cytogenetics and/or increased blasts who are younger, or who are at unacceptably high risk of infection because of neutropenia or who have an impaired quality of life because of platelet and/or red blood cell transfusion requirements, irrespective of age, may benefit from induction chemotherapy as used for treatment of AML.

In general, the benefit is limited, and the toxicity of induction therapy can be prohibitive in older patients.

Topotecan has been used to treat symptomatic patients with MDS either as a single agent²⁰⁷ or in combination with HiDAC.²⁰⁸ Although higher CR rates (56% versus 37%) were noted in Phase II trials using the combination as compared to single-agent topotecan, a subsequent large retrospective analysis comparing topotecan and HiDAC and FLAG regimens with standard idarubicin and cytarabine, showed that the newer regimens are likely inferior with respect to CR incidence, DFS, and OS.²⁰⁹ When adjusted for age, induction therapy of high-risk MDS yields an incidence of CR, and even cytogenetic CR, not very different from that seen in de novo AML. Remission durations, however, tend to be brief.²¹⁰

Pgp-reversal agents have been evaluated in high-risk MDS. Phase III trials comparing anthracycline and ara-c combinations with and without cyclosporine A²¹¹ or quinine,²¹² suggested response and DFS benefits in the experimental arms.

An analysis of outcomes following intensive therapies in selected patients with MDS, in some instances incorporating transplantation, and categorized according to the IPSS, indicates patients with intermediate-1, intermediate-2, and high-risk disease had survivals of 2.6, 3.4, and 0.9 years, respectively.²¹³ A pilot evaluation of myeloablative therapies in patients with MDS demonstrated a 12-month median DFS, with 29% of patients disease free at 4 years²¹⁴; 110 patients who underwent allografts from HLA-matched related or unrelated donors showed a 5-year survival ranging between 8% and 30%, with poor outcomes associated with TBI-containing preparative regimens and the use of cyclophosphamide and targeted blood levels of busulfan without TBI leading to better results.²¹⁵ Reduced-intensity allogeneic transplant regimens are being investigated to reduce the toxicity and expand the applicability of transplantation for patients with poor-risk MDS. An innovative and preliminarily effective example of this approach used photopheresis, pentostatin, and TBI as the preparative regimen in patients with MDS (median age, 54), who then received either matched related or unrelated allografts.²¹⁶

Immunosuppressive Therapy for MDS

CsA and antithymocyte globulin (ATG) have been studied in patients with MDS using as a rationale the possible contribution of cytotoxic T-cell-mediated marrow suppression to cytopenias. Oligoclonal expansions of T cells have been linked to the pathogenesis of MDS,²¹⁷ with clinical responses to immunosuppressive therapies accompanying suppression of such clonal populations.²¹⁸ Combined treatment with ATG and CsA has induced major responses in patients with aplastic anemia who clinically overlap with cases of hypoplastic MDS on the basis of having typical MDS clonal cytogenetic abnormalities.²¹⁹ Using either horse or rabbit ATG, significant responses were seen in 10 of 35 patients with MDS, with all responses occurring in patients with refractory anemia (RA), particularly in those with brief disease duration.²²⁰ Ten of 20 patients with MDS and less than 10% marrow blasts (8 of 13 responders had RA) developed transfusion independence following treatment with equine ATG.²²¹ Durable CRs following ATG therapy were seen in 4 of 18 patients with RA and RARS. Limited efficacy and significant toxicity were observed in another trial of ATG in unselected patients with MDS.²²²

Five of nine patients with hypoplastic RA developed red cell and/or platelet responses to treatment with CsA.²²³ A multicenter study of CsA in MDS showed significant erythroid responses irrespective of marrow cellularity that was confined to patients with RA, particularly those positive for HLA-DR15 and without adverse cytogenetics.²²⁴ A higher probability of response to ATG or CsA can be predicted among younger patients who are HLA DR15 positive and have had short periods of red cell transfusion dependence.²²⁵

Antioangiogenic, Cytokine, and Signal Transduction Modulatory Therapies

As observed in trials of patients with MDS using immunosuppressive therapies, responses to treatments aimed at inhibiting angiogenic mediators are most likely to occur in patients with low-risk MDS and to consist mainly of increments in the hemoglobin. Thalidomide induced such responses in 19% of 83 registered patients, only 51 of whom completed 12 weeks of therapy and were considered evaluable.²²⁶

CC5013 (Revlimid) is a derivative of thalidomide that has more potent antiangiogenic effects while inducing less neurotoxicity and more myelosuppression. Early data using this orally available agent suggest that tolerable doses can induce major clinical and cytogenetic responses in patients with low and Int-1 MDS.²²⁷ Larger Phase II trials in MDS and in MDS with isolated del(5q) are in progress.

Both thalidomide and Revlimid inhibit angiogenesis while also suppressing the activity of tumor necrosis factor (TNF)- α , death signals such as Fas ligand (CD95) and its receptor,^{228,229} and other proapoptotic mediators such as tumor necrosis factor (TNF)-related apoptosis-inducing ligand (TRAIL).²³⁰ Attempts to downregulate such pathways have included small trials of the TNF receptor antagonists Remicade, given as a single agent,²³¹ and Etanercept, given with low-dose thalidomide.²³² Modest, mostly erythroid responses occurred in a minority of low-risk patients.

Direct inhibition of vascular endothelial growth factor (VEGF) receptors and related tyrosine kinases has been studied using PTK787, an orally available agent. In a trial that included 12 patients with high-risk MDS, a suggestion of slowing of disease progression was noted.²³³ Another VEGF receptor family inhibitor that also targets mutant FLT3 and is available only parenterally is SU5416, which induced a PR in 1 of 22 patients with poor-risk MDS.²³⁴

Amifostine has been used to promote hematopoiesis in MDS, acting through a mechanism that may entail inhibition of p53-mediated apoptosis.²³⁵ Fifteen of 18 patients treated with a twice-weekly IV schedule of this agent developed responses in at least one lineage. Doses above 200 mg/m² were associated with fatigue, nausea, and vomiting. All 10 patients treated with amifostine and epo, some of whom also were treated with G-CSF, developed brief responses.²³⁶

Another therapy that putatively inhibits proapoptotic cytokines is the combination of pentoxifylline, ciprofloxacin, and dexamethasone, which has induced modest bilineage responses in 9 of 18 patients²³⁷ and transfusion independence in 4 of 17.²³⁸

Arsenic trioxide (ATO) is an agent that may promote apoptosis of leukemic progenitors while inhibiting production of VEGF-A and the growth of vascular endothelium while promoting nonterminal differentiation of hematopoi-

etic precursors.²³⁹ Six of 25 patients in a Phase II trial responded to APO, some with trilineage responses despite high-risk disease.²⁴⁰ Eleven had stable disease lasting 2 to 6 months. Moderately severe toxicity was seen, with more than 40% of patients developing febrile neutropenia, thrombocytopenia, and gastrointestinal side effects. Early findings from another Phase II trial of ATO, combined with low-dose thalidomide, showed trilineage responses in a minority of patients, 2 of whom had inv(3)(q21q26.2).²⁴¹

Signaling pathways induced by members of the Ras family of oncogenic proteins have been implicated in the pathogenesis of MDS and CMML and have been targeted using agents that inhibit farnesyl transferase (FT), an enzyme which is crucial to the activation of Ras proteins.²⁴² R11577 (tipifarnib) is an orally available FT inhibitor that was studied in 21 patients with MDS, with 6 responses (3 hematologic improvement, 2 PR, 1 CR). Although the agent proved myelosuppressive, the DLT consisted of fatigue and confusion. Significant activity (33% major response) was seen in another Phase II trial of tipifarnib in poor-risk AML and MDS.²⁴³ Lonafarnib is another orally available FT inhibitor. In a Phase II trial of 32 patients with advanced MDS and 35 with CMML, half of whom had Int-2 or high-risk disease, there were 2 CR (1 MDS, 1 CMML) and 10 hematologic improvements (3 MDS, 7 CMML). Therapy was discontinued by 26% of patients because of fatigue, nausea, vomiting, and anorexia.²⁴⁴ Continuous treatment with lonafarnib at a dose of 200 mg po bid was well tolerated; hematologic improvement occurred in 3 of 15 patients with MDS and normalization of monocyte counts in 6 of 12 patients with CMML.²⁴⁵

Epigenetic Modulatory Therapies

Transcription of genes important for differentiation and proliferation is affected by the extent of methylation in promoters as well as by the level of acetylation of histones that, in the unacetylated state, entwine DNA into transcriptionally silent euchromatin. These pathways are illustrated in Figure 63.4. Agents that target enzymes involved in these epi-

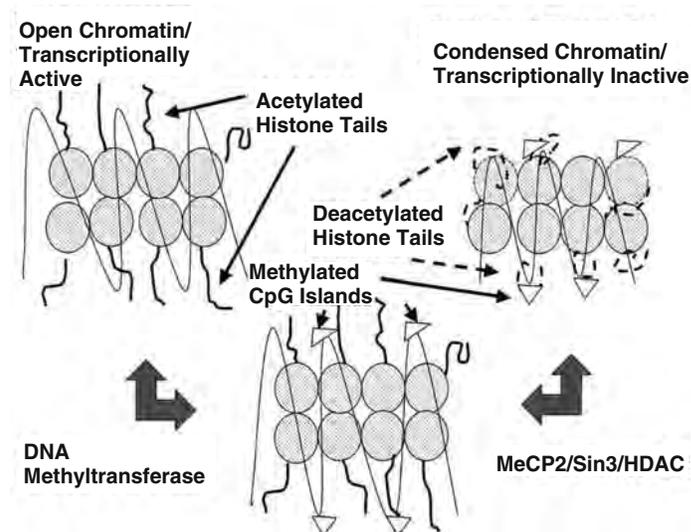

FIGURE 63.4. Epigenetic mechanisms affecting gene transcription: methylation of CpG sequences in promoter regions can prevent gene transcription as can the tightening of DNA into heterochromatic by the coiling of deacetylated histone proteins. (From Mufti et al.,²¹¹ by permission of *Hematology*.)

^f5–20 mg/m² i.v./1 hr days 1–5 \times 2 weeks; included 16 patients with AML. Prolonged infusions also studied with similar outcomes in AML/MDS, days 1–7 q 2 weeks or days 1–21 q 28 days with 1/23 patients developing neurotoxicity.²⁸³

^gOnly AML patients treated.

genetic modifications of DNA structure and function have entered clinical trials.

Table 63.11 outlines findings of studies in MDS using agents that target either DNA methylation or histone acetylation. 5-Azacytidine has gained U.S. Food and Drug Administration (FDA) approval for treatment of MDS, largely on the basis of a randomized Phase II trial that demonstrated meaningful benefits with respect to overall survival, time to leukemic transformation,²⁴⁶ and quality of life.²⁴⁷ Other agents undergoing investigation include depsipeptide,²⁴⁸ suberoylanilide hydroxamic acid (SAHA),²⁴⁹ and valproic acid.²⁵⁰

Many interesting compounds are in the process of being studied alone and in combination with chemotherapy in therapies for MDS and AML. The further development of these agents requires well-designed and -conducted clinical trials. Advances in treatment outcomes, it is hoped, will follow.

Acute Lymphoblastic Leukemia

Olatoyosi M. Odenike,
Laura C. Michaelis,
and Wendy Stock

Acute lymphoblastic leukemia (ALL) is a malignant hematologic disease characterized by the accumulation of immature cells within the marrow space that are arrested at the lymphoblast stage of development, with consequent suppression of normal hematopoiesis. ALL is not a biologically uniform disease; rather, it is a collection of heterogeneous entities characterized by distinct phenotypic, cytogenetic, and molecular-genetic profiles. The characterization and study of these subtypes has led to a risk-adapted approach to therapy, an approach pioneered by clinicians involved with the study of ALL in children, which has now been extended to the diagnosis and treatment of adult ALL. Much progress has been made over the years, particularly in pediatric ALL where cure rates are now in the 80% range. In contrast, for adults with ALL, only approximately one-third of patients achieve long-term disease-free survival. Utilization of newer molecular techniques, such as gene expression profiling, will lead to an improved understanding of the biology of the disease, as well as identification of new drug targets and unique drug susceptibility and resistance profiles. Ultimately, these insights will lead to a more refined and targeted approach to therapy with subsequent significant improvement in the cure rates for adults afflicted with this disease.

Etiology and Epidemiology

Incidence

The estimated number of new cases of ALL in the year 2003 in the United States was 3,600. There is a slight male preponderance, with 2,100 of these cases occurring in males.¹ ALL is the most common malignancy diagnosed in children and constitutes 25% of childhood malignancies and more than 70% of all childhood leukemia diagnoses.²

ALL is a relatively rare disease in adults; 30% of ALL cases occur in adults, and it represents about 20% of adult acute leukemias. There is a bimodal distribution to the incidence of the disease, with an initial peak in early childhood, which then declines during the adolescence and young adulthood years, and a second smaller peak that occurs in patients older

than 50.² The age-adjusted incidence is 1.6 in 100,000 in adults (i.e., 16 cases per 1 million people).³

Etiology

ALL is largely an acquired disease and, similar to most other malignancies, is a progressive clonal disorder driven by genetic mutations. The inciting event or etiologic agent remains obscure in almost every instance.⁴ Various factors have been implicated including hereditary factors, viruses, and environmental factors, such as ionizing radiation. It is likely that a complex interplay of genetic and environmental factors may underlie the development of most cases of ALL.

CONGENITAL DISORDERS AND HEREDITY

Several inherited genetic syndromes have been associated with an increased predisposition to acute leukemia. Overall, these account for about 5% of acute leukemias (both lymphoid and myeloid) and often involve genes encoding proteins whose functions relate to DNA repair and genomic stability.

One of the best known examples of an inherited predisposing genetic syndrome is Down's syndrome (DS). The incidence of acute leukemia is 10- to 20-fold higher in children with DS when compared with children without DS. Gene dosage, altered folate metabolism, mutations of genes, or disomy of a leukemia predisposition gene on chromosome 21 are among the presumed mechanisms of leukemogenesis in DS patients.^{5,6} There are no distinct acquired genetic mutations to date that have been associated with the pathogenesis of ALL occurring in Down's syndrome patients. Klinefelter's syndrome and inherited syndromes associated with excessive chromosomal fragility, such as Fanconi's anemia, Bloom's syndrome, and ataxia-telangiectasia have also been associated with an excess risk of ALL.⁷⁻⁹

Apart from congenital inherited predisposition syndromes, other genetic factors, including prenatal factors, may contribute to the development of acute leukemia. Important insight into the prenatal origin of acute leukemia has been gathered from observations regarding the concordance rates of acute leukemia occurring in monozygotic twin pairs. In

general, the concordance rate in monozygotic twin pairs aged from birth to 15 years has been reported in a number of surveys to be between 5% and 25%. However, when infant leukemias (less than 1 year of age) are separated from other cases occurring later in childhood, the concordance rate for infant leukemias approaches 100%, in contrast to the concordance rate for childhood ALL, which remains around 10%. Analysis of archived neonatal blood spots (Guthrie cards) demonstrates identical clonal origin of the leukemia in the majority of cases of acute leukemia occurring in monozygotic twin pairs in infants and children and provides crucial evidence supporting the in utero initiation of leukemogenesis.¹⁰ Concordant leukemia has been reported only rarely in adults.¹¹

In infant leukemias, the majority of which are characterized by chromosomal rearrangements involving the *MLL* gene, it is probable that by the time the infants are born, the process of leukemogenesis is almost complete. This hypothesis is supported by the very short latency period and almost synchronous diagnosis of leukemia in identical twin infants. Maternal exposure to natural or medicinal topoisomerase II substances, including dietary bioflavonoids, has been implicated as possible etiologic agents in these infant leukemias, particularly, because therapy-related leukemias following prior chemotherapeutic exposure to topoisomerase II inhibitors have also been associated with *MLL* rearrangements.^{10,12}

Childhood ALL (more than 1 year of age) occurring in twin pairs may be characterized by chromosomal rearrangements involving the *TEL-AML1* fusion gene and a longer period of postnatal latency, suggesting that additional postnatal genetic mutations or events are necessary for leukemogenesis.¹⁰ The finding on analysis of Guthrie cards that nontwinned children with ALL had detectable clonotypic *TEL-AML1* or rearranged *IGH* sequences at birth supports the concept of prenatal initiation of leukemia in most cases of pediatric ALL.^{13,14} In addition, a recent survey of normal cord blood samples revealed the incidence of the *TEL-AML1* fusion transcript to be about 1% (a frequency that is 100 times the incidence of overt ALL involving this fusion transcript), lending further credence to the hypothesis that additional "hits" are required postnatally for the generation of overt acute leukemia in childhood ALL.¹⁵

VIRUSES

Epstein-Barr virus (EBV), a human herpesvirus that is the etiologic agent for infectious mononucleosis, is also associated with Burkitt's lymphoma and mature B-cell ALL, as well as lymphomas arising in immunosuppressed patients [such as acquired immunodeficiency syndrome (AIDS)-related and posttransplant lymphoproliferative disorders].¹⁶ EBV efficiently transforms B lymphocytes in vitro, and its role in the pathogenesis of lymphoproliferative disorders in immunosuppressed individuals may occur via aberrant signal transduction mediated by EBV-associated membrane proteins.¹⁷ This virus is not a known etiologic agent for typical (precursor B/precursor T) ALL.

ENVIRONMENTAL FACTORS

Various environmental factors have been postulated as contributing to the development of ALL, but in most cases there

is a paucity of direct evidence linking these factors to leukemogenesis. For example, in children of higher socioeconomic status, an increased incidence of ALL has been observed and has been associated with a delayed exposure to common childhood infections as a result of improvements in hygiene, altered patterns of social contacts, and minimal or lack of exposure to breastfeeding. These observations have led to the hypothesis that a rare abnormal response following exposure to common infectious agents may be an important etiologic factor, especially in those cases of childhood ALL occurring in the 2- to 4-year-old age group.¹⁸

There is a definite relationship between exposure to ionizing radiation and the development of ALL. High acute doses of ionizing radiation, such as occurred in survivors of the atomic bomb explosions in Hiroshima and Nagasaki are more causally linked to leukemogenesis than chronic low-level exposure.^{19,20}

Previously, exposure to nonionizing radiation in the form of low-energy electromagnetic fields as occurs with residential high-voltage power lines has been implicated; recently, however, this form of exposure has been largely excluded as an etiologic factor.²¹

Cigarette smoking in adults has been investigated in a case-control study conducted by the Cancer and Leukemia Group B (CALGB). An increased risk of developing ALL was observed in smokers over the age of 60 years (odds ratio, 3.40; 95% confidence interval, 0.97–11.9).²²

SECONDARY ALL

Secondary acute leukemias can occur following chemotherapy or radiation therapy for other malignancies. Most of these leukemias are myeloid and occur after prior treatment with alkylating agents or topoisomerase II inhibitors. An increasing number of ALL cases are being reported following exposure to chemotherapy with topoisomerase II inhibitors. These therapy-related ALL cases have been associated with the chromosomal rearrangements involving the *MLL* gene and typically occur within 2 years of initial exposure to the chemotherapeutic agent(s).²³

Pathology and Pathogenesis

The integrated application of cytochemical stains, immunophenotyping, and cytogenetic and molecular genetic studies, in conjunction with the morphologic evaluation of ALL blasts, has led to a more definitive characterization of the various biologic subtypes of ALL. This comprehensive approach to the classification of ALL has impact on significantly risk group assignment, prognosis, and approach to therapy.

Morphology

FAB CLASSIFICATION

Acute lymphoblastic leukemia cells have historically been subclassified on the basis of the differences in their appearance under the light microscope. The French-American-British (FAB) group described three categories of lymphoblasts

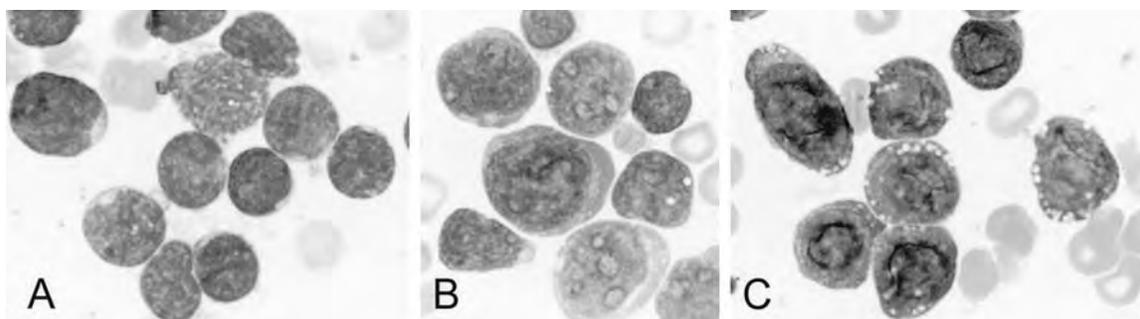

FIGURE 64.1. Cytomorphology of lymphoblasts (Wright-stained bone marrow aspirate smears). (A) Small uniform blasts, previously called “L1” according to French–American–British (FAB) morphologic classification. (B) Lymphoblasts are varied in size with several large blasts with prominent nucleoli, referred to as “L2” according to

FAB morphologic classification. (C) Burkitt leukemia cells, previously characterized as “L3” blasts according to FAB morphologic criteria. Blasts are large, with deeply basophilic cytoplasm and prominent vacuoles.

based on cell size, nuclear cytoplasmic ratio, prominence of nucleoli, degree of cytoplasmic basophilia, and vacuolation.^{24,25}

L1 lymphoblasts are small and homogeneous with high nuclear to cytoplasmic ratio, inconspicuous nucleoli, and scant pale blue cytoplasm (Figure 64.1). When compared with normal lymphocytes in the peripheral blood or bone marrow aspirate smears, the L1 lymphoblasts are larger, approximately double in size, and the nuclear chromatin is more homogeneous and less condensed. L2 lymphoblasts are larger and pleomorphic with more abundant cytoplasm and prominent nucleoli. There is frequently a combination of these more variable “L2” lymphoblasts in addition to the typical “L1” lymphoblasts. Approximately two-thirds of adults are classified as having L2 ALL.

The distinction between L1 and L2 lymphoblasts does not define specific disease entities because L1 and L2 ALL show no consistent correlation with specific phenotypic or cytogenetic features. These terms (L1 and L2) are now largely descriptive and have not been adopted in the current World Health Organization (WHO) classification of ALL, which is based on immunophenotype and genotype.²⁶ In contrast, L3 lymphoblasts are quite distinctive. The blasts are large and more homogeneous with deeply basophilic cytoplasm that typically contains well-defined vacuoles. The nuclei are large, with prominent nucleoli and a finely stippled chromatin.

These lymphoblasts are characteristic of Burkitt leukemia/lymphoma and have unique immunophenotypic and genotypic features.

WHO CLASSIFICATION²⁶

In an attempt to arrive at a classification system that would be more relevant and informative to clinicians, the WHO developed new diagnostic guidelines for malignant diseases of hematopoietic and solid tumors. The WHO has proposed that a 20% or greater number of lymphoblasts is sufficient for a diagnosis of ALL. In addition, the WHO classification scheme has abandoned the distinction between L1 and L2 morphologies (Table 64.1) because of the lack of correlation of these subtypes with specific immunophenotypic, genetic, or clinical characteristics.

Cytochemistry and Immunohistochemistry

Cytochemical stains are a useful adjunct to the phenotypic evaluation of the blast population and facilitate the evaluation of various cytoplasmic constituents.

Myeloperoxidase (MPO) activity is specific for myeloid differentiation and helps to distinguish AML from ALL.

The periodic acid–Schiff (PAS) reaction may be positive in lymphoblasts; usually this staining is localized and the nuclei

TABLE 64.1. Immunophenotype in acute lymphoblastic leukemia (ALL).

World Health Organization (WHO) category	Lineage	Phenotype
Precursor B-cell lymphoblastic leukemia	B-lineage	
	Pro-B ALL	TdT+, HLA-DR+, CD19/22/79A+, CD10–, cμ–, sIg–
	cALL	TdT+, HLA-DR+, CD19/22/79A+, CD10+, cμ–, sIg–
Burkitt's leukemia	Burkitt	TdT–, HLA-DR+, CD19/22/79A+, CD10+, sIg–
	Pre-B ALL	TdT+, HLA-DR+, CD19/22/79A+, CD10+, cμ+, sIg–
Precursor T-cell acute lymphoblastic leukemia	T-lineage ALL	
	Pro-T ALL	TdT+, HLA-DR±, cCD3+
	Pro-T ALL	TdT+, HLA-DR±, cCD3+, CD2/CD5±, CD7+
	Cortical T ALL	TdT+, HLA-DR–, cCD3+, CD2/5/7+, CD4+/CD8+, CD1a+
Mature T ALL	TdT±, CD3+, CD2/5/7+, CD4+ or CD8+, CD1a–	

TdT, terminal deoxynucleotidyl transferase.

may be partially encircled by a rim of PAS reactivity. In contrast, myeloblasts are usually PAS negative, although block PAS staining may be seen in some cases of AML.²⁷

Terminal deoxynucleotidyl transferase (TdT), a nuclear DNA polymerase that inserts nucleotide sequences at splice sites required for recombination of immunoglobulin and T-cell receptor genes, is positive in 95% of L1/L2 lymphoblasts but may also be positive in some cases of AML.²⁸ Therefore, although no single cytochemical stain is by itself specific, the use of cytochemistry is an important component and integral to the workup that helps to distinguish ALL from AML.

Immunophenotype

Immunophenotypic analysis involves the use of specific monoclonal antibodies to recognize distinct epitopes of surface and intracellular antigens that define stages of maturation of lymphoid and myeloid cells. This technique has significantly improved the classification of acute leukemias.²⁹ Immunophenotyping may be performed by flow cytometry or by immunohistochemistry and has a central role in confirming a morphologic diagnosis of ALL and in the separation of B- and T-cell ALL.

Immunophenotyping provides information about lineage (myeloid versus lymphoid, B-lineage versus T-lineage), defines the degree of cell maturation, and has contributed to a prognostically relevant view of the leukemic blasts in ALL.³⁰ Specific immunophenotypic profiles identified at diagnosis may also be useful for the subsequent evaluation of minimal residual disease.^{31,32}

B-LINEAGE DISEASE

A significant majority of cases of ALL (approximately 70% to 80%) are of B-lineage.^{33,34} B-lineage ALL can be further subclassified into subtypes that correspond to different levels of maturation in B-cell development. The WHO classification scheme (see Table 64.1) recognizes the broad categories "precursor B" and "precursor T ALL," because of the lack of conformity and questionable significance of further subclassifying these two groups.²⁶

Precursor B ALL includes pre-pre-B ALL (pro-B ALL), common ALL (c-ALL, common precursor-B ALL), and pre-B ALL. Immunophenotypic characteristics are summarized in Table 64.1. The most common subtype of B-lineage ALL is c-ALL, occurring in about 50%, and is positive for CD10 (common ALL antigen, CALLA), B-cell markers (CD19, CD22), TdT, and cytoplasmic CD79A, but lacks cytoplasmic IgM (μ) and surface immunoglobulin (sIg) expression. Pro-B ALL is less common, lacks CALLA expression, is at an earlier level of maturation, and has been associated with a worse prognosis. Pre-B ALL is more mature and is characterized by expression of cytoplasmic μ and lack of expression of sIg.

Burkitt's leukemia (mature B-cell ALL) is characterized by a "mature B" phenotype with surface immunoglobulin (sIg) expression and FAB L3 morphology. This subtype of ALL is also associated with specific cytogenetic changes that are described in more detail next.³⁵

T-LINEAGE DISEASE

T-lineage ALL accounts for 15% to 25% of adult ALL and can also be further subdivided based on the stage of thymocyte

maturation (see Table 64.1).³⁶ Again, because of the variability in marker expression and lack of conformity of these subdivisions, the WHO recognizes only the "precursor T-group" without further immunophenotypic categorization (Table 64.1).²⁶

The most common subtype of T-lineage ALL is cortical T-ALL, which corresponds to an intermediate or cortical thymic stage of development. Cortical T-ALL is characterized by expression of pan-T-cell markers: CD2, cytoplasmic CD3 (cCD3), CD7, CD5, coexpression of CD4 and CD8, and expression of CD1a. More-primitive subtypes of T-ALL include pro-T ALL and pre-T ALL. A subtype that is more mature than cortical T-ALL is the mature T-ALL (see Table 64.1).^{37,38} T-ALL typically occurs in young male patients with a high white blood cell (WBC) count and a mediastinal mass.³⁹

ALL WITH MYELOID ANTIGEN EXPRESSION

Coexpression of myeloid markers is relatively common in ALL, occurring in about 15% to 50% of adults with the disease, and does not necessarily indicate bilineage involvement. The myeloid markers CD13 and CD33 are the most frequently expressed, but these cases are characteristically myeloperoxidase negative.^{26,40} Recently, more uniform grading systems have been instituted with stricter criteria to help define the biphenotypic entity.⁴¹

Cytogenetics and Molecular Genetics

Recurring nonrandom chromosomal rearrangements occur in the majority (60% to 85%) of ALL cases and confer important prognostic information.⁴² In addition, these chromosomal aberrations provide us with a unique insight into the pathobiology of the disease, unraveling critical molecular events, such as the role of oncogenic fusion genes that arise from chromosomal translocations, or tumor suppressor genes that are lost in chromosomal deletions. Cytogenetic analysis is therefore a critical component of the evaluation of any patient with ALL and will often facilitate diagnosis and subtype classification while simultaneously providing prognostic information for treatment planning.

The nonrandom chromosomal aberrations in ALL include both numerical and structural abnormalities. The incidence of common structural abnormalities and the associated molecular correlates are depicted in Table 64.2.

NUMERICAL ABNORMALITIES

Hyperdiploidy is the gain of additional chromosomes so that the total number of chromosomes per cell exceeds the normal complement of 46. In general, hyperdiploidy is more common in pediatric ALL, occurring in about 28% of cases, in contrast to adult ALL, where the incidence is in the 5% range.⁴³ The good prognosis seen in association with hyperdiploidy (especially in cases with more than 50 chromosomes) in childhood ALL is less obvious in adult ALL with hyperdiploidy. The less favorable prognosis in adult ALL may be explained in part by the presence of associated poor-prognosis structural rearrangements, such as the Philadelphia chromosome.⁴⁴

Hypodiploidy, which occurs when chromosomes are lost, is associated with a poor prognosis. Hypodiploidy is seen in

TABLE 64.2. Molecular and immunophenotypic correlates of common chromosomal translocations in adult ALL.

Phenotype	Karyotype	Genes involved	Frequency (%)
Pro-B	t(4;11)(q21;q23)	<i>MLL-AF4</i>	3–6
Pro-B	t(11;19)(q23;p13)	<i>MLL-ENL</i>	<1
Pre-B	t(1;19)(q23;p13)	<i>E2A-PBX1</i>	3
B-lineage	t(17;19)(q22;p13)	<i>E2A-HLF</i>	0.5–1
B-lineage	t(9;22)(q34;q11)	<i>BCR-ABL</i>	25–30
B-lineage	t(12;21)(p13;q22)	<i>TEL-AML1</i>	1–3
Mature B (sIg+)	t(8;14)(q24;q32)	<i>IGH-MYC</i>	5
Mature B (sIg+)	t(2;8)(p12;q24)	<i>IGK-MYC</i>	1
Mature B (sIg+)	t(8;22)(q24;q11)	<i>IGL-MYC</i>	<1
T-lineage	t(10;14)(q24;q11)	<i>TCRA-HOX11</i>	8
T-lineage	t(7;10)(q35;q34)	<i>TCRB-HOX11</i>	<1
T-lineage	t(1;14)(p32;q11)	<i>TCRD-TAL1</i>	1
T-lineage	t(11;14)(p15;q11)	<i>TCRA-LMO1</i>	1
T-lineage	t(11;14)(p13;q11)	<i>TCRA-LMO2</i>	1

2% to 8% of ALL, and has been demonstrated to have prognostic significance independent of other presenting variables, such as age and presenting WBC count.^{42,44}

STRUCTURAL ABNORMALITIES

In adult ALL, the most common structural abnormalities are chromosomal translocations that involve the exchange of material between two or more chromosomes. Many of the genes located at translocation breakpoints are known or putative transcription factors or protein kinases. The molecular consequence of several of these translocations is the creation of a chimeric fusion gene that may lead to a block in cellular differentiation and/or aberrant cellular proliferation by disrupting the normal function of the affected transcription factors or by causing aberrant growth factor signaling through constitutively activated protein kinases.⁴⁵ Chromosome translocations in ALL may also result in the regulatory element of a gene, such as the immunoglobulin gene (in B-lineage ALL) or the T-cell receptor gene (in T-lineage ALL) being fused to a structurally intact proto-oncogene (such as the *MYC* proto-oncogene in the t(8;14) in mature B cell ALL), resulting in deregulated expression of the latter gene.⁴⁶ In the following section, some of the more common structural abnormalities are reviewed.

CHIMERIC FUSION GENES

t(9;22)(q34;q11) AND *BCR/ABL*

The t(9;22) or the Philadelphia (Ph) chromosome is the most common recurring chromosomal aberration in adult ALL, occurring in 25% to 30% of cases.^{42,47} It is rare in childhood ALL, occurring in only about 5% of cases. This translocation, which was initially identified in chronic myelogenous leukemia (CML),⁴⁸ results in the fusion of the 3'-region of the *ABL* gene on chromosome 9 to the 5'-region of the *BCR* gene

on chromosome 22. In CML and approximately 20% of Philadelphia chromosome positive (Ph+) ALL cases, the breakpoint in the *BCR* gene is within a 5.8-kb major breakpoint cluster region (M-bcr) and results in a 210-kDa fusion protein (p210). In contrast, in the majority of patients with Ph+ ALL, the breakpoint in the *BCR* gene is upstream of the M-bcr region and a smaller 190-kDa protein (p190) is produced; this fusion rarely occurs in CML.⁴⁹ A less common fusion transcript involving a significantly larger portion of the *BCR* gene and encoding for a 230-kDa (p230) protein has also been described.⁵⁰

The incidence of the Ph chromosome may be underestimated by conventional cytogenetic analysis, and the *BCR/ABL* fusion has been detected in up to 40% of newly diagnosed adult ALL patients in some studies utilizing more sensitive PCR techniques.⁵¹ The presence of the Philadelphia chromosome or *BCR/ABL* fusion in ALL portends a poor prognosis and is associated with a higher WBC count, older age, FAB-L2 morphology, and B-lineage phenotype. Expression of CD19, CD10, and CD34 and coexpression of myeloid markers, such as CD13 or CD33 is common.³⁹

The fusion protein results in the constitutive activation of the ABL tyrosine kinase with subsequent deregulatory effects on downstream signaling pathways, such as the RAS pathway, and the PI-3 kinase/Akt pathway leading to abnormal cellular proliferation and inhibition of apoptosis.⁵² Persuasive evidence that the p210 and p190 proteins are the cause of the phenotypic abnormalities seen in CML and ALL has been obtained from experiments in transgenic mice or mice transduced with the fusion protein by retroviral transfer, which develop myeloproliferative disease and ALL.^{53,54} A highly potent and relatively specific inhibitor of the ABL tyrosine kinase, imatinib mesylate (STI-571), has been developed that has emerged as a standard therapy for CML⁵⁵ and is now being integrated into clinical trials and treatment regimens in patients with Philadelphia chromosome positive (Ph+) ALL, as discussed next.

11q23 TRANSLOCATIONS AND *MLL*

The human chromosome band 11q23 is associated with an astonishing number of recurrent chromosomal abnormalities including translocations, insertions, and deletions. It is involved in more than 20% of acute leukemias. In ALL, the most common translocation involving chromosome band 11q23 is the t(4;11)(q21;q23), which is present in approximately 60% of infant ALL and 10% of adult cases.⁵⁶ The cloning of the 11q23 breakpoint region revealed the *MLL* (myeloid-lymphoid leukemia or mixed-lineage leukemia) gene, named for its involvement in both myeloid and lymphoid leukemias.⁵⁷ *MLL* is also involved in the myelodysplastic syndrome, biphenotypic leukemias, and in therapy-induced AML and ALL (particularly following treatment with topoisomerase II inhibitors).⁵⁸ In general, leukemias involving the *MLL* gene have a poor prognosis.

This gene (also known as *ALL1*, *HRX*, and *HtrX-1*) spans 100kb and encodes a large and complex protein with several regions of homology to the *Drosophila trithorax* (*trx*) protein.⁵⁹ Developmental studies using animal models demonstrate that *MLL* positively regulates *HOX* gene expression. *HOX* genes, in general, are important determinants of the mammalian body plan, and are also differentially

expressed in subsets of hematopoietic cells. More recent studies suggest that *MLL* is required for normal generation of hematopoietic stem cells in the embryo.⁶⁰

MLL is involved in translocations of at least 50 different partner genes, several of which have now been cloned. In spite of the large size of the gene, the translocation breakpoints in *MLL* cluster around an 8.3-kb region in the 5'-region of the gene. The clustering of the breaks makes it possible to detect virtually all *MLL* rearrangements with a 0.74-kb cDNA probe on Southern blot analysis.⁶¹ The fusion genes that result consist of 5' *MLL* and 3' partner gene. Several of the proteins encoded for by these partner genes have transcriptional-effector domains, suggesting that transcriptional dysregulation by these chimeric fusion proteins may be a common pathway facilitating *MLL*-mediated leukemogenesis.⁶²

t(12;21)(p13;q22) AND *TEL/AML1*

The *t(12;21)(p13;q22)*, which results in the *TEL/AML1* fusion transcript, is the most common gene rearrangement in childhood ALL, occurring in about 27% of cases.^{63,64} This cryptic translocation between *TEL*, a member of the ets family of transcription factors, and *AML1*, a member of the core-binding factor (CBF) transcription complex, is detected only rarely by standard cytogenetics because the translocation does not substantially affect the banding pattern of the chromosomes involved. It is easily detectable by molecular techniques, such as fluorescence in situ hybridization (FISH) and reverse transcriptase-polymerase chain reaction (RT-PCR). Leukemic cells exhibit a precursor B-cell phenotype, and the presence of this fusion transcript is associated with a good prognosis in childhood ALL.⁶⁴⁻⁶⁶ In adult ALL, the *TEL/AML1* transcript is much less prevalent and was found in only 3% of cases, and little is known about its prognostic significance.^{42,67}

19p13 TRANSLOCATIONS AND *E2A*

Chromosome band 19p13 is involved in two known translocations in ALL: these include the *t(1;19)(q23;p13)*, which results in the fusion of the *E2A* gene, located on chromosome 19 to the *PBX1* gene located on chromosome 1, and a less common variant, the *t(17;19)(q21;p13)*, which results in the *E2A-HLF* chimeric fusion gene. The *t(1;19)(q23;p13)* has been identified in 5% of childhood ALL overall, but is relatively uncommon in adults, with an incidence of about 3%.⁴⁵ There is a strong association with the pre-B ALL phenotype (cytoplasmic Ig positive), with the incidence being 25% to 30% in this subgroup of patients with childhood ALL.⁶⁸ This fusion gene (*E2A-PBX1*) encodes a potent transcription factor containing the transactivator domains of *E2A* and the DNA-binding homeodomain of *PBX1*, and induces lymphoid malignancies in transgenic mouse models.⁶⁹

The 17;19 translocation that involves *E2A* and *HLF* (hepatic leukemia factor), a basic leucine zipper transcription factor on chromosome 17, is relatively rare, occurring in about 0.5% of ALL patients, but has distinct clinical and immunophenotypic correlates. Patients have a pro-B immunophenotype and often present with hypercalcemia and disseminated intravascular coagulation (DIC). Prognosis is poor.

DYSREGULATED EXPRESSION OF STRUCTURALLY INTACT GENES

8q24 TRANSLOCATIONS AND *MYC*

The translocation *t(8;14)(q24;q32)* and its less common variants, *t(2;8)(p12;q24)* and *t(8;22)(q24;q11)*, result in juxtaposition of the *MYC* locus on chromosome band 8q24 to the immunoglobulin gene (*Ig*) regulatory sequences on chromosome bands 14q32 (*IgH*), 2p12 (*IgL*), and 22q11 (*IgK*), respectively.^{70,71} *MYC* translocations are associated with virtually all cases of Burkitt's leukemia and lymphoma, and have an overall incidence of less than 5% in both pediatric and adult ALL. The disease has a mature B-cell phenotype and FAB L3 morphology, and patients frequently present with central nervous system (CNS) involvement and extramedullary disease.^{42,72} These translocations bring the translocated *MYC* gene under the control of the transcription regulatory sequences in the proximity of the *Ig* loci, resulting in the dysregulation and constitutive activation of the intact *MYC* proto-oncogene. The normal allele of *MYC* remains silent. *MYC* is frequently associated with human cancers and plays a critical role in regulating cell proliferation, growth, apoptosis, and differentiation. Overexpression or inappropriate expression of the *MYC* protein, a basic loop-helix-loop (bHLH) protein that acts in the nucleus, results in maturation block and abnormal cellular proliferation. Transgenic mice carrying the *MYC* oncogene fused to the *Ig* gene enhancer, develop B-lineage lymphoid malignancies, thus underscoring the central role of *MYC* overexpression in the pathogenesis of these malignancies.⁷³ The critical genes that are responsible for *MYC*-mediated malignant transformation are poorly defined and remain the subject of ongoing studies.⁷⁴

TRANSLOCATIONS INVOLVING THE T-Cell RECEPTOR LOCI

In T-lineage ALL, several recurring chromosomal rearrangements have been described that involve the T-cell receptor alpha (*TCR-α*) and delta (*TCR-δ*) locus on chromosome 14q11, the T-cell receptor beta (*TCR-β*) locus on 7q32-36, and rarely, the T-cell receptor gamma (*TCR-γ*) locus on 7p15. These translocations result in the juxtaposition of the enhancer elements of these T-cell receptor genes to one of a variety of transcription factors, resulting in dysregulation or aberrant expression of the latter genes. The genes involved in these reciprocal rearrangements include *MYC* (8q24), *TAL1/SCL* (1p32), *TAL2* (9q32), *LYL1* (19p13), *LMO1/RBTN1* (11p15), *LMO2/RBTN2* (11p13), and *HOX11* (10q24).

The *t(10;14)(q24;q11)* involving the *HOX 11* gene on 10q24 and the *TCR-α* locus on chromosome 14q11 occurs in 4% to 7% of childhood cases and up to 14% of adults, and has been associated with a favorable prognosis.^{75,76} The variant translocation *t(7;10)(q35;q34)* juxtaposes the *HOX 11* gene to the *TCR-β*.⁴²

TAL1, *TAL2*, *LYL1*, and *MYC* all encode for transcription factors with a characteristic bHLH motif that allows for protein-protein interaction. These genes are expressed at very low levels in normal thymocytes but at high levels in leukemic cells that have undergone translocations involving these genes. Therefore, it is postulated that inappropriate expression of these genes in a thymocyte triggers leukemic transformation.^{77,78} These submicroscopic rearrangements are

not detectable by routine cytogenetics but are readily detected using Southern blot or PCR techniques. The *TAL1* gene rearrangements occur in 25% to 30% of pediatric ALL but are very uncommon in adult ALL.^{42,79}

Another class of transcription factors involved in chromosomal rearrangements in T-ALL includes *LMO1/RBTN1* and *LMO2/RBTN2*, which belong to the rhombotin gene family. The proteins encoded by these genes contain cysteine-rich regions called LIM domains that are able to bind to nucleic acids or other proteins. *LMO2* and *TAL1* dimerize and interact in erythroid cells and T-cell leukemias and may act synergistically to induce T-cell leukemias.^{80,81} Both genes play a critical role in normal hematopoiesis, and severe defects in erythropoiesis occur in mice that are deficient in either gene.⁸²

More recently, dysregulation of the Notch signaling pathway has emerged as an important mechanism of leukemogenesis in patients with T-ALL. *Notch* genes encode transmembrane receptors that are activated by ligand-mediated proteolysis, leading to a cascade of downstream signaling events which regulate differentiation, proliferation, and apoptosis in several tissues.⁸³ The exact mechanism by which activation of the Notch signaling pathway leads to neoplastic transformation is unknown. Overexpression of the *Notch 3* gene has been demonstrated in all T-ALL patients examined, and is significantly reduced or absent in remission and in other types of ALL.^{83,84} *Notch-3* expression in T-ALL is associated with the expression of its target gene *HES1* and of *pT α* (the invariant chain of the pre-T-cell-receptor, TCR), suggesting that a signaling defect at the pre-TCR checkpoint may be responsible for T-cell leukemogenesis.⁸³

TUMOR SUPPRESSOR GENES AND ABNORMALITIES OF CHROMOSOME 9p

The protein products encoded for by tumor suppression genes normally suppress tumor formation in differentiating cells; therefore, inactivation of such genes would lead to malignant transformation. Loss of the expression of tumor suppressor genes through chromosomal deletions (allelic loss), mutations, or epigenetic changes, such as DNA hypermethylation of promoter regions of such genes is an important pathogenetic mechanism in ALL. Abnormalities of chromosome band 9p, including deletions, unbalanced translocations, mutations, or loss of the entire chromosome, have been reported in 7% to 13% of ALL cases.^{42,85} Two candidate tumor suppressor genes, *p16^{INK4A}* and *p15^{INK4B}*, have been localized to 9p21. These genes encode for proteins that inhibit cyclin-dependent kinases (CDK) 4 or 6 and play a critical role in regulating the cell cycle.

Inactivation of the *p16^{INK4A}* and *p15^{INK4B}* genes by deletions or by epigenetic silencing occurs in almost all cases of childhood T-lineage ALL and in a small number of cases of B-lineage ALL.^{45,86} Other cell-cycle regulators, such as the CDK inhibitor *p57KIP2*, have also been implicated in ALL pathogenesis. Inactivation of *p57KIP2* via DNA hypermethylation has been reported in approximately half of newly diagnosed and relapsed adult ALL cases, and in combination with other critical cell-cycle regulators such as *p73* and *p15^{INK4B}* is correlated with a worse overall survival.⁸⁷

RB AND *TP53* TUMOR SUPPRESSOR GENES

The *RB* gene, located on chromosome 13q14, controls entry into the cell cycle. Hypophosphorylated RB inhibits the ability of the E2F family of transcription factors to transcribe genes necessary for entry into the S phase. In contrast, hyperphosphorylation of RB, which occurs via the action of CDKs, drives the cell cycle forward, leading to cellular proliferation. Mutations of the *RB* gene that have been described in 50% to 60% of adult ALL cases cause inactivation of the *RB* pathway and facilitate malignant transformation.^{88,89} In addition, inactivation of the *RB* pathway can also occur via the loss of expression of *p16^{INK4A}* and *p15^{INK4B}* (CDK inhibitors described above), providing an additional mechanism for leukemogenesis.⁴⁵

The *TP53* gene, a prototypic tumor suppressor gene located on chromosome 17p13, encodes the p53 transcription factor. p53 becomes activated in response to DNA damage, hypoxia, or aberrant cellular proliferation, and triggers cell-cycle arrest or apoptosis. Aberrant expression of p53, indicative of mutations in the gene, has been described in approximately one-quarter of patients with adult ALL.^{88,89} In addition, components of the p53 pathway such as *HDM2* and *p14^{ARF}* are frequently mutated.⁴⁵

COOPERATIVE MUTATIONS

ALL probably arises as a result of complex and progressive genetic alterations. The genetic abnormalities arising from chromosomal abnormalities, including translocations have already been described. These genetic aberrations, which impair differentiation, may cooperate with other genetic alterations that confer a proliferative or survival advantage to facilitate leukemogenesis. These cooperating genetic events may include abnormalities in tumor suppressor genes, which have also been discussed, or mutations in receptor tyrosine kinases, such as the *FLT-3* mutations, which are described briefly next.⁴⁵

FLT-3 MUTATIONS

FLT-3 is a receptor tyrosine kinase that plays an important role in hematopoietic stem cell development. Constitutive activation of this receptor (via activating mutations or autocrine secretion of the *FLT3* ligand) contributes to aberrant signaling and uncontrolled cellular proliferation.⁹⁰ *FLT-3* overexpression has been described in ALL occurring in infants with *MLL* rearrangements or hyperdiploidy (more than 50 chromosomes), suggesting that overexpression of the receptor may facilitate the development of leukemia in patients with those chromosomal rearrangements.^{91,92}

Gene Expression Profiling

Gene expression profiling utilizing DNA microarrays is a relatively new technique that allows for the simultaneous analysis of thousands of genes within a given specimen and has emerged as a powerful tool for the biologic subclassification of ALL. DNA microarrays can accurately identify known genetic profiles and also provide unique insights into the biology of specific ALL subtypes. For example, using microarray analysis, it was possible to accurately distinguish AML and ALL and also B-lineage versus T-lineage ALL. Distinct

gene expression profiles or signatures were associated with specific subsets of ALL and correlated with the presence of specific molecular-genetic aberrations, such as *TEL-AML1*, *BCR-ABL*, *E2A-PBX1*, and *MLL*.⁹² Indeed, gene expression profiling demonstrated that leukemias involving the *MLL* gene are characterized by a unique profile of coexpression of early lymphoid- and myeloid-specific genes, suggesting immortalization of an early multipotent progenitor cell.⁹¹ In childhood T-ALL, microchip analysis could identify previously unrecognized molecular subtypes, and the association of activation of particular oncogenes to defined stages of thymocyte development could be made.⁹³

Clinical Evaluation

Presenting Features and Diagnostic Evaluation

The accumulation of large numbers of abnormal, immature lymphoid cells in the bone marrow and the subsequent suppression of the normal hematopoietic progenitor cells account for many of the nonspecific symptoms and signs in the adult presenting with acute lymphocytic leukemia (ALL). Most patients present after less than 3 months of symptoms. Symptoms may include, but are not limited to, pallor, dyspnea, fatigue or malaise, bone pains, myalgias, and anorexia. Hepatomegaly and splenomegaly due to leukemic infiltration are present in 40% to 60% of patients with ALL and may lead to complaints of abdominal fullness or early satiety.⁹⁴ Lymphadenopathy is more common in ALL than acute myeloid leukemia (AML) but does not typically precede bone marrow or peripheral blood involvement. Fatigue and malaise have multiple overlapping causes, with cytokine release, hypermetabolic demand, and anemia all playing variable roles. Bone pain and myalgias may be due to the increased cell mass in the marrow space.

Objective signs of disease may include petechiae, easy bruising, or mucosal bleeding, all manifestations of thrombocytopenia. Pallor and dyspnea are also commonly seen. Both anemia and thrombocytopenia may be the consequence of redistribution of space and resources in the bone marrow favoring the malignant cell line or because of peripheral blood events, including hemolysis, disseminated intravascular coagulation (DIC), or sequestration in enlarged splenic venules. Fever, which occurs in 40% to 50% of adult patients with ALL,⁹⁴ may be caused by cytokine release in the setting of accelerated cell turnover, or, more ominously, by infection in the setting of neutropenia. Elevated white blood cell (WBC) counts may be present, but the risk of leukostasis and secondary cerebral and pulmonary complications is somewhat less than it is in AML because of the smaller size and cell-surface characteristics of the lymphoblasts, which render them less “sticky” than myeloblasts.

The heterogeneity of the disease subtypes can also, occasionally, be manifest in the initial clinical presentation. For example, the clinical presentation of mature B-ALL is characterized by a high degree of CNS (12%) and organ (32%) involvement.⁹⁵ Adults with B-cell ALL are more often older and the majority are male. In T-cell ALL, the typical patient is a male in his twenties or thirties with an anterior mediastinal mass and leukocytosis. Philadelphia chromosome

positive, precursor B-ALL in adults also favors older males, whereas the cytogenetic abnormality of t(4:11) is seen in a younger population. ALL can present at any age in either gender, so a full diagnostic evaluation is imperative whenever leukemia is considered in the differential diagnosis.

The complete evaluation of ALL in the adult requires a full history and physical, focusing, in particular, on physical evidence of occult infection, bleeding disorders, and neurologic dysfunction. Cranial nerves III through VII are the most commonly involved in meningeal leukemia.⁹⁴ Full laboratory studies should be performed, including a peripheral blood smear, electrolytes, and a panel of tumor lysis parameters (lactate dehydrogenase, uric acid, phosphorus, and calcium), as well as a search for evidence of possible DIC. All patients should have a chest radiograph and a bone marrow biopsy and aspirate. In the case of patients in the high-risk categories, HLA haplotyping of all siblings should be initiated as soon as feasible. Because ALL treatment is tailored to risk groups, it is vital that accurate cytogenetic, immunohistochemical, immunophenotypic, and molecular studies are performed on the bone marrow aspirate, and bone marrow morphology should be evaluated by an experienced hematopathologist.

Among the initial diagnostic challenges is to exclude non-neoplastic lymphoid proliferative syndromes. On occasion, infectious mononucleosis caused by either Epstein-Barr (EBV) or cytomegalovirus (CMV) can be similar in presentation to ALL. The reactive T cells in EBV can resemble blast cells and, therefore, require adequate stains to exclude the possibility of ALL.

Prognostic Factors and Risk Stratification

ALL is a heterogeneous disease defined by distinct biologic and clinical features that affect the prognosis. The ability to identify groups of ALL patients with differing prognoses based on these features has improved the outcome in childhood ALL⁹⁶ and is beginning to translate into risk-adapted therapy in adult ALL. Table 64.3 summarizes both low- and high-risk features that have been identified from a variety of clinical studies in adult ALL. It is important to note that prognostic features may vary according to treatment; for example, mature B-cell ALL (Burkitt's type), once considered a very poor risk subset, is now a curable disease in a significant percentage of patients with the introduction of new therapies that were successfully piloted in children with this disease subset.^{95,97,98}

Consistently recognized prognostic factors in adult ALL are discussed briefly next. These prognostic factors can be used to provide a general risk assessment for prognosis and for treatment planning. As many as 75% of adults with ALL can be considered relatively “high risk” with an expected disease-free survival of only 25% to 35%. Only approximately 25% of patients can be considered “standard risk” with anticipated survival rates of more than 50%.

Age at Diagnosis

Most clinical trials^{34,99-101} have noted a marked difference in both complete remission (CR) rate and disease-free survival (DFS) in ALL patients, depending on patient age. This is well

TABLE 64.3. Prognostic factors in adult ALL identify risk groups for treatment: stratification.

<i>Prognostic factor</i>	<i>Good risk</i>	<i>Standard risk</i>	<i>Poor risk</i>
Clinical	<30 years	30–60 years old	60 years >30,000/ μ L (Precursor B) CR > 2–4 weeks
Age	<30,000/ μ L	<30,000/ μ L	
Presenting WBC	CR < 2–4 wks	CR, 2–4 wks	
Time to complete remission (CR)			
Immunophenotype	Mature B-Burkitt type Precursor T	Precursor B	Pro B Early T (only 1–3 T-cell markers)
Molecular/cytogenetics	High hyperdiploid t(8;14), t(2;8) or t(8;22)	Normal Karyotype	t(9;22)/BCR-ABL t(4;11)/MLL-AF4 +(8) del(7)
Minimal residual disease ^a	<10 ⁻⁴ after induction <10 ⁻⁴ or negative during first years	—	>10 ⁻³ after induction >10 ⁻⁴ or increasing during first year of therapy

^aRemains to be validated in a large, prospective series.

illustrated by a combined analysis of the pediatric and adult Medical Research Council (MRC) trials,¹⁰² which demonstrated a progressive decline in CR rate and remission-free survival with increasing age. Older adolescents and young adults fare less well than children ages 2 to 10 years, and with increasing age, survival decreases continuously. Both comorbid medical conditions resulting in increased toxicity of induction and postremission therapy and the presence of higher-risk biologic features contribute to the adverse prognosis of older adults with ALL, for whom disease-free survival is consistently less than 20% in patients over age 60. A higher level of multidrug resistance has been reported in older adults with ALL, which may contribute to lower CR rates. Shorter remission duration in older adults is also a consequence of the higher frequency of adverse cytogenetic features, including the t(9;22)(q34;q11), or Philadelphia chromosome, which may occur in as many as 40% of adults over the age of 50.^{103,104} In addition, precursor-T-cell ALL, currently associated with a more favorable prognosis in adult ALL, is less common in older patients.¹⁰⁵

Leukocyte Count at Presentation

The majority of clinical studies have identified a high presenting WBC count as an adverse prognostic factor that influences both CR rate and duration.^{34,106–108} From these studies, the absolute stratification number varies, ranging from more than 15,000 to 30,000/ μ L, and retains its significance in multivariate analyses in patients with precursor-B ALL. Despite intensification of recent regimens, lower remission durations in this subset of patients persist, particularly in those with WBC counts higher than 100,000/ μ L.¹⁰⁹ The same degree of hyperleukocytosis has not been as clearly associated with an adverse prognosis in precursor-T ALL, where patients routinely present with higher WBC counts. A cutoff point of more than 100,000/ μ L has been associated with higher relapse rates in earlier, but not in all, recent adult series.^{34,110}

Failure to Attain a Complete Remission in Less Than 4 to 5 Weeks

Several clinical studies have identified the importance of time required to attain first remission as a significant prognostic factor in adult ALL.^{101,111} Early clearance of blasts is an impor-

tant predictor of survival in pediatric ALL; response to chemotherapy is now evaluated as early as 7 days after initiation of treatment as an important prognosticator,¹¹² and early treatment response to prednisone has been shown to be of importance in adult ALL as well.¹¹³

Immunophenotype

As treatments have evolved, the prognostic value of specific immunophenotypes has changed. Immunophenotypic classification is an essential component of the diagnostic workup in ALL. As previously noted, the outcome for mature B-cell ALL (surface immunoglobulin+) has improved substantially with specific short-course high-intensity therapies that are described in detail in the risk-adapted treatment section following. Similarly, the addition of cytarabine and cyclophosphamide to adult treatment regimens has produced better outcome for patients with precursor T-ALL.^{101,114,115} From childhood ALL studies, it has been suggested that high-dose methotrexate and asparaginase may also be beneficial for postremission therapy in precursor T-ALL.^{116,117} However, even this relatively favorable prognostic group can be further subdivided. In a Cancer and Leukemia Group B (CALGB) study, it was demonstrated that the number of T-cell antigens coexpressed by the lymphoblasts correlated with DFS. Patients with coexpression of six or more T-cell markers (indicating a higher degree of lymphoid maturation) on their leukemia cells enjoyed 86% DFS and overall survival (OS) at 3 years in comparison to DFS and OS of only 17% and 30%, respectively, for T-ALLs with expression of only one to three markers (immature or early T-ALL).³⁹ Similarly, the German study group, German Multicenter Study Group for the Treatment of ALL (GMALL), found that the most relevant prognostic marker in T-ALL was immunologic subtype, with inferior survival noted for patients with early T-ALL characterized by absence of CD2, CD1a, and surface CD3 on the lymphoblasts.¹¹⁸ In precursor B-lineage ALL, immunophenotypic subset analysis has revealed an inferior DFS for patients with pro-B ALL (TdT+, CD19/22/79a+, CD10–) compared to patients with common precursor B ALL (TdT+, CD19/22/79a+, CD10+).^{119–121} Finally, with the advent of multiagent chemotherapy programs, coexpression of myeloid antigens, which occurs in as many as 35% of adult ALL cases

and was previously associated with a poor prognosis, is no longer considered an adverse prognostic feature.^{34,39,122}

Cytogenetics/Molecular Genetics

Cytogenetic abnormalities occur in about 60% to 70% of adults with ALL and are among the most important prognostic factors in adult ALL.^{76,108} The CALGB stratified patients into three prognostic groups based on cytogenetics: poor (including t(9;22), t(4;11), -7 and +8), normal diploid, and miscellaneous (all other structural aberrations) with DFS of 11%, 38%, and 52%, respectively.⁴⁷ In this series, a higher frequency (35%) of patients with precursor T-ALL had a normal karyotype. In particular, all larger series have identified that the presence of the Philadelphia chromosome, t(9;22)(q34;q11), and translocations involving the *MLL* gene on chromosome 11q23, the most common of which is the t(4;11)(q21;q23), are independently associated with short CR duration and survival.^{42,44,76} The Philadelphia chromosome is the most commonly recurring abnormality (overall, 25% to 30%) in adult ALL and increases in frequency with age. Allogeneic stem cell transplantation in first remission is advocated for these high-risk patients and is discussed next. In contrast, patients with precursor T-ALL and the t(10;14) appear to have durable remissions.³⁴ Other abnormalities that have been associated with favorable outcomes in pediatric ALL, the *TEL-AML1* fusion gene (1% to 3%), resulting from a cryptic translocation, t(12;21)(p13;q22), and a hyperdiploid karyotype (2% to 5%), occur rarely in adult ALL.^{123,124} Furthermore, from the limited data available, it is not clear that adults with a hyperdiploid karyotype have the same excellent prognosis as children.⁴⁷ In earlier pediatric and adult studies, an adverse prognosis was associated with translocations involving the *E2A* gene on chromosome 19, the t(1;19)(q23;p13), and a rarer variant, the t(17;19)(q21;p13); however, with more intensive chemotherapy combinations, these patients appear to be faring considerably better and are no longer considered in the poor-risk category.^{42,125}

During the past several years, insights into the molecular pathogenesis of ALL are beginning to translate into prognostic information that may be useful for treatment stratification in the future. For example, abnormalities of cell-cycle regulatory genes, including the tumor suppressor genes *p16*, *p53*, and *Rb*, occur frequently in adult ALL and have been associated with a poor prognosis (median survival, 8 months) when at least two of these genes are mutated or deleted in leukemic stem cells. In contrast, patients with zero or one of these genes affected had a median survival time of 25 months.⁸⁹ More recently, gene expression array studies have identified a small set of novel genes that confer good or poor outcome in studies of pediatric ALL.^{92,93} These studies require further confirmation and must be extended to adult patients, but hold great promise to identify patients at high risk for relapse in whom novel therapies or more intensive consolidation, such as allogeneic stem cell transplant in first remission, may be appropriate.

Minimal Residual Disease Studies

Polymerase chain reaction (PCR) and flow cytometric techniques have recently been used to monitor the persistence of

the leukemic clone during treatment in an attempt to identify patients who are in morphologic and cytogenetic remission, but in whom there is persistence of subclinical disease, or minimal residual disease (MRD), and who may be at increased risk for relapse. These sensitive techniques rely on the ability to identify a unique marker of the leukemia cells; for PCR techniques, monitoring of a recurring fusion gene (e.g., *BCR-ABL*) or a clone-specific rearrangement of the immunoglobulin heavy chain or T-cell receptor genes, have been used.³² For flow cytometric MRD monitoring, an aberrant immunophenotype of the leukemic blasts (e.g., presence of myeloid antigens on a lymphoid progenitor cell) can be identified at diagnosis and used for MRD monitoring. These molecular techniques have far greater sensitivity than standard cytogenetic techniques and may detect from 1 in 10,000 to 1 leukemia cell in a background of 1 million normal cells. Using both semiquantitative and more precise quantitative techniques, a number of studies in both pediatric and adult ALL have now provided preliminary evidence that MRD detection at specific time points following achievement of remission is an independent prognostic factor that may predict early relapse.¹²⁶⁻¹³⁰

Although the prognostic value of MRD detection is still under evaluation, improvements in standardization of MRD techniques¹³¹ will provide a better means of comparing MRD data. The goal of MRD monitoring is to design treatment trials where prospective MRD quantification at specific treatment time points can be used to stratify postremission therapy. To date, there is quite convincing evidence in both pediatric and adult ALL studies of MRD that a high level of MRD at the end of induction therapy is associated with a higher relapse rate.^{126,127,130} Furthermore, the continuous detection of high levels of MRD during consolidation and maintenance therapy, or the reemergence or increase in MRD, appears to herald relapse. In contrast, declining or negative MRD results are associated with a favorable prognosis.¹²⁹ Importantly, MRD levels have been confirmed as an independent prognostic variable in a number of recently published pediatric and adult analyses.¹²⁹⁻¹³² Therefore, it seems reasonable that quantitative MRD analysis may be incorporated as a prognostic variable considered during risk assessment of postremission treatment options.¹³³

Two general strategies for clinical intervention based on MRD monitoring have been proposed and are being piloted in several pediatric and adult ALL trials: intensification of postremission treatment (e.g., allogeneic stem cell transplant in first remission) for patients with high levels of MRD,¹³⁴ or decreased duration or intensity of treatment for patients with low or undetectable levels of MRD.¹³⁵ For example, the GMALL group has begun a prospective study with MRD-based treatment decisions after 1 year of chemotherapy in patients considered standard risk according to conventional risk factors described previously (Table 64.4). For MRD low-risk patients, defined as MRD levels less than 10^{-4} at all postremission time points, treatment will be stopped after 1 year and maintenance therapy will be omitted, whereas MRD high-risk patients, defined as patients with MRD greater than 10^{-4} at any postremission time point, will have treatment intensification, focusing on allogeneic stem cell transplantation.¹³⁵

TABLE 64.4. Results of recent chemotherapy studies in adult ALL.

Trial	Reference	Year	No. of patients	Randomized	Intervention/design	CR rate	Progression-free survival (PFS), %	Comments
CALGB 9111	114	1998	198	Yes	Benefit of G-CSF and consolidation	82%	23 months ^a	G-CSF improved CR rates, decreased induction deaths, but did not improve disease-free survival (DFS) or overall survival (OS)
PETHEMA ALL-89	253	1998	108	Yes	Benefit of delayed intensification	86%	41% (5 years)	No benefit to intensification
MDACC	147	2000	203	No	"HYPER-CVAD" alternating cycles of intensive therapy	91%	39% (5 years)	No l-asparaginase/no cranial radiotherapy (RT) administered in this regimen
MRC UKALL XA	161	1991	618	Yes	Benefit of early or late intensification	88%	28% (5 years)	No clear benefit to intensification, but decreased relapses in patients with early intensification
University of California (San Francisco) 8707	142	2002	84	No	Intensified/cyclical but shortened postremission therapy	93%	52% (5 years)	Approach may be effective for standard risk ALL
GMALL 05/93	153	2001	1200	Yes	a) Intensification by risk group b) Intensification of maintenance therapy	86%	47% (5 years)	Long-term follow-up ongoing
GIMEMA ALL 0288	151	2002	794	Yes	a) Addition of cyclophosphamide to induction b) Benefit of early intensification	82%	2 years ^a	Neither induction nor postremission intensification improved CR or DFS

^aMedian survival.

Treatment Strategies in Adult Acute Lymphoblastic Anemia

Treatment programs in adult ALL incorporate multiple active agents into complex regimen-specific sequences that have evolved from the successful strategies employed in pediatric ALL. The goal of these dose-intensive regimens is rapid cytoreduction with restoration of normal hematopoiesis, prevention of the emergence of drug-resistant subclones, prophylaxis of sanctuary sites such as the CNS, and eradication of persistent MRD with prolonged maintenance chemotherapy. Therapy is generally divided into several phases: induction, postremission consolidation or intensification, CNS prophylaxis, and maintenance therapy.

Chemotherapy

INDUCTION THERAPY

The combination of prednisone, vincristine, and L-asparaginase, taken directly from pediatric regimens, formed the backbone of early trials in adult ALL. The three-drug combination resulted in CR rates of 40% to 65%, but remission duration was only 3 to 7 months. The addition of an anthracycline, daunorubicin or doxorubicin, increased the CR rate to between 72% and 92% and the median remission duration to approximately 18 months.^{99,136–139} In a subsequent study performed by the CALGB, two different anthracyclines, daunorubicin and mitoxantrone, were compared during induction therapy.¹⁴⁰ CR rates in both arms were similar, suggesting that anthracycline choice did not result in a significant therapeutic advantage. More recent Phase II studies have suggested that intensification of the daunorubicin dose during induction may improve CR rates and DFS^{141,142} and is the focus of an ongoing trial in the CALGB.¹⁴³

The choice of glucocorticoid may also be important. Several studies from the pediatric groups suggest substitution of dexamethasone for prednisone may provide better antileukemic activity, in part through the achievement of higher drug levels in the cerebrospinal fluid.^{144–146} The M.D. Anderson adult ALL trials have utilized dexamethasone during induction and postremission therapy as part of their "HYPER-CVAD" regimen,¹⁴⁷ and the CALGB is exploring the substitution of dexamethasone for prednisone during induction and postremission therapy in their ongoing study for previously untreated adult ALL, CALGB 10102.

The contribution of casparaginase to adult ALL regimens is somewhat controversial, particularly, because significant toxicities, including hepatotoxicity, pancreatitis, and coagulopathy occur with increasing frequency in older adults with ALL. A randomized Japanese study, albeit using a somewhat unconventional dose of L-asparaginase, failed to demonstrate an improvement in CR rate or survival for patients receiving L-asparaginase, vincristine, doxorubicin, and prednisone in comparison to those receiving the latter three drugs without L-asparaginase.¹⁴⁸ A retrospective analysis performed by the CALGB demonstrated a marginal benefit in DFS for adults who received all prescribed doses of L-asparaginase in comparison to those who failed to receive all recommended doses.¹⁴⁹ Recently, optimization of L-asparaginase pharmacokinetics with prolonged asparagine depletion has been studied by the CALGB, utilizing the polyethylene glycol (PEG) con-

jugate of this agent; however, final analysis of toxicity and efficacy has not yet been reported.

Given the high CR rates of up to 75% to 95% (see Table 64.4) that are now routinely achieved using a four-drug regimen (usually an anthracycline, a glucocorticoid, vincristine, and L-asparaginase), it has been difficult to demonstrate further improvement with additional drugs during induction in the large, heterogeneous groups of adult ALL patients who are enrolled in clinical trials. During the past decade, the German Multicenter ALL cooperative group (GMALL) has also utilized a 5- to 7-day "pro-phase" with prednisone and cyclophosphamide that is given before initiation of standard induction therapy as an effective, gentle method of cytoreduction that decreases the risk of tumor lysis syndrome following initiation of standard induction chemotherapy in this often rapidly proliferating disease.¹¹⁰ Randomized studies examining the addition of other active agents, such as cyclophosphamide or cytarabine during induction and/or early consolidation, have not documented improved overall response rates.^{150,151} Nevertheless, the addition of these agents to specific subsets of ALL may have a positive impact on outcome. For example, the inclusion of cyclophosphamide to the four-drug induction employed by the CALGB, induced a CR rate of 96% in patients with T-ALL and improved DFS as compared to historical studies.¹¹⁴ A similar result was noted by the German multicenter ALL group (GMALL) with improved outcome of T-ALL with early utilization of cyclophosphamide and cytarabine.^{107,152,153}

An effective alternative approach to induction therapy of adult ALL that has been studied at the Memorial Sloan-Kettering Cancer Center avoiding exposure to the toxicities of L-asparaginase, steroids, and vincristine employs high-dose cytarabine and mitoxantrone with 84% of patients achieving CR.¹⁵⁴ Fractionated doses of cyclophosphamide and high doses of methotrexate (without exposure to L-asparaginase) have also been employed successfully with high CR rates of more than 90% by investigators at M.D. Anderson.¹⁴⁷

CONSOLIDATION/INTENSIFICATION

Despite excellent CR rates of more than 90% in many series of adult ALL, the long-term DFS over the past decade remains relatively low compared to children with ALL, ranging from 25% to 50%. Postremission therapy in adult ALL has employed numerous drugs and schedules, including modification of the standard induction regimens, rotational multi-agent consolidation cycles, and intensification of treatment with autologous or allogeneic stem cell transplantation. In addition to the drugs employed for induction, postremission regimens have incorporated numerous active agents, including cytarabine, etoposide, VM26, methotrexate, 6-mercaptopurine (6-MP), and 6-thioguanine (6-TG). Because of the complexity of schedules and heterogeneity of drugs employed, it is difficult to assess the value of any individual treatment component, and further elucidation will undoubtedly require the incorporation of a more biologically defined risk-oriented approach to postremission therapy. Given the relative infrequency and heterogeneity of adult ALL, these advances may only be made in large cooperative group clinical trials.

This discussion focuses on the outcome of postremission consolidation therapy in selective, large prospective studies

(summarized in Table 64.4), and the role of stem cell transplantation in first remission is considered below in a separate section.^{110,114,141,147,151,155-158} Several recent adult ALL trials have addressed a postremission dose-intensity question. As with induction therapy schema, these chemotherapy regimens have evolved from pediatric ALL studies that have demonstrated improved DFS for high-risk patients¹⁵⁹ when intensive, myelosuppressive treatment modules are incorporated into postremission therapy. In a large Phase II study from the CALGB, patients received both early and late intensification courses of treatment with eight drugs followed by maintenance chemotherapy for 2 years after diagnosis.¹¹⁴ Compared to previous CALGB trials where less intensive postremission therapy was administered, the median remission duration and survival improved to 29 and 36 months, respectively. Investigators at M.D. Anderson have also explored dose intensification in their "HYPER-CVAD" regimen where eight courses of chemotherapy are given, with alternating cycles composed of fractionated cyclophosphamide, doxorubicin, vincristine, and dexamethasone in cycles 1, 3, 5, and 7 with high-dose methotrexate and high-dose cytarabine in cycles 2, 4, 6, and 8. Using this approach, the median survival for 204 patients treated between 1992 and 1998 was 35 months with a 5-year survival of 39%.¹⁶⁰

The Italian multicenter group, GIMEMA, addressed the potential benefit of intensive postremission therapy by randomizing 388 patients to receive either postremission intensification followed by maintenance chemotherapy (187 patients) or early progression to maintenance chemotherapy (201 patients).¹⁵¹ With follow-up of 8 years, there was no difference between the two groups, with 36% DFS in patients receiving consolidation therapy followed by maintenance and 37% DFS in patients randomized to maintenance therapy alone. This outcome may have been influenced by the fact that only 35% of patients randomized to the consolidation/maintenance arm completed therapy according to the recommended schedule because of lack of compliance and treatment-related toxicity. In the Medical Research Council (MRC) UKALL XA, a postremission dose-intensity question was also evaluated. Patients were randomized to receive early combination chemotherapy intensification with cytarabine, etoposide, daunorubicin, and 6-TG at 5 weeks, at 20 weeks, at both time-points, or to no intensification chemotherapy.^{155,161} The early block of intensive treatment appeared to prevent disease recurrence; however, the overall improvement in 5-year DFS for patients who received intensification therapy was estimated at only 2%.

Successive German multicenter trials have been evaluating the effect of subset-specific dose intensification during postremission therapy. Recently, patients with standard-risk B-lineage ALL received high-dose methotrexate, T-ALL patients received postremission cyclophosphamide and cytarabine, and high-risk B-lineage patients received both high-dose methotrexate and high-dose cytarabine.¹⁵³ The median remission duration was 57 months for standard-risk patients with a 5-year survival of 55%. However, this approach did not appear to improve the outcome of high-risk patients, except for those with pro-B ALL who achieved a continuous CR rate of 41% in contrast to only 19% for other high-risk patients. The outcome for high-risk patients with stem cell transplantation in first complete remission (CR1) has been explored by other groups and is discussed next.

CNS PROPHYLAXIS

Only 2% to 10% of adults with ALL present with CNS involvement at the time of diagnosis^{114,162}; however, CNS relapse may be expected in 50% to 75% of patients at 1 year in the absence of CNS-directed therapy.^{163,164} The diagnosis of CNS leukemia requires the presence of more than five leukocytes per microliter in the cerebrospinal fluid (CSF) and the identification of lymphoblasts in the CSF differential.¹⁶⁵ Patients with CSF involvement may be asymptomatic or present with headache, meningismus, malaise, fever, or cranial nerve palsies. False-negative CSF results may occur in patients with predominantly cranial nerve involvement. Risk factors for CNS leukemia in children include an age of 1 year or younger, extreme leukocytosis (more than 100,000/ μ L), T-lineage and mature B-cell immunophenotypes, lymphadenopathy, and organomegaly.^{166,167} Mature B-cell ALL, high serum lactate dehydrogenase levels, and high proliferative index (more than 14% of lymphoblasts in the G₂M/S phase of the cell cycle at diagnosis) have been associated with a higher risk of CNS disease in adult ALL.¹⁶²

CNS prophylaxis using intrathecal (IT) methotrexate and 2400 cGy cranial irradiation, widely employed in early pediatric ALL studies, clearly reduced the incidence of CNS disease and was subsequently introduced into early adult ALL treatment studies with demonstration of a decrease in CNS relapses.¹⁶⁸ More recent studies have reduced the radiation dose to 1,800 cGy.^{106,169} Combinations of these approaches can reduce CNS relapse rates to less than 5% to 10% and also may decrease the rate of bone marrow relapse.¹⁵⁹ However, long-term follow-up of survivors of pediatric ALL has demonstrated that combined irradiation and IT therapy results in neuropsychiatric sequelae, including seizures, premature dementia, cognitive dysfunction, and growth retardation; however, its long-term effects on adults remain uncertain.¹⁷⁰

In adult ALL, the concomitant use of cranial irradiation and IT therapy is often quite toxic and may result in delays in delivery of postremission intensification therapy. These toxicities have prompted both the pediatric and adult cooperative groups to evaluate alternative strategies for CNS prophylaxis. Alternative strategies have included triple IT therapy with methotrexate, cytarabine, and a corticosteroid without cranial irradiation,¹⁷¹ or IT therapy combined with high-dose systemic therapy with CSF-penetrating drugs, including methotrexate, cytarabine, and L-asparaginase and corticosteroids. Systemic administration of dexamethasone achieves higher CSF levels than prednisone and has a longer half-life in the CSF than prednisone¹⁷²; as discussed previously, in a randomized pediatric trial, dexamethasone resulted in a lower incidence of CNS disease compared to prednisone.¹⁴⁴

Recent studies suggest that effective CNS prophylaxis with CNS relapse rates less than 5% can be achieved in adults with ALL using combination IT and high-dose systemic chemotherapy without cranial irradiation, even in patients at high risk for developing CNS disease.^{147,162,173} Other investigators have reported that the use of high-dose cytarabine without any other CNS therapy resulted in only a 4% incidence of CNS relapse in adult ALL.¹⁷⁴ In contrast, in the GMALL studies, attempts to omit or postpone CNS irradiation led to higher CNS relapse rates.¹⁷⁵ Therefore, although several effective strategies for CNS prophylaxis have been

described, no single “best” approach for CNS prophylaxis in adult ALL currently exists. Future trials may explore a risk-oriented approach to CNS prophylaxis with the goals of minimizing toxicity and optimizing efficacy. Table 64.5 summarizes CNS prophylaxis regimens and outcome in recent adult ALL clinical trials.

MAINTENANCE CHEMOTHERAPY

The use of maintenance therapy in adult ALL, as with all components of therapy discussed thus far, is based upon its efficacy in children with this disease. The theoretical basis for employing maintenance therapy is that prolonged exposure to antimetabolites may kill slowly dividing and potentially drug-resistant subclones that remain after induction and consolidation therapy. In addition, these agents might have a favorable therapeutic index on the leukemic as compared to normal stem cells, thus allowing selective growth of normal marrow with eventual senescence of remaining leukemia cells. Unlike other components of therapy already described, there have been no randomized studies justifying the use of maintenance therapy in adult ALL.

The backbone of maintenance therapy consists of daily 6-MP and weekly methotrexate for 18 to 36 months, often with the addition of periodic “pulses” of vincristine and prednisone or dexamethasone. Only one study has randomized patients between conventional and a dose-intensive maintenance therapy schedule¹⁰⁹; this study failed to demonstrate any improvement in outcome. However, attempts at omitting maintenance therapy in several different adult ALL studies have yielded unchanged or inferior results.^{140,174,176} These studies suggest that maintenance therapy should be included in the treatment plan of patients with ALL. However, the role of maintenance therapy in particular subsets such as T-ALL is uncertain, and there appears to be no benefit to prolonged maintenance therapy for patients with mature B-cell ALL who respond well to short-term dose-intensive regimens (described in a separate section following) and rarely relapse beyond the first year of treatment.

Stem Cell Transplantation

ALLOGENEIC STEM CELL TRANSPLANTATION IN FIRST REMISSION

As described earlier, the best postremission therapy for adults with ALL is still unclear. For younger patients under the age of 60, allogeneic stem cell transplantation (allo-SCT) has been the treatment of choice for high-risk patients with adverse cytogenetics, including those with a t(9;22) and t(4;11), as discussed next. However, for other adults with ALL, the optimal treatment strategy and indications for allo-SCT in CR1 are being explored in a number of studies.

Survival for adult ALL patients following matched sibling allo-SCT in first remission is approximately 50% (range, 20%–80%).¹⁷⁷ Several studies have tried to compare the outcome of allo-SCT versus chemotherapy in first remission (Table 64.6); however, this comparison has been problematic because of selection bias and lack of available matched sibling donors for as many as 70% of patients. The International Bone Marrow Transplant Registry (IBMTR) compared 251 patients who received intensive postremission chemotherapy with 484 patients who received matched sibling allo-SCT.¹⁷⁸ Adjustments were made for differences in disease characteristics and time to treatment. The 9-year DFS rates were similar, 32% for chemotherapy and 34% for allo-SCT. However, the causes of treatment failure differed with a higher recurrence rate of 66% for chemotherapy patients versus 30% for those receiving allo-SCT. Treatment-related mortality was the main cause of failure in patients who received allo-SCT.

A large French multicenter trial (LALA 87) compared allo-SCT with chemotherapy or autologous stem cell transplantation (auto-SCT) in first remission.¹⁷⁹ After exclusions, 572 patients were analyzed, and 10-year follow-up results were recently published.¹⁵⁸ At 10 years, based on an intent-to-treat analysis, survival was 46% for those receiving allo-SCT compared to 31% for those receiving consolidation chemotherapy alone ($P = 0.04$). In the allo-SCT arm, 92 of 116 patients

actually received transplantation with a median time of 63 days between achievement of CR and transplantation. The value of allo-SCT appeared clearly after patients were classified into standard-risk and high-risk groups. High risk was defined as having one or more of the following factors: presence of the Ph chromosome, null ALL, age more than 35 years, WBC count more than 30×10^9 , time to complete remission more than 4 weeks. In the high-risk group, the overall survival at 10 years was 44% versus only 11% for the control arm ($P = 0.009$). In the standard-risk group, there did not appear to be a distinct survival advantage for allo-SCT over chemotherapy; here, survival rates were 49% and 39%, respectively ($P = 0.6$). These results support the value of allo-SCT in first CR for high-risk patients.

The MRC UKALL12/ECOG 2993 study is the largest prospective randomized trial designed to evaluate the role of allo-SCT as postremission therapy in adult ALL, and accrual is ongoing.¹⁸⁰ All patients received two phases of induction therapy and were assigned in first remission to receive allo-SCT if they had a histocompatible sibling donor, whereas those without a related donor are randomized to auto-SCT versus consolidation and maintenance chemotherapy. To date, more than 1,300 patients have been recruited, and the results reported so far have focused on the Ph+ patients ($n = 875$). An intention-to-treat analysis showed a significantly reduced relapse rate of 24% in Ph- patients assigned to allo-

graft ($I = 190$) in comparison to 60% for those randomized to auto-SCT or chemotherapy ($P = 0.0001$). There was a tendency for improved 5-year event-free survival (EFS) in patients assigned to allo-SCT, 52%, versus 36% for the randomized group ($P = 0.05$) that was most noticeable for patients classified as standard risk (5-year EFS of 64% for allo-SCT versus 46%; $P = 0.05$). These data are very preliminary and require further follow-up; however, in contrast to the LALA study, there appears to be a trend toward a beneficial effect for allo-SCT for younger adult ALL patients (age less than 50) in first remission, regardless of risk group.

AUTOLOGOUS STEM CELL TRANSPLANTATION

Autologous SCT (auto-SCT) has been explored in adult ALL; however, the prospective, randomized studies described above demonstrate that relapse-free survival has been inferior when compared to allo-SCT. Moreover, no advantage in survival has been demonstrated with auto-SCT compared with continued postremission chemotherapy alone.^{99,181} Disease-free survival at 3 years following auto-SCT in first remission in two of the largest trials reported was only 28% and 39%, respectively,^{158,182,183} which is not better than survival rates reported in recent chemotherapy trials of adult ALL.

Because relapse remains the main cause of failure following auto-SCT, several approaches to eradicate MRD have been

TABLE 64.7. Outcome of allo-SCT in CR2 or beyond.

CR2, second complete remission.

^aRemains to be validated in large, prospective series

explored. One approach to MRD modulation following auto-SCT has been the addition of conventional postremission chemotherapy to auto-SCT programs. Seventy-seven patients in first remission received auto-SCT followed by a maintenance chemotherapy program consisting of pulsed methotrexate, 6-mercaptopurine, vincristine, and prednisone.¹⁸⁴ The 10-year DFS and OS were 50% and 53%, respectively. These results were associated with a better outcome than with historical control patients receiving an auto-SCT, but these data have not been confirmed by other groups.¹⁸⁵ An alternative approach to MRD modulation that has been explored is *ex vivo* “purging” of the collected autologous stem cells using chemotherapy and/or immunotherapy with monoclonal antibodies directed against the lymphoblast. Although detection of less than 5% leukemia in the autograft has been associated with significantly improved outcome after auto-SCT for ALL,¹⁸⁶ the clinical benefit of *ex vivo* treatment of the autologous stem cells has not been clearly established and should only be investigated in the context of prospective clinical trials.¹⁸⁷

TRANSPLANTATION BEYOND FIRST REMISSION

There are no convincing data suggesting that durable remissions can be achieved with standard chemotherapy for adults with ALL in or beyond CR2 (Table 64.7). It appears that allo-SCT for adults in or beyond CR2 is superior to chemotherapy, with long-term DFS rates of 14% to 43% reported in a number of report studies.^{188,189} The outcome of auto-SCT has been compared to matched unrelated donor allo-SCT for ALL for patients in second or later remission.¹⁸⁹ The DFS rate was superior for matched unrelated donor SCT (42% ± 11% versus 20% ± 9%) owing to a significantly higher relapse rate with auto-SCT, suggesting that the graft-versus-leukemia effect of allo-SCT may reduce the incidence of relapse. The outcome of matched unrelated donor allo-SCT for patients with active ALL at the time of transplant was not significantly different

from that of patients with unrelated allo-SCT in third or later remission and was 16% ± 8%. In contrast, there were no long-term survivors in patients receiving an auto-SCT in third or later remission. Therefore, at the time of relapse, allo-SCT should be recommended as the treatment of choice for appropriate patients.

Risk-Adapted Therapy

MATURE B-CELL ALL

The evolution of treatment for mature B-cell ALL (FAB L3), characterized by the presence of surface immunoglobulin and overexpression of the *MYC* oncogene resulting from chromosomal translocation, illustrates a fundamental paradigm for acute leukemia in general; that is, that the proper assessment of risk, based on immunophenotype and cytogenetics, early response to therapy, and comorbidities, should dictate the choice of treatment regimen. This risk-adapted treatment strategy evolved from the experience in treatment of pediatric leukemias. The adaptation of successful pediatric regimens for mature B-cell ALL to the adult population has dramatically improved the outcome for adults with this aggressive form of ALL.

Mature B-cell ALL is rare in both children and adults. It comprises only 2% to 4% of all cases of adult ALL and 1% to 2% of childhood cases and had been associated with a dismal outcome with very few long-term survivors.¹⁶⁷ But, as was noted as early as 1975, the clinical entity resembles Burkitt's lymphoma, a disease of much higher prevalence in children where several important observations about disease biology prompted the development of a novel treatment approach that capitalized on the rapid growth rate of these cells.^{167,190,191} Investigators at St. Jude Children's Hospital postulated that (1) the 48- to 72-hour cell cycle that characterizes Burkitt's growth pattern might be better targeted by a

fractionated dosing schedule and (2) the use of a synergistic alternating regimen might prevent emergence of a resistant subclone.¹⁹² The approach employed fractionated high-dose cyclophosphamide, followed by doxorubicin, vincristine, and intensive CNS-directed therapy using combined IT methotrexate, high-dose systemic methotrexate with leucovorin rescue, and cytarabine with alternating cycles given for 24 weeks. Notably, patients did not receive maintenance therapy. Results showed that 93% (27 of 29) achieved a complete remission. Although 81% of patients with stage III Burkitt's lymphoma were disease free for 2 years, only 2 of 10 patients with initial involvement of CNS and/or marrow who achieved a remission were apparently cured of their disease.¹⁹² The addition of high-dose methotrexate and cyclophosphamide or ifosfamide to subsequent regimens improved the CR rate in the pediatric population to approximately 90%, and the leukemia-free survival improved to between 50% and 87%.⁹⁷

This approach was subsequently applied to the adult population, and a series of studies followed that are summarized in Table 64.8. The French SFOP (Societe Francaise d'Oncologie Pediatrique)⁹⁵ and German multicenter studies⁹⁷ employed a similar strategy to the pediatric approach with the addition of an initial cytoreductive "pre-phase" of treatment, usually consisting of a steroid and cyclophosphamide to minimize the risk of the metabolic complications of tumor lysis syndrome. The schedules did not include the more traditional ALL reinduction or maintenance therapy. Compared to the historical controls treated with more traditional ALL regimens, the adult patients had higher complete remis-

sion rates, 63% and 74% versus 44%, and a higher overall survival rate, 49% and 51% versus 0%.

In 1999, researchers at the M.D. Anderson published their experience of using the Hyper-CVAD regimen in adults with mature B-ALL.¹⁶⁷ The median age was 58, much older than previously published trials in adults. The therapeutic protocol consisted of eight courses of alternating intensive chemotherapy using Hyper-CVAD as described previously (in the postremission treatment section): courses 1, 3, 5, and 7 entailed hyperfractionated cyclophosphamide, and dexamethasone with vincristine and doxorubicin in the latter half of the treatment cycle. Even-numbered courses included methotrexate and cytarabine with leucovorin rescue. Prophylactic granulocyte colony-stimulating factor (G-CSF) was administered with the goal of completion of all eight courses within 5 to 6 months of diagnosis. Intrathecal therapy included methotrexate and cytarabine. The Hyper-CVAD protocol produced CR in 21 in 26 patients, or 81%. Female sex, a decreased performance status, albumin less than 3g/dL, and hepatosplenomegaly were all associated with a lower likelihood of achieving CR. This treatment regimen resulted in a 3-year OS rate of 49%. Survival was much better among patients younger than 60 years: 77% versus 17%. The authors concluded that the addition of hyperfractionated cyclophosphamide and high-dose methotrexate had a superior 3-year survival for patients in comparison to their usual ALL treatment protocol (49% versus 21%; $P = 0.07$). The M.D. Anderson trial was the first to include a high percentage of older patients, and the authors speculated that the poor survival rate in this subset resulted from poor tolerance of the dose

TABLE 64.8. Studies of mature B-cell ALL and small noncleaved cell lymphoma (SNCL).

Cooperative group/institution	Patients	Design	Early mortality	CR	Relapse	DFS	OS	Conclusion
Societe Francaise d'Oncologie Pediatrique (SFOP) ⁹⁵	Untreated adults with SNCL ($n = 41$) or mature B-cell ALL ($n = 24$)	Retrospective Treated with one of three SFOP pediatric regimens	4%	89%	12%	71% 3 years	74% 3 years	Pediatric protocols can be used in adults with efficacy and tolerable toxicities
German Multicenter Study Group for the Treatment of ALL (GMALL) ⁹⁷	Untreated adults with mature B-cell ALL ($n = 68$)	Two prospective studies High-dose, short-duration regimens vs. historical treatment	8%–9%	63%–74%	23%–47%	50%–71% 4–8 years	49%–51% 4–8 years	Compared to historical regimens, new protocols adopted from pediatric literature improve CR, DFS, and OS
M.D. Anderson (MDACC) ¹⁶⁷	Untreated adults mature B-cell ALL ($n = 26$)	Prospective, nonrandomized Hyper-CVAD	19%	81%	43%	61% 3 years	49% 3 years	Highly significant association between older age and poor prognosis
Cancer and Leukemia Group B (CALGB) ^{193,194}	Untreated adults with SNCL ($n = 30$) or mature B-cell ALL ($n = 24$)	Prospective, nonrandomized High-intensity, short duration Alternating courses of chemo With and without prophylactic CNS RT	7%	75%–83%	28%–38%	52% 5 years	46%–57% 5 years	Long-term, disease-free survival possible in about 50% of patients; prophylactic CNS radiation is unacceptably toxic and does not provide added benefit

intensity, requiring subsequent delays and decreases in dose intensity, or a biologically different disease.

A prospective trial of patients with both small noncleaved non-Hodgkin's lymphoma and mature B-cell ALL conducted by the CALGB, has recently been updated.^{193,194} A total of 75 patients were enrolled, with a median age of 44 years (range, 18–71 years). The treatment regimen included a “pre-phase,” similar to the French and German studies. Subjects then received two alternating treatment regimens at 3-week intervals for a total of seven courses. IT chemotherapy with methotrexate, cytarabine, and hydrocortisone was administered, initially during each treatment cycle. The protocol also initially employed CNS irradiation for all patients, although this was eliminated (and reserved only for patients with active CNS disease at presentation) after interim analysis showed severe neurotoxicity, including transverse myelitis. The CR rate was 80%, and 45% of the mature B-cell ALL patients were long-term survivors. Few relapses occurred more than 1 year after completion of treatment. The CALGB¹⁹⁴ concluded that the individuals who had received CNS irradiation as well as aggressive IT chemotherapy experienced higher degrees of neurotoxicity without a significant DFS advantage and suggested that omission of the cranial radiation was reasonable for patients without overt CNS disease.

The conclusions of the cumulative experience to date argues for the following treatment principles. (1) Mature B-cell ALL should be identified at diagnosis to allow entry into treatment studies that capitalize on this disease's rapid cell cycling and subsequent sensitivity to fractionated cyclophosphamide and high-dose methotrexate. (2) Intensive high-dose methotrexate and aggressive intrathecal chemotherapy can eliminate the need for prophylactic cranial irradiation. (3) Prolonged maintenance therapy does not appear to be necessary. (4) Older age is a consistently poor prognostic indicator.

The addition of hematopoietic growth factor support (e.g., G-CSF) to current trials may decrease toxicity and allow more patients to complete the aggressive treatment that is recommended. Because mature B-cell ALL is strongly CD20+, the use of rituximab (anti-CD20) is a rational addition to treatment that is being explored in ongoing trials in an attempt to improve DFS. The role of autologous or allogeneic SCT as initial consolidation or salvage therapy for high-risk patients (many of them elderly) has not been well defined and requires further study. Those patients with relapse often have rapidly progressive disease that is not amenable to successful tumor reduction necessary for consolidation with auto- or allo-SCT.

PHILADELPHIA CHROMOSOME POSITIVE (Ph+) ALL

Patients with Ph+ ALL pose a great therapeutic challenge to clinicians because the t(9; 22) occurs in 20% to 30% of adult ALL and is not considered curable with standard chemotherapy. The remission rate for these patients is approximately 60% to 80% with intensive induction therapy regimens, but the long-term survival with standard postremission therapy is less than 10%.^{47,195} Therefore, attempts to improve outcome in Ph+ ALL have focused on dose intensification with allo-SCT.

Allo-SCT is recommended for patients with Ph+ ALL in first remission. In a preliminary report from the MRC UKALL X11/ECOG E2993 study, the event-free survival (EFS) at 3 years for 35 patients with Ph+ ALL in CR1 was 38%; in com-

parison, 3-year EFS was only 5% for those patients who received postremission chemotherapy or auto-SCT in CR1.¹⁵⁷ Other studies report survival rates between 30% and 60%.^{196–199} It is difficult to draw conclusions from these small series, which vary considerably with respect to median age of the patients, stage of disease (CR1 or beyond), type of transplant preparative regimen, choice of graft-versus-host disease (GVHD) prophylaxis, and supportive care. However, from all these series, it appears that patients fare best when transplanted in first remission. The efficacy of HLA-matched unrelated donor (MUD) transplants has also been explored to allow more patients to undergo this potentially curative treatment. In one small series of 18 young patients (median age, only 25 years) with Ph+ ALL who underwent a MUD allo-SCT, the DFS at 2 years was 49% in this selected group, which is similar to rates reported for HLA-matched sibling transplants.²⁰⁰ With improvements in GVHD prophylaxis, MUD transplants are also being explored in older patients with Ph+ ALL in CR1.

The most exciting recent development in the treatment of Ph+ ALL has been the intriguing early results observed with imatinib mesylate (STI571, Gleevec; Novartis, East Hanover, NJ). Imatinib is a potent and selective inhibitor of BCR-ABL tyrosine kinase.²⁰¹ In a study of 56 patients with recurrent and refractory Ph+ ALL, imatinib at 400 or 600mg was given once daily.²⁰² The CR rate was 29%; however, responses were not durable, with only 6% of patients sustaining a response of at least 4 weeks. Nevertheless, the rapidity of response in these refractory patients and the relatively high CR rate has prompted the exploration of the efficacy of this agent in frontline therapy of Ph+ ALL. Imatinib is being combined with standard chemotherapy,²⁰³ where initial reports suggest that CR rates may be higher than with chemotherapy alone, and is also being tested for its ability to reduce disease burden before and after auto- or allo-SCT. Potentially, the most important application of imatinib mesylate will be for older Ph+ patients for whom allo-SCT may not be feasible. The GMALL have initiated a randomized multicenter Phase II study to determine the safety and efficacy of imatinib in Ph+ ALL patients more than 55 years of age as first-line single-agent induction therapy and with concurrent administration of postremission consolidative chemotherapy for a duration of up to 1 year.²⁰⁴

ALL WITH 11Q23 (*MLL*) ABNORMALITIES

The t(4;11)(q21;q23) is the most common recurring abnormality involving the *MLL* gene on chromosome 11q23 and occurs in 5% to 10% of adult ALL cases.^{61,205,206} These cases are characterized by an early (pro-B) immunophenotype, with expression of CD19, CD22, CD24, and cytoplasmic CD79a and coexpression of myeloid antigens, whereas CD10 is negative. Patients often present with high leukocyte counts, hepatosplenomegaly, and CNS involvement. With standard induction and consolidation chemotherapy, survival for these patients is poor, with less than 15% probability of DFS at 5 years.⁴⁷ The GMALL has reported that these patients fare considerably better when an allo-SCT is performed in CR1, with reports of more than 50% of patients achieving long-term DFS.¹²⁰ In the GMALL series, the t(4;11) patients had superior outcomes to other high-risk patients receiving allo-SCT in CR1, perhaps as a result of the additional benefit that these patients may have obtained from receiving high-dose cytarabine.

bine and mitoxantrone before undergoing allo-SCT. Based on these data, the current recommendation is to identify a donor for allo-SCT early in CR1 for patients with MLL gene rearrangements. In addition, they may benefit from intensive cytoreduction with a high-dose cytarabine-based regimen that may be given as early consolidative therapy while a suitable donor is being identified.

Supportive Care

Improvements in outcome of patients with ALL are, in part, attributable to advances in supportive care of these high-risk patients. Among these advances are new agents for the prevention and treatment of neutropenic infection and its attendant complications, the use of hematopoietic growth factors, and careful prophylaxis against tumor lysis syndrome.

Infectious disease complications secondary to neutropenia are the primary cause of treatment-related morbidity and mortality in acute leukemia, and the risks seem to be especially high in patients over age 60.¹¹⁴ As such, preventing prolonged neutropenia with prophylactic use of granulocyte-stimulating growth factors has been the target of multiple investigations and clinical practice guidelines.²⁰⁷⁻²¹⁰ Several of these studies have focused on adults with ALL.^{114,210} Two sequential studies of G-CSF use during induction therapy performed by the German ALL cooperative group, the GMALL, demonstrated a reduction in the duration of neutropenia, a reduction in the number of nonviral infections, and less frequent interruptions in chemotherapy schedules. These benefits, however, did not translate into improved disease-free or overall survival.²¹¹

In 1998, the CALGB published results of its large, prospective, randomized trial of G-CSF given during induction and consolidation chemotherapy.¹¹⁴ Subjects who received G-CSF required fewer days to neutrophil recovery following induction chemotherapy for ALL. Subjects in the G-CSF group also had a shorter hospitalization time, and both a higher CR rate (87% versus 77%) and fewer induction deaths (5% versus 11%). However, G-CSF did not allow for a compressed course of chemotherapy or shorten the overall time required to undergo induction and consolidation. The overall toxicity was not lessened, infectious complications were no different, and there was no significant difference in OS or DFS between individuals who had received the G-CSF and those who had received placebo. Notably, in patients older than age 60, the CR rate for patients receiving G-CSF was 81% compared with 55% in the placebo arm. Induction deaths were also decreased, thus allowing more patients to progress to postremission therapy. In conclusion, the use of G-CSF during intensive treatment of ALL appears reasonable; however, none of the studies has demonstrated improvement in DFS or OS when hematopoietic growth factors are employed during treatment of ALL.²¹²

Treatment of Relapse

Currently, more than half of adult patients with ALL relapse despite the use of intensive combination chemotherapy programs. Most relapse within the first 2 years.²¹³ More than 80% of relapses occur first in the bone marrow, while the remainder occur in extramedullary sites, primarily the

CNS. Relapses in other sites such as lymph nodes, skin, or testes occur much less frequently. Patients with an isolated extramedullary relapse have a very high risk for subsequent bone marrow relapse and should receive systemic chemotherapy following local treatment.

Treatment of Central Nervous System Leukemia

Patients with CNS leukemia at the time of diagnosis usually receive more intensive IT therapy, with or without cranial irradiation and continue planned induction therapy. Frequently, these patients are treated with twice-weekly IT therapy until the CSF is cleared of lymphoblasts, followed by four weekly treatments while continuing with the standard protocol prophylaxis therapy. Thereafter, these patients receive once-monthly injections of intrathecal therapy for 1 year.^{147,214} CNS irradiation may be deferred until completion of induction therapy unless patients have evidence of cranial nerve root involvement. With appropriate CNS-directed therapy, patients presenting with CNS involvement can expect a similar outcome compared to patients lacking this complication.¹¹³

Patients who have an isolated CNS relapse require a different approach. From the pediatric literature, children with a CNS relapse have a dismal prognosis, with fewer than 20% achieving long-term survival.²¹⁵ It appears that the poor outcome of these patients is primarily the result of hematologic relapse rather than resistant CNS disease.²¹⁶ Therefore, the current approach to CNS relapse in children is to treat with systemic reinduction chemotherapy together with IT chemotherapy, followed by cranial irradiation. Using this approach, the Pediatric Oncology Group treated 83 children with isolated CNS relapses with 6 months of reinduction chemotherapy and consolidation therapy, followed by craniospinal irradiation and maintenance chemotherapy for 2 years from the time of relapse.²¹⁷ The EFS at 4 years was 71% for all patients, which approaches the results observed overall for children with newly diagnosed ALL. Insufficient data exist concerning the management of isolated CNS leukemia in adults, but a similar approach may be reasonable. An alternative approach for patients who do not respond to conventional CNS therapy may be the use of depo-cytarabine, a slow-release formulation of cytarabine that may be given every 3 weeks.^{218,219}

Although stem cell transplantation is a reasonable approach for adults with CNS relapse, it may not always be an effective means of management of CNS leukemia. In one study, the probability of CNS relapse was 52% for patients with a history of or active CNS disease at the time of transplant.²²⁰ The probability of CNS relapse in this study was less, 17%, for patients who received IT methotrexate after BMT, although the risk of leukoencephalopathy in these patients was significantly higher.

General Strategy for Systemic Relapse of ALL

A variety of treatment protocols have been employed in relapsed or refractory patients. However, in almost every instance, the median remission duration has been less than 6 months, and only a small fraction of these patients become long-term survivors. The best results for such patients have been obtained with allo-SCT in second remission, reviewed earlier in the section on stem cell transplantation, where

studies report DFS rates of 14% to 59%. Therefore, when feasible, the goal of salvage therapy is to obtain a second (or subsequent) remission and proceed to allo-SCT.

Chemotherapy Options

The choice of optimal chemotherapy to obtain a second remission is influenced by the initial induction/consolidation regimen, the duration of first remission, features of the disease at relapse, and the availability of a suitable allogeneic donor. Single agents that have been utilized include nucleoside analogues (usually cytarabine), anthracyclines, nonanthracycline intercalators (mitoxantrone), epipodophyllotoxins, alkylating agents (ifosfamide), and antifolates (usually high-dose methotrexate).²²¹⁻²²⁵ The divergent CR rates range from 0% to 73% and are influenced by the heterogeneity of the patients, as noted earlier. In general, however, combination chemotherapy has been more effective at inducing subsequent remissions and is most successful in patients with prolonged first remissions of more than 1 year. In these cases, reinduction using a regimen identical, or similar, to the initial successful treatment plan can be considered. High-dose cytarabine-containing regimens may be the most successful for achievement of CR, with rates of 38% to 80%. The drug has been combined with mitoxantrone,^{188,226,227} with an anthracycline,²²⁸ and with L-asparaginase,²²⁹ or an epipodophyllotoxin.^{230,231}

New Drugs in Clinical Trials

Relapse, particularly in older adults (age more than 60 years) with ALL and for those with short CR1 (less than 1 year), is associated with a very poor outcome with median survival of 2 to 4 months¹⁶⁰; therefore, these poor-risk patients should be encouraged to participate in Phase I/II trials of investigation agents and novel therapeutic approaches.

A unique nucleoside analogue, clofarabine, has been demonstrated to have efficacy in relapsed pediatric and adult ALL, with response rates in the 17% to 32% range as a single agent.²³²⁻²³⁴ Its mechanisms of action include the inhibition of ribonucleotide reductase and of DNA polymerase. Combination studies of clofarabine with cytarabine have also demonstrated efficacy in heavily pretreated patients.²³⁵ Based on its efficacy in relapsed pediatric ALL, an application to the Federal Drug Administration is pending, and this may be the first new drug approved for use in relapsed ALL in many years.

Recently, therapy targeted to specific biologic risk groups has been exploited with some success and may be the focus of future novel therapeutics in ALL. Nelarabine (GW506U78) is an analogue of deoxyguanosine. Previous studies have demonstrated that immature T lymphocytes are extremely sensitive to the cytotoxic effects of deoxyguanosine. The toxicity of deoxyguanosine to T cells is related to the accumulation of deoxyguanosine triphosphate (dGTP), with subsequent inhibition of ribonucleotide reductase, inhibition of DNA synthesis, and resultant cell death. Prior Phase I studies determined a maximum tolerated dose of 40 mg/kg/day for 5 days in adult patients.^{236,237} The dose-limiting toxicity was neurologic, consisting of seizures, obtundation, and ascending paralysis. As predicted by preclinical studies, the highest response rates were observed in patients with relapsed T-cell ALL and lymphoblastic lymphoma (LBL).

To decrease the risk of neurologic toxicities, a dosing regimen of 1.5 g/m² given IV once per day on an alternate-day schedule (days 1, 3, 5) was recently tested in an intergroup study carried out by the CALGB and the Southwest Oncology Group (SWOG) in adults with relapsed/refractory T-cell ALL or LBL.²³⁸ The overall response rate (CR + PR) for the 38 evaluable patients was 32% (95% CI, 18%–49%). The 1-year OS was 32% (95% CI, 16%–47%) and the 1-year DFS was 40% (95% CI, 10%–70%). These results suggest that nelarabine is well tolerated and has significant antitumor activity in patients with relapsed or refractory T-cell lymphoblastic leukemia/lymphoma, prompting consideration to incorporate nelarabine into frontline therapy for patients with T-lineage ALL.

A similar subset-specific approach is being explored using imatinib mesylate, the BCR-ABL tyrosine kinase inhibitor, in adults with Ph+ ALL in CR1, as described earlier (see section on Ph+ ALL). Although its greatest potential for improving DFS is likely to be in CR1 patients, imatinib as a single agent may induce transient responses in patients with relapsed or refractory disease, allowing such patients to proceed with an allo-SCT in second or subsequent remission. In vitro studies have demonstrated either additive (daunorubicin, interferon-alpha) or synergistic effects (cytarabine)²³⁹; therefore, combination therapy with imatinib should be tested for patients with relapsed Ph+ ALL. Another tyrosine kinase inhibitor that is directed against CD-19, B-43-Genistein, was shown to demonstrate activity in a Phase I trial of 15 heavily pretreated ALL patients. The CD19 receptor is expressed at high levels on leukemic cells of most ALL patients, is absent on hematopoietic stem cells, and is physically associated with the Src family of protein tyrosine kinases to form a transmembrane tyrosine kinase receptor with important signal transducing properties.²⁴⁰

Monoclonal antibodies targeted to epitopes present on the lymphoblasts are also being evaluated. Campath-1H is a monoclonal humanized form of a rat antibody active against CD52, an antigen present on nearly all normal B and T lymphocytes that may be present on the surface of most cases of ALL.^{241,242} Although the experience with this antibody in relapsed, refractory ALL has been limited, Campath has been shown to clear blasts from the peripheral blood after failure of traditional chemotherapy.^{242,243} The CALGB has recently begun testing the feasibility of incorporating Campath-1H into the initial treatment of adult ALL in an attempt to eradicate MRD in early CR1 (CALGB 10102). Rituximab, a chimeric humanized mouse antibody directed against CD20, which is expressed in approximately 20% of ALL cases, is also being explored as an adjunct to standard chemotherapy in frontline and salvage therapy. Initial reports from the M.D. Anderson suggest that its addition may improve response rates²⁴⁴; longer follow-up is needed to determine its potential to improve DFS. Based on decreases in tumor size that were demonstrated using an immunotoxin, anti-B4 blocked ricin (anti-B4-bR); this immunotoxin, which is directed against the surface epitope, CD19, has also been tested in relapsed and frontline ALL.^{245,246} Although this approach was feasible as intensification therapy in CR1, there did not appear to be a DFS benefit compared to previous studies. A new generation of conjugated antibodies is being developed, and one of these agents (toxin-conjugated anti-CD22; Wyeth) may soon enter clinical trials in advanced ALL.

The Future: Targeted Agents

Rationale for the use of other novel agents that may target specific pathogenetic pathways in ALL exists. Potential candidates for future study include drugs that target P-glycoprotein, encoded by the multidrug resistance (MDR1) gene, which may be overexpressed in drug-resistant ALL.^{247,248} A number of these agents are currently in development and have entered clinical trials in AML but remain to be tested in ALL. Oblimersen (formerly G3139), an antisense oligonucleotide directed against bcl-2, which is frequently overexpressed in ALL,²⁴⁸ may be combined with standard agents in an attempt to overcome drug resistance and facilitate chemotherapy-induced apoptotic cell death.²⁴⁹ There is also good rationale for testing the efficacy of hypomethylating agents, such as 5-azacytidine or 2-deoxy 5-azacytidine, because hypermethylation has been associated with drug resistance and is reported in 10% to 50% of de novo and nearly all cases of relapsed or refractory ALL.¹⁶⁰ Overexpression of FLT-3, a receptor tyrosine kinase, occurs in cases of infant ALL with either *MLL* gene rearrangements or hyperdiploidy.⁹¹ Continuous signaling by the receptor contributes to the abnormal growth of leukemia cells, which can be blocked by a small molecule tyrosine kinase inhibitor of FLT-3 in vitro in primary leukemia cells containing *MLL* gene rearrangements.⁹¹ Thus, the rationale exists for clinical trials of FLT-3 receptor tyrosine kinase inhibitors²⁵⁰ in these subsets of ALL. In preclinical studies, induction of apoptosis in ALL cell lines has recently been demonstrated after treatment with a histone deacetylase inhibitor.^{251,252}

Conclusions

The majority of adults receiving treatment for ALL will achieve remission; however, despite improvements in selected patient subsets, fewer than half of adult ALL patients are long-term survivors. Future advances for this relatively rare group of diseases will require the insights gained from participation in well-designed cooperative group clinical trials. Rapidly emerging insights into the molecular pathogenesis and monitoring of these heterogeneous disorders will improve prognostic ability, aid in risk stratification and treatment choice, and guide new molecularly targeted drug development. Using a risk-adapted approach based on patient characteristics and molecular-cytogenetic features of the disease, as outlined here, will facilitate the development of more individualized and successful treatments to improve outcome for adults with ALL.

Chronic Lymphocytic Leukemia and Related Chronic Leukemias

Thomas S. Lin and John C. Byrd

The treatment of chronic lymphocytic leukemia (CLL) and related chronic leukemias remains palliative, although long-term survival has been achieved for the subset of patients with hairy cell leukemia. Despite this, the past decade has seen tremendous advancements in the understanding and treatment of these diseases, with the advent of purine analogues, such as fludarabine and monoclonal antibodies, such as rituximab and alemtuzumab. This chapter focuses on recent developments in identifying prognostic factors in CLL, as well as advances in the treatment of these diseases. Particular emphasis is given to the expanding role of monoclonal antibody therapies in these diseases.¹⁻³

Chronic Lymphocytic Leukemia

The Disease

Chronic lymphocytic leukemia (CLL) is the most common adult leukemia in the Western world, accounting for a third of newly diagnosed adult leukemia patients; approximately 7,000 patients are diagnosed annually in the United States.⁴ The vast majority (95%) of patients present with B-CLL, but a small percentage have T-CLL that, by the current World Health Organization (WHO) classification, would be accorded the title T-cell prolymphocytic leukemia. The optimal treatment for newly diagnosed CLL remains undefined. Although most patients with CLL respond to initial therapy, treatment is not curative, and several large randomized studies failed to show a survival advantage for early treatment of asymptomatic, early-stage patients.⁵⁻⁷ Despite the advent of new therapeutic agents, such as fludarabine, which have resulted in improved complete response (CR) rates and progression-free survival (PFS), overall survival (OS) has not improved to date.⁸⁻¹⁰ The inherent resistance of CLL to cytotoxic therapy is largely the result of defective apoptosis. In contrast to acute leukemias, which are characterized by uncontrolled proliferation, CLL arises from cellular defects in programmed cell death.

CLL is a disease of the elderly with a median age at diagnosis of approximately 65 years; most patients are 50 or older.⁴ The male-to-female ratio is approximately 1.7, and men have a poorer prognosis than women. An increasing

number of younger patients are being diagnosed at an earlier stage of the disease; however, it is unclear whether this reflects a change in the natural history of the disease or merely a change in surveillance practices. Despite its indolent nature, the impact of CLL on survival in both young and elderly patients is substantial. Median expected life expectancy in patients diagnosed before age 50 is 12.3 years, compared to 31.2 years in the age-matched control group.¹¹ Although CLL reduces the life expectancy of younger patients, the poorest survival following diagnosis is observed in elderly patients.

Establishing the initial diagnosis of CLL, as defined by the NCI (National Cancer Institute) Working Group, requires an absolute lymphocytosis of more than 5,000/ μ L.⁴ Morphologically, the lymphocytes must appear mature with less than 55% prolymphocytes. The bone marrow aspirate smear must show more than 30% of all nucleated cells to be lymphoid, or the bone marrow core biopsy must show lymphoid infiltrates compatible with marrow involvement by CLL. The overall cellularity must be normocellular or hypercellular. Immunophenotyping must reveal a predominant B-cell monoclonal population sharing a B-cell marker (CD19, CD20, CD22, CD79b) with the CD5 antigen, in the absence of other pan-T-cell markers. Surface immunoglobulin (Ig) density is generally low; CLL cells can rarely have bright-surface Ig expression but almost always express CD23 without overexpression of cyclin D1. The WHO classification includes small lymphocytic lymphoma (SLL) with CLL, as SLL and CLL represent similar immunophenotypic and genetic diseases.

Staging Systems

Patients with CLL are staged utilizing either the Rai or Binet system.⁴ Both systems stage patients by the sites of disease and/or degree of cytopenias induced by marrow replacement. Patients can be categorized into three groups. In the modified Rai system, patients in the low-risk group (stage 0) exhibit lymphocytosis alone, intermediate-risk patients also have lymphadenopathy (stage I) and/or splenomegaly (stage II), and high-risk patients have anemia (hemoglobin less than 11.0 g/dL, stage III) and/or thrombocytopenia (platelets fewer than 100×10^9 /L, stage IV). The Binet system stages patients by the number of sites involved for low- and intermediate-

risk (stage A less than three lymphatic regions, stage B three or more lymphatic regions); advanced-stage C patients have anemia (hemoglobin less than 10.0 g/dL) or thrombocytopenia (platelets fewer than $100 \times 10^9/L$). A prospective comparison of these two staging systems by the French Cooperative Group on CLL demonstrated the Binet system to be more effective at discriminating outcome among early-stage patients. Subsequent studies identified a group of patients with smoldering CLL, whose risk of progression to symptomatic CLL was 14% to 17% at 5 years, and whose clinical outcome matched age-matched control population. However, both clinical staging systems fail to discriminate adequately the expected clinical outcome for a large subset of early-stage CLL patients. Improved prognostic discriminating tests are needed to improve our ability to predict clinical outcome and allow adoption of risk-adaptive strategies in this diverse disease.

New Genetic Markers That Identify High-Risk Prognostic Features in CLL

A rapidly evolving area of CLL research is the identification of negative prognostic factors that predict for early progression, poor response to therapy, and inferior survival. CLL is a heterogeneous disease, with a widely varied natural history. New molecular techniques have identified several factors that predict how quickly patients will require therapy or will relapse after treatment. Interphase cytogenetic analysis, using fluorescence in situ hybridization (FISH) probes, is one such useful tool and allows detection of chromosomal abnormalities that may not be seen by traditional metaphase analysis. Interphase FISH analysis of 325 CLL patients detected chromosomal abnormalities in 82% of patients.¹² The most common findings were deletion of 13q14 (55% of patients), trisomy 12 (16%), translocation or deletion of 17p13 (7%), and deletion of 11q22–23 (18%). Deletion of 13q14 leads to loss of a presumed tumor suppressor gene at the D13S25 locus. Deletion of the 13q14 locus predicts a favorable prognosis, with a median survival of 133 months (compared to 111 months for normal karyotype) and a median treatment-free interval of 92 months. Trisomy 12 is often seen in patients with advanced disease and is associated with a higher percentage of prolymphocytes and atypical immunophenotype; however, median survival (114 months) was identical to that of patients with normal karyotype. Deletion of 17p13 results in loss of the p53 tumor suppressor gene at 17p13.1 and predicts for the worst outcome among CLL patients, with poor response to standard alkylator and fludarabine therapy. Median survival was only 32 months, with a treatment-free interval of 9 months. Deletion of 11q22–23 is associated with extensive lymphadenopathy and poor prognosis; median survival was 79 months and treatment-free interval 13 months.¹² As in other hematologic malignancies, complex karyotype, with two or more cytogenetic abnormalities, is associated with a poor prognosis.

V_H GENE MUTATIONS

Studies to date have not shown a uniform correlation between cytogenetic abnormalities and the presence or absence of mutated variable Ig heavy chains (IgV_H) in CLL. However, several publications have demonstrated that unmu-

tated IgV_H correlates with an increased likelihood of requiring early treatment, poorer response to therapy, and inferior survival.^{13–20} IgV_H genes of 84 CLL patients were sequenced; 38 patients (45%) had unmutated IgV_H, whereas 46 patients (55%) had mutated IgV_H. Median survival of Binet stage A patients with unmutated IgV_H was 95 months, compared to 293 months for patients with mutated IgV_H; survival was similarly poorer for Binet stage B and C patients with unmutated IgV_H.¹³ Correlation between the absence of mutated IgV_H chains and CD38 expression of CD38 has been noted in some studies, but CD38 expression itself is an independent predictor of response to therapy.^{14,15,21} Both the intensity of and percentage of CLL cells with CD38 expression (20%–30% or more of total CLL cells) are predictors of survival.^{14–17,22,23} CD38 expression has been used as a surrogate marker for unmutated IgV_H, but 28% of CLL patients have discordant CD38 expression and IgV_H mutational status.¹⁶ Median survival was significantly worse in patients with unmutated IgV_H and CD38 expression (8 years) than in patients with mutated IgV_H and absent or low CD38 expression (26 years). The same investigators reported a median survival of 310 months for patients with mutated IgV_H, compared with 119 months for unmutated IgV_H. However, the correlation with CD38 expression and V_H mutation status has not been observed by other groups. By comparison, loss or mutation of p53 in the same group of 205 CLL patients was associated with a median survival of only 47 months.²⁴

ZAP-70

Recently, expression of zeta-associated protein 70 (ZAP-70), which is normally expressed in T lymphocytes, has been identified as a surrogate marker of IgV_H mutation status. This expression was initially identified in genomic profile studies, and differential expression was subsequently verified at the mRNA and protein levels.²⁵ CLL cells with unmutated IgV_H expressed detectable levels of ZAP-70, whereas ZAP-70 could not be detected in CLL cells with mutated IgV_H. Ligation of the B-cell receptor complex resulted in tyrosine phosphorylation of ZAP-70, association of ZAP-70 with the surface Ig, and increased tyrosine phosphorylation of cytosolic proteins, including p72syk.²⁶ Analysis of 56 CLL patients showed that all 32 patients expressing ZAP-70 on 20% or more of CLL cells had unmutated IgV_H, whereas 21 of 24 patients expressing ZAP-70 on less than 20% of leukemic cells, had mutated IgV_H. ZAP-70 expression did not change over time and was correlated with rapid progression and inferior survival in Binet stage A patients.²⁷ A similar analysis of 107 CLL patients demonstrated a 93% correlation between ZAP-70 expression and IgV_H mutation status. CLL cells with unmutated IgV_H had 5.5-fold-higher expression of ZAP-70 than did patients with mutated IgV_H.²⁵ Thus, ZAP-70 appears to be the gene whose expression best predicts IgV_H mutation status.

p53 AND ATM

p53 gene inactivation is a highly predictive marker for drug resistance and inferior survival in patients with CLL.^{28–30} Mutations of the p53 tumor suppressor gene are seen in 10% to 20% of patients with untreated CLL, become more frequent with disease progression, and predict for poor response to alkylator or purine analogue therapy.^{29–32} Deletion of 17p13.1 results in loss of the p53 gene and predicts for the

worst outcome among CLL patients. Median survival with alkylator or fludarabine therapy was only 32 months, with a treatment-free interval of 9 months.¹² A similar study showed that loss or mutation of p53 was associated with a median survival of 47 months.²⁴

p53 can be inactivated by mutations of the ATM (ataxia telangiectasia mutated) gene, another potential common high-risk molecular feature of CLL that has been less well characterized. ATM phosphorylates p53, allowing p53 to initiate DNA repair,³³⁻³⁵ and ATM-deficient cells have increased sensitivity to both X-ray- and free-oxygen-radical-induced DNA damage.^{36,37} Diminished or absent ATM protein expression, usually associated with loss or mutation of the ATM gene, negatively affects survival in CLL.³⁸⁻⁴¹ In one series of 43 CLL patients, tumor cells from all 13 patients with p53 ($n = 6$) or ATM ($n = 7$) mutations failed to undergo apoptosis following *ex vivo* irradiation.⁴² Tumor cells from patients with ATM mutations showed diminished DNA repair and did not undergo apoptosis in response to *in vitro* radiation, compared to CLL cells with intact ATM and normal stimulated B lymphocytes. Thus, CLL cells with primary or secondary p53 dysfunction are predisposed to increased chromosomal damage with therapy, which leads to additional genetic instability and tumor cell resistance. Identifying therapies that circumvent dysfunctional p53 function is, therefore, a high priority.

Treatment of CLL

WHEN TO TREAT

In the absence of symptoms, observation is the current practice employed for newly diagnosed patients, based upon several studies demonstrating no improvement in overall survival for asymptomatic CLL patients receiving early therapeutic intervention with chlorambucil therapy.⁷ A meta-analysis that included data involving 2,048 patients in six trials demonstrated a slightly higher death rate (42.6%) among those treated early versus those randomized to deferred therapy (41.6%), although this difference was not significant.⁷ It must be noted that each of these studies included a large proportion of patients with smoldering or early-stage disease. For this population of patients, therapeutic benefit would require an improvement in overall survival in excess of that observed in the age-matched control population without CLL. Furthermore, each of these studies employed chlorambucil, an agent that yields a low CR rate. With more effective therapies and use of risk stratification with new molecular techniques, reconsideration of this approach in well-designed trials seems quite prudent; this is further substantiated by the now-recognized genetic clonal evolution of CLL that occurs over time from initial diagnosis. This clonal evolution coincides with increasing resistance to apoptosis. Efforts within the German CLL Study Group and several U.S. groups are under way to examine this question with newer CLL therapies.

Determining what constitutes sufficient symptomatology to initiate treatment in CLL is subjective and confounds comparison of clinical trials. To assure uniform study entrance criteria, an NCI-sponsored Working Group on CLL established guidelines for initiation of treatment.⁴³ These indications include the presence of nonautoimmune cytopenias

(Rai stage III and IV), symptomatic lymphadenopathy or hepatosplenomegaly, disease-related B symptoms or fatigue, extreme lymphocytosis (greater than $150\text{--}300 \times 10^9/\text{L}$), and autoimmune hemolytic anemia or thrombocytopenia not controlled with steroids. It is imperative to determine if a patient's symptoms are caused by CLL or a comorbid medical condition. The decision of when to start therapy remains one of the most challenging issues physicians caring for patients with CLL must make.

ALKYLATOR THERAPY

Chlorambucil and other alkylating agents served as first-line therapy for CLL for many decades.⁴ Chlorambucil is generally administered as pulse therapy (40 mg/m² orally every 28 days). Although a high-dose (15 mg/day) continuous dosing schedule has been used in several large European studies and has obtained results superior to those of pulse therapy, high-dose therapy is associated with greater myelosuppression and frequently requires dose reduction. Although high-dose therapy may be more effective if maximal cytoreduction is desired, the less intensive pulse dosing schedule should generally be used outside the setting of a clinical study.

FLUDARABINE THERAPY

Fludarabine-based regimens have shown significant clinical efficacy in relapsed and previously untreated CLL.⁴⁴⁻⁵¹ The introduction of purine analogues has led to more effective therapies for CLL, as evidenced by improved CR rates and PFS; however, no advantage in OS has been observed to date. Although fludarabine was initially approved for alkylator-refractory CLL, the drug has since become standard therapy for previously untreated CLL, based on several large randomized studies showing improved CR and PFS rates compared to alkylator-based regimens.⁸⁻¹⁰ These studies are summarized in Table 65.1. A multicenter European study of 196 evaluable patients randomized to fludarabine or CAP showed a higher overall response rate (ORR) in favor of fludarabine (60% versus 44%). This advantage was true in both previously treated ($n = 96$, 48% versus 27%) and untreated ($n = 100$, 71% versus 60%) patients, although the difference was not statistically significant in the untreated group. Fludarabine achieved a longer median duration of response than did CAP, with a tendency toward longer OS in previously untreated patients.⁸ A randomized, multicenter American study confirmed these findings in 509 previously untreated CLL patients, who were randomly assigned to receive fludarabine 25 mg/m² IV daily for 5 days every 28 days, chlorambucil 40 mg/m² PO every 28 days, or fludarabine 20 mg/m² daily for 5 days and chlorambucil 20 mg/m² PO every 28 days, for up to 12 cycles. The combination arm was closed for reasons of excessive toxicity. Fludarabine achieved superior CR, ORR, median duration of remission, and median PFS (20%, 63%, 25 months, 20 months, respectively) than did chlorambucil (4%, 37%, 14 months, 14 months, respectively). However, there was no statistically significant difference in OS (66 versus 56 months), although the study employed a cross-over design.⁹ Finally, a multicenter French study randomized 938 patients with previously untreated Binet stage B and C CLL to fludarabine, CHOP, or CAP. Although CHOP and fludarabine achieved better response rates than CAP, overall survival (67-70 months) was identical in all three treatment groups.¹⁰

TABLE 65.1. Selected clinical trial results with fludarabine in previously untreated chronic lymphocytic leukemia (CLL) patients.

Reference	Regimen	Phase	No. of patients	CR	ORR	Mean PFS (months)	Mean OS (months)
8	Flu	III	52	23	71	NR	NR
	CAP		48	17	60	7	54
9	Flu	III	170	20	63	20	66
	CLB		181	4	37	14	56
	Flu + CLB		123	20	61	Not Rep	55
10	Flu	III	341	40	71	32	69
	CHOP		357	30	72	30	67
	CAP		237	15	58	28	70
50	Flu + Cy	II	17	51	92	Not Rep	Not Rep
51	Flu + Cy	II	34	35	88	NR	NR
191	Flu + Cy	II	36	42	64	Not Rep	Not Rep
192	Flu + Cy	II	59	47	78	Not Rep	Not Rep
52	Flu	III	105	9	86	23	NR
	Flu + Cy		104	20	94	28	NR
93	Flu + Ritux	Ran II	51	47	90	NR	NR
	Flu then Ritux		53	28	77	NR	NR
97	Flu + Cy + Ritux	II	202	68	90	NR	NR

Flu, fludarabine; CAP, cyclophosphamide, adriamycin, prednisone; CLB, chlorambucil; CHOP, cyclophosphamide, adriamycin, vincristine, prednisone; Cy, cyclophosphamide; Ritux, rituximab; CR, complete response rate; ORR, overall response rate; PFS, progression-free survival; OS, overall survival; NR, not reached; Not Rep, not reported.

Thus, although large randomized studies demonstrated superior response rates and durations with fludarabine, compared to alkylator-based regimens, no survival advantage was seen with single-agent fludarabine (see Table 65.1).

FLUDARABINE COMBINATION REGIMENS

To improve response rates over those seen with single-agent fludarabine, the purine analogue has been combined with cyclophosphamide (Flu/Cy). A large single-institution study administered fludarabine 30 mg/m² IV and cyclophosphamide 300–500 mg/m² IV daily for 3 days for up to six cycles to 128 patients with CLL (see Table 65.1). Because of myelosuppression, the dose of cyclophosphamide was decreased from 500 mg/m² ($n = 11$) to 300 mg/m² ($n = 91$). The ORR was 80% in patients naïve or sensitive to fludarabine but only 38% in fludarabine-refractory patients. This regimen achieved a 35% CR rate in previously untreated patients, similar to that expected with single-agent fludarabine. However, only 8% of patients achieving CR had minimal residual disease detectable by flow cytometry, and the median time to progression was not reached despite a median follow-up of 41 months.⁵¹ Retrospective comparison of this result to a previous study of fludarabine and prednisone at this same institution demonstrated Flu/cy to be significantly better. Based in part upon this observation, a large study by the German CLL Study Group randomized 375 previously untreated patients to standard fludarabine versus Flu/Cy (fludarabine 30 mg/m² IV and cyclophosphamide 250 mg/m² IV daily for 3 days) every 28 days for six cycles. The ORR (94% versus 86%), CR (20% versus 9%), and median PFS (28.2 versus 22.8 months) were better in the Flu/Cy arm,⁵² although toxicity was significantly worse in the combination arm. However, it must be noted that the fludarabine arm did poorly in this study, and that the CR rate obtained in the combination arm was less than the 35% rate reported by the M.D. Anderson group.⁵¹ A slightly different regimen (fludarabine 20 mg/m² IV days 1–5 and

cyclophosphamide 600 mg/m² IV day 1 every 28 days for six cycles) was administered to 37 patients with non-Hodgkin's lymphoma (NHL) and 17 patients with CLL. Patients were given granulocyte colony-stimulating factor (G-CSF) support beginning on day 8 of each cycle. The ORR and CR rates were 92% and 51%, respectively; the ORR and CR rates in the 17 CLL patients were 100% and 47%, respectively.⁵⁰ This second regimen is currently being tested as part of a large randomized Phase III U.S. Intergroup effort. The choice of fludarabine or Flu/Cy as the backbone upon which to add the monoclonal anti-CD20 antibody rituximab or other monoclonal antibody therapies, depends upon whether one believes that the current data support the contention that Flu/Cy is superior to fludarabine. At the present time, these authors prefer the use of fludarabine alone for such combination approaches.

MONOCLONAL ANTIBODIES

Monoclonal antibodies offer the potential of targeted therapy with minimal toxicity to normal cells, and clinical studies over the past decade have demonstrated the feasibility, safety, and clinical efficacy of these agents in many solid and hematologic cancers. Monoclonal antibodies are now used to treat diseases as diverse as acute myeloid leukemia (AML), diffuse large B-cell NHL, mycosis fungoides, and CLL.^{53–59} Recombinant DNA technology has allowed the generation of chimeric and “humanized” murine monoclonal IgG antibodies. Murine sequences are replaced with the human Fc fragment, resulting in humanized IgG molecules whose Fab portions contain only the murine sequences required to recognize the target antigen. These humanized antibodies are significantly less immunogenic and produce less infusion toxicity.^{60–62} The human Fc fragment also allows chimeric antibodies to induce antibody-dependent cellular cytotoxicity (ADCC) and complement-dependent cytotoxicity (CDC). Thus, humanized monoclonal antibodies are better tolerated and more effective.

TABLE 65.2. Summary of monoclonal antibodies available in CLL.

Antibody	Antigen	Description	Clinical status
IDEC-C2B8 (Rituximab)	CD20	Chimeric	FDA approved
Campath-1H (Alemtuzumab)	CD52	Humanized	FDA approved
Hu1D10 (Apolizumab, Remitogen)	1D10 (HLA-DR β)	Humanized	Clinical trials
IDEC-152 (Lumiliximab)	CD23	Primatized	Clinical trials

ROLE OF MONOCLONAL ANTIBODIES IN CLL

The failure of traditional cytotoxic agents to cure CLL may result from the disease's indolent nature, as well as intrinsic resistance mechanisms to chemotherapy. Only a small fraction of CLL cells undergo growth and division at a time. Cytotoxic agents often act only against dividing cells undergoing transcription and DNA replication and thus are ineffective against resting cells. Fludarabine, which acts against both dividing and nondividing cells, is an exception to this rule. The inherent resistance of CLL to chemotherapy is the result of defective apoptosis. Antiapoptotic proteins, such as Bcl-2, Mcl-1, and XIAP are overexpressed, and high levels of Mcl-1 are associated with failure to achieve CR to fludarabine.⁶³ ADCC and CDC are observed after antibody therapy,^{64,65} but monoclonal antibodies may exert their effects in CLL primarily by inducing apoptosis.^{66,67} Thus, monoclonal antibodies act directly against the cellular defects in apoptosis that give rise to CLL. Table 65.2 summarizes the major monoclonal antibodies in current clinical use or clinical studies in CLL.

RITUXIMAB

Preclinical Studies Rituximab (Rituxan, IDEC-C2B8), a chimeric murine monoclonal antibody that recognizes the CD20 antigen on the surface of normal and malignant B cells, is the best studied and most widely used monoclonal antibody in lymphoid malignancies. CD20, a calcium channel that interacts with the B-cell receptor complex, is an excellent target; it is expressed in 90% to 100% of CLL and B-cell NHL and is not internalized or shed. However, significant levels of soluble CD20 have been detected in the sera of patients with CLL by one group, and increased circulating CD20 levels correlated with beta-2-microglobulin levels and advanced-stage disease.⁶⁸ Circulating CD20 levels correlated with poor survival, and the prognostic value was independent of Rai stage.⁶⁹

Rituximab induces ADCC and CDC, activates caspase 3, and induces apoptosis.⁶⁴⁻⁶⁷ Rituximab induces apoptosis *in vitro* within 4 hours; this induction is independent of complement but requires cross-linking with anti-Fc γ antibody. The ratio of the antiapoptotic protein Mcl-1 to the proapoptotic protein Bax was significantly elevated in CLL patients who did not respond to rituximab, compared with responders.⁷⁰ Complement activation may be important, as increased expression of complement inhibitors CD55 and CD59 resulted in resistance to rituximab in NHL cell lines and CLL cells.^{65,71} Blocking CD55 and CD59 resulted in a fivefold increase in rituximab-induced cell lysis of poorly

responding CLL samples, although CD55 and CD59 levels did not predict complement susceptibility.⁷¹ However, baseline expression of CD55 and CD59 was not associated with clinical response to rituximab in 21 treated patients.⁷⁰ Thus, although rituximab may act through more than one mechanism, induction of apoptosis appears to be a major contributor to the elimination of CLL cells.

Clinical Studies: Single-Agent Weekly Rituximab Phase I clinical studies in indolent B-cell NHL established a dose of 375 mg/m² IV weekly for four doses, although the length of treatment was empirically established. In the pivotal Phase II trial in 166 patients with relapsed or refractory indolent B-cell NHL or CLL, an ORR of 48% was seen (CR 6%) with a median response duration of 12 months.⁵⁸ Patients with indolent follicle center B-cell NHL had an ORR of 60%, whereas only 4 of 30 patients with small lymphocytic lymphoma (SLL)/CLL (13%) responded. A British study of 48 patients using the same schedule achieved only 1 partial response (PR) in 10 patients with relapsed or refractory SLL/CLL (10%), although the ORR was only 27% in patients with follicular NHL.⁷² A similar study observed only 1 PR in 9 evaluable patients with fludarabine-refractory CLL (11%), although 7 patients had stable disease.⁷³ A study of 7 patients with refractory or relapsed CLL observed a striking, but transient, reduction (median, 93%) in peripheral lymphocyte count, but nodal disease was not affected.⁷⁴ The German CLL Study Group administered weekly rituximab to 28 patients with previously treated CLL; 7 patients (25%) achieved PR with a median duration of 20 weeks. Forty-five percent of patients experienced at least 50% reduction of peripheral lymphocyte count lasting 4 weeks or longer.⁵⁷ Finally, a Nordic multicenter study observed an ORR of 35% in 24 heavily pretreated CLL patients, with a median duration of response of only 12.5 weeks. Interestingly, 17 of 20 patients (85%) with adenopathy experienced greater than 50% reduction in nodal disease, whereas only 2 of 18 patients (11%) had reduction of marrow disease.⁷⁵

Thus, weekly rituximab has limited activity in CLL (Table 65.3). Rituximab effectively reduces peripheral blood lymphocytosis but is less effective at reducing bone marrow or nodal disease. The preferential response of peripheral

TABLE 65.3. Selected Phase II trials of weekly rituximab in CLL and small lymphocytic lymphoma (SLL).

Reference	Doses	Prior therapy	Evaluable patients	Response rate (ORR)
McLaughlin et al., 1998 ⁵⁸	4	Yes	30	13%
Nguyen et al., 1999 ⁷²	4	Yes	10	10%
Winkler et al., 1999 ⁷³	4	Yes	9	11%
Ladetto et al., 2000 ⁷⁴	4	Yes	7	0%

Thomas et al., 2001 ⁷⁸	8	No	21	90%

lymphocyte count may be caused by increased CD20 expression on circulating CLL cells compared to bone marrow cells. In quantitative flow cytometric studies, circulating CLL cells bound an average of 9,050 anti-CD20 molecules compared with only 4,070 molecules for bone marrow CLL cells and 3,950 molecules for lymph node CLL cells.⁷⁶ In addition, stromal cells in bone marrow and lymph nodes may provide a survival advantage to CLL cells in these environments over circulating CLL cells.

Initial CLL Therapy with Rituximab Weekly rituximab may be more effective in previously untreated SLL/CLL (see Table 65.3). Forty-four previously untreated patients with SLL/CLL received four weekly doses of rituximab 375 mg/m²; the ORR after the first course of rituximab was 51% (CR 4%). Twenty-eight patients with stable or responsive disease received additional maintenance therapy with 4-week courses of rituximab every 6 months for up to four cycles, with an increase in the ORR to 58% (CR 9%). However, the median PFS of 19 months was shorter than the 36- to 40-month median PFS obtained by the same group using an identical regimen in previously untreated patients with follicle center NHL.⁷⁷ Nonetheless, this response duration was similar to that noted in the intergroup study with fludarabine, suggesting rituximab does have significant efficacy in the treatment of CLL. A second study of eight weekly doses of rituximab 375 mg/m² in 31 untreated, early-stage, asymptomatic CLL patients (21 evaluable) not meeting criteria for treatment by the NCI 96 criteria, with a beta-2-microglobulin level of 2.0 mg/dL or more, showed an ORR of 90% (CR, 19%; nodular PR, 19%).⁷⁸ The majority of patients achieved only PR, with few patients attaining CR. Toxicity in both studies was minimal except for initial infusion toxicity. Thus, although quite effective and nontoxic as a palliative regimen, rituximab as a single agent is unlikely to significantly alter long-term survival in CLL.

Limitations of Weekly Rituximab in CLL Several theories may explain the inferior efficacy of weekly rituximab in CLL, compared to its activity in indolent follicle center NHL. First, CLL/SLL cells express lower CD20 density than follicle center NHL cells, decreasing the number of target antigen sites and the amount of antibody delivered to individual tumor cells. In an analysis of 70 patients with chronic B-cell leukemias and 17 normal donors, normal B lymphocytes expressed 94,000 CD20 molecules per cell. Although other chronic B-cell leukemias, such as mantle cell lymphoma and hairy cell leukemia expressed between 123,000 and 312,000 CD20 molecules per cell, CLL cells expressed only 65,000 CD20 molecules per cell.⁷⁹ However, an analysis of 10 patients with CLL did not identify a correlation between CD20 expression and clinical response to rituximab.⁸⁰ A more plausible explanation is that the large intravascular burden of circulating CLL cells may alter the pharmacokinetics of rituximab and result in accelerated clearance of antibody from plasma. Lower trough concentrations of rituximab were observed in CLL patients who did not respond to therapy; the importance of serum rituximab levels was documented in follicle center NHL.^{81,82} Serum concentrations of rituximab decrease more rapidly after treatment in CLL than in follicle center NHL. In addition, the presence of soluble CD20 in the sera of CLL patients suggests that free CD20, derived from cell membrane fragments or shed antigen, may contribute

to rapid clearance of rituximab. However, a relationship between soluble CD20 levels and response to rituximab has not been demonstrated.⁶⁸ Finally, intrinsic mechanisms of resistance, such as overexpression of antiapoptotic proteins or p53 mutations may contribute to the common resistance of CLL to rituximab and cytotoxic therapy.

Rituximab Dose Escalation: Improved Clinical Response Investigators have taken two different strategies to overcome these pharmacokinetic and pharmacodynamic obstacles. Fifty patients with previously treated CLL ($n = 40$) or other B-cell leukemias ($n = 10$) received weekly rituximab dose-escalated to 2,250 mg/m².^{83,84} Although no CLL patient achieved CR, the ORR was 40%, and a statistically significant dose-response relationship was observed; 22% of patients treated with 500 to 850 mg/m² responded, compared to 75% of patients treated with 2,250 mg/m². The ORR was 36% for CLL and 60% for other B-cell leukemias; median response duration was 8 months. Eight of 12 patients (67%) at 2,250 mg/m² developed grade 2 toxicity, primarily fatigue, but no grade 3 or 4 toxicity was observed.

Alternatively, 33 patients with relapsed or refractory SLL/CLL received thrice-weekly rituximab for 4 weeks.⁵⁶ Patients received 100 mg over 4 hours on the first day of therapy and 250 mg/m² ($n = 3$) or 375 mg/m² ($n = 30$) thereafter. This "stepped-up" dosing schedule was designed to minimize infusion-related toxicity. The ORR was 45% (CR, 3%), and median response duration was 10 months. Thirteen patients developed transient infusion-related toxicity that appeared to be related to cytokine release [tumor necrosis factor-alpha (TNF- α), interferon-gamma (IFN- γ), interleukin 8 (IL-8), and IL-6] but resolved by the third infusion. Thus, both dose escalation and thrice-weekly dosing improved the response rate in SLL/CLL and established a role for rituximab in the treatment of relapsed CLL. Both approaches produced few complete responses, but no therapeutic agent achieves a significant CR rate in relapsed or refractory CLL.

Toxicity Infusion-related side effects constitute the most common toxicity of rituximab but are manageable, particularly with use of a "stepped-up" dosing schedule. Patients can develop transient hypoxemia, dyspnea, and hypotension, which are partly caused by inflammatory cytokine release. Although initial studies suggested that patients with high lymphocyte counts may be at greater risk of this cytokine release syndrome, subsequent larger studies failed to support this finding. Tumor necrosis factor-alpha (TNF- α) and interleukin-6 (IL-6) peak 90 minutes after start of infusion, and their rise is accompanied by fever, chills, hypotension, and nausea.⁷³ These side effects are most severe with the first infusion and resolve by the third infusion in the thrice-weekly dosing schedule.⁵⁶ An uncommon but potentially severe toxicity is tumor lysis syndrome, which is generally observed in patients with high numbers of circulating CLL cells.^{85,86} Patients at risk should receive prophylactic allopurinol, hydration, and careful observation, and it may be necessary to administer the first dose in an in-patient setting. However, patients who develop tumor lysis syndrome to the first dose of rituximab can safely receive subsequent doses, especially after the number of circulating CLL cells is reduced.⁸⁵ Other toxicities are minimal and should not affect administration of the antibody.

Combination Therapy There is great interest in combining monoclonal antibody therapy with cytotoxic chemotherapy in the treatment of lymphoid malignancies, and several studies have specifically examined rituximab. The low CR rates to single-agent rituximab indicate that combination with traditional cytotoxic drugs or other monoclonal antibodies may be necessary for rituximab to significantly affect long-term survival in CLL. Several clinical trials examined the use of rituximab in combination regimens against B-cell lymphoid malignancies, including CLL.^{54,87-90} Rituximab was successfully combined with fludarabine in both NHL and CLL.^{91,92} Concurrent administration of these two agents to 104 previously untreated CLL patients in a randomized phase II CALGB trial yielded a higher CR rate (47%) than did sequential administration (28%).⁹² Patients received standard fludarabine 25 mg/m² days 1 to 5 every 4 weeks for six cycles (see Table 65.1). Patients were randomized to receive concurrent rituximab 375 mg/m² on day 1 of each cycle, with an additional day 4 dose during cycle 1, or sequential rituximab 375 mg/m² weekly for four doses beginning 2 months after completion of fludarabine. The median duration of response was not reached at 23 months. The 104 patients in this study experienced improved ORR (84% versus 63%), CR (38% versus 20%), 2-year PFS (67% versus 45%), and 2-year OS (93% versus 81%), compared to 179 previously untreated patients who received single-agent fludarabine in a prior CALGB trial.⁹³

A multicenter European Phase II study of concurrent fludarabine and rituximab in 31 evaluable patients with CLL achieved an ORR of 87% (CR 32%), with a median duration of response of 75 weeks. Patients received fludarabine 25 mg/m² days 1 to 5 every 4 weeks for four cycles, and rituximab 375 mg/m² every 4 weeks for four doses, beginning on day 1 of cycle 3 of fludarabine. ORR and CR were similar in previously treated (ORR 91%, CR 45%) and untreated patients (ORR 85%, CR 25%). Sixteen patients developed a total of 32 infections, and 1 patient died of cerebral hemorrhage caused by prolonged thrombocytopenia.⁹⁴ The highest CR rate was achieved by a single-institution study using a combination regimen of fludarabine, cyclophosphamide, and rituximab (FCR). One hundred two evaluable patients received fludarabine 25 mg/m² and cyclophosphamide 250 mg/m² on days 2 to 4 of cycle 1 and on days 1 to 3 of cycles 2 to 6, in addition to rituximab 375 mg/m² on day 1 of cycle 1 and 500 mg/m² on day 1 of cycles 2 to 6. The ORR was 73% (CR 23%), and 5 of 13 patients in CR achieved molecular remission.⁹⁵ The same authors administered FCR to 202 previously untreated CLL patients with symptomatic disease requiring initiation of therapy by NCI criteria (see Table 65.1), achieving a CR rate of 68%.⁹⁶ Molecular remissions were observed in 49 of 100 tested patients who achieved CR (49%) and 9 of 27 patients who achieved nPR or PR (33%); 14 of 33 polymerase chain reaction (PCR)-negative patients developed molecular evidence of relapse, usually within 24 months of completing treatment.⁹⁷ The major toxicities of this regimen were grade 4 neutropenia and infection, which occurred in 20% and 17%, respectively, of treatment cycles.⁹⁸

Finally, an aggressive upfront regimen incorporating fludarabine and rituximab has been given to 13 previously untreated patients with CLL, as cytoreductive therapy before autologous stem cell transplantation. Patients received fludarabine 25 mg/m² days 1 to 3, cyclophosphamide 200 mg/m²

days 1 to 3, and mitoxantrone 10 mg/m² day 1 every 4 weeks for four to six cycles, followed by rituximab 375 mg/m² weekly for four doses. All patients responded (ORR, 100%; CR, 77%), and 4 patients (31%) achieved a molecular remission.⁹⁹ The ability of this regimen to induce complete hematologic and molecular remissions is promising, although patients have not been followed long enough to determine if these initial remissions will be durable.

Radioisotope Conjugates of Anti-CD20 Anti-CD20 monoclonal antibody has been conjugated to the radioisotopes yttrium-90 (⁹⁰Y-ibritumomab; Zevalin) and iodine-131 (¹³¹I-tositumomab; Bexxar). Several published clinical trials have demonstrated the efficacy of Zevalin and Bexxar in indolent B-cell NHL, particularly indolent follicle center NHL; the results of these trials have been extensively reviewed elsewhere. There has been reluctance to use Zevalin and Bexxar in patients with SLL/CLL because of concern about myelotoxicity resulting from bystander radiation to normal hematopoietic cells in patients with significant marrow disease. Nonetheless, results of a Phase I dose study indicated that Bexxar is effective in previously treated patients with advanced CLL. Eleven patients with heavily pretreated CLL received a total body dose of 35 to 55 cGy; 3 patients (27%) achieved PR and 6 patients (55%) had stable disease.¹⁰⁰ As expected, myelosuppression was the dose-limiting toxicity and was related to the total radiation dose. A similar study of Zevalin for minimal residual disease was conducted in 13 evaluable CLL patients who had achieved a PR ($n = 12$) or nodular PR ($n = 1$) to prior therapy. Significant responses were seen in 2 patients, and prolonged neutropenia (ANC less than 1,000 for median of 42 days) and thrombocytopenia (less than 100,000 for median of 42 days) were observed.¹⁰¹ Thus, myelosuppression will likely limit the clinical use of Zevalin and Bexxar in patients with significant marrow disease. However, radioisotope conjugates may be more effective than rituximab in SLL/CLL patients with bulky nodal disease, due to delivery of radiation to surrounding tumor cells. Future studies of Zevalin and Bexxar in SLL/CLL should focus on patients with primarily bulky lymphadenopathy and limited marrow involvement. In addition, sequential combination regimens with agents, such as Campath-1H, which effectively reduces blood and marrow disease but has limited activity against nodal disease, should be investigated.

Summary Rituximab is active in CLL, although dose intensification is needed to obtain maximal clinical benefit. Single-agent rituximab produces few CRs and will not, by itself, substantially improve long-term survival in CLL. The combination of rituximab with fludarabine has improved CR rates, and further studies are needed to determine if a higher CR results in improved long-term survival. Although most studies have combined rituximab with traditional cytotoxic agents, several trials are now examining the use of rituximab with other monoclonal antibodies, such as Campath-1H.

CAMPATH-1H

Preclinical Studies Campath-1H (Alemtuzumab) is a humanized anti-CD52 monoclonal antibody that effectively fixes complement and depletes normal lymphocytes and lymphoma cells.¹⁰²⁻¹⁰⁴ CD52, a 21- to 28-kDa glycopeptide expressed on the surface of nearly all human lymphocytes,

monocytes, and macrophages; a small subset of granulocytes, but not erythrocytes, platelets, or bone marrow stem cells. CD52 is expressed on all CLL cells and indolent B-cell NHL cells.^{105,106} Its physiologic function remains unknown, but cross-linking of CD52 on B-cell and T-cell lymphoma cell lines resulted in growth inhibition.¹⁰⁷ Antibody binding of CD52 results in profound complement activation and ADCC. CD52 is not shed, internalized, or modulated. Thus, CD52 is an ideal antigen for targeted immunotherapy. However, the ubiquitous expression of CD52 on normal lymphocytes and monocytes has resulted in increased hematologic and immune toxicity with Campath-1H, manifested by neutropenia, prolonged lymphopenia, and infectious complications.

Campath-1H acts *in vivo* by inducing programmed cell death. *In vivo* blood samples showed 19% to 92% reduction in expression of the antiapoptotic protein Bcl-2 in six of eight patients undergoing Campath-1H therapy.⁸² In addition, expression of the antiapoptotic proteins Mcl-1 and XIAP was downregulated by treatment with Campath-1H. Campath-1H induced activation of caspase 3 and cleavage of the DNA repair enzyme poly(ADP-ribose) polymerase (PARP), indicating that apoptosis is an important mechanism of action of this antibody.⁸²

Clinical Trials Phase I studies established a dose of 30 mg IV three times per week for 4 to 12 weeks. Campath-1H induced significantly more infusion toxicity than rituximab, and a stepped-up dosing schedule was necessary to diminish initial infusion toxicity and make the antibody tolerable. An initial dose of 3 mg was given on day 1, 10 mg on day 2, and 30 mg on day 3; once the full dose of 30 mg was achieved, patients were given 30 mg thrice weekly. Several clinical studies established the efficacy of Campath-1H in CLL, as summarized in Table 65.4.^{59,108–111} A multicenter, European Phase II study administered Campath-1H 30 mg thrice weekly for up to 12 weeks to 29 recurrent and refractory CLL patients. The ORR was 42%, but only 1 patient (4%) achieved CR.⁵⁹ The antibody cleared CLL cells from the peripheral blood in 97% of patients but was less effective at eliminating marrow (36%) or nodal disease (7%).

The pivotal CAM211 trial administered the same Campath-1H regimen to 93 heavily pretreated, fludarabine-refractory CLL patients; an intent-to-treat ORR of 33% was observed, although only 2% of patients achieved CR.¹¹⁰ Median time to progression for responders was 9.5 months, with a median overall survival of 16 months for all patients and 32 months for responders. The median peripheral blood

CLL count decreased by more than 99.9%, but the antibody was less effective against nodal disease. Although 74% of all patients with nodal disease responded, with 27% experiencing resolution of their adenopathy, patients with bulky lymph nodes did significantly poorer. Although 90% of patients with lymph nodes measuring less than or equal to 2 cm responded, with 64% achieving resolution of their adenopathy, only 12% of patients with lymph nodes greater than 5 cm responded, with no patients enjoying resolution of their adenopathy. All patients were placed on prophylactic antibacterial and antiviral agents, and toxicity was manageable. Patients with poor performance status did markedly worse than patients with no or minimal symptoms from their disease.

The activity of Campath-1H in CLL was confirmed by a multiinstitutional study in 136 patients with fludarabine-refractory B-CLL who received Campath-1H 30 mg thrice weekly for up to 12 weeks on a compassionate basis.¹¹² The ORR was 40% (CR 7%), and median PFS and OS of responders were 7.3 and 13.4 months, respectively. Similarly, 41 patients with relapsed B-CLL and 1 patient with T-CLL were treated with Campath-1H 30 mg IVB thrice weekly for 4 weeks in a single-institution study.¹¹³ Two patients with B-CLL achieved CR (5%), and 9 patients achieved PR (21%), for an ORR of 26%. Interestingly, 7 of 12 patients with B- or T-PLL responded (3 CR, 4 PR, ORR 58%). Although Campath-1H was more effective at eliminating disease in peripheral blood (CR, 36%; PR, 36%) and bone marrow (CR, 41%; PR, 28%) than in lymph nodes (CR, 23%; PR, 13%), a greater response in nodal disease was seen in this study than in previous trials using Campath-1H. A recent update of this study showed an ORR of 35% (CR, 12%) in 78 patients with indolent lymphoproliferative disorders (42 CLL), with a median duration of response of 18 months.¹¹⁴ Although Campath-1H is effective therapy in previously treated patients with CLL, the antibody is less effective against bulky lymphadenopathy than it is against peripheral blood or bone marrow disease. In addition, patients with an ECOG performance status of 2 or greater had a 0% response rate in the pivotal study, likely the result of inability to tolerate the initial infusion toxicity and worsening of cytopenias often observed with Campath-1H therapy.

Upfront Therapy in Previously Untreated Patients A Phase II clinical trial administered subcutaneous (SC) Campath-1H to 41 previously untreated patients with CLL. Patients received a prolonged course of Campath-1H 30 mg SC three times per week for up to 18 weeks. Except for transient grade I–II fever, first-dose reactions were minimal. The

TABLE 65.4. Summary of Campath-1H studies in CLL.

Reference	No. of patients	Weeks of Rx	Prior Rx	% CR	% PR	Overall response
111	9	6–18	No	33	55	89
59	29	6	Yes	4	38	43
108	6	6–12	Yes	0	50	50
193	24	4–16	Yes	0	33	33
194	6*	4–6	Yes	83	N/A	83
195	9*	6	Yes	55	N/A	55
196	29	NR	Yes	34	25	59
197	92	4–12	Yes	2	31	33

ORR was 87% in the 38 patients who received at least 2 weeks of treatment, and the intent-to-treat ORR was 81%.¹¹⁵ Campath-1H was most effective at clearing disease from peripheral blood (CR 95%), but bone marrow (CR + nodular PR, 66%) and nodal disease (ORR, 87%; CR, 29%) also responded to therapy. Some patients who achieved CR in the marrow required the full 18 weeks of therapy to do so, suggesting that prolonged administration of Campath-1H may be necessary to clear marrow disease. Median time to treatment failure had not been reached at time of study report (18+ months). Thus, SC administration of Campath-1H is feasible, and longer courses of Campath-1H may produce ORR and CR rates similar to those observed with fludarabine. It must be emphasized, however, that SC administration of Campath-1H does not diminish the infectious risk of this agent.

Immunosuppression and Infectious Complications

Infections constitute the major complication of Campath-1H therapy.^{102,116,117} All 50 previously treated NHL patients in a multicenter European study developed profound lymphopenia. Opportunistic infections and bacterial septicemia occurred in 14% and 18% of patients, respectively, and 6% of patients died of infection.¹¹⁸ Infections occurred in 55% of patients (27% grade 3–4), and 13% developed septicemia in the CAM211 study.¹¹⁰ Although Campath-1H also inhibits B cells, CD8+ T cells, natural killer (NK) cells, and monocytes, the most profound effects of the antibody are on CD4+ T lymphocytes.^{119–121} Treatment with 5 to 10 daily IV infusions of Campath-1H almost completely depleted lymphocytes, and lymphocyte subsets recovered with varying kinetics. NK cells and monocytes recovered to normal within 1 to 2 months, whereas B-cell numbers returned to normal within 5 months. CD8+ T cells returned to 50% of pretreatment levels by 2 months but did not increase further, and CD4+ T cells never reached 20% of pretreatment levels despite 18 months follow-up.¹¹⁹ In 41 CLL patients given SC Campath-1H for up to 18 weeks, NK and NK-T cells remained severely suppressed more than 12 months afterward; however, no late infectious complications were observed.¹²²

Paroxysmal nocturnal hemoglobinuria (PNH)-like T cells emerge during or immediately after Campath-1H treatment in many patients. These PNH-like cells cannot synthesize glycosylphosphatidylinositol (GPI) anchor glycans, lack GPI-linked surface proteins, such as CD52, and are resistant to CD52-mediated killing. Preliminary studies demonstrated that, despite lacking GPI-linked proteins, these PNH-like T cells are functional immune effector cells.¹²³ This finding may explain why the great majority of severe opportunistic infections that occur with Campath-1H are observed during active Campath-1H therapy rather than after treatment.

Lymphocyte recovery may depend on the dosing schedule, as the absolute CD4+ T-cell count reached a nadir of 2/ μ L by week 4 but increased to 84/ μ L by week 12 in the CAM211 trial.¹¹⁰ In 42 refractory CLL patients (median CD3+ T-cell count, 1,900/ μ L) treated with Campath-1H, extreme lymphopenia of less than 30/ μ L was seen in all patients after a median of 2 weeks of therapy. At a median follow-up of 14 months, the median CD3+ T-cell count recovered to 930/ μ L and the median CD4+ T-cell count to 320/ μ L.¹²³ Campath-1H depleted CD52+ myeloid peripheral blood dendritic cells, resulting in inhibition of the stimulatory activity of peripheral blood mononuclear cells (PBMCs) in allogeneic mixed-

lymphocyte reactions. Depletion of CD52+ dendritic cells also inhibited the ability of PBMCs to present antigen to purified CD4+ T lymphocytes.¹²⁴ This effect may explain the low rate of graft-versus-host disease (GVHD) in allogeneic stem cell transplants using Campath-1H.^{125,126}

This prolonged inhibition of T-lymphocyte and dendritic cell function may limit the clinical use of Campath-1H, particularly in combination regimens with other immunosuppressive agents, such as fludarabine. Patients receiving Campath-1H must be placed on appropriate prophylaxis for *Pneumocystis pneumoniae* (PCP) and varicella zoster virus (VZV). They should be monitored for cytomegalovirus (CMV) reactivation during and for at least 2 to 3 months after therapy. With these prophylactic measures, Campath-1H can be administered safely and with acceptable toxicity.

Infusion Toxicity Infusion-related toxicity occurred in 93% of patients in the CAM211 study, although the majority of reactions were grade 1 or 2. Rigors (90% overall, 14% grade 3), fever (85% overall, 17% grade 3, 3% grade 4) and nausea (53%) were the most common infusion-related toxicities.¹¹⁰ Similar rates of rigors (71%), fevers (65%), and nausea (45%) were reported in the multicenter study of 136 B-CLL patients, and almost all infusion toxicities were grade 1 or 2.¹¹² Most toxicity was observed with the first infusion.¹¹⁰ This first-dose cytokine release syndrome involves TNF- α , IFN- γ , and IL-6.¹²⁷ TNF- α levels increase by greater than 1,000-fold after Campath-1H infusion, and TNF- α is a most important cytokine in this syndrome.^{128,129} Ligation of the low-affinity Fc receptor for IgG, Fc γ RIIIa, on NK cells results in release of TNF- α , and may play a central role in inducing infusion toxicity to Campath-1H.¹²⁷ These infusion side effects are generally responsive to corticosteroid administration, when severe.

Hematologic Toxicity Campath-1H has significant hematologic toxicity, given the presence of CD52 on many hematopoietic cells. The multicenter study of 136 CLL patients noted 26% neutropenia (22% grade 3 or 4), 35% thrombocytopenia (23% grade 3 or 4), and 21% anemia (11% grade 3).¹¹² Many patients who develop cytopenias develop grade 3 or 4 toxicity, resulting in severe infectious complications. Although fever, rigors, and nausea may be bothersome and uncomfortable to patients, cytopenias and infectious complications constitute the medically serious toxicities of Campath-1H. However, these toxicities are clinically manageable with proper monitoring of peripheral blood counts and appropriate antibiotic prophylaxis. Granulocyte-macrophage colony-stimulating factor (GM-CSF) should be avoided, as GM-CSF exacerbates infusion-related toxicity, by inducing TNF- α , without significantly improving granulocyte recovery.¹²⁸

Combination Therapy Laboratory evidence from our institution indicates that Campath-1H may synergize with fludarabine in vivo.⁸² A small study of 6 CLL patients, refractory to fludarabine alone and Campath-1H alone, suggests that such synergy exists. Fludarabine was given at a dose of 25 mg/m² IV for 3 to 5 days, and Campath-1H was given at 30 mg IV three times weekly for 8 to 16 weeks. One patient achieved a CR (17%), and 5 patients achieved a PR, for an ORR of 83%; flow cytometric analysis could not detect residual CLL cells in the 2 patients. Patients received prophylac-

tic co-trimoxazole and acyclovir, and no serious adverse events were noted.¹³⁰ A larger study using fludarabine 30mg/m² UV and Campath-1H 30mg IV for 3 days every 28 days for 4 cycles achieved 9 CR and 3 PR in 14 evaluable patients with relapsed CLL (ORR 86%). Of note, 1 heavily pretreated patient died of fever of unknown origin. The use of a lower total dose of Campath-1H in this study may diminish long-term toxicity, particularly infections.

The combination of Campath-1H and rituximab can be given safely and may have clinical activity in patients with relapsed CLL. Nine patients received rituximab 375mg/m² weeks 1 and 3 to 5, in combination with Campath-1H 3, 10, or 30mg thrice weekly, weeks 2 to 5, in a Phase I dose-escalation study.¹³¹ Toxicity was acceptable, with no opportunistic infections or treatment-related deaths. Eight patients (89%) experienced significant reduction (median, 95% decrease) in peripheral lymphocyte count, but no objective responses by NCI criteria were seen. A second study administered rituximab, 375mg/m² weekly for four doses, with Campath-1H 30mg on days 3 and 5 of each week, to 48 patients with relapsed or refractory lymphoproliferative disorders, including 32 patients with CLL and 9 patients with CLL/PLL.¹³² The ORR was 52% (CR, 8%), with a median time to progression of 6 months. Nearly all CLL and CLL/PLL patients had resolution of peripheral blood lymphocytosis, but only 11 of 33 patients had clearing of marrow disease (33%), and 24 of 41 patients had more than 50% reduction of nodal disease (59%). Fifty-two percent of patients developed infections, and CMV reactivation was seen in 27% of patients.

Summary As a result of the ubiquitous expression of CD52 on lymphocytes and monocytes, Campath-1H causes significantly more hematologic and immune toxicity than does rituximab. However, infectious complications are manageable with adequate antibiotic prophylaxis. The majority of patients receiving Campath-1H experience infusion toxicity, but toxicity is manageable with a "stepped-up" dosing schedule. In addition, infusion toxicity usually diminishes as therapy progresses. Campath-1H demonstrates greatest activity against CLL cells in peripheral blood, although prolonged therapy may be able to achieve CR in bone marrow. The antibody is less effective against nodal disease; responses are almost exclusively PR. Despite its limitations, Campath-1H is the only approved therapy for CLL that shows activity in relapsed patients with loss or mutation of p53. Thus, further study of Campath-1H is needed. Given its infusion toxicity, future trials will likely center on use of subcutaneous, rather than intravenous, Campath-1H. Despite initial promising results, further studies are needed to determine that subcutaneous administration is as effective as IV dosing in relapsed CLL.

INVESTIGATION AGENTS

Hu1D10

Hu1D10 (Apolizumab, Remitogen) is a humanized murine IgG monoclonal antibody whose antigenic epitope is a polymorphic determinant on the major histocompatibility (MHC) class II HLA-DR beta chain.¹³³ The 1D10 epitope is present on normal and malignant B lymphocytes, dendritic cells, macrophages, and some activated T lymphocytes. 1D10 is expressed in 50% of acute lymphocytic leukemia, 50% of

diffuse large cell NHL, 50% to 70% of follicle center NHL, and 80% to 90% of CLL.¹³⁴ Expression is uniformly strong in tumors that are ID10 positive. Hu1D10 induces ADCC and CDC, as well as apoptosis, by a caspase-independent pathway.^{133,134}

An initial phase I study in 20 patients with NHL demonstrated that Hu1D10 can be given safely at doses that show potential clinical efficacy.¹³⁵ Patients received weekly doses, ranging from 0.15 to 5mg/kg, and a regimen giving the drug on 5 consecutive days was also examined. Infusion-related toxicity was common, but manageable, and included fever, chills, nausea, vomiting, rash, flushing, and hypotension. Four of 8 patients with follicle center NHL responded (1 CR, 3 PR), with a median time to response of 106 days. A Phase II multicenter study in 21 patients with relapsed indolent B-cell lymphoproliferative disorders, including 5 with SLL, treated with Hu1D10 at 0.5 or 1.5mg/kg weekly for four doses, showed good tolerance.¹³⁶ Studies in CLL are ongoing.¹³⁷

ANTI-CD23

CD23 is another potential target of monoclonal antibody therapy; similar to CD20 and CD5, CD23 is expressed on the overwhelming majority of CLL cells. A chimeric macaque-derived anti-CD23 antibody, p6G5G1, has been developed.¹³⁸ Although these antibodies have been developed as possible therapies for asthma and other allergic disorders, the ubiquitous expression of CD23 on CLL cells indicates that preclinical studies of these compounds in CLL should be pursued. Recently, *in vitro* studies of a humanized anti-CD23 monoclonal antibody, IDEC-152 (Lumiliximab), demonstrated that cross-linked IDEC-152 induced apoptosis in fresh CLL cells from 5 patients. In addition, IDEC-152-induced apoptosis was enhanced in the presence of fludarabine or rituximab.¹³⁹ In a Phase I study, 25 evaluable patients with relapsed CLL received IDEC-152 at 125 to 500mg/m² IV weekly for four doses. Dose-limiting toxicity was seen in 2 of 10 patients treated at the highest dose, but toxicity was acceptable. Twenty-four patients (96%) achieved a decrease in peripheral lymphocytosis, and 8 of 19 patients (42%) treated at the 375 to 500mg/m² doses experienced more than a 50% reduction in their disease.¹⁴⁰

FLAVOPIRIDOL

Flavopiridol is an *N*-methylpiperidinyl, chlorophenyl flavone that induces apoptosis in CLL cells by activating caspase 3.¹⁴¹ Caspase 3 acts distal to p53; thus, induction of apoptosis by flavopiridol is p53 independent.¹⁴² Flavopiridol also induces profound decreases in the levels of Mcl-1 and XIAP in CLL cells *in vitro*.¹⁴³

Phase I clinical studies determined a safe, tolerable dose of 50mg/m²/day given as a continuous intravenous infusion (CIVI) over 72 hours.¹⁴² Unfortunately, Phase II studies using this schedule demonstrated no response, including a trial in 10 patients with recurrent or refractory mantle cell lymphoma.¹⁴⁴ Despite plasma flavopiridol concentrations of 200 to 400nM, no apoptosis was seen in peripheral blood mononuclear cells (PBMCs) of patients who received this CIVI schedule.^{145,146} This discrepancy is caused by increased binding of flavopiridol to human serum proteins. *In vitro* assays of apoptosis have used fetal calf serum (FCS) in culture media. However, the free flavopiridol concentration

decreased from 63% to 100% to 5% to 8% if human plasma was substituted for FCS, resulting in an increase in 1-hour and 24-hour LC₅₀ values from 670 and 120nM to 3,510 and 470nM, respectively.^{146,147} Thus, CIVI dosing does not achieve pharmacologically effective drug concentrations, resulting in lack of clinical responses.¹⁴⁵⁻¹⁴⁷ Bolus dosing achieves the necessary LC₅₀, and a Phase II study giving flavopiridol 50mg/m² by 1 hour IVB on days 1 to 3 in 36 previously treated, mostly fludarabine-refractory patients, demonstrated activity (14%), with a median response duration of 8 months. Pharmacokinetic modeling indicates an optimal dosing schedule of 30-minute IVB followed by 4-hour CIVI, and initial results of an ongoing Phase I study show activity with clinical response in p53-deficient patients and tumor lysis.¹⁴⁸

STEM CELL TRANSPLANTATION

AUTOLOGOUS STEM CELL TRANSPLANTATION

Studies of autologous stem cell transplantation (SCT) in CLL have produced mixed results because of patient selection and the variable use of stem cell purging. Disease-free survival (DFS) has ranged from 25% to 69%, with similar discrepancies in overall survival (OS).¹⁴⁹⁻¹⁵³ A British Medical Research Council (MRC) study recently achieved 5-year DFS and OS of 78% and 52%, respectively, in 65 patients.¹⁴⁹ Sixteen of 20 evaluable patients achieved molecular remission by PCR examination of IgVH gene rearrangement. A retrospective German study of 58 CLL patients (20 mutated, 38 unmutated) showed that unmutated IgVH remained an adverse prognostic factor despite autologous SCT.¹⁵⁴ Median time to clinical relapse was 37 months in the unmutated group, whereas only 1 mutated patient relapsed 4 years post-SCT; 2-year probability of relapse was 19% and 0%, respectively, for unmutated and mutated patients. Nonetheless, unmutated patients still enjoyed a 2-year OS of 89%. A similar German study matched 44 patients who underwent autologous SCT with 44 similar patients who received chemotherapy without SCT.¹⁵⁵ Unmutated IgVH was seen in 66% of both cohorts. Median survival from diagnosis for unmutated patients was 139 months for SCT, versus 73 months for chemotherapy, with a hazard ratio (HR) of 0.31 ($P = 0.02$). Although patients with genetic risk factors such as unmutated IgVH still do poorly compared to good- or intermediate-risk patients who undergo autologous SCT, autologous SCT still confers benefit to high-risk CLL patients.

Despite these promising results, autologous SCT in CLL is limited by several factors. First, patients have significant marrow and blood involvement that may result in contamination of the stem cell product despite cytoreductive therapy.¹⁵⁶ Second, prior fludarabine therapy may cause myelosuppression and hamper collection of an adequate number of autologous stem cells; peripheral stem cell mobilization was unsuccessful in 33% of patients in the MRC study.¹⁴⁹ Third, the high-dose conditioning regimens used in autologous SCT are associated with a significant risk of secondary MDS or AML; 8% of patients in the MRC study developed MDS/AML [149]. Finally, extensive studies in follicle center lymphoma¹⁵⁷ and multiple myeloma¹⁵⁸ have not demonstrated that autologous SCT is curative in hematologic malignancies that are incurable with standard chemotherapy. In particular, this last factor has damped enthusiasm for further studies of autologous SCT for CLL, particularly for

patients who have an HLA-identical sibling donor. Given the limitations of autologous SCT, the major focus of clinical research in SCT for CLL has shifted to allogeneic SCT.

MYELOABLATIVE ALLOGENEIC SCT

Allogeneic SCT offers theoretical advantages over autologous SCT in CLL. Contamination of the stem cell source and inadequate stem cell collection are not obstacles, and the use of an allogeneic donor allows for an immunologic graft-versus-leukemia (GVL) effect. Limited data suggest that TBI-containing conditioning regimens are superior to BuCy in CLL. A small study of 25 patients by the Seattle group revealed a 100-day treatment-related mortality (TRM) of 57% for BuCy ($n = 7$), compared to 17% for TBI regimens ($n = 18$). Five-year actuarial survival was 56% for 14 patients transplanted with TBI regimens during 1992-1999.¹⁵⁹ An M.D. Anderson study of Cy/TBI in 28 CLL patients observed a 100-day TRM of 11%. Five-year PFS and OS were 78% and 78%, respectively, for chemosensitive patients, compared to 26% and 31% for refractory patients.¹⁶⁰

A retrospective EBMT study of 135 patients showed 54% 3-year OS and 40% 100-day TRM.¹⁶¹ Similar findings were reported by the IBMTR, with 45% 3-year OS and 30% 100-day TRM in 242 patients.¹⁶² The high TRM may be explained in part by the late stage of the disease in many of these patients. Median time from diagnosis to SCT was 41 and 46 months, and 37% of patients in the EBMT study were chemorefractory entering transplant.^{161,162} Although there are no randomized studies, a retrospective comparison by the M.D. Anderson showed 3-year DFS of 57% for allogeneic SCT, versus 24% for purged autologous SCT.¹⁶³

Thus, myeloablative allogeneic SCT may offer superior DFS in CLL, compared to autologous SCT. Although 3-year DFS after allogeneic SCT is approximately 50%,¹⁵⁹⁻¹⁶³ longer follow-up is needed to determine if disease remissions are durable. However, the advantage in markedly decreased relapse rates with allogeneic SCT is offset by a higher TRM,^{161,162} decreasing enthusiasm for this treatment modality in CLL. Limited data indicate that Bu/Cy may be particularly toxic in this population; in contrast, TBI regimens have acceptable TRM.¹⁵⁹ To preserve the immunologic GVL effect while reducing TRM, the focus of clinical SCT research in CLL has turned to nonmyeloablative allogeneic SCT.

NONMYELOABLATIVE ALLOGENEIC SCT

Ideally, the GVL effect of allogeneic SCT can be harnessed, while reducing TRM from acute GVHD, acute infection, and organ toxicity associated with myeloablative SCT. Several studies have specifically examined CLL.^{2,164-167} Fludarabine, busulfan, and antithymocyte globulin (ATG) were administered to 30 German CLL patients; the stem cell source was a matched related ($n = 15$) or unrelated ($n = 15$) donor.^{164,165} Grade 2 to 4 acute GVHD was observed in 56% of patients, whereas 75% developed chronic GVHD.¹⁶⁵ Responses were seen in 93% of patients, with 40% achieving CR. Of note, it took up to 2 years for patients to achieve CR, suggesting a GVL effect. All patients achieved a molecular CR by PCR, but only 6 patients were in continued molecular CR after a median follow-up of 2 years. Two-year TRM, PFS, and OS were 15%, 67%, and 72%, respectively.¹⁶⁵

The EBMT retrospectively examined 77 CLL patients who received a variety of nonmyeloablative conditioning regimens, following by allogeneic SCT.² One-year TRM was 18%,

and the 2-year probability of relapse was 31%. Two-year DFS and OS were 56% and 72%, respectively. Nineteen patients received donor lymphocyte infusion (DLI) for relapse or incomplete donor chimerism, but only 7 responded to DLI (37%). Unfortunately, this study was complicated by the heterogeneity of conditioning regimens and the use of ATG or Campath-1H for T-cell depletion in 40% of patients.

A recent German study indicated that nonmyeloablative allogeneic SCT may be superior to autologous SCT in obtaining clinical and molecular remissions in high-risk CLL patients with unmutated IgVH, due to a GVL effect. Seven of 9 patients (78%) became negative by PCR for allele-specific IgVH after day + 100 post-SCT; attainment of molecular CR occurred after DLI or development of chronic GVHD. In contrast, only 6 of 26 control CLL patients (23%) achieved a PCR-negative state after autologous SCT.¹⁶⁶ Thus, an immunologic GVL effect appears to be important in CLL and may confer a long-term survival advantage for allogeneic over autologous SCT, given sufficient time.

Summary CLL remains incurable by standard therapies; thus, SCT should be considered, especially for younger patients and patients with high-risk genetic features who likely will do poorly with chemotherapy. Nonmyeloablative allogeneic SCT is the most promising transplant modality in CLL and is the focus of most SCT studies in CLL. Short-term DFS of 50% to 75% has been obtained with acceptable TRM,^{2,165,166} and molecular responses have been obtained with the onset of GVHD or the therapeutic use of DLI.¹⁶⁵ However, long-term follow-up is lacking, and it is unclear whether the DFS observed at 2 years will prove durable over time. Myeloablative allogeneic SCT should be considered for patients with bulky or refractory disease,¹⁶⁰ and a TBI-containing regimen should be utilized to reduce TRM.¹⁵⁹ Finally, autologous SCT should be considered for high-risk CLL patients who do not have an allogeneic option. Although autologous SCT has not proven curative in CLL, autologous SCT still confers a survival advantage to patients with unmutated IgVH.^{154,155} However, it is necessary to limit the number of prior therapies, particularly fludarabine-based regimens, given that insufficient stem cells are collected from a third or more of CLL patients being considered for autologous SCT. Several other excellent textbooks and reviews cover this topic in greater detail.¹⁻³

The Future: Risk-Stratified Therapy

For decades, treatment of CLL has been based upon clinical staging systems, such as the Rai and Binet systems. However, these staging systems cannot predict the likelihood or duration of clinical response to therapy. The growing wealth of information about the prognostic implications of cytogenetic abnormalities, IgVH mutations, CD38 expression, and ZAP-70 expression in CLL is revolutionizing the clinical management of CLL. A risk-stratified approach is at hand by which therapy can be selected for an individual patient based upon his or her likelihood of achieving a CR and the likely duration of that response. Patients with deletion of 13q14 or mutated IgV_H, who are likely to have an indolent course or enjoy a long duration of response to fludarabine, can be managed conservatively with initial observation and fludarabine-based therapy when treatment is indicated. Patients

with deletion of 17p13 or unmutated IgV_H, who are likely to relapse rapidly after therapy, should be treated aggressively. Nonmyeloablative allogeneic SCT should be considered in first remission for patients with deletion of 17p13. Thus, a risk-stratified approach offers the promise of therapy that is best tailored to the medical needs of the individual patient.

Prolymphocytic Leukemia (PLL)

B-PLL

B-cell prolymphocytic leukemia (B-PLL) is a rare disease. B-PLL can be diagnosed de novo or arise by transformation from preexisting B-CLL. A retrospective French study of 41 B-PLL patients revealed a median age of 67 years, median OS of 5 years, and median EFS of 37 months.¹⁶⁸ Age and anemia were the only two factors associated with poor outcome. De novo patients and patients who had transformed from B-CLL had similar outcomes.¹⁶⁸ A similar retrospective Israeli study of 35 B-PLL patients found anemia and lymphocytosis, but not age, to be significant prognostic factors.¹⁶⁹ A 47% PR rate and median response duration of 32 months were observed in 17 patients treated with chlorambucil/prednisone or COP. Two PR and 1 CR, with median response duration of 30 months, were observed in 6 patients treated with CHOP.¹⁶⁹ Impressive results were achieved with 2-chlorodeoxyadenosine (2-CDA, cladribine) in 8 B-PLL patients (4 previously untreated). Patients received 2-CDA 0.1 mg/kg/day by CIVI for 7 days, every 28 to 35 days, for two to five cycles. Responses were observed in all 8 patients (5 CR, 3 PR); however, median response duration was only 14 months for patients achieving CR and 3 months for patients achieving PR.¹⁷⁰

T-Cell PLL

T-PLL cells are characterized by relatively open chromatin and prominent nucleoli and typically express CD2, CD3, CD5, and CD7. Patients with T-PLL do extremely poorly; analysis of 78 adult T-PLL patients revealed a median survival of only 7.5 months. Fifteen of 31 patients treated with pentostatin responded (48%), with a CR rate of 10% and median survival of 16 months in responders.¹⁷¹ Fifty-five T-PLL patients received pentostatin 4 mg/m²/week for 4 weeks, then every 2 weeks until maximal response. The ORR was 45%, with 5 patients (9%) achieving CR.¹⁷²

CAMPATH-1H

Novel therapies are desperately needed in T-PLL. Several studies have demonstrated significant clinical activity of the anti-CD52 monoclonal antibody Campath-1H in T-PLL. Campath-1H was given to 15 T-PLL patients, most of whom had failed pentostatin.¹⁷³ The ORR was 73%, and 9 patients achieved CR (60%); in addition, retreatment with Campath-1H induced second CR in 3 patients who relapsed after initial Campath-1H therapy. In comparison, only 3 of 25 similar T-PLL patients (12%) at the same institution achieved CR to pentostatin. Two patients developed severe bone marrow aplasia, and 1 patient died of this complication. A subsequent study by the same authors administered Campath-1H 30 mg IB thrice weekly until maximal response to 39 T-PLL, includ-

ing 30 who had failed pentostatin.¹⁷⁴ The ORR was 76% (CR, 60%), with a median disease-free interval of 7 months (range, 4–45 months). Finally, a retrospective report of 76 T-PLL patients, who were given Campath-1H thrice weekly for 4 to 12 weeks, demonstrated an ORR of 51% (CR, 40%) with a median duration of CR of 9 months.¹⁷⁵ Median overall survival was 7.5 months, although patients who achieved CR had a median survival of 15 months. Ten patients (13%) developed a total of 15 infections, and severe cytopenias occurred in 6 patients (8%). Two patients (3%) died of treatment-related mortality. Thus, Campath-1H is the most active single agent in T-PLL and, in contrast to its results in CLL, is able to produce CR in up to 60% of patients with relapsed T-PLL.

CORRELATION OF CD52 EXPRESSION WITH CLINICAL RESPONSE

The greater activity of Campath-1H in T-PLL may be due to increased expression of CD52 on T-PLL cells. Quantitative flow cytometry was used to measure CD52 expression in 24 B-CLL patients, 21 T-PLL patients, and 12 normal volunteers.¹⁷⁶ Interestingly, CD52 expression was significantly higher on normal T lymphocytes than on normal B lymphocytes, and T-PLL cells expressed higher levels of CD52 than did B-CLL cells. In addition, CD52 expression was slightly higher in patients who responded to Campath-1H. These results suggest that the likelihood of clinical response to Campath-1H may be related to the level of CD52 expression.

SUMMARY

Although B-PLL is considered to have a poor prognosis, retrospective multicenter studies have shown a median survival of 5 years,¹⁶⁸ with median response duration of 30 to 32 months, to alkylator based chemotherapy.¹⁶⁹ Although very high CR and OR rates were attained with 2-CDA, response duration was surprisingly short.¹⁷⁰ Thus, chlorambucil and COP should be considered first-line therapy for B-PLL, and 2-CDA should be considered for relapsed disease. In contrast to B-PLL, T-PLL exhibits a very poor prognosis, with a median survival of only 7.5 months.¹⁷¹ Campath-1H and pentostatin are the only two therapies that have shown significant activity in large trials in T-PLL.^{174,175} Given the short duration of response to therapy, patients with T-PLL should be referred for allogeneic SCT, preferably on clinical study, in first remission. Although there have been no adequately sized studies of SCT in T-PLL, allogeneic SCT should be considered in light of this disease's grim prognosis. Patients with relapsed T-PLL who are not candidates for SCT should be considered for clinical trials.

Hairy Cell Leukemia

The Disease and Chemotherapy

Hairy cell leukemia (HCL) is another disease within the family of indolent B-cell lymphoproliferative disorders. In contrast to CLL or follicle center NHL, in which standard chemotherapy is strictly palliative, many patients with HCL are cured with conventional chemotherapeutic agents, such

as deoxycoformycin (pentostatin) and 2-CDA. Long-term follow-up of 241 HCL patients treated with pentostatin as initial therapy ($n = 154$) or salvage therapy after failure of interferon- α ($n = 87$), showed estimated 5- and 10-year survival rates of 90% and 81%, respectively. Five- and 10-year RFS rates were 85% and 67%, respectively, in 173 patients who achieved CR to pentostatin.¹⁷⁷ Analysis of 230 French patients with HCL, two-thirds of whom had failed prior therapy, treated with deoxycoformycin 4mg/m²/day every 2 weeks for a median of 9 cycles, demonstrated an ORR of 96% (CR, 79%). Estimated DFS and OS were 88% and 89% at 5 years and 69% and 89% at 10 years, respectively.¹⁷⁸ Similar long-term follow-up of 207 assessable HCL patients treated with 2-CDA 0.1mg/kg/day by CIVI for 7 days, revealed an ORR of 100% (CR, 95%), with a median duration of first response of 98 months; 37% of patients relapsed at a median of 42 months after therapy. OS was 97% at 108 months.¹⁷⁹ A recent study demonstrated that 2-CDA can be given by SC bolus at a dose of 0.14mg/kg/day for 5 consecutive days. ORR and CR rates of 97% and 76% were seen in 62 HCL patients (33 previously untreated), with a median time to treatment failure of 38 months.¹⁸⁰ Both cladribine and pentostatin, therefore, remain acceptable therapies for patients with hairy cell leukemia. These authors prefer the use of pentostatin because of the longer remissions observed in multicenter trials as compared to those results derived with cladribine. In addition, pentostatin studies were inclusive of hairy cell leukemia patients with active infection, whereas many of the phase II cladribine studies excluded such patients. However, the period of cladribine administration is shorter and is therefore preferred by many practicing oncologists.

Rituximab

Hairy cell leukemia that is resistant to therapy with purine analogues has a poor prognosis, and treatment options are limited for patients whose disease becomes refractory to pentostatin and/or 2-CDA. Thus, despite the generally favorable prognosis of this disease, monoclonal antibody therapy is a treatment modality of significant interest in HCL. The monoclonal antibody that has been best studied in HCL is the anti-CD20 antibody rituximab. Several case reports and a few series have demonstrated the efficacy of rituximab in this disease. Ten patients with relapsed or progressive HCL who had previously received treatment with 2-CDA or pentostatin/interferon- α received four weekly doses of rituximab at 375 mg/m². The ORR was 50%, with 1 patient achieving CR and 4 patients attaining PR. Grade 1–2 infusion toxicity occurred during the first dose of rituximab but extinguished with subsequent doses. Fifty percent of patients experienced greater than 50% reduction of bone marrow involvement, 1, 3, and 6 months after completion of rituximab therapy.¹⁸¹ A second study administered a similar schedule of rituximab to 8 patients with relapsed HCL and 3 patients with previously untreated HCL. The ORR was 64%, with 6 patients achieving CR and 1 patient PR. The median duration of response was 14 months (range, 0–34 months), and infusion-related toxicity was minimal.¹⁸² A third study gave a similar schedule to 24 HCL patients who had failed prior 2-CDA. ORR and CR rates were 25% and 13%, respectively, and median time to relapse had not been reached at 15 months.¹⁸³ To examine whether increase in dosage results in improved clinical

response, 8 weekly doses of rituximab 375 mg/m² were given to 15 patients with relapsed or primary refractory HCL. Patients who achieved PR, but not CR, received an additional four weekly doses of rituximab. The ORR was 80%; 8 patients (53%) attained CR, 2 patients (13%) achieved hematologic CR but had residual (1%–5%) marrow involvement by HCL, and 2 patients (13%) experienced PR. Median duration of response was not reached after a median follow-up of 32 months; 5 patients relapsed after 8, 12, 18, 23, and 39 months, respectively, and 7 remained in remission. Toxicity was minimal, and no infections were noted.¹⁸⁴

Thus, in contrast to CLL, weekly dosing of rituximab achieves a significant response rate in HCL, although preliminary data suggest that a longer course of therapy may result in an improved CR rate. Rituximab therapy does not appear to induce greater infusion-related toxicity in HCL than in NHL. The efficacy of weekly rituximab therapy and decreased infusion toxicity in HCL, compared to CLL, may be caused by the lower circulating tumor burden in HCL and the absence of soluble CD20 in HCL patients.

BL-22

The murine IgG 2 monoclonal antibody LL2 recognizes CD22 and has been conjugated to biologic effectors in an attempt to target these toxins to HCL cells.¹⁸⁵ RFB4(dsFv)-PE38 (BL22) is a recombinant immunotoxin generated by fusion of the variable Fv portion of the anti-CD22 monoclonal antibody RFB4 to a truncated form of *Pseudomonas* exotoxin A. Sixteen patients with cladribine-resistant HCL received BL22 every other day for three doses in a Phase I dose-escalation study.¹⁸⁶ Eleven patients achieved CR (69%) and 2 patients attained PR (13%). The 3 patients who failed to respond received low doses of BL22 or had preexisting antibodies that neutralized the toxin. Median follow-up was 16 months, and 3 of the 11 complete responders relapsed but then attained second CR after retreatment with BL22. Common toxicities were transient hypoalbuminemia and transaminitis, but the most serious toxicity was reversible hemolytic uremic syndrome in 2 patients.

LMB-2

LMB-2 (anti-Tac(Fv)-PE38) is a recombinant immunotoxin derived by fusion of the variable Fv portion of the anti-CD25 monoclonal antibody anti-Tac to a truncated form of *Pseudomonas* exotoxin A.¹⁸⁷ CD25 (Tac) is the beta chain of the high-affinity IL-2 receptor and is expressed on the cell surface of T-cell malignancies, as well as HCL.^{188,189} In an initial phase I study, LMB-2 induced major responses, including 1 CR, in 4 of 4 patients with refractory HCL who had failed standard therapy.¹⁸⁷ Minimal residual disease was detectable by flow cytometry of the bone marrow aspirate of the patient who achieved hematologic CR. This initial study was expanded to a larger Phase I dose-escalation trial, and 31 additional patients with refractory CD25+ lymphomas and leukemias received LMB-2 at dose levels ranging from 2 to 63 µg/kg IVB every other day for three doses.¹⁹⁰ In contrast to the 100% ORR (25% CR) in HCL, only 4 of the other 31 patients responded, and no other patient achieved CR. Thus, refractory HCL is particularly amenable to therapy with LMB-2.

Summary

Deoxycoformycin and 2-CDA remain the therapies of choice for newly diagnosed HCL. Although 2-CDA is more commonly used because the schedule is more convenient, both drugs achieve similarly excellent results and can be used to treat HCL patients. Patients who relapse after, or are refractory to deoxycoformycin and 2-CDA, should receive rituximab. SCT is rarely used in HCL, given the disease's indolent course and its excellent response to conventional therapies.

Conclusions

The understanding and treatment of CLL and related chronic leukemias constitute a rapidly growing area of clinical research. Great strides are being made toward identifying prognostic genetic factors in CLL, with the goal of developing risk-adapted therapeutic strategies in this disease. The advent of fludarabine and other purine analogues reinvigorated clinical research in CLL and other chronic leukemias, and ongoing trials are examining the optimal treatment regimens in CLL. Monoclonal antibody therapy is perhaps the most exciting area of translational and clinical investigation. Although antibodies such as rituximab and Campath-1H have shown great promise in CLL, studies have clearly demonstrated that monoclonal antibodies as single agents will not produce long-term survival. Thus, ongoing trials are studying the optimal use of rituximab and Campath-1H in combination regimens in CLL. Results of initial studies combining monoclonal antibodies with fludarabine and other cytotoxic agents have been promising, and several trials are currently studying monoclonal antibody combinations. Although studies to date have been conducted primarily in CLL, monoclonal antibodies have also shown significant efficacy and promise in T-PLL and HCL. Each disease must be considered a separate entity; agents and dosing schedules that are effective in lymphoma or a particular chronic leukemia are not necessarily active in other chronic leukemias. Each chronic lymphoid malignancy is different, and diseases should not be "lumped" together.

Chronic Myeloid Leukemia

Meir Wetzler

M.T. is a 26-year-old woman with chronic myeloid leukemia (CML) diagnosed during her annual physical examination. Her disease is in the chronic phase, without any high-risk features.^{1,2} She has no significant prior medical history. Her sister is a 6/6 HLA antigen match and is in excellent health. Neither sister has been pregnant. M.T. presents for consultation about whether to be treated with imatinib or to undergo allogeneic stem cell transplantation (SCT). She is well informed and has downloaded several articles from the Internet.

In attempting to apply evidence-based medicine in the treatment of chronic myeloid leukemia (CML), it must be acknowledged that a randomized study comparing imatinib mesylate therapy and allogeneic stem cell transplantation (SCT) has not been conducted. The question that will remain at the end of this chapter is whether such a study is feasible, or even ethical. The treatment of CML could represent a paradigm in oncology as well as a unique set of challenges.

Definitions and Molecular Pathogenesis

CML is a clonal expansion of a hematopoietic stem cell resulting from a reciprocal translocation between chromosomes 9 and 22. This translocation results in the head-to-tail fusion of the breakpoint cluster region (*BCR*) gene on chromosome 22q11 with the *ABL* (named after the abelson murine leukemia virus) gene located on chromosome 9q34. Untreated, the disease is characterized by the inevitable transition from a clinically benign chronic phase, often with an interposed accelerated phase, to blast crisis.

The cytogenetic hallmark of CML, found in 90% to 95% of patients, is the t(9;22)(q34;q11.2). The reciprocal 9;22 translocation was originally recognized by the presence of the resultant shortened chromosome 22 (22q-), designated as the *Philadelphia chromosome*. Some patients may have complex translocations (designated as *variant translocations*) involving three, four, or five chromosomes (usually including chromosomes 9 and 22). However, the molecular consequences of these changes appear similar to those resulting from the typical t(9;22). Patients should have evidence of the translocation by either cytogenetics, fluorescence in situ hybridization (FISH), or molecular techniques to make a diagnosis of CML.

The product of the fusion gene resulting from the t(9;22) plays a central role in both the genesis and the treatment of CML. The chimeric gene is transcribed into a hybrid

BCR/ABL messenger RNA species in which exon 1 of *ABL* is replaced by variable numbers of 5' *BCR* exons. The Bcr/Abl fusion proteins that then result, p210^{*BCR/ABL*}, contain NH₂-terminal domains of Bcr and COOH-terminal domains of Abl. A rare breakpoint, occurring within the 3'-region of the *BCR* gene, yields a fusion protein of 230 kDa, p230^{*BCR/ABL*}. The role of the Bcr/Abl fusion proteins in leukemogenesis has been substantiated in several laboratory models.

The mechanism(s) by which p210^{*BCR/ABL*} promotes the transition from the benign state to the fully malignant state is still unclear. Messenger RNA for *BCR/ABL* can occasionally be detected in normal individuals. However, fusion of the *BCR* sequences to *ABL* results in three critical functional changes: (1) the Abl protein becomes constitutively active as a tyrosine kinase enzyme and activates downstream kinases that prevent apoptosis, (2) the DNA protein-binding activity of Abl is attenuated, and (3) the binding of Abl to cytoskeletal actin microfilaments is enhanced.

The molecular events associated with transition to the acute phase, or blast crisis, are poorly understood. Some depend on increased activity of the oncogenic kinase [e.g., an additional t(9;22),³ deletions adjacent to the translocation breakpoint on the derivative 9 chromosome⁴], and some most probably result from *BCR/ABL*-independent mechanisms [e.g., trisomy 8, or 17p- (p53 loss),³ lack of production of the retinoblastoma protein, alterations in *RAS*, or presence of an altered *MYC*]. Finally, progressive de novo DNA methylation at the *BCR/ABL* locus has also been shown to herald the onset of blast crisis.⁵⁻⁷

Physical Findings

In most patients, the abnormal finding on physical examination at diagnosis is minimal to moderate splenomegaly; mild hepatomegaly is found occasionally. Persistent splenomegaly despite continued therapy is a sign of disease acceleration. Lymphadenopathy and myeloid sarcomas are unusual except late in the course of the disease; when they are present, the prognosis is poor.

Hematologic Findings

Elevated white blood cell counts, with various degrees of immaturity of the granulocytic series, are present at diagnosis. Usually less than 5% circulating blasts and less than 10%

blasts and promyelocytes are noted. Cycling of the counts may be observed in patients followed without treatment. Platelet counts are almost always elevated at diagnosis, and a mild degree of normochromic normocytic anemia is present. Leukocyte alkaline phosphatase is characteristically low in CML cells. Serum levels of vitamin B₁₂ and vitamin B₁₂-binding proteins are generally elevated. Phagocytic functions are usually normal at diagnosis and remain normal during the chronic phase. Histamine production secondary to basophilia is increased in later stages, causing pruritus, diarrhea, and flushing.

At diagnosis, bone marrow cellularity, primarily of the myeloid and megakaryocytic lineages, with a greatly altered myeloid to erythroid ratio, is increased in almost all patients with CML. The marrow blast percentage is generally normal or slightly elevated. Marrow or blood basophilia, eosinophilia, and monocytosis may be present. Although collagen fibrosis in the marrow is unusual at presentation, significant degrees of reticulin stain-measured fibrosis are noted in about half the patients.

Disease acceleration is defined by the development of increasing degrees of anemia unaccounted for by bleeding or chemotherapy, cytogenetic clonal evolution, or blood or marrow blasts between 10% and 20%, blood or marrow basophils 20% or greater, or platelet count less than 100,000/ μ L. *Blast crisis* is defined as acute leukemia, with blood or marrow blasts 20% or more. Hyposegmented neutrophils may appear (Pelger-Huet anomaly). Blast cells can be classified as myeloid, lymphoid, erythroid, or undifferentiated, based on morphologic, cytochemical, and immunologic features. About half the cases are myeloid, one-third lymphoid, 10% erythroid, and the rest are undifferentiated.

Prognostic Factors

Several prognostic models have been developed that identify different risk groups in CML. The most commonly used staging systems were derived from multivariate analyses of prognostic factors. The Sokal index¹ was based on chemotherapy-treated patients and the Hasford system² on interferon-treated patients. Table 66.1 compares the two prognostic systems. When applied to a data set of 272 patients treated with interferon-alpha (IFN- α), the Hasford system predicted survival time more accurately than the Sokal score; it identified more low-risk patients but left only a small number of cases in the high-risk group.⁸ Preliminary results suggest that the Hasford system is applicable to imatinib-treated patients, but it has not yet been validated in patients undergoing transplantation.

TABLE 66.2. Response criteria in chronic myeloid leukemia (CML).

Hematologic	
Complete response ^a	White blood cell count <10,000/ μ L, normal morphology, normal hemoglobin and platelet counts
Incomplete response	White blood cell count \geq 10,000/ μ L
Cytogenetic	
Complete response	Percentage of bone marrow metaphases with t(9;22)
Partial response	0
Minor response	\leq 35
No response	36–85 ^b
	85–100
Molecular	
	Presence of <i>BCR/ABL</i> transcript by RT-PCR
Complete response	None
Incomplete response	Any
Major response	\geq 3 log reduction
Minor response	<3 log reduction

^aComplete hematologic response requires the disappearance of splenomegaly.

^bUp to 15 normal metaphases are occasionally seen at diagnosis (when 30 metaphases are analyzed).

Treatment

This chapter evaluates the treatment options for CML in chronic phase by a computerized literature search of the MEDLINE database for English-language manuscripts. Observational, retrospective, randomized studies and meta-analyses were reviewed. Case reports were excluded. Survival was the primary objective for defining treatment efficacy, but other measures, such as hematologic, cytogenetic, and molecular responses, were included. At present, the definition of cure in CML is durable, nonneoplastic, nonclonal hematopoiesis, which entails the eradication of cells containing the *BCR/ABL* transcript (Table 66.2). Only recommendations for which there was direct evidence of improved outcome are presented.

Treatment Options

The treatment paradigm for CML is undergoing rapid evolution because of the availability of a curative treatment (allogeneic SCT) that has significant toxicity on the one hand, and on the other, a new, seemingly effective treatment (imatinib) without significant toxicity, but also without long-term follow-up data.

Allogeneic SCT

Allogeneic SCT is currently the only curative therapy for CML and, when feasible, may be the treatment of choice.

TABLE 66.1. Comparison of the Sokal and Hasford prognostic systems.

	<i>Sokal</i> ¹ (chemotherapy-based)	<i>Hasford</i> ² (interferon-based)
Age (years)	0.116 (age–43.4)	0.666 when age \geq 50
Percentage of blasts	0.0887 (blasts–2.1)	0.0584 \times blasts
Spleen size	0.0345 (spleen–7.51)	0.042 \times spleen
Platelet count	0.188 [(platelet/700) ² –0.563]	1.0956 when \geq 1.5 \times 10 ⁹ /L
Percentage of eosinophils		0.0413 \times eosinophils
Percentage of basophils		0.20399 \times basophils \geq 3%

TABLE 66.3. Comparison of peripheral blood and bone marrow in recipients of matched sibling allogeneic transplantation for CML.

Study	Design	No. of patients	Results
Couban ¹⁸	Multicenter randomized trial	109 ^a	Benefit in overall survival favoring PBSC ^b
Champlin ¹⁹	Retrospective database cohort	346 ^c	Similar 1-year cumulative incidence of relapse, probability of leukemia-free survival, and risk of treatment failure
Elmaagacli ²⁰	Retrospective analysis	41 ^c	Similar 3-year survival with a trend toward increased acute GVHD in patients undergoing PBSC transplantation

GVHD, graft-versus-host disease; PBSC, peripheral blood stem cell.

^aFirst chronic-phase and more-advanced stages were presented together.

^bAt 30 months.

^cPatients in first chronic phase only.

However, it is complicated by a high mortality rate. Outcome of SCT depends on multiple factors associated with (1) the patient (age, comorbidities, and phase of disease); (2) the type of donor [syngeneic (monozygotic twins) or HLA-compatible allogeneic, related or unrelated]; (3) the preparative regimen; (4) presence and severity of graft-versus-host disease (GVHD), and (5) the ability to prevent or treat relapse after transplantation.

THE PATIENT

As experience has been gained and safety and efficacy of transplantation have been established, it has become clear that patients should have acceptable end-organ function, be younger than 65 to 75 years, and have a healthy and histocompatible donor. Furthermore, observational studies have demonstrated that survival after SCT in the accelerated and blastic phases of the disease is significantly inferior because of a very high rate of relapse.^{9,10} The pre-imatinib Seattle data demonstrated that bone marrow transplantation (BMT) has a better outcome in early chronic phase (1 to 2 years from diagnosis) compared to later in the course of the disease.¹¹ Another issue in young patients, and particularly, young female patients, is the very high likelihood of infertility following transplantation.

THE DONOR

Transplantation from a related donor who is either fully matched or mismatched at only one HLA locus should be considered the optimal curative treatment for CML. With HLA-identical sibling BMT in the chronic phase, observational studies have reported 5-year disease-free survival in 40% to 70% of patients, with a 25% relapse rate.^{9,10,12,13} Retrospective analysis revealed that male recipients with female donors have an increased risk of developing chronic GVHD, leading to a lower relapse rate but increased mortality.¹⁴ Moreover, for patients in chronic phase less than 1 year from diagnosis and younger than 30 years, BMT from an HLA-matched unrelated donor resulted in similar 5-year disease-free survival as matched sibling donor transplantation in comparative analyses.¹⁵⁻¹⁷ For all other groups, patients receiving transplants from unrelated individuals have higher rates of graft failure (odds ratio, 5.39) and acute (relative risk,

1.31) and chronic (relative risk, 1.48) GVHD, compared to those who receive allogeneic transplants from related individuals.¹⁷

Peripheral blood is now being studied as a source of hematopoietic progenitor cells; it may offer less risk for the donor as well as more rapid engraftment. One randomized study¹⁸ and two retrospective studies^{19,20} compared bone marrow and peripheral blood in recipients of matched sibling allogeneic transplants (Table 66.3). These studies demonstrated an overall survival benefit for recipients receiving peripheral blood stem cells (PBSC) in the randomized study,¹⁸ but similar survival in the two retrospective studies.^{19,20} In unrelated donors, a retrospective study²¹ demonstrated no difference in incidence and severity of GVHD and improved disease-free survival for peripheral blood compared to bone marrow stem cell transplants (Table 66.4). No randomized studies have been reported so far. At the present time, some centers collect bone marrow and some collect peripheral blood from donors for newly diagnosed CML patients. Umbilical cord blood may permit mismatched SCT with notably less GVHD; graft-versus-leukemia (GVL) effects do not appear to be impaired.^{22,23} A problem with cord blood as a source is obtaining an appropriate number of progenitor cells to reconstitute hematopoiesis in an adult.

PREPARATIVE REGIMENS

Four randomized studies compared cyclophosphamide and total-body irradiation with busulphan and cyclophosphamide.²⁴⁻²⁷ Long-term follow-up in these studies²⁸ demonstrated (Table 66.5) no significant differences in the incidence

TABLE 66.4. Comparison of peripheral blood and bone marrow in recipients of unrelated allogeneic transplantation in CML.

	BMT	PBSC	P
Number	54	37	
Acute GVHD grade III-IV	13 (24)	3 (8)	<0.05
DFS at 1,000 days (%)	64	91	<0.05
Overall survival at 1,000 days (%)	66	94	<0.02

BMT, bone marrow transplant; DFS, disease-free survival; GVHD, graft-versus-host disease; PBSC, peripheral blood stem cells.

of venoocclusive disease of the liver, speed of engraftment, or the 3-year probabilities of relapse, event-free survival, or overall survival. Significantly, more patients in the total-body irradiation arm experienced cataracts and avascular necrosis. However, chronic GVHD was associated with increased risk of irreversible alopecia in patients treated with busulphan. There was no significant association between busulphan levels and regimen-related toxicity,^{29,30} but low levels were associated with an increased risk of relapse in one study.²⁹ Intravenous busulphan allows better control of plasma levels.^{31,32} Nonmyeloblastic transplants in which the prepar-

ative regimen is aimed at eliminating host lymphocytes rather than eradicated bone marrow and maximizing GVL effect are being tested.^{33,44} Reduced toxicity with preserved antitumor efficacy is the goal. Table 66.6 summarizes the published observational studies. Interestingly, for studies that included only patients in chronic phase,^{38,40,44} overall survival was 75%, 85%, and 87%, and disease-free survival was 63%, 85%, and 80%. However, the follow-up is relatively short and no randomized studies have been published so far.

Chances of pregnancy after conditioning with busulfan and cyclophosphamide are slim.^{45,46} Reduced-intensity transplantation may prevent alopecia, but little is known about its effects on fertility, nor are there long-term data on overall and disease-free survival following this conditioning method.

DEVELOPMENT AND TYPE OF GVHD

Development of grade I GVHD (mild maculopapular rash involving less than 25% of body surface area, or less than 1000 mL diarrhea/day, or bilirubin less than 3 mg/dL⁴⁷), as compared to no GVHD, decreases the risk of relapse.⁴⁸ A lower relapse rate is observed also in patients with grade II GVHD, but these patients have a substantially higher transplant-related mortality rate.⁴⁸ The decreased relapse rate may be caused by a GVL effect. Depletion of T lymphocytes from donor marrow can prevent GVHD but results in an increased risk of relapse, exceeding the relapse rate after syngeneic SCT. Thus, T lymphocytes from the donor marrow mediate a significant antileukemic, or GVL, effect, and even syngeneic marrow^{49,50} may exhibit limited GVL activity in CML.

TREATMENT AND PREVENTION OF POSTTRANSPLANT RELAPSE

Further support for the existence of an immunologically mediated GVL effect came from the observation that donor

leukocyte infusions (without any preparative chemotherapy or GVHD prophylaxis) can induce hematologic and cytogenetic remissions in patients with CML who have relapsed after allogeneic SCT (Table 66.7).^{51–54}

The effect of imatinib in the chronic phase of the disease prompted its study in patients who relapse after allogeneic SCT.^{55–57} Retrospective studies (Table 66.8) with small numbers of patients have shown that imatinib can control CML that has recurred after allogeneic SCT but is associated with myelosuppression and recurrence of GVHD. Studies of imatinib treatment after allogeneic SCT to prevent relapse in patients with advanced disease at the time of transplantation (patients at high risk for relapse) or patients undergoing non-myeloblastic transplants are under way. No randomized trials have compared donor lymphocyte infusions to imatinib for patients who relapse after allogeneic SCT.

Imatinib Mesylate

Imatinib mesylate (Gleevec, STI571) functions through competitive inhibition at the adenosine triphosphate (ATP)-binding site of the Abl kinase, which leads to inhibition of tyrosine phosphorylation of proteins involved in Bcr/Abl signal transduction.⁵⁸ It shows a high degree of specificity for Bcr/Abl, the platelet-derived growth factor receptors and *c-kit* tyrosine kinases. Imatinib induces apoptosis in cells expressing Bcr/Abl. Based on its antileukemic activity in vitro, it was tested in clinical trials.

Most patients with CML in chronic phase have a rapid hematologic response to imatinib therapy. In the initial studies⁵⁹ with imatinib in patients with chronic-phase CML

who have been intolerant to IFN- α , 95% of patients achieved complete hematologic remissions, 60% achieved major cytogenetic remissions, and 41% achieved complete cytogenetic remissions. Those who did not achieve at least a major cytogenetic remission following 3 months of imatinib therapy had a higher risk of progression of the disease to the accelerated/blastic phases. The accelerated⁶⁰/blastic^{61–63} phases of the disease are less responsive to imatinib and the outcome of treatment is less favorable (overall survival at 12 months: accelerated phase, 74%⁶⁰; blastic phase, 22%⁶¹/32%⁶²/28%⁶³). These studies led to U.S. Food and Drug Administration approval of imatinib for patients who were intolerant or unresponsive to IFN- α or for patients in the accelerated/blast crisis phases of the disease.

In newly diagnosed CML, a recent randomized phase III study of imatinib (400 mg/day) versus IFN- α and cytarabine,^{64,65} demonstrated complete hematologic remission rates of 95.3% with imatinib, compared to 55.5% with IFN- α and cytarabine, after 18 months of treatment (Table 66.9). Similarly, the complete cytogenetic remission rate was 73.8% in patients treated with imatinib, compared to 8.5% in patients treated with IFN- α and cytarabine. Progression to accelerated/blastic phases of the disease was noted in 3% of patients treated with imatinib compared to 8.5% of patients treated

with IFN- α and cytarabine.⁶⁴ In addition, levels of *BCR/ABL* transcripts were studied in patients who had a complete cytogenetic remission following 12 months of treatment.⁶⁵ The levels decreased by at least 3 log in 57% of those on the imatinib arm, compared to 24% of those on the IFN- α and cytarabine arm. No survival data will be available from this study as it had a cross-over option and most patients on the IFN- α and cytarabine arm have crossed over to imatinib. Finally, imatinib offered a clear quality of life advantage as compared to IFN- α and cytarabine in newly diagnosed CML.⁶⁶ These results led to rapid U.S. Food and Drug Administration approval of imatinib for newly diagnosed CML patients.

Imatinib is administered orally and has an acceptable toxicity profile. The main side effects are fluid retention, nausea, muscle cramps, diarrhea, and skin rashes. The management of these side effects is usually supportive. Myelosuppression is the most common hematologic toxicity and patients with longer time from diagnosis, those previously treated with busulphan, and those who had cytopenias induced by IFN- α , are at higher risk.⁶⁷ Myelosuppression may result from eradication of the malignant clone and delayed recovery of the normal nonclonal progenitor cells. Blood and platelet support should be provided, and the imatinib dose should rarely be reduced in the absence of infection. Use of erythropoietin to treat anemia during imatinib therapy has become standard practice despite the absence of clinical studies, but there is concern that erythropoietin will promote resistance against imatinib.⁶⁸ Similarly, the use of granulocyte colony-stimulating factor (G-CSF) has gained acceptance with only small observational studies to support it.^{69,70} Imatinib doses below 300 mg per day seem ineffective and may lead to development of resistance.⁷¹

Resistance to imatinib occurs by mechanisms that are either *BCR/ABL* dependent (gene amplification, mutations at the kinase site, enhanced expression of multidrug exporter proteins) or *BCR/ABL* independent (alternative signaling pathways functionally compensating for the imatinib-sensitive mechanisms). Imatinib resistance has been shown to have an unfavorable prognosis in the accelerated and blast crisis phases of the disease. Specifically, patients who do not achieve major cytogenetic remission within 3 months of initiation of imatinib have shorter survival than patients who achieve that level of remission.⁶⁰⁻⁶³ Both *BCR/ABL*-dependent and *BCR/ABL*-independent mechanisms of imatinib resistance are being targeted in clinical trials. Although no randomized studies have been published, a phase II clinical trial of high-dose imatinib in newly diagnosed patients with chronic-phase CML was recently published.⁷² In comparison to a historical control group receiving standard-dose imatinib, patients treated with high-dose imatinib had significantly higher rates of complete cytogenetic response and molecular response.⁷²

Interferons

When allogeneic SCT was not feasible, IFN- α therapy was previously the treatment of choice before the availability of imatinib. Only longer follow-up of patients treated with imatinib will demonstrate whether IFN- α will still have a role in the treatment of CML. The interferons are a complex group of naturally occurring proteins produced by eukaryotic cells in response to viruses, antigens, and mitogens. Three distinct

groups of IFN species have been identified: IFN- α , IFN- β , and IFN- γ . Although various interferons have become available for clinical investigation, most data have been generated with IFN- α preparations.

Interferons have potent, pleiotropic biologic effects, with a spectrum of antiviral, microbicidal, immunomodulatory, and antiproliferative properties. Although interferons down-regulate the expression of several oncogenes and cytokines, they also upregulate the expression of IFN regulatory factor 1 (a transcriptional activator with antioncogenic activity), adhesion molecules, and the histocompatibility genes. Interferons also inhibit angiogenesis and induce a cellular immune response. However, their mode(s) of action in CML is still unknown.

Meta-analysis of seven randomized studies revealed that patients treated with high-dose (5×10^6 units/m²/day) IFN- α survived longer than patients treated with hydroxyurea or busulphan,⁷³ with 5-year survival rates of 51% and 42%, respectively. Interestingly, pegylated recombinant IFN- α and recombinant IFN- α had similar efficacy and toxicity profiles in a randomized study.⁷⁴ In addition, the combination of high-dose IFN- α with cytarabine produced better results in one randomized study⁷⁵ but not in another (Table 66.10).⁷⁶ At least two randomized trials^{77,78} did not detect any significant difference between high- and low-dose (2.5×10^6 units/m²/day or 3×10^6 units/5 days/week) IFN- α with regard to complete cytogenetic response, survival, and transformation rates. Furthermore, low-dose IFN- α with cytarabine failed to show any benefit over low-dose IFN- α with or without the addition of hydroxyurea in two randomized studies.^{79,80} In summary, low-dose, as opposed to high-dose, IFN- α may be used in combination with imatinib in future clinical trials aimed at increased response to imatinib or preventing imatinib resistance.

Patients develop both acute and chronic side effects from IFN- α therapy. Acute side effects (flu-like symptoms) appear early in the course of the treatment. Most flu-like symptoms respond to acetaminophen, and tachyphylaxis develops within 1 to 2 weeks. Chronic reactions, such as fatigue and lethargy, depression, weight loss, myalgias, and arthralgias, occur in about half of patients and often require dose reduction. Patients also report cough, postnasal drip, and dry skin. Infrequently, immune-mediated thrombocytopenia and anemia develop. In addition, long-term therapy has been associated with late autoimmune side effects, such

as hypothyroidism and occasional generalized autoimmune phenomena.

The most important persistent side effects in patients with CML who are treated with IFN- α are neuropsychiatric. All patients treated with IFN- α are subject to some neurologic toxicity, the most common symptom being lethargy. Up to 20% of patients have neurologic side effects that are associated with compromised quality of life and reduced ability to carry out their regular activity, such as full-time work. From at least one observational study,⁸¹ it seems that patients with a pretreatment neurologic or psychiatric diagnosis are at significantly increased risk of developing severe neuropsychiatric toxicity.

Chemotherapy

Innovative approaches are still important in CML because the exact role of imatinib in the armamentarium of CML is still not clear. Initial management of patients with chemotherapy is currently reserved for rapid lowering of white blood cell counts, reduction of symptoms, and reversal of symptomatic splenomegaly. Hydroxyurea, a ribonucleotide reductase inhibitor, induces rapid disease control. The initial dose is 1 to 4 g/day, and the dosage should be reduced by half with each 50% reduction of the leukocyte count. Unfortunately, cytogenetic remissions with hydroxyurea are uncommon. Busulphan, an alkylating agent that acts on early progenitor cells, has a more prolonged effect. However, it is rarely used because of its serious side effects, which include unexpected, and occasionally fatal, myelosuppression in 5% to 10% of patients, as well as pulmonary, endocardial, and marrow fibrosis and an Addison-like wasting syndrome.

Intensive combination chemotherapy has also been used in chronic-phase CML, with 30% to 50% of patients achieving complete cytogenetic responses. However, these cytogenetic remissions have been short-lived. Consequently, intensive combination chemotherapy regimens are being used today only to mobilize normal progenitors in the blood to collect circulating stem cells for autologous transplantation.

Autologous SCT

Autologous SCT could potentially cure CML if a means to select the residual normal progenitors, which coexist with their malignant counterparts, could be developed. As a source of autologous hematopoietic stem cells for transplantation, blood offers certain advantages over marrow (e.g., faster engraftment and no necessity for general anesthesia). Normal hematopoietic stem cells appear with increased frequency in the blood of patients with CML during the recovery phase after chemotherapy, with G-CSF priming. A role for imatinib prestem cell collection to achieve minimal residual disease and to maintain this status following transplantation is being currently investigated.⁸²⁻⁸⁴ However, only a few patients have been reported to successfully engraft following imatinib therapy. Therefore, such approaches should be implemented only in clinical trials.

Leukapheresis and Splenectomy

Intensive leukapheresis may control the blood counts in chronic-phase CML; but this procedure is expensive and cum-

bersome. It is useful in emergency situations in which leukostasis-related complications, such as pulmonary failure or cerebrovascular accidents are likely. It may also have a role in the treatment of pregnant women in whom it is important to avoid potentially teratogenic drugs.

Splenectomy was used in CML in the past because of the suggestion that evolution to the acute phase might occur in the spleen. However, this does not appear to be the case, and splenectomy is now reserved for relief of pain associated with splenomegaly unresponsive to chemotherapy or with recurrent splenic infarcts, or improvement of significant anemia or thrombocytopenia associated with hypersplenism. Splenic radiation is used rarely to reduce the size of the spleen.

Minimal Residual Disease

After allogeneic SCT, residual disease may be detected by reverse transcriptase-polymerase chain reaction (RT-PCR) analysis during the first 6 months in patients who subsequently achieve a long-lasting remission, according to a multivariate analysis of 346 patients.⁸⁵ However, RT-PCR results, by 6 months, classified as negative, positive at a low level (less than 100 *BCR/ABL* transcripts/ μ g RNA and/or *BCR/ABL-ABL* ratio of less than 0.02%), or positive at a high level (transcripts levels exceeding the above) did predict outcome in one observational study,⁸⁶ with probabilities of relapse of 16.7%, 42.9%, and 86.4%, respectively. Late persistence of RT-PCR positivity appears to indicate a reduced probability of cure.^{85,87} Therefore, after allogeneic SCT, patients are often divided according to RT-PCR results into one of three groups: (1) persistently positive, (2) intermittently negative, and (3) persistently negative. These three groups have low, intermediate, and high probability of disease-free survival, respectively. Although these data suggest that patients who are persistently RT-PCR positive more than 6 months after allogeneic SCT need additional therapeutic interventions, this conclusion has not been rigorously established. The studies have used an assortment of techniques for measuring minimal residual disease, the level of sensitivity has been variable, and the durations of patient follow-up have been short. For example, quantitative real-time RT-PCR may provide a less sensitive tool (sensitivity in the range of 1:10⁴ to 1:10⁵) to predict relapse in CML as compared to competitive nested PCR (sensitivity in the range of 1:10⁵ to 1:10⁶).⁸⁸ In patients who do not have any evidence of GVHD and are intermittently or persistently RT-PCR positive, GVL may be induced by administering donor lymphocytes to eradicate the residual leukemia cells.⁵¹⁻⁵⁴ Another approach is the use of imatinib to eradicate minimal residual disease.⁵⁵⁻⁵⁷

In contrast to the results achieved with allogeneic SCT, only a minority (5% to 10%) of patients develop molecular remission following imatinib therapy.^{65,89-92} Extrapolating from the SCT data, patients without molecular remission are likely to be at high risk of relapse. However, patients with AML with t(8;21) who are in long-term remission have persistent multipotent progenitor cells expressing *AML1/ETO* transcripts.⁹³ Therefore, it is unclear whether achieving durable molecular remission with imatinib should indeed be the goal of treatment in CML. This question will be answered only with long-term follow-up of imatinib-treated patients.

Recommendations

The encouraging results with imatinib have steered many clinicians to offer it as a first-line therapy for newly diagnosed CML patients, including those who otherwise would have benefited from transplant (e.g., young patients with sibling-matched donors). This approach may be unwise because the clinical studies so far have very short follow-up, thus limiting knowledge regarding the cure rate associated with imatinib. There is a risk that, by delaying transplantation, either new clonal cytogenetic abnormalities will develop in Philadelphia chromosome-negative cells⁹⁴⁻¹⁰⁶ or transplantation after the development of resistance may be associated with worse outcome.^{107,108}

If transplantation is selected, evidence-based data are available to recommend BMT with a preparatory regimen that includes busulphan and cyclophosphamide. Only one randomized trial¹⁸ with 30 months follow-up demonstrated better survival with PBSC versus bone marrow as a source of stem cells. Further, the data from reduced-intensity preparatory regimens are intriguing, but no randomized studies or long-term follow-up data are available at this point. Therefore, physician experience and patient preference must be factored into the treatment selection process.

Discussion of both treatment options with a patient is indicated. The decision should focus on the outcomes, risks, and toxicities of the two approaches. Some centers would employ allogeneic SCT in patients younger than 30 years of age, as the risk of transplant-related toxicity is minimal in that population. A proposed treatment plan for the newly diagnosed patient with CML is presented in Figure 66.1.

There is no clear answer for M.T. However, if she elects to start treatment with imatinib, it is imperative that her response be followed carefully. Consensus based on clinical experience suggests monitoring cytogenetics or peripheral blood FISH every 3 to 6 months. Patients who achieve a complete cytogenetic remission should have bone marrow cytogenetics every 6 months, alternating with peripheral blood

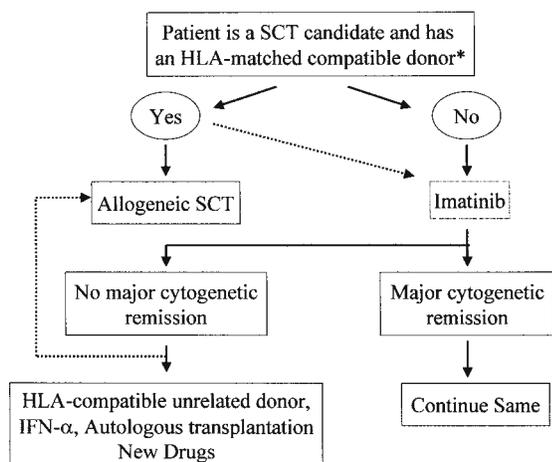

FIGURE 66.1. Flow chart for the therapy of newly diagnosed chronic myeloid leukemia (CML). Patients with an HLA-compatible donor have the possibility to undergo allogeneic stem cell transplantation (SCT) as initial therapy or treatment with Imatinib. The *asterisk* denotes centers that employ allogeneic SCT only if Imatinib fails to induce a response. *Dotted lines* denote lack of long-term survival data.

quantitative RT-PCR. SCT will be revisited at any sign of disease progression, for example, increasing BCR/ABL transcript levels.

An Evidence-Based Approach to the Management of Hodgkin's Lymphoma

Craig H. Moskowitz

Thomas Hodgkin reported the initial cases of this distinct malignant lymphoma in 1832. The term *Hodgkin's disease* (HD) was used because of the uncertainty as to whether this entity was a tumor or an infection. Based on the evidence proving that the Hodgkin Reed–Sternberg cell is a B cell, the term *Hodgkin's lymphoma* (HL) is the correct term, although physicians are reluctant to change to this terminology.

Approximately 7,500 new cases of HL are diagnosed each year in the United States; slightly more men than women develop this disease. Successive refinements in therapy have led to a continuous improvement in survival, which now exceeds 80% at 5 years (see Chapter 103, Medical and Psychosocial Issues in Hodgkin's Disease Survivors). There is a fine balance, however, on achieving these excellent results without excessive toxicity. Appropriately, the focus on therapy has shifted toward tailoring management based on pretreatment prognostic factors. Treatment strategies must try to reduce toxicity in patients expected to do well while at the same time to not compromise or even intensify therapy in those with poor risk features.

The following chapter critically evaluates the evidence regarding the optimal management for patients with HL. This is not an exhaustive review of HL; the goal of this chapter is to make appropriate treatment recommendations based on the available evidence, and attempt to identify areas for needed clinical research. Treatment recommendations concerning the management of untreated HL are made by reviewing important multicenter randomized studies, as well as other supporting evidence that investigates specific subgroups. For relapsed and refractory patients, there are only two random assignment clinical trials evaluating autotransplantation. Therefore, to fully understand the role of autologous and allogeneic transplantation, large single-institution or registry-based studies are also reviewed. Areas of special interest, including the origin of the Hodgkin Reed–Sternberg cell, the role of Epstein–Barr virus in the pathogenesis of HL, and the use of positron emission tomography (PET) imaging in the staging evaluation of HL are evaluated. For the important topic of secondary breast cancer, large registry-

based series are summarized and recommendations to decrease the incidence of this unfortunate complication are discussed.

What Is the Evidence That the Hodgkin's–Reed–Sternberg Cell Is a B Cell?

In the HL lymph node biopsy specimen, a small number of the neoplastic Hodgkin and Reed–Sternberg (HRS) cells, usually less than 2%, are admixed with a major population of B cells, T cells, plasma cells, eosinophils, neutrophils, histiocytes, and stromal cells.¹ Modern pathologic classification includes two major subtypes: 95% of patients have classic HL (nodular sclerosis, mixed cellularity, lymphocyte-rich, and lymphocyte-depleted) and 5% have lymphocyte-predominant HL.² In classic HL (cHL), the HRS cells express the activation markers CD30 and CD15 and generally lack B-lineage antigens. In lymphocyte-predominant HL (LPHL), the situation is opposite: B-cell markers are expressed and CD30 and CD15 are absent.³

During the past 5 to 10 years, elegant papers describing the clonality of the HRS cell were reported.^{4–8} A given V (D) J gene rearrangement is specific for a B cell and its descendants; sequence analysis of V gene rearrangements determines clonality. Standard molecular biologic techniques, such as Southern blotting or the polymerase chain reaction (PCR), using total DNA from an involved lymph node have been successful in determining clonality in non-Hodgkin's lymphoma (NHL). However, because there are so few HRS cells within the lymph node specimen in HL, these standard techniques have failed in HL. The clonal nature of the HRS cell was made possible by the combination of micromanipulation of HRS cells from frozen samples and PCR amplification of genes from these single cells.^{9,10}

Two groups, one from Cologne and the other from Berlin, have published the majority of the evidence concerning the clonal nature of the HRS cell. Analysis of the Ig and T-cell receptor loci of single HRS cells revealed that these cells are a monoclonal population of tumor cells and that nearly all

are derived from B cells. These clonal B cells are different in cHL and LPHL.

Upon antigen-dependent activation in lymphoid tissues, B cells enter the primary follicle and form a germinal center (GC). B-cell proliferation and selection are driven by the process of somatic hypermutation. Only cells producing Ig with high affinity to the antigen survive in the GC; the rest are eliminated by apoptosis. Specific stages of B-cell development can be identified by sequence analysis of the rearranged V genes. Immature B cells carry unmutated V genes; GC B cells accumulate somatic mutations and have ongoing somatic mutations, whereas GC-derived memory B cells no longer acquire somatic mutations.^{11,12}

The HRS cells of both types of HL have somatic mutations in their V region genes.^{13,14} In cHL there is usually no evidence of ongoing somatic mutation, but in 25% of cases analyzed by Rajewsky et al., mutations were found that rendered the original functional Ig rearrangement nonfunctional.¹⁵ These are called crippling mutations and include mutations resulting in the generation of stop codons or reading frame shifts. These HRS cells should be removed by apoptosis but are not¹⁶ (see discussion in section on Epstein–Barr virus). Recently, a study using gene expression profiling reported that a series of B-cell-specific genes are downregulated in cHL. The authors speculate that the HRS cell in cHL downregulates surface immunoglobulin (BCR) and its downstream signals.¹⁷ In most cases of LPHL, the rearranged Ig genes carry no crippling mutation, and in fact there is evidence of ongoing somatic mutations.^{18,19} Also, in contrast to cHL, the LPHL tumor clone shows evidence of selection for expression of a functional antigen receptor; this is supported by the detection of mRNA for kappa or lambda light chains in the HRS cells in LPHL but not cHL. Based on the foregoing evidence, it is clear the HRS cells of both cHL and LPHL are clonally derived GC B cells.²⁰ Further research is needed to determine why the HRS is not removed by apoptosis.

What Is the Evidence That Epstein–Barr Virus Has a Role in the Pathogenesis of Hodgkin’s Lymphoma?

The age–incidence curve in cHL is described as bimodal. In developing countries, the first peak is seen in childhood and the second in the older age group, whereas in developed countries the first peak is seen in young adulthood.²¹ This finding suggests an infectious etiology as the cause of the disease.^{22,23} A severalfold increase in the risk of HL occurs after infectious mononucleosis (IM), which is the typical clinical manifestation to primary Epstein–Barr virus (EBV) infection in adolescent children.^{24,25}

EBV-positive and -negative cases of HL have different age distributions, with EBV-negative cases having a unimodal age distribution in young adulthood. Recently, Hjalgrim et al. compared incidence rates of HL in two population-based Danish cohorts of patients who were tested for IM: 17,045 patients with serologic evidence of EBV infection and 24,614 with no evidence.²⁶ Biopsy specimens of HL occurring during this time were also tested for EBV. The data suggest that only serologically confirmed IM was associated with an increased

incidence of HL. Sixteen of 29 tumors obtained from patients with a history of IM had evidence of EBV. There was no evidence of an increased risk of EBV-negative HL after IM. The relative risk for EBV-positive HL after IM was 4, and the median incubation time from IM to HL was only 4.1 years.

The literature suggests that there is an altered antibody pattern to EBV in patients before clinically presenting with HL, with elevated titers against viral capsid antigen and EBV nuclear antigens compared with controls. This finding may suggest a more severe primary EBV infection. *In situ* hybridization methods to detect EBV DNA provided the first demonstration of its existence in HRS cells. Subsequently, the demonstration of EBV early RNA (EBER1 and EBER 2) sequences in the HRS cells provided a sensitive method for detecting latent infection. This technique is the accepted test to determine latent EBV infection in lymph node samples.²⁷ The linear genome of EBV has a variable number of 500-base-pair tandem repeat sequences at both ends. Because the number of repeats varies between patients but is constant within an individual patient, it can be used as a clonal marker in EBV-infected cells.

Three different patterns of expression of EBV latent genes and cellular antigens have been described *in vitro* and are referred to latency types I, II, and III. HRS cells exhibit the type II form of latency gene expression being limited to the EBERs, Epstein–Barr nuclear antigen I (EBNA1), and latent membrane proteins 1 and 2 (LMP1 and -2). What is the evidence that EBV is important in the pathogenesis of HL? There is a high level of LMP1 expression in HRS that can induce B-cell activation markers as well as IL-10 production. IL-10 production is more frequent in EBV-positive HRS cells when compared with EBV-negative counterparts, and some groups speculate that this accounts for the failure of cytotoxic T lymphocytes (CTL) to recognize the HRS cell. LMP1 also protects B cells from cell death by upregulating several anti-apoptosis genes, including *bcl-2*. LMP1 appears to function as a constitutively activated tumor necrosis factor receptor and, as a result, can activate a variety of signaling pathways, including NF- κ B.^{28–32} Members of the NF- κ B family of transcription factors play a role in cellular activation, immune responses, and oncogenesis.^{33–35} In most cells they are kept inactive by complexing with members of the I κ B family, whose degradation activates NF- κ B. Constitutive NF- κ B activation has been consistently detected in HRS cells, and nuclear NF- κ B expression can be stained for by immunohistochemistry.³⁶

Although NF- κ B activation is a common feature in HRS cells, the molecular route is different in EBV-positive and -negative HL. In single HRS cells, Jungnickel et al. detected clonal mutations in two of three cases of EBV-negative cases of I κ B α gene but none in EBV-positive cases.³⁷ This finding suggests that the constitutive activation of NF- κ B by LMP1 in EBV-positive cases may be substituted by I κ B α gene mutations in HRS cells not infected by EBV. Despite improvements in our understanding of the pathogenesis of HL, the precise contribution of EBV remains unknown. Many questions concerning EBV and HL need to be resolved but two appear critical: (1) Why is there no effective immune response to LMP1 and -2 expressing HRS cells, and (2) What is the reason we are unable to detect EBV in all cases of HL?

What Is the Evidence That There Is a Standard Management for Early-Stage Disease?

Multiple treatment options exist for early-stage (ES) HL, and the standard approach is controversial.³⁸⁻⁴⁰ The reason for the controversy stems from the premise that despite diverse initial therapeutic options with different disease control rates, outcome is excellent in patients who relapse; therefore, overall survival tends to be the same. There are supporters of radiation therapy (RT) for initial therapy who argue that many ESHL patients avoid chemotherapy, which can be reserved for patients who fail RT. Supporters of combined modality therapy (CMT), in which the number of cycles of chemotherapy, as well as the RT fields, continue to be reduced, argue that disease control is best with this approach despite the fact that patients who fail need to receive an autologous stem cell transplant. Finally, there is a recent trend to use full-course chemotherapy alone. The rationale for this approach is to decrease the incidence of secondary solid tumors, specifically, breast cancer. In deciding the optimal treatment strategy, one must understand that ESHL encompasses distinct subgroups of patients with different prognostic factors. These prognostic factors can help tailor therapy with the goal to ensure an excellent progression-free survival (PFS) with minimal long-term side effects.

Prognostic Factors Help Guide Treatment Decisions in ESHL

Historically, patients with stage I-II HL with favorable prognostic features were candidates for short primary RT, whereas patients with unfavorable prognostic factors tended to receive full-course CMT.⁴¹⁻⁴⁵ This section evaluates if this approach is correct on the basis of the evidence of prospective randomized trials.

Many factors that originally predicted for a high risk of occult abdominal disease in pathologically staged patients are no longer relevant in the era of clinical staging with subsequent CMT. These factors are still important in the design of prospective clinical trials in which the goal is to reduce therapy but maintain a high PFS rate. The factors that are commonly reported include male sex, age greater than 40 years, B symptoms or an ESR greater than 50, mixed-cellularity HL (MCHL) or lymphocyte-depleted HL (LDHL) histology, large mediastinal mass (LMA), extranodal extension, infradiaphragmatic disease, and three or four sites of lymph

node involvement above the diaphragm. Using these prognostic factors, three groups of early-stage patients are usually defined: very favorable, favorable, and unfavorable ESHL. Very favorable ESHL accounts for only 5% of cases, with no specific randomized studies addressing this cohort of patients, and it is not discussed further (Table 67.1).

A number of multicenter randomized clinical trials are reported in favorable/unfavorable ESHL. The concepts of these trials include the following: decrease the number of chemotherapy cycles, avoidance of leukemogenic chemotherapeutic agents, reduce the dose of RT, decrease the size of the RT field or eliminate RT altogether.

Extended-Field Radiotherapy as Primary Therapy for ESHL Is Replaced by Combined Modality Therapy

In general, before the 1990s, extended-field primary RT was the treatment of choice for ESHL. Complete response rates were greater than 90%, but 30% of patients relapsed. Although the majority of these relapsing patients can be cured with standard-dose chemotherapy, there is a higher risk of secondary cancers and cardiac complications in these patients.

The HD7 trial of the German Hodgkin's Disease Study Group (GHSG) consisted of ABVD for two cycles and subtotal nodal irradiation (STLI) versus STLI alone. At a planned interim analysis, the complete response rates were the same, but freedom from treatment failure (FFTF) was 96% in the CMT arm versus 87% in the STLI arm.⁴⁶

The Southwest Oncology Group (SWOG) recently published the results of a randomized trial of doxorubicin and vinblastine × 3 and STLI versus STLI alone in ESHL. The study was closed at the second planned interim analysis because of superior failure-free survival (FFS) in the CMT arm (94% versus 81%).⁴⁷

The EORTC/GELA H7F and H8F trials significantly reduced the irradiated volume in the combined modality arm to include only the site of the originally involved nodes (involved field) as opposed to STLI on the radiation-alone arm. Still, the combined modality arm yielded significantly better relapse-free survival rate than radiation alone.^{48,49} Based on the results of the GHSG, EORTC, and SWOG studies, STLI for the treatment ESHL is no longer recommended (Table 67.2).

MOPP Is Replaced by ABVD as the Standard Chemotherapy Regimen in ESHL

The EORTC H6 twin randomized studies were reported 10 years ago. The study was divided into favorable and unfavorable groups.⁵⁰ Focusing on the unfavorable group (H6U), patients were clinically staged and randomized to receive ABVD × 3/mantle RT/ABVD × 3 versus MOPP × 3/mantle RT/MOPP × 3. ABVD achieved better results with less hematologic and gonadal toxicity.

Our group at Memorial Sloan-Kettering Cancer Center (MSKCC) conducted a randomized trial of MOPP × 4 and involved-field RT versus four cycles of thiotepa, bleomycin, and vinblastine (TBV) and involved-field RT. For MOPP and RT, the CR percentage was 98% (60 of 61), and at 5 years, the percentage of patients remaining in CR was 90%, with freedom from progression of 89% and overall survival of 91%. For TBV and RT, the CR percentage was 93% (55 of 59), with a 5-year duration of CR of 83%, freedom from progression of 81%, and overall survival of 91% (*P* greater than 0.15). The median follow-up at the time of the publication was 65 months (range, 7 to 96 months). Short-term toxicity, except for transient leukopenia, was far less for TBV and RT than for MOPP and RT.⁵¹ Based on these results, standard MOPP chemotherapy is no longer used in the management of ESHL.

Can the Dose of RT be Reduced in CMT in ESHL?

Although the treatment results obtained with chemotherapy and RT are superior to STLI in favorable early-stage HD, the next objective was to see if the radiation field could be reduced safely in an effort to reduce toxicity. Several randomized studies were conducted in this setting; however, the majority of patients have a large mediastinal mass (LMA) and are at unfavorable risk. The Istituto Nazionale Tumorie Milan Trial has provided the clearest data regarding the adequacy of radiation volume reduction. From 1990 to 1996, 140 patients with ESHL (IA bulky IB; IIA bulky; and IIEA) were randomly assigned to four cycles of ABVD, followed by STLI with the same regimen followed by involved-field radiotherapy (IFRT). The dose of RT ranged from 30 to 36 Gy to unin-

involved and involved sites, respectively. After a median follow-up of 87 months, CR rates were 100% after ABVD + STLI versus 97% after ABVD + IFRT; freedom from treatment failure (FFTF) was 97% versus 94% and overall survival (OS) 93% versus 94%, respectively.⁵²

The EORTC H8U trial randomly assigned unfavorable patients to four cycles of MOPP/ABVD plus IFRT (36–40 Gy) with the same chemotherapy followed by STLI (36–40 Gy). FFTF was the same in both groups, 92% in each arm.⁵³

The GHSG HD8 study randomly assigned unfavorable early-stage patients to receive four cycles of cyclophosphamide, vincristine, procarbazine, and prednisone (COPP)/ABVD followed by either extended or involved field. At a median follow-up of 56 months, FFTF was 86% (in each arm), and no difference in relapse rate or survival was observed. Acute side effects were more frequent in patients who received the extended-field RT.⁵⁴ Based on these clinical trials, CMT using extended-field RT is no longer recommended (Table 67.3).

Can the Number of Chemotherapy Cycles and Dose of RT Be Reduced in ESHL?

An important study that just finished accruing patients is the HD10 trial of the GHSG. In this trial, reduction of the number of ABVD chemotherapy cycles, as well as reduction of RT dose in the IFRT, was tested in favorable ESHL patients. Thus, patients were randomly assigned between four cycles of ABVD followed by IFRT (30 Gy, arm A), four cycles ABVD + 20 Gy IFRT (arm B), two cycles ABVD + 30 Gy IFRT (arm C), and two cycles ABVD + 20 Gy IFRT (arm D). Between May 1998 and June 2000, 486 HL patients with ESHL [i.e., CS I, II without risk factors (favorable)] received one of these four treatments, and 390 patients (80%) are currently evaluable. At the first interim analysis in 2001 when the median observation time was 18 months, the CR rate was 98% and only 1% of patients had either progressive disease or no change. Overall survival (SV) rate was 98% and FFTF was 96%. The trial reached the target recruitment and was closed in January 2003. This critical study hopes to determine if less chemotherapy and RT can maintain the high FFTF rates with less toxicity in patients with favorable ESHL.⁵⁵

Can Chemotherapy Alone Be Used in the Management of ESHL?

Three important randomized studies evaluated the use of chemotherapy alone in ESHL. These patients have favorable and unfavorable features, but no patients have large mediastinal masses. At Memorial Sloan-Kettering Cancer Center (MSKCC), we tested the hypothesis that CMT was superior to ABVD alone in ESHL. We randomly assigned 152 patients to six cycles of ABVD alone or ABVD for six cycles and extended-field RT (EFRT). In intent-to-treat analysis, the CR rates were 94% in both cohorts. At 5 years, 91% of patients receiving CMT and 87% receiving ABVD alone continue in CR ($P = 0.61$). FFTF at 5 years is 86% for CMT and 81% for ABVD alone ($P = 0.6$). Interestingly, the overall survival (OS) trends are in favor of CMT (97% for CMT versus 91% for ABVD alone; $P = 0.08$).⁵⁶ Nachman et al., for the Children's Cancer Group (CCG), randomly assigned 501 patients who achieved an initial CR to risk-adapted combination chemotherapy to low-dose IFRT (21 Gy) or no further treatment. Patients receiving CMT had an OS of 92% versus 87% for patients treated with chemotherapy alone ($P = 0.057$). However, if one analyzes the data by therapy received there is a survival benefit for CMT ($P = 0.0024$).⁵⁷ An intergroup study [NCI of Canada and Eastern Cooperative Oncology Group (ECOG)] compared standard therapy STLI (favorable patients) or ABVD \times 2 and STLI (unfavorable patients) to ABVD \times 4 alone for both favorable and unfavorable patients. The median duration of follow-up is 4.2 years. The experimental arm, ABVD \times 4, had an inferior PFS to that of standard therapy ($P = 0.006$).⁵⁸ There is a large ongoing trial in favorable early-stage patients with classic HL. All patients receive six cycles of EBVP (epirubicin, bleomycin, vinblastine, and prednisone). Only patients who achieve a CR are randomized to either IFRT of 36 Gy, IFRT of 20 Gy, or no radiation. Last year, the EORTC/GELA groups closed the no RT arm due to an excessive number of relapses in this group. The study remains open for randomization on the two combined modality arms.⁵⁵

The evidence from these three studies suggests that, for patients with ESHL without a large mediastinal mass, four to six cycles of chemotherapy alone is inferior to the same chemotherapy and consolidative RT.

Summary

The following recommendations can be made concerning ESHL: all the previously mentioned randomized studies indicate that CMT should be standard therapy. Although short-course chemotherapy and extended-field RT are superior to chemotherapy alone, this strategy is unlikely to reduce long-term treatment-related morbidity and mortality. Although it has been shown that the radiation field can be safely reduced in unfavorable patients receiving CMT, we await follow-up of the HD10 trial if this can be achieved in favorable ESHL patients. There is no evidence that four to six cycles of chemotherapy is equivalent to the same chemotherapy and IFRT. At the present time, four cycles of chemotherapy, preferably ABVD, followed by IFRT (30–36 Gy), should be considered standard therapy for favorable and unfavorable patients with ESHL. These recommendations must be made with caution, however, in the light of the increased incidence of secondary breast cancer in young women treated with CMT (discussed in a later section).

What Is the Evidence That There Is a Standard Management for Advanced-Stage Disease?

ABVD Replaces MOPP as Standard Therapy for Advanced-Stage HL

Advanced-stage HL (ASHL) comprises all stage III and IV disease as well as selected patients with stage IIB disease, including those with a LMA, extranodal disease, or massive splenic involvement. The landmark report by DeVita et al., 36 years ago, determined that more than 80% of patients with ASHL achieved a CR to the MOPP chemotherapy program; 50% of patients have had long-term PFS.^{40,59,60} The ABVD regimen has replaced MOPP as the standard chemotherapy program of HL, primarily because of a more favorable toxicity profile.⁶¹ The modern era of ASHL begins with the results of a three-arm randomized CALGB study reported by Canellos et al. In this multicenter trial, three regimens were compared: ABVD for 6 to 8 cycles, MOPP for 6 to 8 cycles, and MOPP alternating with ABVD for 12 cycles. RT was not administered. Patients who relapsed after either MOPP or ABVD alone were switched to the opposite regimen. The CR rate to MOPP was inferior to the other arms (67%, 82%, and 83%, respectively; $P = 0.006$). FFTF was also inferior with MOPP (50%, 61%, and 65%, respectively); however, OS was the same in each arm.⁶² Although this prospective trial shows an improved FFTF with the ABVD regimens even at a median follow-up of 10 years, OS is the same, reflecting the ability of high-dose therapy and autologous stem cell transplantation to salvage these patients. Based on the equivalent efficacy of ABVD and MOPP alternating with ABVD, the better short- and long-term toxicity profile seen with ABVD alone makes ABVD the benchmark against which newer regimens need to be compared. Three important questions need to be addressed: (1) Can prognostic factors help tailor therapy for patients with ASHL? (2) Are there randomized data showing that newer regimens are superior to ABVD or an ABVD equivalent? (3) Should adjuvant RT be used for patients with ASHL?

Can Prognostic Factors Guide Therapy in ASHL?

Therapy with ABVD or an ABVD-equivalent chemotherapy program fails to cure patients with ASHL one-third of the time, but just as important is the fact that some patients are overtreated unnecessarily. A number of pretreatment clinical prognostic factors have been identified to have independent prognostic value.⁶³ An international database on HL was developed to help define a prognostic model for ASHL. The factors defined are based on more than 5,000 patients treated with ABVD or an ABVD-equivalent chemotherapy program, and include age greater than 45 years, male sex, stage IV versus III disease, serum albumin less than 4 g/dL, hemoglobin less than 10.5 mg/dL, white blood cell count more than 15,000/mm³, and absolute lymphocyte count less than 600/mm³. These seven factors comprise the international prognostic index (IPI) for ASHL developed by Hasenclever et al.⁶⁴ (Table 67.4). Clinically, patients can be divided into three risk groups. Patients with an IPI score of 0–2 (low risk), accounting for 57% of ASHL, have a freedom from progression rate (FFP) of 74%. Patients with an IPI score of 3 (intermediate risk), accounting for 23% of ASHL, have an FFP of 60%. Patients with an IPI score of 4 or more (high risk), only

TABLE 67.4. Risk factors and survival for advanced-stage Hodgkin's lymphoma (ASHL).

	<i>IPI model</i>	<i>MSKCC model</i>
Risk factors (RF)	Age >45, male sex, albumin <4, hemoglobin <10.5 WBC >15 K, ALC < 600 Stage IV disease	Age >45, elevated LDH, large mediastinal mass, >1 extranodal site, low hematocrit, inguinal nodal involvement
Good risk	0–2 RF, FFTF (74%)	<2 RF, FFTF (>90%)
Intermediate risk	3 RF, FFTF (60%)	
Poor risk	>4 RF, FFTF (47%)	≥2 RF, FFTF (<50%)

19% of ASHL, have an FFP of 47%. When reviewing studies in ASHL, it is important to evaluate these risk factors. Patients with high-risk disease may benefit from a more aggressive chemotherapy program and, conversely, low-risk patients do not need to be overtreated with more toxic regimens.

MOPP/ABV Hybrid Is No Better Than ABVD in ASHL

In 1985, Klimo and Connors reported the results of the MOPP/ABV hybrid regimen. MOPP is administered on day 1 and 7 and ABV on day 8; dacarbazine was omitted in this regimen, and the dose of doxorubicin was increased from 25 mg/m² to 35 mg/m². IFRT was administered to some patients postchemotherapy. At 4 years, the OS rate was 90%.^{65,66} This Phase II study led to two randomized studies comparing the hybrid to alternating MOPP/ABVD. The National Cancer Institute of Canada (NCIC) randomly assigned 301 patients who failed extended-field RT to the hybrid versus the alternating regimen. The OS rates at 5 years were not statistically different, but the hybrid regimen had more hematologic toxicity.⁶⁶ An intergroup trial of 737 patients compared the hybrid to six cycles of MOPP followed by three cycles of ABVD. At 8 years, FFS was superior with the hybrid regimen (64% versus 54% $;$ $P = 0.01$).⁶⁷ Although prognostic factors were not evaluated in this study, many physicians at the time considered the hybrid the standard of care for ASHL.

Recently, Duggan et al. reported the results of a randomized intergroup study of the ABVD versus MOPP/ABV hybrid. The major endpoints of the study were FFS and OS. Patients were eligible if they had untreated ASHL or if they relapsed after RT alone. All patients received 8 to 10 cycles of chemotherapy. Eight hundred fifty-six patients were randomly assigned to one of the two regimens, and the median follow-up at the time of the publication was 6 years. The CR rate, FFS, and OS were the same with the two regimens. When evaluating these endpoints based on the IPI score, there were no differences between the two cohorts. Although the efficacy endpoints between the two regimens are the same, the toxicity endpoints were quite different. There was a statistically significant increase in acute pulmonary and hematologic toxicity seen with the hybrid regimen ($P = 0.06$ and 0.001 , respectively). More important, there was an increased incidence of myelodysplasia or secondary acute leukemia with the hybrid regimen as compared to ABVD. There was a total of 13 cases of MDS or AML; 11 of these patients were treated with the hybrid.⁶⁸ The results of this study are clear: the two regimens have equal efficacy, but the hybrid regimen

is more toxic and its use can no longer be recommended. ABVD continues to be the standard regimen for ASHL.

HD9 Trial of the GHSG: Escalated BEACOPP Improves Survival in Poor-Risk Patients with ASHL

To improve on the results with ABVD in ASHL, subsequent studies involved two different treatment strategies. The first is dose intensification with the active agents in HL and the second is a change in the scheduling similar to some of the weekly chemotherapy programs for aggressive NHL, such as MACOP-B.⁶⁹

Intensification of therapy can be via two distinct pathways: the first is to give higher doses of chemotherapy using a standard schedule and the second is to consolidate with upfront high-dose chemotherapy and autologous stem cell transplantation. From 1993 to 1998, the GHSG randomly assigned 1,201 patients with ASHL to eight cycles of COPP/ABVD (ABVD equivalent) to that of either standard doses of BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, prednisone, and procarbazine) or escalated BEACOPP (Figure 67.1). Patients in any of the three cohorts were eligible to receive IFRT postchemotherapy if a residual nodal mass was at least 2 cm postchemotherapy or if there was bulky disease at presentation. At the first interim analysis, the COPP/ABVD arm was stopped due to inferior results. The final analysis included 260 patients

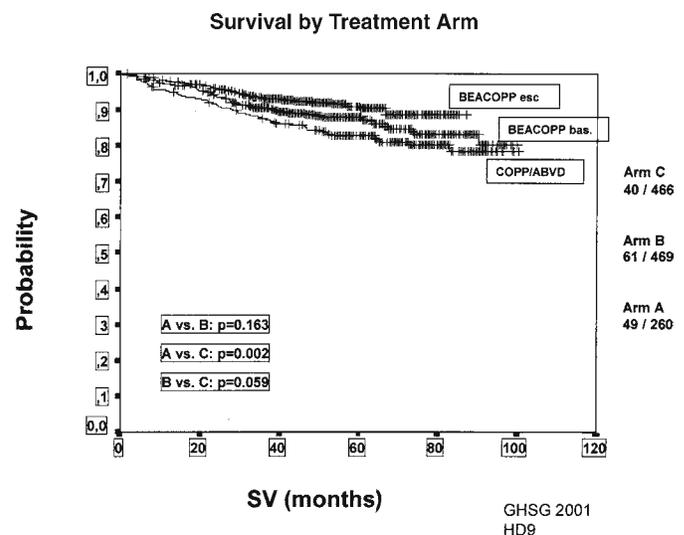

FIGURE 67.1. Survival by treatment arm.

receiving COPP/ABVD, 469 receiving standard-dose BEACOPP, and 466 patients receiving escalated BEACOPP. At 5 years, FFTF and OS rates for COPP/ABVD, standard-dose BEACOPP, and escalated BEACOPP were 69% and 83%, 76% and 88%, and 87% and 91%, respectively. FFTF and OS were statistically significantly superior for escalated BEACOPP when compared to COPP/ABVD ($P = 0.04$ and 0.002 , respectively). There was, however, a higher incidence of grade three/four hematologic toxicity for the escalated BEACOPP regimen despite universal use of granulocyte colony-stimulating factor (G-CSF). The IPI score was available for only a minority of patients. Interestingly, 5-year OS for patients with IPI scores of 0–3 are similar for COPP/ABVD, BEACOPP, and escalated BEACOPP: 84% to 92%, 86% to 93%, and 90% to 95%, respectively. The critical result, however, is the 5-year FFTF for patients with at least four risk factors. The results are as follows: 59% for COPP/ABVD, 74% for standard BEACOPP, and 82% for escalated BEACOPP.⁷⁰ This randomized clinical trial has two obvious conclusions: a randomized study is required for patients with 0 to 3 risk factors comparing ABVD and escalated BEACOPP with all patients receiving RT for bulky or residual disease, and the available evidence suggests that escalated BEACOPP is a standard treatment option for patients with four or more IPI risk factors.

Consolidative Upfront ASCT Is No Better Than ABVD for Patients with ASHL

As described in a later section (see What Is the Evidence That There Is a Standard Management for Relapsed/Refractory Disease?), high-dose therapy and autologous stem transplantation is the treatment of choice for relapsed and primary refractory HL. If dose escalation of standard-dose chemotherapy can improve FFTF, then it is possible that high-dose therapy (HDT) and autologous stem transplantation (ASCT) may have a role as consolidation treatment for patients with unfavorable ASHL. The underlying question is identifying which patients were most likely to fail standard treatment. Before the publication of the IPI, another similar prognostic model was in use. The lymphoma service at MSKCC found that the following six risk factors were predictive for CR duration and relapse-free survival in ASHL: age greater than 45, elevated LDH, an LMA, at least two extranodal sites of disease, inguinal node involvement, and a low hematocrit.^{71,72} Patients with at least two factors were considered poor risk. Based on this model, an intergroup study randomly assigned patients to eight cycles of ABVD-equivalent chemotherapy or four cycles of the same chemotherapy followed by HDT and ASCT. All patients were eligible to receive postchemotherapy RT if they had initial bulky disease or residual nodal masses.⁷³ There was no difference in the CR rate, FFS, or OS between the two arms. Based on these results, one can conclude that unfavorable patients defined by the MSKCC index do not benefit from a consolidative upfront ASCT.

Weekly Chemotherapy and Consolidative RT for ASHL

A scheduling change of the active chemotherapeutic agents in HL to weekly schedule is the principle of the Stanford V regimen.⁷⁴ The concept is threefold: decrease the cumulative

doses of doxorubicin, nitrogen mustard, and bleomycin, add etoposide, and consolidate with more intensive radiotherapy. By definition, all lymph nodes greater than 5 cm pretreatment receive full-dose RT (36 Gy) at the conclusion of the 12 weeks of chemotherapy. An update of the Stanford experience was recently published in which 142 patients with ASHL were treated. The 5-year FFP and OS rates were 89% and 96%, respectively. Patients with an IPI score of 0–2 had a significantly superior FFP to those with scores of 3 or greater (94% versus 75%; $P = 0.0001$). There were no cases of secondary leukemia.⁷⁵ We analyzed our 7-year experience at MSKCC in 126 patients treated with the Stanford V combined modality regimen. Sixty-seven patients (53%) had extensive local disease, 26 patients (21%) had stage III, and 33 patients (26%) had stage IV. Seventy-five patients (58%) had B symptoms and 20 patients (16%) had at least four adverse factors included in the IPI score. At a median follow-up of 36 months (range, 12 to 92 months), the 3-year FFTF was 80% and OS was 91%. Patients with none to three IPI factors had FFTF and OS of 86% and 95%, respectively; patients with four or more factors had FFTF and OS of 50% and 75%, respectively. Cox regression analysis indicated that IPI of 4 or more is a significant predictor for both FFTF and OS (P less than 0.0001). There were 25 (20%) failures of treatment (9 patients had primary refractory HL, 1 died of hepatic failure, and 15 patients relapsed). Of the 25 failures, 14 patients were successfully salvaged with high-dose chemoradiotherapy and ASCT. The 3-year freedom-from-second-relapse for all patients who failed Stanford V was 55%. No secondary leukemia was observed, and 7 successful pregnancies were reported by our 65 female patients. Our study confirms the excellent results reported with Stanford V and radiotherapy by the Stanford group, indicates the relevance of the IPI model in determining outcome of this program, and demonstrates that failures of Stanford V remain highly salvageable with high-dose chemoradiotherapy.⁷⁶

Randomized Data of Weekly Combined Modality Therapy Versus Standard Schedule Combined Modality Therapy in ASHL

Unfortunately, weekly therapy has not been successful in two prospective randomized studies. Radford et al. reported the results of weekly chemotherapy with the VAPEC-B (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, and prednisolone) versus ChIVPP/EVA (chlorambucil, vinblastine, procarbazine, prednisolone, etoposide, vincristine, and doxorubicin) hybrid. There were 282 patients randomized; RT was administered to sites of bulky disease or residual nodal involvement postchemotherapy. At 5 years, FFP and OS was significantly better for the hybrid arm (82% and 89% versus 62% and 82%; P less than 0.001). When analyzing the IPI score, all risk groups had improved survival with the hybrid.⁷⁷ The Italian Lymphoma Study group reported the results of 355 patients randomly assigned to ABVD, Stanford V, or a novel 10-drug regimen. Patients received RT only if they had bulky disease; hence, a variation of the standard RT practices for Stanford V as described previously. Only CR and relapse rates are available but they are inferior for Stanford V (CR rates: 89% for ABVD, 83% for the 10-drug regimen, and 74% for Stanford V; relapse rates: 6% for ABVD, 4% for the 10-drug regimen, and 16% for Stanford

V).⁷⁸ Despite these issues, there is an ongoing United States Intergroup trial comparing ABVD and Stanford V in ASHL. Until these results are available, weekly therapy cannot be recommended as standard of care for any patient with ASHL.

Does Adjuvant or Consolidative RT Improve Outcome in Patients with ASHL?

As described previously, many treatment programs included RT after full-course chemotherapy in ASHL. The evidence for this approach is controversial. The contribution of RT tends to be used as part of a planned CMT approach, as with Stanford V, or to convert an uncertain CR to a CR, as with escalated BEACOPP. The premise is that patients with ASHL relapse at bulky or residual sites and, if radiated, FFTF can be improved. The results of the early large randomized studies are conflicting.

Pavlovsky et al. randomly assigned 151 patients to six cycles of MOPP-equivalent chemotherapy (CVPP, CCNU, vinblastine, procarbazine, and prednisone) or the same therapy with RT interspersed between cycles 3 and 4. The CR and FFS rates were significantly better for CMT approach ($P = 0.01$ and 0.001).⁷⁹ The results for chemotherapy alone in this study were extremely poor and difficult to explain.

The SWOG treated 278 patients with six cycles of an alternating regimen and then randomly assigned patients to low-dose RT to all lymph node sites or observation. There was no difference in remission duration, relapse-free survival, or OS between the two groups. In a planned subset analysis, patients with either nodular sclerosis pathology or bulky disease had significantly better remission duration with the addition of RT.⁸⁰

Diehl et al. treated 288 patients with an alternating regimen, and patients achieving a CR were randomly assigned to 20Gy RT to initially involved fields or to an additional cycle of COPP/ABVD chemotherapy. There were no statistically significant differences in the two treatment programs.⁸¹

The CALGB treated 258 patients with one of four treatment programs: CVPP alone for 6 cycles, CVPP for 12 cycles, CVPP for 6 cycles followed by 25 Gy RT, or CVPP for 3 cycles followed by 25 Gy RT and then 3 more cycles of CVPP. Relapse in irradiated sites occurred in only 6% of responding patients, but there was no impact on OS. In fact, doubling the number of cycles of CVPP also had no impact on OS.⁸²

Because the data were confusing after these publications, a meta-analysis of the randomized studies performed from 1972 to 1988 was reported by Loeffler et al. Data were available on 1,740 patients treated on 14 different trials. There were two distinct study designs. RT was randomly assigned after chemotherapy or patients were randomly assigned to RT or additional chemotherapy. Nearly all the chemotherapy regimens used in these studies were MOPP or MOPP-equivalent

regimens. In the additional RT design, there was 11% improvement in CR duration in the RT groups (P less than 0.001); OS was the same. In contrast, when CMT was compared with the cohorts that received additional chemotherapy, CR duration was the same but OS was superior with patients who did not receive RT ($P = 0.045$). The conclusion of this meta-analysis should be approached with caution because MOPP or MOPP-equivalents are no longer used.⁸³

Three recent random assignment studies have been published, adding to the confusion. The GELA (Groupe d'études des Lymphomes) reported the results of a randomized study comparing two different chemotherapy regimens [MOPP/ABV to ABVPP (doxorubicin, bleomycin, vinblastine, procarbazine, and prednisone)] followed by a second randomization for patients achieving a complete or partial response to two more cycles of the same chemotherapy or subtotal nodal irradiation. The study included 559 patients. After induction chemotherapy, 418 patients were evaluated for the consolidation phase. OS at 5 years in the MOPP/ABV groups were the same between additional chemotherapy and RT (85% versus 88%). After ABVPP, OS was superior for the chemotherapy arm (94% versus 78%; $P = 0.002$).⁸⁴

The Children's Cancer Group (CCG) randomly assigned 501 patients achieving a CR to low-dose IFRT or observation. The 3-year FFTF was 87% for all patients, 92% for those randomized to receive RT and 87% randomized to observation ($P = 0.06$). An alternative analysis based on therapy actually received was undertaken that excluded the patients randomized to receive RT who refused the intervention. In this "as-treated" analysis, there was a significant improvement in FFTF for those patients who received RT (93% versus 85%; $P = 0.002$).⁵⁷

Most recently, the EORTC randomly assigned 421 patients in CR after MOPP/ABV chemotherapy to RT or observation. The dose of RT was 24Gy administered to all initially involved nodal sites and 16–24Gy to all initially involved extranodal sites. Patients in partial remission were all treated with 30Gy to nodal areas and 18–24Gy to extranodal sites. The median follow-up is 6.5 years. The 5-year OS rates for the RT and observation groups were 85% and 91%, respectively ($P = 0.07$). Those patients who had a partial response to MOPP/ABV had event-free and OS rates after RT of 79% and 87%. Based on these three studies using ABVD-equivalent chemotherapy, RT clearly did not improve the outcome for patients in CR after full-course chemotherapy⁸⁵ (Table 67.5).

Summary

The IPI score can help guide standard management in ASHL; this is the concept of risk-adapted therapy. The goal is to use optimal management such that the IPI score is no longer rel-

TABLE 67.5. Randomized cooperative group studies of adjuvant RT in ASHL.

Study	Patients randomized	Chemo	RT	FFTF—RT—no RT	OS RT—no RT
SWOG	278	MOP-BAP × 6	IF	79%–68%	79%–86%
GHSG	100	COPP/ABVD × 4	IF	76%–79%	92%–96%
CCG	501	Doxorubicin based	IF	92%–87%	
EORTC	421	MOPP/ABV	EFRT		85%–91%

evant. It is clear that 80% of patients with an IPI score of 0–3 do well with ABVD and if not, are highly salvageable with high-dose therapy and ASCT (see following discussion). There is no evidence that any of the new treatment programs are superior to ABVD in this subset of patients. In patients who require CMT with zero to three risk factors because of bulky disease, the Stanford V regimen is a reasonable alternative to ABVD, although randomized data are lacking. In the subset of patients with four to seven risk factors, escalated BEACOPP offers a survival advantage. It is important to remember that this is a combined modality treatment program and these excellent results include the use of adjuvant RT. In patients receiving ABVD or ABVD-equivalent treatment programs, such as alternating or hybrid regimens, there is no evidence to use adjuvant RT in patients who achieve a complete remission to full-course chemotherapy.

What Is the Evidence That Positron-Emission Tomography Imaging Should Be Used to Determine If Additional Therapy Is Needed After the Completion of the Standard Chemotherapy Program?

Careful staging in HL is critical to determine the prognosis of the patient and to design an optimal treatment strategy. Standard staging evaluation includes history, physical examination, routine laboratory studies, including a CBC, liver function tests, ESR, bone marrow biopsy, chest X-ray, and computed tomography (CT) scanning of the chest, abdomen, and pelvis with contrast. CT scanning has limited utility in discerning active disease in normal-size lymph nodes or in some extranodal sites, particularly bone. In addition, CT scans cannot differentiate between posttreatment fibrosis from active HD. Functional imaging improves the accuracy of HL staging. For many years, gallium scanning has complemented CT for staging and response evaluation. Fluorine-18 fluorodeoxyglucose positron emission tomography (PET) has virtually replaced gallium scanning in the United States as the functional imaging test of choice for a variety of reasons that include improved resolution, reduced nonspecific abdominal uptake, and ease of administration. There are at least three small single-center reports prospectively comparing gallium and PET scanning in lymphoma patients; both NHL and HL patients were included. In each study, PET scanning had a significantly higher sensitivity for depicting active disease. The major problem with PET is the high rate of false-positive results.^{86–88}

The critical questions facing physicians regarding PET imaging include the following: What is the positive predictive value (PPV) and negative predictive value (NPV) of PET imaging in evaluation of a residual mass after initial therapy, and does a positive PET scan posttreatment preclude the need for biopsy confirmation of active disease? Most patients with HL have a residual mass on CT scan following the completion of initial therapy. These masses contain one of the following: fibrosis, necrotic tissue, residual HL, or an unsuspected concurrent diffuse large B-cell lymphoma. There are a number of publications specifically addressing the role of PET imaging in this situation. Many of these series contain patients with both HL and NHL.

First, NPV is defined as a negative PET result in a patient who is progression free and PPV is defined as a positive PET result in a patient who has a subsequent relapse. There are six studies with more than 25 patients reported. The NPV ranges between 90% and 96%. Summarizing, 178 patients had a negative PET scan at the end of treatment of which 15 relapsed corresponding to a NPV of 91.6%. The PPV ranges from 46% to 100%. Summarizing, 65 patients had a positive PET scan at the end of treatment of which 50 relapsed, corresponding to a PPV of only 77%.^{89–97} Because therapy for relapsed or primary refractory HL generally includes stem cell transplantation, the following recommendation is reasonable: all patients should have a pretreatment and posttreatment CT and PET scan. If the PET scan is positive, a biopsy is mandatory. In patients with a normal PET scan, monitoring of any size residual mass, by CT, is warranted.

What Is the Evidence That There Is a Standard Management for Relapsed/Refractory Disease?

The majority of patients with HL are cured with radiation therapy and/or combination chemotherapy. However, patients who relapse after attaining a complete remission with chemotherapy and those with primary refractory disease have a poor outcome with conventional salvage regimens. Treatment results with standard-dose second-line regimens produce low complete remission rates and minimal survival benefit. Longo et al. reported a median survival of only 16 months in 51 patients treated with MOPP chemotherapy who never achieved a complete remission; similar results were seen in patients who failed MOPP/ABV hybrid or alternating regimens with a long-term event-free survival of 8%.^{98,99} Over the past 15 years, many clinical trials using high-dose chemotherapy or chemoradiotherapy (HDT) with autologous stem cell transplantation (ASCT) in this setting have been reported, and approximately 40% of patients appear to be cured using this approach.¹⁰⁰

Most early transplant studies included heavily pretreated patients, which influenced the morbidity and mortality of HDT. The introduction of G-CSF, peripheral blood progenitor cells as opposed to bone marrow as the stem cell graft, better transfusion practices, and more effective antibiotics have decreased transplant-related mortality from 15% to less than 3% in most series. Despite this improvement in supportive care, long-term FFTR has improved by at most 10% in recent studies. Therefore, there are a number of prognostic factors that predict for outcome.

Chemosensitive Disease Is Required to Achieve Benefit from HDT/ASCT

Two randomized studies comparing standard-dose second-line chemotherapy (SDSC) with high-dose therapy (HDT) and ASCT have been reported. The British National Lymphoma Investigation (BNLI) randomly assigned relapsed and primary refractory patients to either BEAM (carmustine, etoposide, cytarabine, and melphalan) HDT followed by ABMT or up to three cycles of mini-BEAM with standard support.¹⁰¹ The German Lymphoma study group randomly assigned patients with relapsed HL to either two cycles of dexamethasone-BEAM and BEAM and ASCT or four cycles of dexamethasone-BEAM.¹⁰² Each study

demonstrated a statistically significant improvement in both EFS and PFS for the patients treated on the HDT arms, but neither was powered to show an OS advantage.

The importance of pretransplant cytoreduction with SDSC has been demonstrated in numerous previous reports. In 1993, we published our results using high-dose combined modality therapy in patients with biopsy-proven relapsed and primary refractory HD in our first-generation programs (MSKCC protocols 85-97 and 86-86).^{103,104} The program used accelerated fractionation radiotherapy either as total lymphoid irradiation (TLI) or as an IFRT followed by HDT and bone marrow infusion. The strategy of incorporating radiation into the high-dose treatment regimen is based on the premise that the pattern of relapse post-HDT is similar to relapse following front-line chemotherapy; it most commonly occurs at sites of initial nodal involvement and is therefore amenable to treatment with radiotherapy. One hundred fifty-six patients with relapsed or primary refractory disease were treated; chemosensitive disease to SDSC was not a requirement for subsequent HDT. At a median follow-up of 11 years, the EFS is 45% with no relapses occurring later than 36 months posttransplant. After the introduction of G-CSF, overall mortality of the program decreased from 18% to 6%. These results demonstrated the feasibility of incorporating dose-intensive radiotherapy into HDT for HL and most importantly determined that patients with chemosensitive disease to SDSC had a marked improvement in EFS compared with patients with refractory disease at the time of HDT.

As with aggressive non-Hodgkin's lymphoma, chemosensitive disease to SDSC is now required for transplant eligibility in the United States. There is limited information regarding the optimal SDSC regimen. The following requirements for a SDSC regimen are adequate cytoreduction in at least 75% of patients without extramedullary toxicity or severe bone marrow suppression with subsequent inability to collect an adequate stem cell harvest.¹⁰⁵ Specifically, in the Phase III randomized German study described previously, of the 161 patients enrolled, 13 could not be randomized secondary to dexamethasone-related mortality (8 patients) or severe infection.

We recently reported the results of a comprehensive program for the treatment of 82 patients with relapsed and primary refractory HL (MSKCC protocol 94-68).¹⁰⁶ All patients received uniform cytoreductive chemotherapy with ifosfamide, carboplatin, and etoposide (ICE), and only responders were subsequently offered HDT and ASCT. All patients in this trial had biopsy-proven relapsed or refractory disease, and our data were analyzed by intent to treat. ICE chemotherapy was a highly effective SDSC regimen in HD. The response rate to ICE was 90% with no ICE-related extramedullary tox-

icity. The median number of CD34+ cells/kg collected was 7×10^6 /kg. The Kaplan-Meier estimate of the proportion of patients who are alive, event free, and analyzed by intent to treat at a median follow-up for surviving patients of 6 years is 55%. In the subset of patients who received HDT/ASCT (75 of 82 patients), the EFS is 61%.

Do Patients with Primary Refractory Disease Have a Suboptimal Outcome with ASCT?

Although response to SDSC is the major selection criteria to proceed to ASCT, other prognostic factors may also predict for long-term EFS in patients with relapsed and refractory HD. Some groups have suggested that patients with primary refractory disease do less well than those patients who achieved an initial remission to frontline therapy. Conflicting data have been reported by the North American Autologous Blood and Bone Marrow Transplant Registry (ABMTR), German Hodgkin's Lymphoma Study Group (GHSG), and the Groupe d'Etudes des Lymphoma de l'Adulte (GELA).¹⁰⁷⁻¹¹⁰

The ABMTR series of 122 primary refractory patients had 3-year PFS and OS rates of 38% and 50%, respectively, using a variety of HDT regimens. Although chemosensitivity status was unknown in one-third of patients, it was concluded that only B symptoms at diagnosis and a poor performance status at ASCT predicted a poor outcome.

In the GELA data, primary refractory patients were defined as progression of disease on therapy, less than 50% response, or persistent bone marrow involvement after four cycles of induction chemotherapy. These patients had poor outcomes with HDT and ASCT, with 5-year freedom from second failure of 23%, even though most patients (62%) had chemosensitive disease to SDSC.

The GHSG evaluated 206 primary refractory patients defined as progression of disease or biopsy confirmation of active disease within 90 days postinduction therapy. Although only 70 of these 206 patients actually received HDT and ASCT, the authors concluded that HDT was no better than standard chemoradiotherapy when the data were analyzed by intent to treat.

We recently reported our data for 75 patients with primary refractory HL, which has longer median follow-up than any other reported series. With a median follow-up of 10 years, our results indicate that HDT/ASCT should be considered as standard treatment for patients with primary refractory HD if chemosensitive disease to SDSC is established. We found no difference in EFS for patients with chemosensitive primary refractory versus chemosensitive relapsed disease¹¹¹ (Table 67.6).

TABLE 67.6. Outcome in primary refractory Hodgkin's lymphoma (HL).

Series	Patients (n)	Median follow-up (months)	Biopsy proven	PFS	OS	TD	Chemosensitivity
Vancouver	30	42	55%	42%	30%	18%	N/A
ABMTR	122	28	N/A	38%	50%	12%	NS
GELA	157	50	36%	23%–66%	30%–76%	12%	$P = 0.05$
GHSG	70	52	57%	31%	43%	9%	$P = 0.0001$
SFGM	86	29	None	25%	35%	8%	$P = 0.0001$
MSKCC	75	120	100%	49%	48%	9%	$P < 0.0001$

TABLE 67.7. Adverse prognostic factors for treatment outcome after ASCT for HL.

Vancouver	B symptoms at relapse, extranodal disease at relapse, duration of 1st CR <12 months
Stanford	B symptoms at relapse, pulmonary/bone marrow involvement, more than minimal disease at ASCT
City of Hope	>2 prior regimens, extranodal disease at relapse, PSC as sole stem cell source
M.D. Anderson	>2 prior regimens, extranodal involvement, abnormal performance status, chemorefractory
Boston	>1 extranodal site, ECOG classification >0, progressive disease at ASCT
SFGM	Extranodal relapse, duration of 1st CR <12 months
ABMTR	Chemorefractory, abnormal LDH, KPS <90%
Nebraska	Second-line IPI

CR, complete remission.

Multiple Factors Predict Survival in Relapsed and Primary Refractory HL

Many groups have suggested that a variety of prognostic factors other than refractory disease predicts survival, as summarized in Table 67.7.¹¹²⁻¹¹⁶ In our study of ICE SDSC followed by HDT and ASCT discussed previously, Cox regression analysis determined that the three factors associated with a poor outcome pre-ICE were extranodal sites of disease (ENS), P less than 0.001, initial response duration less than 1 year ($P = 0.001$), and B symptoms (P less than 0.001). Using this three-factor model, we identified three groups of patients with widely disparate outcomes with this treatment approach (Figure 67.2). A favorable risk group having zero or one of these risk factors (65% of the patients) had an EFS of 80% measured from initiation of ICE therapy. Patients with two and three risk factors fared less well, with an EFS of 34% and 12%, respectively.

This three-factor model was the basis of our third-generation risk-adapted comprehensive study (MSKCC protocol 98-71). In this study, patients with zero or one risk factor (ENS, initial response duration less than 1 year or B symptoms at time of study enrollment), group A, were treated exactly the same as in the second-generation program; in that study EFS was 80%. Patients with two risk factors, group B,

received one dose of standard-dose ICE followed by a dose of augmented ICE second-line therapy, as well as a more dose-intense transplant conditioning regimen. Finally, patients with all three risk factors, group C, received a completely different regimen. Cyto-reduction was done with transplant doses of ICE followed by stem cell support, which was followed by a second autotransplant. This three-arm study, however, uses one universal theme: patients must have disease chemosensitive to their "ICE" therapy; that is, group A to standard doses of ICE, group B to augmented ICE, and group C to transplant doses of ICE. The median follow-up of the patients is now 30 months, and patients with multiple risk factors have improved EFS as compared to our previous report.

Summary

In conclusion, HDT and ASCT are standard therapy for patients with relapsed and primary refractory HD, provided chemosensitivity is established. Future studies need to evaluate functional imaging in the transplant setting. In addition, the role of radiotherapy as part of transplant conditioning regimens is not defined in HL, and prospective trials are needed to assess if involved-field radiotherapy can decrease the relapse rate post-ASCT.¹¹⁷⁻¹¹⁹

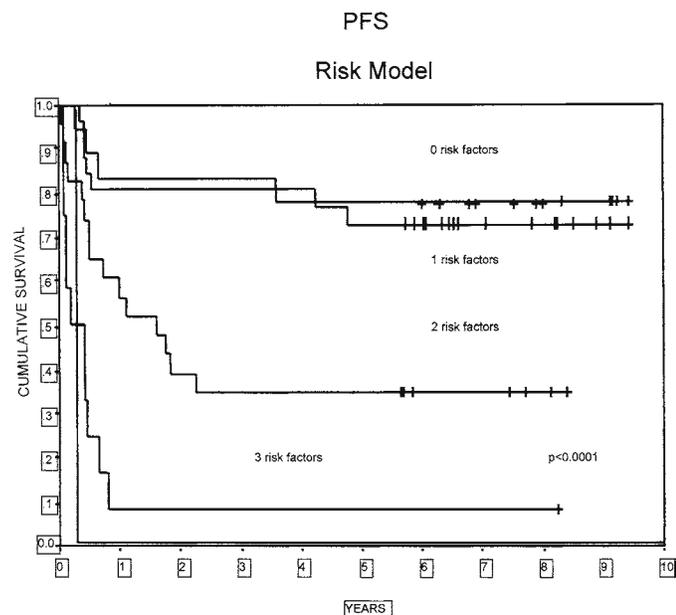

FIGURE 67.2. Progression-free survival (PFS) risk model.

What Is the Evidence That Allogeneic Transplantation Has a Place in the Management of HL?

As described previously, the use of HDT and ASCT is standard therapy for chemosensitive relapsed and primary refractory HL. The indications for and the use of allogeneic stem cell transplantation (allo-SCT) in these patients are poorly defined. The low morbidity with concomitant 40% to 50% long-term PFS rates seen with ASCT has precluded widespread use of allo-SCT. The two main reasons to consider allo-SCT are (1) infusion of a lymphoma-free stem cell product (not a concern in HL), and (2) the graft-versus-lymphoma effect. The major problem with allo-SCT is the high treatment-related mortality compared with ASCT. The EBMT registry recently reported the results of a matched study of allo-SCT for lymphoma for patients treated between 1982 and 1998¹²⁰ that analyzed 1,185 lymphoma transplants. All patients received ablative allo-SCT. All lymphomas were included in the analysis of which 167 patients had HL. Unfortunately, transplant-related mortality in the group of HL

patients was extremely high at 51.7%. In addition, HL was the only lymphoma that showed an inferior relapse-free survival as compared with ASCT. From these data, the conservative use of allo-SCT in patients with HL is correct. Importantly, however, allo-SCT has changed dramatically in the past 5 years with the use of nonmyeloablative approaches.

Reduced-Intensity and Nonmyeloablative Conditioning Regimens

The transplant conditioning regimen in allo-SCT was originally intended to cytoreduce lymphoma while providing immunosuppression to prevent graft rejection. It has become clear in the past decade that the benefit for allo-SCT is largely related to immune-mediated graft-versus-tumor or -lymphoma effect. This premise has led to the use of reduced-intensity (RI) or nonmyeloablative (NMT) conditioning regimens to achieve engraftment and allow for the development of a graft-versus-lymphoma effect as the main form of therapy for the tumor.¹²¹ A few general approaches are currently being used. The nonmyeloablative approaches include using immunosuppressive chemotherapy agents, generally fludarabine, in combination with an alkylating agent. Another technique is based on using low-dose total-body irradiation with or without fludarabine.^{122,123} Last, Mackinnon et al. have led the effort using a T-cell-depleted approach by incorporating the humanized monoclonal antibody alemtuzumab for T-cell depletion, followed by fludarabine and melphalan. Donor lymphocyte infusions are added in patients with residual disease or those not evolving to 100% donor chimerism.¹²⁴ The reduced-intensity conditioning regimen approaches have used standard ASCT conditioning regimens, most commonly BEAM (carmustine, etoposide, cytarabine, and melphalan).¹²⁵ ASCT conditioning regimens can cytoreduce lymphoma, with very low transplant toxicity, and support allogeneic engraftment.

Most reports using either NMT or RI regimens in lymphoma are single-institution studies with fewer than 50 patients, of whom 5 to 15 have HL. It is fairly clear from these reports that NMT offers a reduced risk of early transplant-related mortality compared with conventional transplantation. Despite the lower toxicity, graft-versus-host disease (GVHD) still remains the major limitation of NMT. HL patients with chemorefractory disease achieve minimal benefit. Patients who receive alemtuzumab have a higher incidence of cytomegalovirus reactivation but a lower incidence of GVHD, both acute and chronic. Alemtuzumab-based regimens often require donor lymphocyte infusions to achieve similar tumor control to that of standard regimens.

Reduced-intensity (RI) regimens offer the possibility of early complete donor chimerism as opposed to mixed chimerism often seen with NMT. The largest report is by Faulkner et al., evaluating a BEAM-alemtuzumab RI regimen in patients with lymphoproliferative disorders in which only 5 patients had HL. Sustained, full donor chimerism was seen in 35 of 36 patients.¹²⁶ Treatment-related mortality was 8% in patients who had not failed ASCT but was 50% in those who had failed ASCT. Cooney et al. evaluated BEAM alone in 10 patients with HL who failed ASCT. One year postallo-graft, 9 of 10 patients are alive, with 7 progression free.¹²⁵

Only general recommendations can be made using allo-SCT. (1) A conventional allo-SCT should not be administered

in patients who have failed ASCT. (2) NMT is reasonable therapy for patients who have failed ASCT provided that the disease responds to some form of salvage chemotherapy. (3) In patients with an HLA-identical sibling donor who have poor-risk disease as defined as initial remission duration of less than 1 year with concomitant B symptoms and stage IV disease, RI allo-SCT with regimens, such as BEAM, should be considered instead of ASCT. The use of ASCT for cytoreduction followed by NMT in these poor-risk patients is a reasonable study alternative to RI allo-SCT.

What Is the Evidence That Mantle Radiotherapy Causes Secondary Breast Cancer?

As survival in HL increases, because of the success of initial and second-line therapy, the long-term side effects of this therapy have had a major impact on morbidity and mortality of patients. Recently, Aleman et al. analyzed a group of 1,261 patients with a median follow-up of 18 years post-HL therapy and determined cause-specific mortality. The main cause of death was HL, but after 10 years the main causes of death are similar to the general population; that is, cancer and cardiovascular disease. Unfortunately, the relative and absolute risk of solid tumors and AML, compared to age-matched controls, are markedly increased in HL patients.¹²⁷

The Late Effects Study Group evaluated 1,380 children with HL and determined the incidence of secondary cancers (SC) and the risk factors associated with them. There was 88 SC, either secondary leukemia or solid tumors.¹²⁸ The incidence of secondary leukemia has markedly decreased in the past decade because of the minimal leukemogenic potential of the ABVD regimen as compared to alkylator-based therapy. The focus of this section is to critically review large registry-based databases on secondary breast cancer and recommend strategies to minimize its occurrence without compromising PFS.

In the Late Effects Study Group publication in the *New England Journal of Medicine* in 1996, cumulative incidence of SC was 7.0%, 15 years posttherapy. Solid tumors generally began 12 years postdiagnosis of HL and developed in 56 patients. Breast cancer was the most common solid tumor, occurring in 17 patients. All patients received radiotherapy as part of their HL management. In this young cohort, the risk of breast cancer was 75 times greater than that in age-matched controls and occurred at even a higher rate in those girls radiated between ages 10 and 16. The dose of radiotherapy to the mantle region ranged from 2,000 to 4,750 cGy. The high incidence of breast cancer in this population is most likely related to the effect of radiotherapy on proliferating breast tissue.

The risk of SC was evaluated in a large British cohort of 5,519 patients treated from 1963 to 1993. There was 322 SC in this cohort, but the incidence of breast cancer was very low and was only increased in patients who received radiotherapy alone for the management of their HL. The incidence of breast cancer was also only increased in those women treated with radiotherapy before the age of 25.¹²⁹

Van Leeuwen et al. evaluated 1,253 survivors of HL treated during adolescence or young adulthood in the Netherlands. The median follow-up of these patients at the time of the publication was 14 years. The risk of SC was 7.0; patients

treated before the age of 20 had a 14-fold increase in relative risk of developing a solid tumor, which decreased to 6.5 and 4.2 for patients treated at ages 21 to 30 years and 31 to 39 years, respectively. Once again, for breast cancer, the absolute excess risk increased with decreasing age of initial treatment. Breast cancer risk was increased in all treatment categories except for those patients treated with chemotherapy alone.¹³⁰ Unfortunately, the relative risk of breast cancer in this study was 40, confirming the data of the Late Effects Study Group.

What is likely the definitive study evaluating the risk of breast cancer following radiotherapy and chemotherapy among young women, was recently published by Travis et al.¹³¹ The risk of breast cancer was evaluated in 3,817 women diagnosed before the age of 30, and the goal was to determine estimates of relative and absolute excess risk of breast cancer. Nearly all patients received radiotherapy, with a mean dose of radiation delivered to the breast of 25.1 Gy (range, 12.0–61.3 Gy). The median age at diagnosis of HL was 22, and breast cancer developed in 105 patients at a mean of 18 years posttherapy. Treatment with radiotherapy alone was associated with a 3.2-fold-increased risk of breast cancer, which decreased to 1.4-fold if patients received combined modality therapy consisting of radiotherapy and alkylator-based chemotherapy. The few patients who received chemotherapy alone in this series experienced a reduced risk of breast cancer (relative risk, 0.6). The increased risk of breast cancer occurred at all radiation dose categories but was greatest for patients receiving more than 41 Gy. Interestingly, a decreased risk of breast cancer was associated with the percentage of women who became menopausal from either chemotherapy or radiation to the pelvis. The authors suggest that, if lower doses of radiation to the chest are administered, the relative risk of secondary breast cancer can be attenuated.

In summary, for women who have a history of HL and were successfully treated at a young age, the most significant long-term side effect of therapy is secondary breast cancer. The data are clear: The risk is related to mantle radiotherapy. This risk is increased by the dose of the radiotherapy administered, develops late, usually 15 years or more after initial treatment, and is age related. The highest risk is associated when radiotherapy is administered to young women aged 10 to 20 years; unfortunately, the risk remains markedly increased until the age of 30. Fortunately, primary therapy for HL has changed. All patients now receive chemotherapy as primary treatment of HL, so the role of radiation therapy in management of ESHL is that of consolidation. Hence, the radiation fields are much smaller than in the previously reported registry databases. In fact, the dose of radiotherapy used in modern combined modality series is closer to 25–30 Gy, not 40 Gy as described previously. One hopes that this change in treatment strategy will decrease the risk of secondary breast cancer without compromising PFS.

The Non-Hodgkin's Lymphomas

Andrew D. Zelenetz and Steven Horwitz

The non-Hodgkin's lymphomas (NHLs) represent a group of diseases arising from clonal proliferation of lymphocytes. NHL is the most common hematologic malignancy, with an estimated new patient incidence of 54,000 with 14,000 deaths from disease,¹ accounting for 4% of the new cancer diagnosed in 2004. The NHLs represent a diverse group of diseases with distinctive natural histories and clinical presentations.² This diversity arises from the fact that each of the lymphomas is derived from distinct stages of the complex process of lymphocyte ontogeny. Morphology was the mainstay of diagnosis and classification of NHL for many years. In 1994, the authors of the Revised European and American Lymphoma (REAL)³ sought to create a classification system that defined distinct clinical entities. To accomplish this, the morphologic appearance was supplemented by the incorporation of additional information derived from immunophenotyping, genetics, and clinical features. This classification was the basis for the World Health Organization (WHO) classification of the neoplastic diseases of the hematopoietic and lymphoid tissues.^{4,5} There are 27 entities included in the WHO classification of the non-Hodgkin's lymphoid neoplasms; this number excludes subtypes and subcategories recognized in the WHO classification. The major categories of the WHO classification are shown in Table 68.1.

An exhaustive overview of the management of NHL is beyond the scope of this chapter. Rather, the material herein focuses on the diagnosis, staging, prognostication, and management of the most common diseases and presentations. Very rare entities such as the T/NK (natural killer) lymphoma, adult T-cell lymphoma/leukemia (HTLV)-1-associated adult T-cell lymphoma/leukemia, and Burkitt's lymphoma, among others, are so uncommon that practicing oncologists are likely to encounter them only a few times, if ever, during their career. For these very rare tumors, consultation with a dedicated lymphoma specialist is warranted. Lymphoblastic lymphoma is managed similar to acute lymphoblastic leukemia, as discussed in Chapter 67. The diagnosis and evaluation of small lymphocytic lymphoma (SLL) is similar to that of other indolent lymphoma (see following), although the clinical management is similar to chronic lymphocytic leukemia, as will be reviewed here.

Pathology

In the WHO classification, the initial major discriminator is the cell of origin: B cell versus T/NK cell. The B- and T-cell neoplasms are further classified as being either precursor cell (lymphoblastic) versus mature or peripheral cell. Further discussion of the precursor cell neoplasms is in Chapter 67. The mature or peripheral cell neoplasms of B and T/NK origin make up the vast majority of the cases of NHL. Currently, there is no comprehensive description of the natural history and clinical features of all the NHL diagnoses recognized in the current WHO classification. The characteristics and natural history of the 13 most common entities, comprising about 90% of all the diagnoses of NHL in the United States, have been detailed by the International Lymphoma Classification Project² (Table 68.2).

The distribution of histologic types among 1,403 lymphoma cases has been investigated in the International Lymphoma Classification Project.² Two lymphomas represent more than half of all the cases of NHL in the United States: diffuse large B-cell (DLBCL), 31%; and follicular lymphoma (FL), 22%. Several other types are common (>5%): these include mucosa-associated lymphoid tissue lymphoma (MALT), 5%; small lymphocytic lymphoma (chronic lymphocytic lymphoma type), 6%; peripheral T-cell lymphoma, 6%; mantle cell lymphoma, 6%. All other subtypes are rare or very rare with none seen in more than 2% of cases. The 12 most common subtypes (combining Burkitt's and Burkitt's-like, as is done in the WHO Classification) account for 88% of the diagnoses of NHL in the United States.

Diagnosis

Proper management of NHL begins with an accurate diagnosis, which has traditionally meant an incisional or excisional biopsy to provide adequate material. As already discussed, the WHO classification is not solely dependent on morphology and incorporates immunophenotyping and, in some cases, genetics and clinical information to establish a diagnosis. This change has raised the possibility that the traditional lymph node biopsy could be replaced by fine-needle aspiration (FNA) in conjunction with flow cytometry, which would

TABLE 68.1. World Health Organization (WHO) classification of the non-Hodgkin's lymphomas.

B-Cell Neoplasms	
Precursor B-cell neoplasm	Precursor B-lymphoblastic leukemia/lymphoma (precursor B-cell acute lymphoblastic leukemia)
Mature (peripheral) B-cell neoplasms ^a	B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma
	B-cell prolymphocytic leukemia
	Lymphoplasmacytic lymphoma
	Splenic marginal zone B-cell lymphoma (\pm villous lymphocytes)
	Hairy cell leukemia
	Plasma cell myeloma/plasmacytoma
	Extranodal marginal zone B-cell lymphoma of MALT type
	Nodal marginal zone B-cell lymphoma (\pm monocytoid B cells)
	Follicular lymphoma
	Mantle cell lymphoma
	Diffuse large B-cell lymphoma
	Mediastinal large B-cell lymphoma
	Primary effusion lymphoma
	Burkitt's lymphoma/Burkitt cell leukemia
T-Cell and NK-Cell Neoplasms	
Precursor T-cell neoplasm	Precursor T-lymphoblastic lymphoma/leukemia (precursor T-cell acute lymphoblastic leukemia)
Mature (peripheral) T-cell neoplasms	T-cell prolymphocytic leukemia
	T-cell granular lymphocytic leukemia
	Aggressive NK-cell leukemia
	Adult T-cell lymphoma/leukemia (HTLV-1+)
	Extranodal NK/T-cell lymphoma, nasal type
	Enteropathy-type T-cell lymphoma
	Hepatosplenic gamma-delta T-cell lymphoma
	Subcutaneous panniculitis-like T-cell lymphoma
	Mycosis fungoides/Sézary syndrome
	Anaplastic large-cell lymphoma, T/null cell, primary cutaneous type
	Peripheral T-cell lymphoma, not otherwise characterized
	Angioimmunoblastic T-cell lymphoma
	Anaplastic large-cell lymphoma, T/null cell, primary systemic type

HTLV1+, human T-cell leukemia virus; MALT, mucosa-associated lymphoid tissue; NK, natural killer.

^aB-cell and T-cell/NK-cell neoplasms are grouped according to major clinical presentations (predominantly disseminated/leukemic, primary extranodal, predominantly nodal).

SLL, small lymphocytic lymphoma.

^aThis category includes both Burkitt's and Burkitt's-like, which are combined in the WHO.

have the potential benefit of reduced costs and morbidity. The cytologic diagnosis of lymphoma by FNA has been examined in a large number of series, which have been reviewed.⁶ Overall, a precise NHL diagnosis could be established in 70% of cases representing both initial diagnosis and relapse. There was clearly greater accuracy in diagnosis among the cases suspicious for relapse compared to the initial diagnosis. It is clear that some diagnoses were readily established by the combination of flow cytometry and cytopathology: acute lymphoblastic leukemia/lymphoma as well as SLL/CLL (chronic lymphocytic leukemia). A problem with most of the published series is that they are based on classifying tumors in the International Working Formulation⁷ rather than the REAL or WHO classification in current use. In a series reported by Mourad et al.,⁸ the accuracy of FNA for initial diagnosis was evaluated in a series of 74 cases with classification according to the WHO. This study further evaluated accuracy in diagnosis based on the background and training of the pathologists, comparing dedicated cytopathologists and/or hematopathologists to surgical pathologists lacking this specialized training. The diagnosis of lymphoma was rendered in all cases; however, in only 63% of the cases could the lymphoma be accurately categorized according to the WHO. Flow cytometry significantly enhanced the diagnostic accuracy (84% versus 33%), as did specialized expertise (80% versus 56%). Based on these data, the use of FNA for the initial diagnosis of lymphoma should be discouraged because of the potential for inaccuracy in making a specific diagnosis; however, it can expedite the diagnosis of recurrent disease.⁸⁻¹⁰

In institutions where cytopathologists and/or hematopathologists have appropriate specialized training, FNA may have a greater role, but the surgical biopsy remains the gold standard for diagnosis. The exception to this recommendation is in cases of acute lymphoblastic lymphoma (ALL) and SLL/CLL where a combination of cytopathology and flow cytometry can routinely provide accurate diagnoses. Furthermore, FNA has a role when the differential diagnosis includes lymphoma but an epithelial tumor is considered more likely.¹¹ Given the high potential for a false-negative result in cases that ultimately prove to be lymphoma, it is important that a nondiagnostic FNA be followed by an excisional biopsy.¹¹

Staging and Prognosis

The clinical staging of NHL is taken from the Ann Arbor (AA) staging system developed for Hodgkin's disease as modified at the Cotswold meeting in 1989¹² (Table 68.3). The modification retained the well-known four-stage Ann Arbor system, adding a modifier for bulk (X), and recommending that computed tomography (CT) be included as the method of evaluation of intrathoracic and infradiaphragmatic adenopathy. The staging system is based on the extent of involvement of nodal groups: stage I is a single lymph node group; stage II is multiple lymph node groups on a single side of the diaphragm; stage III disease involves nodal groups on both sides of the diaphragm; and stage IV includes noncontiguous extranodal involvement (e.g., lung nodules, bone marrow). The E modifier denotes direct extension to an extranodal site or isolated involvement of a single extranodal site. A stage is denoted

TABLE 68.3. Cotswold modification of Ann Arbor Staging System.

<i>Stage</i>	<i>Area of involvement</i>
I	Single lymph node group
II	Multiple lymph node groups on same side of diaphragm
III	Multiple lymph node groups on both sides of diaphragm
IV	Multiple extranodal sites or lymph nodes and extranodal disease
<i>Modifier</i>	<i>Description</i>
X	Bulk >10 cm
E	Extranodal extension or single isolated site of extranodal disease
A/B	B symptoms: weight loss >10%, fever, drenching night sweats

clinical (CS) if it is based on physical examination, imaging, and a bone marrow biopsy and denoted pathologic (PS) if confirmed by one more additional biopsy (as in a staging laparotomy). However, in contrast to Hodgkin's disease, NHL does not tend to move through adjacent lymph node groups, thus reducing the general utility of clinical staging. In some of the indolent lymphomas, such as SLL/CLL and FL, bone marrow involvement is so common that most patients have stage IV disease. Furthermore, bone marrow involvement in the indolent lymphomas is not clearly associated with outcome, thereby rendering the clinical staging system of limited value. Frequently, patients are categorized as having early-stage (AA CS I/II) versus advanced-stage disease (AA CS III/IV) as this has been more clinically valuable.

Given the limited value of clinical staging, significant efforts have been undertaken to establish prognostic models that can help guide clinical management and clinical trial design and interpretation. Throughout the decade of the 1980s, a vast number of clinical prognostic models were published that were often developed on limited data sets without validation. Given institutional differences in treatment and patient variables, validation across centers was often difficult. However, these models did identify a number of clinical variables that were important in the prognosis of aggressive lymphoma. To circumvent the limitation of small patient numbers and institutional variation, an international effort was undertaken to identify prognostic factors in patients with aggressive lymphoma treated with anthracycline-based regimens.¹³ From a group of 2,031 patients, five clinical factors [age, performance status, serum lactate dehydrogenase (LDH), extranodal disease, stage] were identified that predicted for both disease-free survival (DFS) and overall survival (OS) (Table 68.4). The 95% confidence intervals of the relative risks of these five variables overlapped, allowing a simple model to be derived based on the number of adverse risk factors: 0-1, low risk; 2, low-intermediate risk; 3, high-intermediate risk; 4-5, high risk. The model divides patients into four similar-sized risk groups with 5-year OS ranging from 26% in high-risk patients to 73% in low-risk patients. A second, age-adjusted prognostic model was derived for patients no more than 60 years of age with only three clinical factors (performance status, LDH, stage) (see Table 68.4). Similar to the full index, the number of risk factors corresponded to the risk group: 0, low risk; 1, low-intermediate; 2,

high-intermediate; 3, high risk. The validation and total samples again divided into four groups, ranging in outcome from 32% in high-risk to 83% in low-risk patients. Although based on retrospective data, both models were derived on a subset of the patients and validated on the remaining patients with similar results. The models have been validated in both aggressive lymphoma as well as other histologies, including follicular lymphoma and mantle cell lymphoma,^{14–16} as well as in relapsed DLBCL.^{17–19} This prognostic model has been very valuable in interpreting trial results as well as in the prospective design of clinical trials for patients with uniform risk.

In patients with follicular lymphoma, the International Prognostic Index (IPI) has more limited clinical utility.²⁰ Although IPI stratifies patients with follicular lymphoma into four risk groups with significantly different outcomes in both progression-free and overall survival, only 11% and 2% of patients fall into the high-intermediate (three factors) and high (four to five factors) risk groups. Others have obtained very similar results when applying the IPI to patients with FL.^{15,21,22} The lack of balance between risk groups limits the utility of the IPI for use in the design of clinical trials.

Recently, a prognostic index specific for patients with follicular lymphoma was published that addresses this limitation.²³ Similar to the IPI, this was an international collaborative effort and included complete data on 4,167 patients. A multivariate analysis identified eight factors that were independent predictors of outcome. To create an easier-to-use index, a subindex containing five variables was evaluated and found to have a very similar predictive value as the eight-factor model. The five factors that comprise the Follicular Lymphoma International Prognostic Index (FLIPI), include number of nodal sites (adverse, five or more); LDH (adverse, greater than normal); age (adverse, age greater than 60 years); stage (adverse, AA III–IV); hemoglobin (less than 12 g/dL) (Table 68.5). Of note, the number of nodal sites is based on a mannequin distinct from that used in the Ann Arbor staging (Figure 68.1). Patients with low-risk disease (zero or one factor, 10-year OS, 70.7%), intermediate risk (two factors, 10-year OS, 50.9%), and high-risk disease (three to five factors, 10-year OS, 35.5%) are divided into similar-sized groups. The IPI and FLIPI share three factors but each is unique in two factors (Figure 68.2); however, these changes enable the FLIPI to be a more clinically useful prognostic model for patients with FL. Thus, the FLIPI could be used to stratify or select patients for risk-adapted therapy trials. The utility of the FLIPI has been validated at relapse in another dataset.²⁴ In a study from Memorial Sloan-Kettering Cancer Center (MSKCC), involving an analysis of 260 patients with FL, the utility of the FLIPI as a reliable means of stratifying prognostic groups was confirmed and, furthermore, histologic grade (1, 2, 3a, 3b) added no additional prognostic information.²⁵

As useful as the IPI has been in serving as a “Rosetta Stone” in the interpretation of clinical trials with differing patient populations and for the design of clinical trials, it does not identify the molecular basis for the prognostic differences. It is through the identification of molecular determinants of prognosis that novel therapeutic targets may be identified. Nonetheless, clinical markers of prognosis represent a very powerful tool in clinical care of the patient.

Prognostic Models Based on Gene Expression Profiles

Gene expression profiling has emerged as an important tool in the identification of prognostic subtypes in hematologic malignancies. A detailed description of the methodology is beyond the scope of this chapter, and the reader is referred to a number of excellent review articles.²⁶⁻²⁹ Briefly, this technology interrogates a tissue or tumor for the expression of thousands of genes simultaneously. The resulting gene expression profile can be analyzed in a number of ways. The two most common analyses are hierarchical clustering and supervised analysis. In hierarchical clustering analysis, spec-

imens are grouped by the relatedness of their overall expression pattern and distinct patterns identified by the construction of dendrograms. The ability of this method to identify distinct subgroups is dependent on the number of subgroups, the sample size, and the distinctiveness of the gene expression profile. This method does not necessarily identify groups with distinct clinical outcome. In supervised analysis, the samples are divided on the basis of known feature of the data set, for example, cured versus refractory. Patterns of gene expression that distinguish between the subgroups are identified. Given the enormous number of genes being examined at one time, an adequate sample size is necessary to identify a robust prognostic model. Furthermore, an

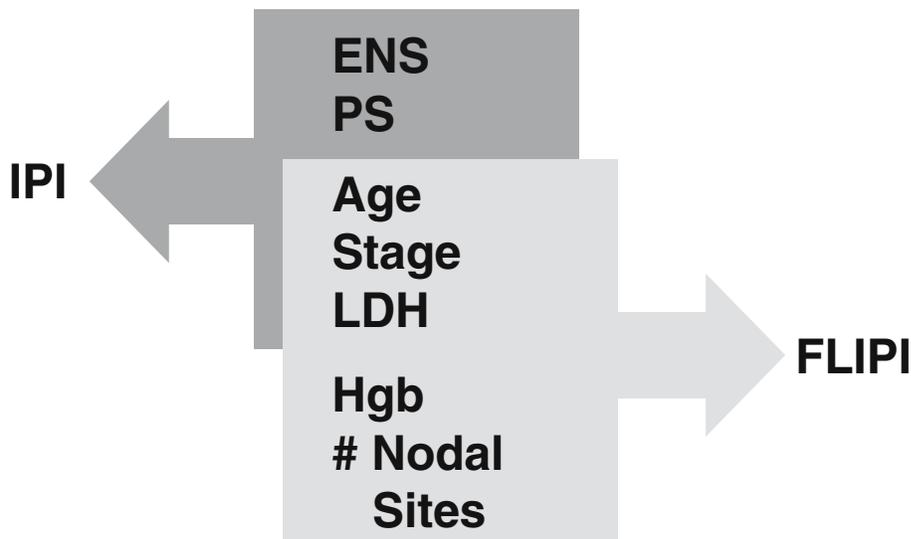

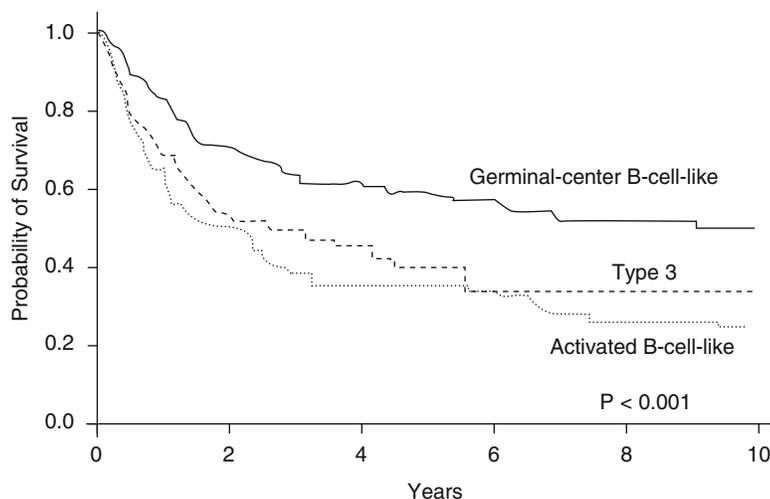

FIGURE 68.2. Similarities and differences between the International Prognostic Index (IPI) and Follicular Lymphoma International Prognostic Index (FLIPI).

No. at risk		0	2	4	6	8	10
Germinal-center B-cell-like	—	115	81	60	46	32	19
Type 3	- - -	52	24	18	10	8	5
Activated B-cell-like	73	35	23	19	8	5

FIGURE 68.3. Outcome of patients with diffuse large B-cell lymphoma (DLBCL) according to the gene expression profile. (From Rosenwald et al.,³² by permission of *New England Journal of Medicine*.)

independent validation sample is ideally needed to confirm the significance of the genes selected in the prognostic model. Both of these approaches have been used to construct prognostic models for NHL.

The initial application of gene expression profiling in lymphoma was conducted by the Leukemia and Lymphoma Molecular Profiling Project (LLMPP). Using the LymphoChip,³⁰ the LLMPP initially identified two molecular subtypes of DLBCL by hierarchical clustering that were named on the basis of the similarity of gene expression with normal B-cell counterparts: germinal center B-cell and active B-cell lymphomas.³¹ This approach was later refined with additional samples into three subgroups with the addition of type III lymphoma.³² Hierarchical clustering per se does not dictate that identified subgroups should have distinct prognoses. Nonetheless, patients with the germinal center B-cell phenotype were demonstrated to have a superior outcome compared to patients with either the activated B-cell or type III, which were very similar (Figure 68.3).³² Currently, gene expression profiling is an investigational tool. Until a simplified technology can be validated in a multicenter setting, the clinical utility of gene expression profiling is limited. This realization led investigators in the LLMPP to determine if routine immunohistochemical markers could differentiate the tumors into germinal center (GC) versus nongermlinal center (non-GC) origins. It has been shown that the results from three antibodies directed at CD10, BCL6, and MUM1 can adequately identify GC versus non-GC.³³

It is very interesting that the molecular prognostic models developed for DLBCL, either based on cell of origin³¹⁻³³ or by supervised analysis to identify genes associated with a poor outcome,³⁴ can subdivide IPI risk groups. This finding suggests that the molecular signatures identified are independent of the IPI and that additional molecular markers remain to be identified that correlate with the clinic prognostic model.

Aggressive NHL: Initial Management of Advanced Stage

The International Working Formulation (IWF) classified NHL by its natural history into three broad groups: low-, intermediate-, and high-grade.⁷ This was an important step in providing some uniformity to clinical trials for NHL. However, IWF intermediate-grade lymphoma, which is referred to here as aggressive NHL, represents a heterogeneous group of disorders, including both B- and T-cell lymphomas. When classified by WHO criteria, aggressive NHL is dominated by DLBCL, with about 10% having peripheral T-cell lymphoma and about 5% other lymphomas. Thus, the results of large-scale trials reviewed here are largely applicable to patients with DLBCL. Patients with DLBCL (including anaplastic B-cell lymphoma) have often been exclusively included in trials developed since the widespread acceptance of the REAL/WHO classification and the development of targeted therapy. Thus, one must be aware that the conclusions drawn from the evidence reviewed here largely apply to DLBCL. A brief discussion of the T-cell lymphoma is included below to help clarify that these entities have unique natural histories and outcomes with therapy.

Evidence for CHOP as the Standard for Aggressive Lymphoma

The publication of the cyclophosphamide, doxorubicin, vincristine, prednisone (CHOP) regimen in 1976³⁵ and the COMLA (cyclophosphamide, vincristine, methotrexate with leucovorin rescue, and cytarabine) regimen in 1980³⁶ ushered in the era of curative therapy for aggressive large-cell lymphoma with approximately 30% of patient achieving long-term remission. In subsequent years, a number of second- and third-generation regimens were introduced for the manage-

ment of aggressive NHL that reported curative outcomes in 55% to 65% of patients. The m-BACOD (methotrexate, bleomycin, doxorubicin, cyclophosphamide, vincristine, and dexamethasone) regimen was typical of a second-generation regimen.³⁷ MACOP-B (methotrexate, doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin)³⁸ and ProMACE-CytaBOM (prednisone, methotrexate, cyclophosphamide, etoposide, cytarabine, bleomycin, vincristine, and methotrexate)³⁹ were representative third-generation regimens. However, many of these studies were performed in single centers with relatively small patient numbers. In 1993, the national high priority intergroup Phase III trial compared CHOP, MACOP-B, ProMACE-Cytabom, and m-BACOD, demonstrating that the outcomes of the four regimens were equivalent and that CHOP was associated with the most modest toxicity. Thus, following this trial, CHOP chemotherapy emerged as the standard regimen for treatment in the United States.

Improvement of Outcome with Increased Dose Intensity and Dose Density

In Europe, the Groupe d'Etude des Lymphomes de l'Adulte (GELA) developed the ACVBP regimen (doxorubicin, cyclophosphamide, vindesine, bleomycin, and prednisone), consisting of an induction phase of intensified chemotherapy and central nervous system (CNS) prophylaxis followed by a sequential consolidation phase.⁴⁰ The GELA conducted a randomized trial to compare the ACVBP regimen to CHOP in previously untreated patients (aged 61 to 69 years) with poor-risk aggressive lymphoma (at least one adverse factor in the age-adjusted IPI). Although there was no difference in complete response rate, the 5-year event-free survival (EFS; 39% versus 29%) and overall survival (OS; 46% versus 38%) significantly favored the ACVBP arm.⁴¹ Building on the CHOP regimen, the German High-Grade Non-Hodgkin's Lymphoma Study Group tested both, the addition of etoposide (CHOEP) to the regimen, as well as increased dose density, comparing standard 21-day cycles to accelerated 14-day cycles (DSHNHL) in both younger and older patients.^{42,43} The toxicity of the CHOEP (when given at both 14- and 21-day intervals) limited the effectiveness of these regimens for patients more than 60 years of age (61 to 75). However, CHOP-14 was superior to CHOP-21 for both EFS (44% versus 33%) and OS (53% versus 41%). For patients younger than 60 years of age, the results were less clear. The 2-week interval did not improve EFS, although there was a marginally significant improvement in OS (85% versus 79%). In the CHOP versus CHOEP comparison, there was a significant improvement in the 5-year estimated EFS (58% versus 69%) but not in the OS. Thus, these data suggest intensification of chemotherapy as with ACVBP, CHOP-14 (in patients 61 to 75), or CHOEP can improve outcomes compared to conventional CHOP given at 21-day intervals. Nonetheless, the failure of multiple second- and third-generation regimens to improve upon the outcomes obtained with CHOP chemotherapy point to the limitation of additional chemotherapy for improving outcome.

Another approach to improving outcome has been the use of infusional chemotherapy. The EPOCH (infusional etoposide, doxorubicin, vincristine with bolus prednisone and cyclophosphamide) was initially tested in 74% of patients with relapsed and refractory disease; 92% of the patients had

had at least four of the drugs previously. The overall response rate was 87%, with complete responses in 27%. A modified regimen, dose-adjusted (DA) EPOCH, was tested in patients with untreated aggressive lymphoma. The dose adjustment was to account for interpatient variability in drug metabolism.⁴⁴ The target was a nadir absolute neutrophil count below $0.5 \times 10^9/L$. Using this approach in 50 patients with newly diagnosed DLBCL, the complete remission rate was 92%. At the median follow-up of 62 months, the progression-free survival (PFS) and OS were 70% and 73%, respectively. Provocatively, the IPI was not associated with outcome. Rituximab has been added to this regimen with improved outcome in selected patients (see following).⁴⁵

High-Dose Therapy as a Component of Initial Therapy

A number of trials have tried to evaluate the role of high-dose therapy with autologous stem cell transplant (HDT/ASCT) in first consolidation for patients with aggressive NHL. The report of the jury of the international consensus conference on high-dose therapy concluded that there were conflicting data regarding the role of HDT/ASCT as consolidation following induction chemotherapy for high-risk patients.⁴⁶ In a subset analysis of the LNH-87 study, patients with high-intermediate and high-risk disease by the age-adjusted IPI had an improved outcome with consolidative HDT/ASCT compared to the conventional therapy in 5-year DFS (57% versus 36%; $P = 0.01$), but the OS benefit was marginally significant (65% versus 52%; $P = 0.06$).^{47,48} In a subset analysis of the Italian Non-Hodgkin's Lymphoma Study Group trial, a similar result was seen in patients with age-adjusted IPI high-intermediate and high-risk disease.⁴⁹ However, in two other studies using an abbreviated course of induction chemotherapy, followed by HDT/ASCT on the investigation arm, compared to conventional chemotherapy on the control arm, demonstrated no superiority for HDT/ASCT consolidation.^{50,51} At the time of the presentation of the LNH-93 trial, the conventional chemotherapy arm had superior EFS (54% versus 41%; $P = 0.01$) and OS (63% versus 47%; $P = 0.003$) compared to the induction chemotherapy followed by HDT/ASCT.⁵⁰ In the German High-Grade Lymphoma Study Group trial, CHOEP \times 5 with involved field radiation therapy (IFRT) was compared to CHOEP \times 3 followed by HDT/ASCT. In this study, survival after relapse was significantly inferior in the HDT/ASCT arm.⁵¹ Another approach to poor-risk aggressive lymphoma has been to intensify the initial therapy. A study from Milan compared MACOP-B to a high-dose sequential (HDS) therapy consisting of high-dose single agents: cyclophosphamide, methotrexate, and etoposide followed by melphalan/total body irradiation with ASCT.⁵² The 7-year EFS (76% versus 49%; $P = 0.004$) favored HDS therapy over MACOP-B. However, there was significant survival advantage for HDS (81% versus 55%; $P = 0.09$), in part, because of the cross-over design of the study. This result raises an important question as to the timing of HDT/ASCT. Is there an advantage to integration of HDT/ASCT as part of initial therapy or is it better to use this approach for patients with recurrent disease after conventional chemotherapy? This question is the subject of ongoing clinical trials; thus, the role of HDT/ASCT as a component of initial therapy for

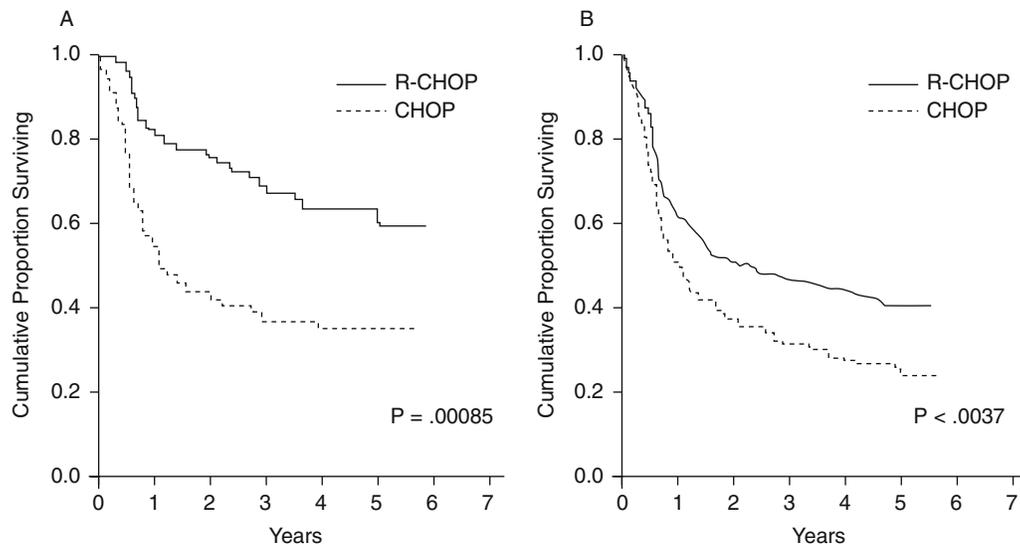

FIGURE 68.4. R-CHOP versus cyclophosphamide, doxorubicin, vincristine, prednisone (CHOP) in patients aged 60–80 with DLBCL: event-free survival (EFS) by age-adjusted IPI. (A) Low-risk patients with IPI scores of 0 or 1; (B) high-risk patients with IPI scores of 2 or 3. (From Coiffier et al.,⁵⁹ by permission of *Blood*.)

poor-risk patients remains investigational as the evidence just discussed does not provide a clear answer.

Addition of Rituximab to Induction Therapy

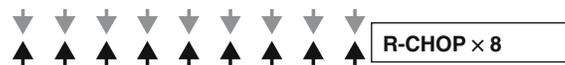

Rituximab is a recombinant chimeric monoclonal antibody with specificity for the human pan-B-cell antigen CD20; it has the original murine variable domain of the parent antibody 2B8 with human IgG-1 heavy-chain and human kappa light-chain constant regions.⁵³ The GELA demonstrated that rituximab had modest single-agent activity with 37% overall response rate in patients with relapsed and refractory DLBCL.⁵⁴ The principal toxicity seen is associated primarily with the initial infusions and, importantly, there is no significant myelotoxicity. The combination of single-agent activity without overlapping toxicity provided a rationale for the combination of rituximab with conventional chemotherapy. A multicenter Phase II study of rituximab (day 1 of each cycle) and CHOP (day 3 of each cycle) for patients with untreated DLBCL was conducted to evaluate safety and efficacy.⁵⁵ Thirty-three patients were treated with six cycles of R-CHOP at 21-day intervals, and the principal toxicities were infusional reactions during the first dose of rituximab and the expected toxicities of CHOP. The addition of the rituximab did not appear to augment the toxicity of the chemotherapy. The overall response rate was 94% with 61% complete responders. At the time of the publication, the follow-up was short (26 months) and the median time to progression had not been reached. Among 13 patients who had a t(14;18) translocation identified by polymerase chain reaction (PCR) at baseline, 11 had molecular remission at the end of therapy. The efficacy was believed to be at least as good as that expected for patients treated with CHOP. Based on these favorable Phase II results, several randomized studies were conducted to see if rituximab enhanced the efficacy of CHOP chemotherapy.^{56–58}

In LNH 98.5, the GELA compared eight cycles of conventional CHOP chemotherapy to eight cycles of the combination of rituximab (day 1 of each cycle) with CHOP (day 1

of each cycle) for patients aged 60 to 80 years.⁵⁶ Addition of rituximab to the CHOP chemotherapy resulted in significant improvement in complete response (76% versus 53%; $P = 0.005$), as well as 5-year EFS (47% versus 29%; P less than 0.00001) and OS (58% versus 45%; $P = 0.0073$).⁵⁹ The benefit has been durable, with increased separation of the Kaplan–Meier survival curves with increasing length of follow-up. The relative benefit of the chemoimmunotherapy is greater in the patients with low- and low- to intermediate-risk disease determined by the age-adjusted IPI; nonetheless, even among the poor-risk patients there is a significant improvement in the outcome (Figure 68.4).

ECOG 4494 examined a very similar patient population (aged 60 and over), although the dosing of the rituximab was different (Figure 68.5).⁵⁷ Two doses of rituximab were administered before cycle 1 and one dose of rituximab was administered before cycles 3, 5, and 7 (if necessary). Treatment was given for six to eight cycles; those in a complete response after four cycles received six cycles and all other patients received eight. In addition to posing the question regarding the role of adding rituximab to CHOP, the trial evaluated the effect of maintenance rituximab (MR) administered for four doses

FIGURE 68.5. Comparison of the schedule of the chemoimmunotherapy arms therapy in the GELA 98-5 and ECOG 4494 trials comparing R-CHOP to CHOP for patients. (GELA, Groupe d'Etude des Lymphomes de l'Adulte; R, rituximab; CHOP, cyclophosphamide, doxorubicin, vincristine, prednisone.)

every 6 months for 2 years. Interpretation of the trial results was complicated by the 2×2 trial design, because it was based on the erroneous assumption that there was no interaction between the randomizations. The overall response rate was unaffected by the second randomization. In contrast to the GELA LNH 98.5 trial, there was no difference in the response rate between the R-CHOP and CHOP (79% versus 76%). Interestingly, the response of the control arm in this trial is similar to the chemoimmunotherapy arm of LNH 98.5. In the pairwise analysis of induction, R-CHOP demonstrated a small benefit at 3 years in EFS (53% versus 46%; $P = 0.04$) but not overall survival. However, this analysis was complicated by the interaction between the induction and maintenance therapies. Because the induction therapy influenced the results of the maintenance, a weighted analysis was performed to elucidate the effect of induction therapy without influence from the maintenance. In this analysis, R-CHOP improved 3-year EFS (52% versus 39%; $P = 0.003$) and OS (67% versus 58%; $P = 0.05$). In the pairwise analysis evaluating maintenance, patients receiving MR had a significant increase in time to treatment failure but not in overall survival. Importantly, the benefit of MR was restricted to patients treated with CHOP induction. The event-free survivals at 2 years for the four treatment groups were R-CHOP, 77%; R-CHOP + MR, 79%; CHOP, 47%; and CHOP+MR, 74%. Thus, E4494 confirmed the benefit of R-CHOP for patients over the age of 60 and demonstrated that in DLBCL MR has no added benefit to induction therapy with chemoimmunotherapy.

Both the GELA LNH 98.5 and ECOG 4494 studies focus on patients 60 years of age and older. Two additional studies have examined the benefit of chemoimmunotherapy for DLBCL in younger patients.^{58,60} The Mint trial was an international intergroup study for patients with untreated DLBCL aged 18 to 60 with low-risk disease (IPI 0 or 1, stages II-IV, and stage I with bulk). Patients were randomized to receive six cycles of a CHOP-like regimen or the same chemotherapy plus rituximab 375 mg/m² given on days 1, 22, 43, 64, 85, and 106. Radiotherapy was planned to sites of initial bulk and/or extranodal involvement.⁵⁸ CHOP-like chemotherapy included CHOEP (44%), CHOP (48%), MACOP-B (4%), and PMitCEBO (prednisolone, mitoxantrone, cyclophosphamide, etoposide, bleomycin, vincristine)⁶¹ (4%); the use of these regimens was balanced in the chemotherapy-alone (CHEMO) and rituximab plus chemotherapy (R-CHEMO) arms. As in the GELA study, the R-CHEMO arm had a higher complete response (CR) (86% versus 68%; P less than 0.0001). This response was associated with an improvement in the estimated 2-year EFS (76% versus 60%; P less than 0.0001) and OS (94% versus 87%; P less than 0.001). This study supports the use of rituximab plus anthracycline-based chemotherapy in the initial management of young patients with very favorable DLBCL; however, it does not directly address patients with poor-risk disease.

Based on the early results of the GELA LNH 98.5 study, the British Columbia Cancer Agency (BCCA) implemented a policy on March 1, 2001, recommending the use of R-CHOP for newly diagnosed patients with advanced-stage DLBCL. To analyze the impact of that policy recommendation, the investigators at the BCCA performed a retrospective analysis comparing the outcomes of patients with newly diagnosed DLBCL for a 3-year period spanning the 18 months before (Pre-R) and

18 months after (Post-R) the policy change.⁶⁰ In the Pre-R group, 9% of the patients received rituximab and in the Post-R group, 85% of the patients received rituximab. Significantly more patients received radiation therapy in the Pre-R group compared to the Post-R (25% versus 15%; $P = 0.04$). For the entire population, the Post-R group had a superior estimated 2-year PFS (71% versus 52%; $P = 0.00009$) and OS (77% versus 53%; $P = 0.0001$) compared to the Pre-R group. However, in the patients younger than 60, the 2-year estimated EFS was not statistically significant (70% post-R versus 60% pre-R; $P = 0.18$). In this subset, the OS was superior (87% post-R versus 69% pre-R; $P = 0.018$), but this finding may reflect differences in second-line therapy in patients treated in different time spans. Although these results confirm the efficacy of R-CHOP in a community setting, they raise a question about the management of younger patients. Clearly, a more careful prospective evaluation of the role of adding rituximab to chemotherapy for young patients with poor-risk DLBCL is necessary.

Rituximab has also been added to the DA-EPOCH regimen.⁴⁵ The complete response rate (CR/CRu) of the 61 evaluable patients was 92%. At the median follow-up of 22 months, the estimated PFS and OS were 79% and 84%, respectively, quite similar to the historical control.⁴⁴ However, in a subset analysis based on the expression of BCL2 as judged by immunohistochemistry, there was an improved outcome in patients whose tumors expressed the BCL2 gene product if they were treated with DA-EPOCH-R compared to DA-EPOCH. Addition of rituximab did not improve the outcome in patients whose tumors did not express BCL2 protein. A similar observation has been made in a retrospective analysis of the GELA LNH 98.5 study.⁶² An analysis of E4494 did not find this relationship between BCL2 protein expression and benefit with rituximab. In E4494, the lack of BCL6 expression was associated with a poorer outcome for patients receiving CHOP (without maintenance) that was not seen in patients receiving rituximab.⁶³ It is possible that in these studies, BCL2 expression or lack of BCL6 expression, is a surrogate for another distinguishing feature, such as nongerminal center lymphomas.³³ Based on these data, it is premature to use the expression of BCL2 protein or the lack of expression of BCL6 protein to select patients for treatment with chemotherapy alone versus chemoimmunotherapy.

Aggressive NHL: Initial Management of Limited-Stage Disease

Radiotherapy Alone for Limited-Stage Aggressive NHL

Before the 1980s, early-stage aggressive lymphoma was initially managed with radiation therapy alone and results depended on the stage at presentation. Patients with clinical stage I disease treated with regional or extended fields could achieve cure rates of approximately 50%. The overall survival of patients with clinical stage II disease treated in a parallel manner was approximately 20%, despite sterilization of the primary site of disease. Selection of patients with pathologic staging and use of total lymphoid irradiation increased the cure rate, but failure was still common.⁶⁴ The failure of radi-

ation therapy to cure early-stage aggressive lymphoma is evidence that systemic disease undetected by clinical staging is commonly present.

Combined Modality Therapy Versus Chemotherapy Alone

Development of effective chemotherapy for advanced-stage aggressive lymphoma led to clinical trials testing the hypothesis that adding chemotherapy to the radiation therapy could improve the control of the systemic, undetected disease through a strategy of combined modality therapy (CMT). A randomized trial of radiation therapy followed by adjuvant CHOP chemotherapy or observation for clinical stage I patients, resulted in significant improvement in 7-year relapse-free survival (RFS) (86% versus 20%) and OS (92% versus 47%).⁶⁵ In this trial, the sequence of CMT was radiation followed by chemotherapy. Although effective, this approach has several practical drawbacks, including the potential of radiation recall with doxorubicin-based chemotherapy, the use of larger fields, and higher doses of radiation to control the primary site of disease. The alternative sequence, chemotherapy followed by radiation, allows for simultaneous cytoreduction of the primary site of disease and treatment of microscopic systemic disease with the potential benefit of permitting smaller radiation fields and lower doses. This approach to CMT is most commonly used in current practice. Chemotherapy followed by involved-field radiation therapy was evaluated in several Phase II studies with favorable results.⁶⁶⁻⁶⁹ This approach was investigated in a Southwest Oncology Group (SWOG) Phase III randomized trial comparing a course of eight cycles of CHOP chemotherapy versus three cycles of CHOP followed by involved-field radiation therapy. When the study was initially published with a median of 5 years of follow-up, there was a significant advantage for PFS (77% versus 64%) and OS (82% versus 72%).⁷⁰ However, subsequent analysis with a median follow-up of 8 years, demonstrated that the advantage of combined modality therapy disappeared as a consequence of late events in the combined modality arm.⁷¹ A stage-modified IPI has been proposed for patients with early-stage disease: CS I versus II; normal versus abnormal LDH; age 60 years or less versus over 60 years; ECOG PS 1 or less versus 2 or more. Patients with zero adverse factors define a very limited-stage group with a 5-year median OS of approximately 90%. Patients with non-bulky disease but having one or more risk factors define a limited-stage group with a 5-year median OS of approximately 70%.⁷² Patients with bulky disease [bulk with mass greater than 10cm or mediastinal mass larger than one-third of the maximal thoracic diameter on posteroanterior (PA) chest radiography] have outcomes similar to those with advanced-stage disease.⁷³ The Eastern Cooperative Oncology Group (ECOG) conducted a randomized study evaluating the role of adjuvant radiation therapy following a full course of eight cycles of CHOP chemotherapy. Patients with a radiographic CR were randomly assigned to involved-field radiation therapy or observation; the study failed to demonstrate a survival advantage for adjuvant low-dose radiation (30Gy) despite a significant improvement in DFS (73% versus 56%) and local control in the CMT arm at 6 years.⁷⁴ The GELA conducted a randomized Phase III trial of ACVBP chemotherapy versus CHOP × 3 and IFRT for patients with CS I or II aggres-

TABLE 68.6. Management of early-stage aggressive lymphoma.

sive lymphoma and no risk factors by the age-adjusted IPI (all patients were 60 years of age or less). At a median follow-up of 7.7 years, the 5-year EFS (82% versus 74%) and OS (90% versus 81%) favored the ACVBP arm. Bulky disease was a poor prognostic factor for both event-free and overall survival. However, in a subset analysis of the patients without bulky disease, EFS and OS still favored the ACVBP arm although the magnitude of the benefit was reduced. The results of these studies are summarized in Table 68.6.

Rituximab as a Component of Early-Stage Disease

The SWOG have presented results of a pilot study investigating the role of chemoimmunotherapy with R-CHOP for three cycles followed by IFRT.⁷⁵ Patients with one or more risk factors in the stage-modified IPI were eligible. Early results suggest an improvement in PFS but not OS compared to historical controls at 2 years. Outside the setting of a clinical trial, the evidence would support the use of R-CHOP × 3 and IFRT for patients with limited-stage disease with risk factors. For patients with very limited stage disease (CS I, no risk factors), CHOP × 3 and IFRT has excellent results. In practice, the very limited-stage patients are not likely to be distinguished from the limited-stage patients and therefore, the addition of rituximab to CHOP would be appropriate, understanding that there is no trial evidence to support this approach. However, definitive evidence of superiority of this approach requires a randomized comparison of chemoimmunotherapy versus chemoimmunotherapy and IFRT. For patients with bulky disease, treatment with regimens appropriate for aggressive lymphoma should be used. Because vindesine is not available in the United States, the ACVBP regimen cannot be used.

Primary Mediastinal Lymphoma

Primary mediastinal large B-cell lymphoma (PMLBL) is a distinct subtype of diffuse large B-cell lymphoma (DLBCL) that accounts for 6% of all non-Hodgkin's lymphoma (NHL).⁷⁶ PMLBL possesses distinctive clinical features, justifying its inclusion as a specific NHL entity in the WHO/REAL classification.^{2,3,5} In contrast to other types of DLBCL, in PMLBL

there is a slight female predominance, younger median age, bulky disease, and uncommon extrathoracic spread at presentation.⁷⁷ Direct extension to the lung, pericardium, chest wall, or pleura is common at presentation and may adversely affect outcomes.^{77,78} Prognostic factor analyses have been inconsistent, and a lack of consensus exists concerning the prognostic utility of the IPI in this disease entity.⁷⁷⁻⁸⁰

Recently, the genetic relationship between PMLBL and DLBCL has been examined using comparative genomic hybridization (CGH). Not surprisingly, similar patterns of BCL-6 gene mutations in the two groups were demonstrated, suggesting a germinal center origin for PMLBL.⁸¹ Expression microarray analysis of PMLBL demonstrates striking similarity to that observed in Hodgkin's disease, which may explain some of the clinical similarities between the two entities.^{82,83}

In general, this entity has been managed similar to DLBCL. There are no trials that have prospectively treated patients with this diagnosis. Therefore, our knowledge about this entity is based on retrospective series, occasionally with conflicting conclusions. The areas of controversy include use of anthracycline-based chemotherapy, upfront HDT/ASCT, dose-dense strategies, and the role of radiation therapy. In the 43 patients identified at the University of Nebraska, the outcome of the patients with PMLBL was similar to those of a large control group of DLBCL.⁸⁴ The GELA identified 141 patients and also concluded that outcome was similar to DLBCL and the management should also be similar.⁷⁷ In a retrospective analysis of 138 patients managed at multiple centers in Italy, treatment with the dose-dense regimens MACOP-B and VACOP-B were associated with superior outcomes compared to CHOP: EFS was 76% versus 40% at P less than 0.001; the OS is not given.⁸⁰ Independent of treatment, there was also a benefit for IFRT versus no radiation ($P = 0.04$), although this was not significant in the multivariate analysis (only attaining a CR and type of chemotherapy were significant). In 141 patients seen at MSKCC, a dose-dense regimen NHL-15⁸⁵ was superior to CHOP and CHOP-like regimens for both EFS (60% versus 34%; P less than 0.001 and OS (84% versus 51%; P less than 0.001).⁸⁶ The effect of RT in this analysis could not be assessed.

The role of rituximab in the management of PMLBL is unknown. The data support the use of dose-dense regimens, such as MACOP-B, VACOP-B, or NHL-15. However, clinical trials specifically for PMLBL or large studies with planned analysis of these patients are necessary to confirm these ret-

spective conclusions. Furthermore, the role of radiation therapy would require evaluation in Phase III trials.

Aggressive T-Cell Lymphoma

T-cell lymphomas form a heterogeneous group of NHLs. They are relatively uncommon, comprising 10% to 15% of all newly diagnosed NHL in the United States. The proportions are reversed in Asia where 70% to 80% of NHL may be of T-cell phenotype. Under the World Health Organization (WHO) classification schema, T-cell lymphomas are divided into disorders that have precursor T cells or are predominantly extranodal or predominantly nodal lymphomas (Table 68.7).

Peripheral T-cell lymphoma (PTCL) represents the largest group of the T-cell lymphomas. PTCL comprised 6% of all NHL in the REAL classification.² In general, T-cell lymphomas are aggressive and have a poor prognosis, with the exception of a few more indolent or favorable subtypes, such as mycosis fungoides, ALK-1-positive anaplastic large-cell lymphoma, and primary cutaneous anaplastic large-cell lymphoma. Most patients with T-cell NHL have a poorer prognosis than their B-cell counterparts. Larger clinical series of T-cell lymphomas report median survivals of less than 2 years and 5-year survival rates between 20% and 30%.^{2,87-89} Failure-free survival for intermediate- and high-risk patients is between 0% and 10% in the larger series with no plateau on the curves for these populations. This poor prognosis is related to both poor sensitivity to chemotherapy, as well as a propensity for T-cell lymphomas to present with poor risk factors.

There are no prospective randomized trials for patients with aggressive forms of T-cell lymphoma. As a result, available outcome data for patients with aggressive T-cell lymphomas are based upon retrospective or subset analyses. In the prirituximab era, patients with aggressive T-cell lymphoma were generally included in trials for aggressive NHL and received the same treatment as patients with DLBCL. In a series from Spain, only 43% (62/144) of patients with non-anaplastic large cell lymphoma (ALCL) T-cell NHL achieved a complete response, whereas a nearly equivalent number, 41% (59/144), were nonresponders to therapy.⁸⁷ In data from the GELA and Mayo Clinic, poor-risk patients had similarly poor response rates in other studies, with CR rates of 42% and 39% when the more favorable patients are excluded.^{89,90}

TABLE 68.7. Classification of the T-cell lymphomas.

<i>Precursor T-cell lymphoma/leukemia</i>	<i>Predominantly nodal</i>	<i>Predominantly extranodal</i>
T-lymphoblastic lymphoma	PTCL, unspecified	Mycosis fungoides
Blastic NK	Angioimmunoblastic-type	Sezary syndrome
LGL	Anaplastic large cell, Alk-1-	ALCL-cutaneous
NK/T-cell leukemia/lymphoma	Anaplastic large cell, Alk-1+	Lymphomatoid papulosis
T-cell CLL/PLL		Subcutaneous panniculitis-like
Adult T-cell		Nasal T/NK
		Enteropathy-type T-cell

Separating and evaluating less favorable patients can be achieved by eliminating favorable histologic subtypes from the analysis and by utilizing the international prognostic index (IPI). As with diffuse large B-cell lymphoma, the IPI can help cull a group of patients with the poorest prognosis.¹³ The simple clinical factors of age (greater than 60 or less than 60 years of age), Stage (I–II versus III–IV), performance status (0–1 versus 2–4), extranodal disease (0–1 site versus 2+ sites), and LDH (normal versus elevated) can separate patients into low, low-intermediate, high-intermediate, and high-risk subgroups. Moreover, the higher-risk patients are overrepresented among the T-cell patients, with 63% to 83% having high-intermediate or high-risk disease at presentation.^{2,89,90} Not surprisingly, the poorest prognosis comes from the higher-risk subgroups. In the GELA series, only 35% of patients with two adverse risk factors and 23% of those with three adverse factors were alive at 5 years.⁸⁹ Similarly poor survival was seen in the Mayo clinic series with 9% of patients with high-risk disease, 28% of patients with high-intermediate risk disease, and only 32% of patients with low-intermediate risk being alive at 5 years.⁹⁰ In the NHL Classification Project, only 10% of high-intermediate or high-risk patients were free from progression at 2 years.⁸⁸

There are few studies on initial therapy specifically for patients with T-cell lymphomas, as most have been treated alongside aggressive B-cell lymphomas with the T-cell patients retrospectively analyzed, as in the series described here. There are no published prospective trials for untreated T-cell lymphoma patients. In a large randomized trial of intermediate-grade lymphoma, CHOP was found to be similar to other combination regimens.⁹¹ Immunophenotype was not assessed, but patients with PTCL were included in this study and CHOP became, and remains, a standard treatment for them. The most homogeneously treated group of T-cell lymphoma patients comes from the GELA series, in which 288 patients with T-cell histology were included in several prospective trials where patients were randomized

according to age, to comparative arms of mBACOD, or ACVB followed by autologous BMT for those in CR, or for older patients, ACVB followed by maintenance therapy or CV(T)P.⁸⁹ It is not possible to conclude a preferred treatment approach from these retrospective series of T-cell patients. However, several principles do emerge. As above, the prognosis for T-cell lymphomas was worse than for B-cell patients, and this difference was primarily seen among the poorer-prognosis patients. Favorable IPI T-cell patients may do as well as their B-cell counterparts. High-dose therapy and autologous stem cell transplantation provided similar results in T- and B-cell patients achieving a CR to initial therapy (see following). Although the outcomes of the transplanted patients are encouraging, only 35% (16/46) patients in this arm achieved a CR, and thus, the majority never became eligible for high-dose therapy.⁸⁹ Hence, the difficulty in treating T-cell lymphomas can be simplified to two problems: poor response to initial therapy, as demonstrated by poor CR rates, and frequent relapses with poor long-term survival for those who do respond.

Aggressive NHL: Treatment at Progression

About half of all patients with aggressive lymphoma either have persistence of tumor following initial therapy (primary refractory disease) or have a relapse after a complete remission. For these patients, high-dose therapy and autologous stem cell transplantation (HDT/ASCT) has been demonstrated to have the greatest potential for a curative outcome (Figure 68.6).⁹² However, this treatment approach has typically been restricted to patients with disease sensitive to second-line chemotherapy.⁹³ For patients in whom HDT/ASCT is not an option because of comorbidities or lack of stem cells, conventional dose chemotherapy has been used with palliative benefit.^{94,95}

Second-Line Chemotherapy

The curative potential of HDT/ASCT is restricted to patients with chemosensitive relapsed disease.⁹⁶ Thus, the effectiveness of the second-line regimen is of paramount importance. To be suitable as pretransplant therapy, a second-line regimen should have the following features: effective cytoreduction, a low incidence of nonhematologic toxicity, a brief duration of therapy, and ability to mobilize peripheral blood progenitor cells.^{97–100} Numerous second-line regimens have been evaluated for the treatment of relapsed and refractory NHL.^{101–107} Some of the most commonly used regimens, ESHAP, DHAP, and mini-BEAM, have some potential limitations that may preclude stem cell transplantation (SCT), including poor stem cell mobilization and nonhematologic toxicities, such as nephrotoxicity (DHAP and ESHAP) and pulmonary toxicity (mini-BEAM). However, these regimens have been used effectively as cytoreduction before HDT/ASCT. The ICE (ifosfamide, carboplatin, etoposide) regimen was developed to minimize the nonhematologic toxicity associated with second-line therapy.¹⁰¹ Overall response rates for various second-line regimens range from 40% to 84% (Table 68.8). There have been limited data on the role of rituximab in second-line therapy. Addition of rituximab to the ICE regimen¹⁰⁵ improved the CR rate compared to a historical control and provided a trend to improve long-term outcome. However, this was in a group of rituximab-naïve patients; the effectiveness in patients already failing chemoimmunotherapy is unknown. There have been no completed randomized comparative trials to determine the standard for second-line therapy.

The second-line regimens have varied in overall response rate and the ability to mobilize peripheral blood progenitor cells, a critical step for successful completion of HDT/ASCT. These are the two most significant parameters in evaluating the effectiveness of a pretransplant cytoreductive regimen. These parameters can be incorporated into a single value, the Mobilization-Adjusted Response Rate [MARR = ORR (%) – Mobilization Failures (%)] (ORR, overall response rate) to evaluate the effectiveness of a cytoreductive regimen.¹⁰⁷ The MARR can be used to evaluate the effectiveness of a second-line therapy as cytoreduction before HDT/ASCT; it is a

primary endpoint in the ongoing CORAL study evaluating R-DHAP versus R-ICE.¹⁰⁸

High-Dose Chemotherapy and Stem Cell Transplant

Patients with relapsed NHL were shown to have favorable outcomes when treated with HDT/ASCT compared to historical controls.^{93,96} Successful cytoreduction by second-line therapy (CR or partial response, PR) was essential to a favorable outcome following HDT/ASCT.⁹⁶ The PARMA study group conducted a randomized Phase III trial of HDT/ASCT versus chemotherapy in patients having had a CR or PR to two courses of second-line chemotherapy. Two hundred fifteen patients were registered to the study and 109 responding patients were randomized: chemotherapy with IFRT ($n = 54$) versus HDT/ASCT ($n = 55$). At 5 years, the EFS (46% versus 12%, $P = 0.001$) and OS (53% versus 32%; $P = 0.038$) favored the patients receiving the HDT/ASCT.⁹² This pivotal study established the curative potential for HDT/ASCT in recurrent disease.

The PARMA study established the role of HDT/ASCT in patients with chemosensitive, relapsed aggressive lymphoma. However, the effectiveness of this approach in patients with chemorefractory disease was not established. Investigators at MSKCC undertook a retrospective analysis of patients treated with ICE followed by HDT/ASCT for refractory aggressive lymphoma.¹⁰⁹ Patients were classified as induction partial responders (IPR; $n = 40$) if they attained a partial response to doxorubicin-based front-line therapy or as induction failures (IF; $n = 45$) if they had less than partial response. Patients in the IPR group had confirmation of active disease by repeat biopsy. The overall response to ICE was 51% with no difference between IF and IPR subsets. In the intent-to-treat analysis (from start of ICE), the estimated 3-year EFS and OS were 22% and 25%, respectively. Among the 42 patients who underwent HDT/ASCT, the estimated 3-year EFS and OS were 44% and 52%, respectively. Thus, the outcome of patients with primary refractory aggressive lymphoma is very similar to those patients with relapsed disease when deter-

mined from the time of HDT/ASCT; however, the response to second-line therapy is lower.

Allogeneic stem cell transplantation offers a tumor-free graft but there is a risk of graft-versus-host disease (GVHD) and graft rejection. A potential benefit is the development of a graft-versus-lymphoma (GVL) effect. Most of the experience is derived from data submitted to transplant registries or retrospective analyses from single centers. No multicenter randomized studies have been conducted comparing autologous and allogeneic sources of stem cells. A review of cases in the European Bone Marrow Transplant registry (EBMT) provided support for a GVL effect with a reduced relapse rate compared to autologous grafts. However, the benefit was outweighed by increased transplant-related mortality with the allogeneic transplants.¹¹⁰ Results from the Ontario transplant registry demonstrated similar survival in patients receiving allogeneic and autologous sources of stem cells despite a lower relapse rate in patients receiving allogeneic stem cells.¹¹¹ In a report from the International Bone Marrow Transplant Registry (IBMTR), 114 patients with recurrent NHL following autologous transplant were analyzed, demonstrating that the transplant was technically feasible, but the 5-year PFS was only 5%, suggesting at best a palliative benefit.¹¹² There has been limited experience with nonmyeloablative allogeneic stem cell transplants for aggressive lymphoma because of the risk of rapid regrowth. A study from the University of Göttingen explored a regimen with intermediate intensity.¹¹³ In this study, the investigators initially T-cell depleted the grafts, followed by unmanipulated grafts with immunosuppression. Although T-cell depletion was associated with a lack of GVHD, the relapse rate was very high; when the T cells were not depleted, the relapse rate was very low but GVHD was problematic. These results support the existence of GVL but point to the difficulty in balancing the GVHD and GVL.¹¹³ Further prospective studies are necessary to determine the role of allogeneic stem cell transplant in the management of recurrent aggressive lymphoma.

Investigators at Stanford University have evaluated the role of rituximab administered as an adjuvant (two 4-weekly courses at day 42 and day 180) following HDT/ASCT in NHL.¹¹⁴ This study included various histologies including DLBCL (71%, $n = 25$), mantle cell lymphoma (MCL) (9%, $n = 3$), and other B-cell lymphomas (20%, $n = 7$). In a subset analysis restricted to the patients with relapsed ($n = 13$) or refractory ($n = 8$) DLBCL, the 2-year estimated EFS and OS were 81% and 85%, respectively. These are very intriguing results, but interpretation is limited because the patients were rituximab naïve; thus, the impact of prior rituximab is unknown. Similar results have been reported for adjuvant rituximab after both autologous and allogeneic stem cell transplant.¹¹⁵ This approach is being tested in an ongoing ECOG trial comparing adjuvant rituximab to observation.

A variety of prognostic models have been developed that have predicted for a favorable outcome post-HDT/ASCT.^{17,19,116,117} In the series from MSKCC, the IPI determined at the start of second-line therapy (sIPI) predicted for estimated 2.5-year failure-free survival (FFS): 45% in patients with low (L) and low-intermediate (LI) risk disease versus 9% in patients with high-intermediate (HI) and high (H) risk disease (P less than 0.001). This analysis was undertaken on a larger group of patients with relapsed and refractory DLBCL and the best discriminator for outcome was sIPI L/LI versus

HI/H risk disease.¹⁹ The predictive significance of the IPI was confirmed in an analysis confined to those patients who underwent HDT/ASCT.^{18,19} Another important factor was the quality of response to second-line therapy, with superior outcome for patients in CR at time of transplant versus those in PR.^{19,117} Thus, it is possible to identify patients with poor outcome with sequential second-line therapy followed by HDT/ASCT. The patients with low- and low-intermediate risk disease do very well with conventional treatment. However, patients with high-intermediate and high-risk disease are poorly served with the conventional approach and should be enrolled in clinical trials.

Indolent Lymphoma: General Considerations

Indolent NHL can be of either B-cell or T-cell phenotype, although the B-cell tumors are far more common. With conventional chemotherapy, patients with indolent B-cell lymphoma have a chronic remitting and relapsing course with a median survival of 10 years and a steady drop in the survival curve without a plateau. Furthermore, the outcome did not change substantially from the 1960s to the early 1990s.¹¹⁸ The introduction of targeted therapy with rituximab and subsequently, with yttrium-90 ibritumomab tiuxetan and iodine-131-tositumomab has provided important new therapeutic modalities but evidence of curative outcomes remains elusive. Therefore, management of indolent lymphoma requires clinicians, like chess players, to think a few moves ahead to try to optimize the sequence of therapy over the course of a chronic illness. Considerations, such as age, comorbidities, prior therapy, symptoms, extent of disease, and impact on end-organ function all affect therapeutic decisions (Table 68.9). The data discussed in the section emphasize approaches to treatment rather than the sequence of therapy, because the treatment sequence is often highly individualized in the absence of curative outcome.

The reader should note that it is impossible to be exhaustive in this review of the management of indolent lymphoma because of space constraints. The reader is referred to excellent reviews on the role of interferon alpha in the management of indolent lymphoma.¹¹⁹⁻¹²⁴ Interferon-alpha is a therapy that has not gained wide acceptance in the United States. No information regarding vaccine is presented because the critical randomized trials are ongoing and without them, understanding the effectiveness of vaccine is impossible.

The indolent lymphomas are characterized by a risk of transformation to an aggressive lymphoma, generally recognized as a poor prognosis with short survival.¹²⁵ However, in the retrospective review of 74 patients with transformation

	Transformation

FL, follicular lymphoma; IPI, international prognostic index.

at Stanford, a subgroup of patients with a favorable outcome after transformation could be identified.¹²⁶ The median time to transformation was 66 months. Factors associated with a good prognosis following transformation, included limited prior therapy (none versus any), limited stage (I/II versus III/IV), and response to prior therapy (CR versus PR or none). Thirty of the patients had a CR after treatment for transformation, and the response duration (RD) was 81 months.

Indolent Lymphoma: Initial Management

Early Stage

MALT lymphoma is the prototype of a localized indolent lymphoma. In contrast, limited-stage early-stage follicular lymphoma is uncommon. Gastric MALT lymphoma, the most common subtype, is associated with *Helicobacter pylori* infection. Numerous studies have demonstrated that clinical remissions can be induced in most cases; however, molecular testing reveals persistence of disease in at least 50% of cases.¹²⁷ Late relapses occur, which are sometimes self-limited, and careful clinical monitoring is essential. A subset of patients fail to respond to or recur following antibiotic therapy; this can be seen particularly in patients with a t(11;18) translocation activating API2-MLT1.^{128,129} These patients can be effectively managed with IFRT with excellent long-term disease control.¹³⁰ MALT lymphoma at other sites can also be effectively controlled by IFRT.¹³¹

About 15% of patients with follicular lymphoma (FL) presented with localized disease, and retrospective studies have demonstrated excellent disease control with IFRT.^{132,133} In the Stanford series, 177 patients with FL, grades 1 and 2, were treated (CS I, $n = 73$; CS II, $n = 104$) with IFRT, and the median OS was 13.8 years; relapse after 10 years was uncommon. In a provocative retrospective analysis, the Stanford group identified 43 patients (CS I, $n = 11$; CS II, $n = 32$) who were observed for early-stage FL, grades 1 and 2.¹³⁴ Radiation was deferred for a variety of reasons. At the median follow-up of 86 months, 63% had not been treated and survival was similar to patients who had undergone IFRT.

The European Organization for Research and Treatment of Cancer (EORTC) conducted a study of radiation in early-stage NHL. Patients with stage I disease were randomized to IFRT or IFRT followed by CVP.¹³⁵ Although FFS favored the combined modality (CMT) arm, it did not affect on overall survival. The MDACC did a study of CHOP-B (CHOP with bleomycin) with IFRT for localized low-grade lymphoma and have reported long-term results; the 10-year time to treatment failure (TTTF) and OS were 76% and 82%, respectively.¹³⁶ A randomized trial is required to determine if CMT has a survival advantage over IFRT alone.

Management of Advanced Stage

Observation

Long-term follow-up has confirmed the incurability of this disease with conventional therapy.¹¹⁸ Because indolent lymphoma is a chronic illness, it is reasonable to postpone initial therapy in asymptomatic patients. The natural history of

patients without bulky lymphadenopathy or symptoms was examined. The overall survival at 10 years was 73%, and the median time to first treatment was 3 years; spontaneous remissions were seen in 23% of patients.^{137,138} The deferral of initial therapy has been examined in prospective randomized trials.^{139,140} The National Cancer Institute (NCI) conducted a study of observation ($n = 44$) (which permitted limited radiation therapy) versus an aggressive regimen of ProMACE-MOPP (prednisone, methotrexate, doxorubicin, cyclophosphamide, etoposide alternating with mechlorethamine, vincristine, procarbazine, prednisone) followed by total nodal irradiation (TNI; $n = 45$) in patients with indolent lymphoma.¹³⁹ At 34 months, 56% of the patients on the observation arm had not required therapy. There was no survival disadvantage to the patients on the observation arm compared to the chemoradiotherapy arm. The Groupe d'Etude des Lymphomes Folliculaires (GELF) compared observation to prednimustine or interferon-alpha for patients with low tumor burden lymphomas.¹⁴⁰ One hundred ninety-three patients were randomized to the three arms with well-balanced clinical characteristics. The median time to treatment was 24 months in the deferred treatment arm. The overall response to treatment, when started in the deferred treatment arm was 70%, which was not different from the overall response in the two treatment arms (78% for prednimustine, 70% for interferon-alpha). Estimated 5-year OS was not affected by deferred therapy (78% observation, 70% prednimustine, 84% interferon-alpha). Selection of patients is important, and the GELF has proposed criteria predicting poor outcomes that have been modified by the National Comprehensive Cancer Network (Table 68.10).^{140,141} The limitation of these data is that all predate the era of immunotherapy in the management of indolent lymphoma. However, since the use of immunotherapy has not affected OS (see following), observation is an appropriate option for selected patients. Deferral of therapy preserves future treatment options without compromising survival.

Chemotherapy

Indolent lymphomas are sensitive to a wide range of chemotherapy, either alone or in combination. It is beyond the scope of this chapter to review the extensive literature regarding the activity of lymphoma in indolent lymphoma. Rather, the focus is on higher-level evidence from randomized trials that help us understand the comparative benefits

of different chemotherapy. In the indolent lymphoma, it is very important to have long-term follow-up because high remission rates are not always associated with superior survival.

The Cancer and Leukemia Group B compared two approaches for the initial management of follicular lymphoma, grades 1 to 2: single-agent therapy versus combination therapy with known curative potential in aggressive disease.¹⁴² The study randomized 228 patients between cyclophosphamide (arm 1) and CHOP-B (CHOP with bleomycin) (arm 2), and the complete response rates were the same in the two arms (66% versus 60%; $P = 0.36$). The 10-year FFS (25% versus 33%; $P = 0.107$) and OS (44% versus 46%; $P = 0.79$) were also not affected by the treatment arm. In a subset analysis of 46 patients with FL, grade 2, the combination therapy was associated with better FFS (9% versus 48%; $P = 0.005$) and OS (25% versus 61%; $P = 0.24$). These results were from an unplanned subset analysis, and the benefit should be confirmed in a larger study. However, it is interesting that a similar observation was reported by the NCI using ProMACE-MOPP.¹⁴³

The role of doxorubicin as a component of initial therapy in indolent lymphoma has been an area of controversy. Retrospective studies have suggested that the addition of doxorubicin did not add to the median overall survival in patient with indolent lymphoma.¹⁴⁴ A trial from the Hospital Saint-Louis in France compared C-MOPP (cyclophosphamide, vincristine, prednisone, procarbazine) to the same regimen with doxorubicin added.¹⁴⁵ The trial identified no difference in EFS or OS with the addition of rituximab to initial therapy; interestingly, the study also found no difference in the risk of transformation to aggressive lymphoma.

Multiple Phase II studies demonstrated activity of fludarabine in patients with untreated as well as relapsed indolent lymphoma. An Italian multicenter trial group evaluated the role of fludarabine in the management of indolent lymphoma in two randomized trials.^{146,147} The first trial compared the single agent fludarabine (F) to the combination of fludarabine and idarubicin (FI) in patients with newly diagnosed indolent and mantle cell lymphoma.¹⁴⁶ The addition of idarubicin did not change overall survival for the entire population, again suggesting that initial therapy with an anthracycline dose did not improve survival in indolent lymphoma. In the follicular lymphoma subset (the only group large enough to be analyzed by itself), there were more CRs (60% versus 40%; $P = 0.007$) with F versus FI, although PFS was greater in the FI arm. This result is difficult to explain. Nonetheless, it establishes fludarabine as an active drug for indolent lymphoma. The second trial compared fludarabine and mitoxantrone (FM, $n = 72$) (with or without rituximab) to CHOP ($n = 68$) (with or without rituximab) in patients with follicular lymphoma.¹⁴⁷ In this trial, molecular remissions were determined by PCR amplification of the t(14;18) translocation. If patients achieved a molecular remission (CR-), they received no further therapy. However, if the molecular test was positive (CR+), patients received adjuvant rituximab. FM had a higher rate of both CR (68% versus 42%; $P = 0.003$) and CR- (39% versus 19%; $P = 0.001$) than the CHOP arm. Rituximab increased the CR- rate in both arms, but the final CR- rate favored the FM ± R arm (71% versus 51%; $P = 0.01$). However, in a short follow-up of only 19 months, there is no difference in PFS or OS.

Rituximab Immunotherapy

The development of the chimeric monoclonal antibody rituximab (C2B8) has been altering the therapy of indolent lymphoma.⁵³ In the early Phase I single-dose, dose-escalation trials, tumor regressions were seen (2 PR and 4 minor responses in 15 patients).¹⁴⁸ A subsequent four weekly dose-finding study identified a biologically effective dose of 375 mg/m², again with clinical responses that were particularly frequent in patients with indolent lymphoma.¹⁴⁹ The subsequent "pivotal" study was a Phase II design that included 166 patients with relapsed and refractory indolent lymphoma treated with four weekly doses of rituximab.¹⁵⁰ The overall response rate was 48%, and the median time to progression was 13 months. The overall response rate was higher in patients with follicular lymphoma (60%) than in the patients with SLL (IWF A) (12%). Based on these data, the U.S. Food and Drug Administration (FDA) approved the clinical use of rituximab for patients with relapsed and recurrent follicular lymphoma. A subsequent Phase II study at the same dose and schedule demonstrated that patients initially responding to rituximab could be retreated at time of progression but the response rate was only 40%.¹⁵¹ These data ushered in the era of immunotherapy that has fundamentally altered the treatment of B-cell NHL. Although these data demonstrate that rituximab has substantial activity, they do not inform us as to the optimal use of this agent.

Rituximab has been used to treat newly diagnosed indolent lymphoma with response rates ranging from 52% to 73% with a PFS of about 12 months.¹⁵²⁻¹⁵⁴ Building upon the single-agent activity in indolent lymphoma, investigators from the Sarah Cannon Cancer Center, evaluated planned retreatment with four weekly courses of rituximab at 6-month intervals.¹⁵⁵ This study demonstrated a 34-month PFS and an increasing CR rate with time. However, the Phase II study design made it difficult to ascertain if either of these observations was superior to a single four week course. The Swiss Group for Clinical Cancer Research (SAKK)¹⁵⁶ examined the role of extended dosing in a randomized trial. Patients were treated with a standard 4-week course of rituximab, followed by a randomization to observation or prolonged therapy given as one dose of rituximab every 8 weeks for four doses; patients with progression after the initial rituximab were excluded from the randomization. Of 185 patients enrolled, the ORR to the rituximab was 67% in chemotherapy naïve patients and 46% in previously treated patients; 151 patients were eligible for randomization. At a median follow-up of 35 months, the median EFS favored the prolonged therapy group (23 months versus 12 months; $P = 0.02$) with a larger benefit in the chemo-naïve subset (36 months versus 19 months; $P = 0.004$). Interestingly, the CR rate was identical in both treatment groups, suggesting that achievement of CR did not require additional rituximab. IgM plasma levels decreased for a significantly longer time after prolonged treatment, but this was not associated with an increased infectious risk. These data support the idea that EFS can be extended with maintenance or prolonged rituximab.

A randomized Phase II study was conducted to determine if maintenance rituximab (four weekly doses every 6 months) was superior to retreatment with four weekly doses of rituximab at disease progression.¹⁵⁷ Patients ($n = 114$) were treated with rituximab and randomized ($n = 90$) if they had stable or

responding disease. The endpoint of the study was the duration of rituximab benefit, which was the same between the two arms: maintenance, 31 months versus retreatment groups, 27 months. However, this randomized Phase II trial does not have sufficient power to draw definitive conclusions, and the ECOG is conducting a large Phase III study (RESORT) to address the question of maintenance versus retreatment at progression.

Chemoimmunotherapy

Phase II studies have suggested that rituximab can add to the clinical benefit of combination chemotherapy in patients with indolent lymphoma. For example, compared to historical controls, rituximab improved the EFS with single-agent fludarabine as well as CHOP.^{158,159} However, small trial sizes and potential selection biases make definitive conclusions impossible to draw. A series of randomized studies have been undertaken to address this question in untreated and relapsed indolent lymphoma.

The German Low Grade Lymphoma Study Group (GLSG) examined the impact of adding rituximab to the FCM (fludarabine, cyclophosphamide, mitoxantrone) regimen in patients with relapsed or refractory FL and MCL.¹⁶⁰ Of 147 patients randomized, 128 were evaluable. In the FL patients, the ORR (94% versus 70%) favored the R-FCM arms. In the FL patient subgroup, there was a benefit in median PFS for the R-FCM, patients (not reached at 3 years) versus FCM (21 months), at $P = 0.0139$. At 2 years, the estimated OS is 90% in R-FCM, as compared with 70% on the FCM arm ($P = 0.0943$). Thus, in rituximab-naïve patients with recurrent disease, rituximab adds a palliative benefit to chemotherapy (no impact on OS) in patients with FL.

A multicenter study in England examined the addition of rituximab to CVP chemotherapy.¹⁶¹ The chemotherapy was a modified CVP with a low dose of cyclophosphamide (750 mg/m²) and prednisone (40 mg/m²). Patients treated with R-CVP had significantly improved OR and CR rates, as well as TTF. However, the study had an unusual definition of time to treatment failure (TTF), considering patients with less than a PR after four cycles as a treatment failure, and this had an disproportionate impact on the chemotherapy arm. Therefore, the TTP is a more reliable comparison in this trial. TTP for R-CVP and CVP was 32 months and 15 months (P less than 0.0001). Although the results in the control arm seem to be suboptimal, this was a study with about 50% of patients with FLIPI high-risk disease. Thus, cross-trials comparisons must be made carefully and take into account the differences in study populations.

The rationale for the combination of rituximab with chemotherapy has been in vitro demonstration with various chemotherapeutic agents.¹⁶²⁻¹⁶⁴ One of the demonstrated synergies was with doxorubicin,¹⁶² which provided the rationale for the R-CHOP regimen.¹⁵⁹ The GLSG conducted a randomized trial of CHOP versus R-CHOP in FL.¹⁶⁵ The study has a second randomization evaluating two doses of interferon-alpha in patients over 60 years of age and evaluating HDT/ASCT versus interferon-alpha in patients 60 years of age or younger. Preliminary results have demonstrated that R-CHOP has superior OR and CR rates. In this study, 606 patients were randomized. However, at the time of presentation, only 394 patients were evaluable. R-CHOP provided

only a modest increase in OR and CR rates. However, R-CHOP significantly increased the median TTF (P less than 0.0007). In the R-CHOP arm at a median follow-up of 3 years, the median TTF had not been reached, compared to 2.6 years for CHOP. However, the analysis is complicated by the second randomization, and further follow-up is necessary to determine if there is a survival benefit.

These randomized trials indicate that rituximab added to chemotherapy can improve OR, CR, and EFS or PFS, but the impact on OS is not yet clear, which is in contrast to the data presented earlier for DLBCL. The long natural history of FL confounds the survival endpoints in these studies. If the data ultimately demonstrate a survival advantage, there will be no controversy regarding the inclusion of rituximab in upfront treatment. However, if the benefit is only on PFS or EFS and not OS, then the timing of the use of rituximab may become crucial. Because patients develop resistance to rituximab, its use early in the course may compromise the later effectiveness of the drug. Thus, further follow up of the chemoimmunotherapy trials is essential.

External-Beam Radiation Therapy and Radioimmunotherapy

Radiation Alone

The role of radiation therapy in the management of indolent lymphoma has been studied for many years. The limitation has been the systemic nature of the disease and the limitation of external-beam radiation therapy (EBRT). Nonetheless, several randomized studies have evaluated the role of EBRT in indolent lymphoma. Radioimmunotherapy (RIT) can be delivered to multiple sites and is effective. However, there are limited randomized data that examine the relative potential of RIT in different patient populations.

Advanced-stage indolent lymphoma is a systemic disease, and when EBRT is used alone total-body irradiation (TBI) is necessary. This approach has been studied in a number of Phase II studies demonstrating feasibility and efficacy.¹⁶⁶⁻¹⁶⁸ A randomized comparison of chlorambucil and prednisone (CP) versus TBI was conducted in 108 patients with indolent lymphoma.¹⁶⁹ The various histologic subtypes were stratified to the two treatment arms. The CR rate and OS for all histologies were not different between the two arms: 59% for CP versus 52% for TBI, and 53 months for CP versus 57 months for TBI. In the subset of patients with FL, there were no significant differences in CR rate or OS. The EORTC conducted a similar trial comparing low-dose TBI to CHVmP (cyclophosphamide, doxorubicin, teniposide, prednisone) in patients with FL.¹⁷⁰ There were 93 patients (84 evaluable): 44 received TBI and 40 CHVmP. The ORR rates, EFS, and OS were not different between the arms. These data support that TBI can be effective for the treatment of indolent lymphoma but that the technical limitations are significant. However, the results provide a sound rationale for the development of the use of RIT.

Two anti-CD20 radioimmunotherapy agents have been approved by the FDA: ⁹⁰Y-ibritumomab tiuxetan and ¹³¹I-tositumomab. In Phase II studies, both agents have demonstrated activity in patients with relapsed and refractory indolent lymphoma, in rituximab-refractory patients, and in transformed lymphoma with ORR (40%–84%) and TTP of 8

to 16 months.¹⁷¹⁻¹⁷⁷ The remissions following RIT can be very durable in a subset of patients.¹⁷⁸ Toxicity of the treatment is largely hematologic. The risk of secondary leukemia is similar to other patients with multiply recurrent indolent lymphoma.¹⁷⁹

Two randomized studies have been conducted to demonstrate superiority over unlabeled antibody. A comparison of the murine antibody tositumomab was compared to ¹³¹I-tositumomab to determine if the radioisotope contributed to the efficacy of the drug.¹⁸⁰ Seventy-eight patients were randomized. ORR significantly favored the radiolabeled antibody compared to the unlabeled antibody: 55% versus 19%, $P = 0.002$. Median response duration (not reached versus 28.1 months) and TTP (6.3 months versus 5.3 months; $P = 0.031$) favored the radiolabeled antibody. Patients with disease progression after tositumomab could cross over to the ¹³¹I-tositumomab arm. Following cross-over to RIT, the ORR (68% versus 16%; $P = 0.002$), median response duration (12.6 versus 7.6 months; $P = 0.001$), and median TTP (12.4 versus 5.5 months; $P = 0.01$) were superior to results with prior unlabeled antibody response. This trial clearly demonstrates that the radioisotope adds efficacy to the treatment.

The second randomized trial rituximab was compared to ⁹⁰Y-ibritumomab tiuxetan to determine if the radioantibody was superior to the chimeric unlabeled antibody.¹⁸¹ The primary endpoint was ORR, and it was underpowered to identify differences in PFS. One hundred forty-three patients were randomized to R alone (70) or RIT (73). The OR and CR rates favored the RIT arm: 80% versus 56%, $P = 0.002$; 30% versus 16%, $P = 0.04$. TTP was not different between arms, but durable responses of 6 months or greater were seen more often following RIT than R (64% versus 47%; $P = 0.03$). These data support the conclusion that RIT provides superior responses, but larger randomized trials are needed to demonstrate if there are benefits in EFS and OS.

Chemotherapy Followed by Radiation

Investigators from Mexico evaluated the role of adjuvant radiation in patients with follicular lymphoma (FL) achieving a CR after initial therapy.¹⁸² Four hundred sixty-nine patients were randomized to observation (control) or to adjuvant radiation therapy to initial sites of bulky disease. At 20 years, there was an advantage for both EFS (41% versus 68%; P less than 0.01) and OS (71% versus 89%; $P = 0.01$). Treatment-related mortality and the secondary myelodysplastic syndrome/acute myelogenous leukemia (MDS/AML) were identical in the two arms.

RIT could provide radiation to all sites of disease without the toxicity and technical difficulty of TBI. SWOG conducted a pilot study (S9911) to evaluate the safety and efficacy of adjuvant ¹³¹I-tositumomab following a course of six cycles of CHOP chemotherapy.¹⁸³ Toxicity was primarily hematologic and was more severe during the chemotherapy than during the RIT. The ORR was 90%. The final response after RIT improved in 57% of the patients who had had less than a CR to CHOP. The estimated 2-year EFS and OS were 81% and 97%, respectively. This trial established the feasibility of sequential chemotherapy and RIT. It is currently being evaluated in a Phase III comparison to rituximab and CHOP chemotherapy (SWOG S0016).

RIT Summary

The optimal use of RIT has not been determined. A recent provocative study of ¹³¹I-tositumomab as initial therapy for FL from the University of Michigan demonstrated high response (OR 95%, CR 75%).¹⁸⁴ Using PCR for the t(14;18) translocation, 80% of the informative patients had molecular remissions. The median PFS was 6.1 years. Toxicity was principally hematologic. These results suggest that in selected patients a single course of RIT can have substantial long-term benefit. Taken together with the CHOP followed by the RIT study already cited, results suggest that RIT may have an important role in the management of indolent lymphoma. However, to determine the appropriate placement in the treatment algorithm for FL, additional randomized trials are necessary.

Transplant

The role of stem cell transplant has been somewhat limited in indolent lymphoma for several reasons. First, these lymphomas are generally seen in older patients for whom stem cell transplant may not be appropriate. Second, the natural history is long, and determining when in the course of treatment to use these therapies is not always clear. Retrospective data from the University of Nebraska suggest the HDT/ASCT should be done in second or third remission; the use of this approach later is no different from in other salvage chemotherapy.¹⁸⁵ Several randomized studies have tried to address the role of stem cell transplant in indolent lymphoma.

The European CUP trial posed the question whether conventional chemotherapy (C) versus HDT/ASCT with unpurged (U) or purged (P) stem cell products was superior for relapsed FL.^{186,187} Of 140 patients registered, 89 patients were randomized. Patients were initially treated with three cycles of CHOP. Responding patients were eligible to proceed to the randomized arm. At the median follow-up of 69 months, HDT/ASCT (both U and P) by the log rank test were significantly superior in PFS ($P = 0.0037$) and OS ($P = 0.079$). The estimated 2-year PFS for C, U, and P were 26%, 58%, and 55%, respectively. Estimated 4-year OS for C, U, and P are 46%, 71%, and 77%, respectively. Thus, in young patients with chemosensitive recurrent FL, HDT/ASCT appears to provide a survival advantage. Purging did not appear to have an effect on outcome.

The GLSG conducted a trial of HDT/ASCT or interferon (INF) in first remission of patients with FL younger than 60 years of age.¹⁸⁸ Three hundred seven patients underwent induction chemotherapy with two cycles of CHOP or MCP (mitoxantrone, chlorambucil, prednisone) and were then randomized to the HDT/ASCT or INF groups. Induction chemotherapy continued until patients had achieved a CR or PR. Two hundred forty patients with FL were evaluable for the comparison of INF versus HDT/ASCT. Of note, patients progressing after INF could cross over to HDT/ASCT, complicating the OS analysis. The PFS favored the HDT/ASCT arm (65% versus 33%; P less than 0.0001). The overall survival curves are identical between the arms, but longer follow-up is necessary. Late transplant complications have not been seen.

A very similar study has been conducted by the Group Ouest Est Leucemies Aigues Myeloblastiques (GOELAM)

study group of a randomized trial comparing CHVMP-INF and induction chemotherapy followed by HDT with purged ASCT in newly diagnosed advanced-stage FL patients.¹⁸⁹ One hundred seventy-two patients were randomized. The HDT arm has a superior OR rate (81% versus 69%; $P = 0.045$) and a longer median EFS (not reached versus 45 months). However, there was no OS advantage because of an excess of secondary malignancies after transplantation. Thus, in neither randomized study of upfront HDT/ASCT has a survival advantage been seen; therefore, this approach should still be considered investigational in the treatment of advanced-stage indolent lymphoma.

Allogeneic stem cell transplant has been used to treat recurrent and refractory indolent lymphoma. However, most reports are small case series. No randomized trials have been conducted. The best quality evidence we have available is from the transplant registry. A joint report from the IBMTR and ABMTR identified 904 patients transplanted with FL, and sought to compare outcome following autologous and allogeneic stem cell transplant.¹⁹⁰ A total of 176 (19%) received allogeneic, 131 (14%) received purged autologous, and 597 (67%) received unpurged autologous transplants. Treatment-related mortality at 5 years was allogeneic SCT, 30%; purged ASCT, 14%; and unpurged ASCT, 8%. Recurrence at 5 years was allogeneic SCT, 21%; purged ASCT, 43%; and unpurged ASCT, 58%. Estimated 5-year survival was allogeneic, 51%; purged ASCT, 62%; and unpurged ASCT, 55%. TBI was associated with higher treatment-related mortality (TRM) but lower recurrence. In this retrospective registry analysis, there was a suggestion of a benefit for purged stem cells not seen in the CUP trial (see above). The toxicity of allogeneic SCT appears to offset the benefit; thus, unless TRM can be significantly reduced, HDT/ASCT appears to be the preferred choice if autologous stem cells can be mobilized.

Mycosis Fungoides

Mycosis fungoides (MF) is an often indolent cutaneous lymphoma composed of CD4+ T cells. It accounts for about 2% of new cases of NHL in the United States, but because of the long survival of many patients, the prevalence is considerably higher.¹⁹¹ Staging for mycosis fungoides utilizes a unique TNM system. Prognosis for mycosis fungoides is stage dependent with stage IA patients having an overall survival similar to unaffected age-matched controls.¹⁹² Moreover, less than 10% of patients with stage IA disease will progress to a higher stage. Patients with stage IIB–IV disease have a much poorer survival and, in contrast to their early-stage counterparts, most of these patients will die of their disease.

Mycosis fungoides generally behaves as a chronic, relapsing illness. Although not curative, many effective treatment strategies have been studied in this disease. These Phase II experiences demonstrate the efficacy of topical therapies, phototherapy, radiation, retinoids, extracorporeal photopheresis, interferon-alpha, fusion proteins, and single-agent and combination chemotherapy. A randomized study compared electron-beam radiation therapy and a combination chemotherapy to sequential topical therapies, showing improved response but no survival benefit for the aggressive approach.¹⁹³

Mantle Cell Lymphoma

Mantle cell lymphoma (MCL) was originally described based on its morphologic appearance variously as centrocytic lymphoma, lymphocytic lymphoma of intermediate differentiation, intermediate lymphocytic lymphoma, or mantle zone lymphoma; unfortunately, the morphology overlapped significantly with other entities, making this diagnosis very difficult to make. It was recognized to be a CD5+ B-cell tumor but was difficult to distinguish from other CD5+ lymphocytic lymphomas on morphologic grounds.^{194,195} The tumors were characterized by a chromosomal translocation $t(11;14)$, and the breakpoint was cloned in the early 1990s and found to juxtapose the immunoglobulin heavy chain (IgH) gene on chromosome 14 to the BCL1/PRAD1/CYCLIN D1 locus on chromosome 11.^{196–199} It became possible to reliably and reproducibly diagnose MCL following the development of immunohistochemical reagents able to identify cyclin D1 in paraffin-embedded tissue sections.²⁰⁰ By flow cytometry, these tumors express the pan-B-cell antigens CD19 and CD20 in addition to CD5. They typically do not express CD23 and FMC7 in contrast focus. The SWOG retrospective study analyzed the outcome of patients previously diagnosed as IWF groups A–E to determine the incidence and natural history of MCL.²⁰¹ MCL represents about 6% of the cases of NHL in the United States² and was typically categorized as diffuse small cleaved cell lymphoma (IWF E). However, some cases were confused with small lymphocytic lymphoma (IWF A) and follicular small cleaved cell lymphoma (IWF B). This study demonstrated that MCL has a tumor with significantly shorter progression-free and overall survival when compared to other small lymphocytic lymphomas.

The role of cyclin D1 expression in the definitive diagnosis of MCL is controversial. There are some cases of lymphoma that have the typical phenotype by flow cytometry (CD20+, CD5+, CD23–) that fail to express cyclin D1. A series from Japan suggests that these tumors have a natural history identical to other small lymphocytic lymphoma,^{202,203} whereas others suggest the outcome is no different.²⁰⁴ However, in many trials, expression of cyclin D1 has been considered necessary for inclusion on trials for MCL.

Much of our knowledge of the natural history of MCL lymphoma has been derived from retrospective studies. The disease has a striking male predominance, for unknown reasons. Although most patients have an aggressive clinical course, a small portion of patients can have an indolent course,²⁰⁵ but these patients have been difficult to identify prospectively. Presentation as early-stage disease (CS I or II) is very uncommon, and information regarding management is either retrospective or anecdotal. Data on 26 patients with limited-stage MCL treated in Vancouver, have been reported,²⁰⁶ with a variety of treatments with 5-year PFS and OS of 45% and 70%, respectively. Age (less than 60 years) and initial use of radiation were found to have a positive effect. Bone marrow, peripheral blood, and gastrointestinal tract involvement is common. In general, the retrospective studies suggest that MCL is responsive to chemotherapy, but remission durations are brief, and median overall survival is about 3 years with no plateau on survival curves.^{207–212} In CHOP-treated patients, the 10-year EFS and OS were 6% and 8%, respectively.²⁰¹ More recently, prospective trials have tried to

determine if the natural history can be altered by intensification of therapy and addition of immunotherapy.

Chemotherapy for MCL

There are few randomized trials of chemotherapy that include patients with MCL. In general, when patients with MCL have been included, it has been as a minor population in larger trials, and it is not possible to draw definitive comparative conclusions regarding the treatment arms.^{146,213} However, in both the comparison of prednimustine and mitoxantrone versus cyclophosphamide²¹³ and that of fludarabine versus fludarabine idarubicin,¹⁴⁶ the patients with MCL had similar overall response rates as the patients with FL, but the complete response rate was lower.

Investigators at the M.D. Anderson Cancer Center (MDACC) have used alternating regimens of hyperCVAD regimen (fractionated cyclophosphamide, vincristine, doxorubicin, dexamethasone) with MA (methotrexate, cytarabine) as treatment for MCL. They initially treated a group of 45 patients (25 patients as initial therapy), alternating chemotherapy with hyperCVAD and MA followed by high-dose therapy and autologous stem cell transplant (HDT/ASCT). Among the 25 previously untreated patients, the 3-year EFS and OS were 72% and 92%, respectively.²¹⁴ These results have been updated and include an analysis restricted to 33 patients who underwent transplant; it did not include patients treated with hyperCVAD/MA who did not proceed to HDT/ASCT. Among the transplanted patients, the DFS and OS were 43% and 77%, respectively.²¹⁵

Rituximab for MCL

SINGLE AGENT

A European intergroup conducted a study of single-agent rituximab in patients with newly diagnosed and recurrent MCL.²¹⁶ In a total of 74 patients (34 untreated, 40 relapsed), the overall response rate was 38%, which was unaffected by prior treatment. The median duration of response was 1.2 years. These results were similar to a small pilot trial using 8 consecutive weeks of treatment, and some patients were treated at a higher dose.⁵⁴ Thus, neither the longer treatment duration nor the higher dose appeared to be important for the single-agent activity in MCL.

The Swiss Group for Clinical Cancer Research (SAKK) conducted a study to determine if prolonged dosing of rituximab could improve the outcome of patients with untreated and relapsed MCL treated with single-agent rituximab.²¹⁷ All patients received four weekly doses of rituximab at the standard dose of 375 mg/m². Patients with stable or responding disease were randomized to observation versus rituximab given at a dose of 375 mg/m² every 8 weeks for an additional four doses. One hundred four patients were treated in this trial with a response rate of 27%. After the induction therapy, PCR amplification of the t(11;14) translocation breakpoint became negative in the peripheral blood of 4 of 20 informative patients and only 1 of 14 informative bone marrows. Sixty-one patients were randomized (stable or responding disease), and there was no difference in outcome (EFS, RD, OS) between the prolonged therapy group and the observation

group. These data demonstrate modest single-agent activity for rituximab in MCL.

CHEMOIMMUNOTHERAPY

The MDACC group built on their experience with the alternating hyperCVAD and MA with the addition of rituximab. Rituximab was added to both the alternating regimens that were administered for a total of six to eight cycles (hyperCVAD and MA are counted as separate cycles).²¹⁸ Ninety-seven patients were treated, and the CR/CRu rate after six cycles was 87%. The estimated 3-year EFS and OS were 67% and 81%, respectively. Despite these encouraging results, the survival curve has no plateau, and there is a steady relapse rate over time, suggesting that the R-hyperCVAD/R-MA regimen alone was not curative. The toxicity of the regimen was significant, with 5 deaths in the study (5%), and 4 patients subsequently developing myelodysplasia syndrome (MDS), with 3 deaths.

Investigators at the Dana Farber Cancer Institute (DFCI) investigated the addition of rituximab to CHOP chemotherapy.²¹⁹ Forty patients were treated in this trial with an overall response rate of 96% (CR, 48%). The median PFS was 16.6 months, no different from historical controls. Twenty-five of the patients had a t(11;14) translocation breakpoint that was amplifiable by the PCR. Nine of 25 patients who had informative PCR, achieved a molecular remission. The median PFS was the same in patients who achieved a molecular remission as those who did not.

The German Low Grade Lymphoma Study Group (GLSG) undertook a large randomized Phase III study of CHOP, with or without rituximab, for patients with untreated MCL.²²⁰ There was a secondary randomization that was stratified by age: patients over 60 were randomized to two doses of adjuvant interferon-alpha and the younger patients were randomized to adjuvant HDT/ASCT or interferon-alpha. One hundred twenty-two patients were randomized: CHOP, *n* = 60; R-CHOP, *n* = 62. Analyzed according to initial randomization, R-CHOP was significantly superior to CHOP in overall response rate (94% versus 75%; *P* = 0.0054) and complete remission rate (34% versus 7%; *P* = 0.00024). There was also a significant benefit in the median TTF (21 versus 14 months; *P* = 0.0131). Despite the improvement in TTF, there was no advantage to the chemoimmunotherapy arm in progression-free or overall survival.

GLSG also evaluated the addition of rituximab to FCM (fludarabine, cyclophosphamide, mitoxantrone) for patients with relapsed and refractory FL and MCL (24 patients in each of the arms).¹⁶⁰ Addition of rituximab did not significantly improve the overall response rate (FCM-R, 58%, versus FCM, 46%; *P* = 0.282), but there was 29% complete remissions with rituximab versus none without. Although there was no difference in the median PFS (FCM-R, 8 months, versus FCM, 4 months; *P* = 0.3887), there was a difference in median OS (FCM-R, not reached, versus FCM, 11 months; *P* = 0.0042). It is unclear why the treatment could result in a significant improvement of OS without an improvement in PFS. Given the small sample size, it is possible the survival benefit reflects an unintentional selection bias.

The National Cancer Institute (NCI) investigators evaluated DA-EPOCH-R with idiotypic vaccination in patients with untreated MCL.²²¹ Twenty-six patients were treated

with DA-EPOCH-R with an overall response rate of 100% (complete response, 92%). Interestingly, the proliferation signature that had been identified to be important in the outcome of patients with MCL treated with CHOP-based regimens^{204,222} was not predictive of outcome with DA-EPOCH-R. The mechanism by which this regimen would overcome the proliferation signature is unknown. The impact of the idiotype vaccination on outcome is unknown. The DA-EPOCH-R regimen profoundly affected on humoral responses although T-cell responses to the Id-KLH/GM-CSF vaccine were seen.

Stem Cell Transplantation

The role of HDT/ASCT in the management of MCL has been controversial. Investigators at the DFCI undertook a retrospective analysis of the outcome of those who underwent high-dose chemoradiotherapy and anti-B-cell monoclonal antibody-purged autologous bone marrow transplantation (ABMT) for MCL in first or subsequent remission.²²³ The results were very discouraging, with no evidence of a plateau on the survival curve, and an estimated DFS and OS at 4 years of only 31% and 62%, respectively. In another small study of 24 patients, the EFS was 55% at 5 years, but again there was no evidence of a plateau on the survival curve.²²⁴ The data between 1988 and 1998 for 195 patients with MCL provided to the European Blood and Marrow Transplant Registry (EBMT), or the Autologous Blood and Marrow Transplant Registry (ABMTR) were reviewed.²²⁵ At the median follow-up of 3.9 years, the estimated 5-year PFS and OS were 33% and 55%, respectively. There was a significantly worse outcome for patients not in first complete remission (CR1) compared to those in CR1 (relative risk, 2.99; $P = 0.001$).

The European MCL network undertook a randomized Phase III study to evaluate the role of consolidation of the first remission with HDT/ASCT.²²⁶ Patients were initially treated with four to six cycles of CHOP-like chemotherapy. Patients achieving a PR or CR were randomized to either two additional cycles of the same chemotherapy, followed by interferon-alpha, or to stem cell mobilization with dexamethasone, carmustine, etoposide, cytarabine, melphalan, followed by total-body irradiation (TBI) and cyclophosphamide. Patients who progressed after the interferon arm were eligible to cross over to the high-dose therapy arm. One hundred twenty-two patients were randomized: 60 to HDT/ASCT and 62 to interferon-alpha. Induction therapy included CHOP in 61%, R-CHOP in 26%, and other CHOP-like regimens in 13%, and these were relatively well balanced between arms. Patients receiving consolidation with HDT/ASCT versus interferon-alpha had a superior median PFS (36 months versus 17 months; $P = 0.0108$). Despite a trend in improvement in OS, this was not statistically significant; however, the survival analysis was complicated by the cross-over design. Despite the improvement in PFS with HDT/ASCT in first remission, there is no plateau on the survival curve to suggest a group of patients being cured with this therapy.

Allogeneic stem cell transplantation has also been investigated for patients with relapsed/refractory MCL. Anecdotal experience with conventional myeloablative allogeneic transplantation, suggests that some patients can have long-term disease-free benefit.^{227,228} Investigators at Johns Hopkins iden-

tified 58 patients with MCL in their transplant registry who received either autologous or allogeneic stem cells.²²⁹ Nineteen patients received an allograft. In this analysis, there was no clear evidence of a graft-versus-tumor effect, because the actuarial risk of relapse was similar between those who received either autologous or allogeneic stem cells. There was no difference in 3-year EFS (70%) between allogeneic and autologous transplant performed in CR1.

A trial of nonmyeloablative allogeneic stem cell transplantations was conducted at the MDACC.²³⁰ Eighteen patients were treated in two trials that differed in the chemotherapy regimen: fludarabine, cyclophosphamide, high-dose rituximab ($n = 13$), and cisplatin, fludarabine, cytarabine ($n = 5$). The median number of prior treatments was three, and 5 patients had prior HDT/ASCT. Complete remissions were seen in 94%, and 3 patients progressed. One of the 3 was reinduced into CR with donor lymphocyte infusions. The estimated 3-year current EFS was 82% (this includes the patient reinduced into CR). Investigators at the Fred Hutchinson Cancer Research Center (FHCRC), evaluated a nonmyeloablative approach using fludarabine and 2Gy TBI for patients with relapsed and refractory MCL.²³¹ Thirty-three patients were treated (HLA-matched related, $n = 16$; unrelated, $n = 17$), including 14 patients who had had a prior HDT/ASCT. Stable engraftment occurred in 31 of the patients. Of the 30 patients undergoing the procedure in CR ($n = 13$), or with responding disease ($n = 17$), only 1 patient had relapse. The relapse mortality was 9%, but regimen-related mortality was 24% at 2 years. The estimated 2-year DFS and OS were 60% and 65%, respectively.

New Approaches

RADIOIMMUNOTHERAPY

Mantle cell lymphoma is sensitive to radiation; however, the role of external-beam radiation is limited in the management of the disease because of the systemic nature of the disease. Radioimmunotherapy is a means of providing systemic radiation therapy to multiple sites of disease. Preliminary results of two trials have been presented. Untreated patients with MCL were treated with sequential radioimmunotherapy (RIT) with ¹³¹I-tositumomab (65–75 cGy, whole body) followed by conventional CHOP chemotherapy.²³² There was an overall response rate to the RIT of 83% (CR, 50%) and the chemotherapy improved the CR to 90%. Investigators at MDACC treated a group of 15 patients with relapsed and refractory MCL with ⁹⁰Y-ibritumomab tiuxetan (0.3–0.4 mCi ⁹⁰Y/kg).²³³ There was an overall response rate of 33% (all CR/CRu). These trials are very preliminary and response durations are not available, although they suggest conventional-dose RIT has activity in both untreated and relapsed/refractory disease.

At the FHCRC, the role of high-dose RIT with stem cell support for MCL was investigated.²³⁴ The systemic distribution of disease, with extensive bone marrow and peripheral blood involvement, raised the concern that the dosimetry of RIT in MCL would be different from that in other tumors. In 25 patients with MCL treated with high-dose RIT, the biodistribution and dosimetry were similar to other histologies.²³⁵ Sixteen patients were treated with ¹³¹I-tositumomab at a dose calibrated to deliver 20 to 25 Gy to normal organs, followed

10 days later by high-dose etoposide (30–60 mg/kg) and cyclophosphamide (60–100 mg/kg). Patients then had autologous stem cells reinfused. At 3 years, the PFS and OS are 61% and 91%, respectively, in a population that had a median of three prior treatment and 7 patients with chemorefractory disease. Substitution of high-dose RIT is a promising approach, but larger controlled studies are necessary to validate these findings.

NOVEL AGENTS

Bortezomib is a reversible inhibitor of the protease approved for the treatment of relapsed and refractory multiple myeloma.²³⁶ This drug has been evaluated in the treatment of MCL at both MSKCC and MDACC. Both centers used a dose of bortezomib (1.5 mg/m² on days 1, 4, 8, and 11 every 21 days) that was associated with significant asthenia, neuropathy, and thrombocytopenia.^{237,238} However, in a limited number of patients, the response rate was reported to be approximately 50%. Additional data have been presented by the NCIC and St. Bartholomew's.^{239,240} In these trials, the schedule was the same but the dose was 1.3 mg/m², and this appeared to be mildly less toxic; asthenia, thrombocytopenia, and neuropathy remained significant toxicities. The activity was maintained at the lower dose, with overall response rates of 36% (St. Bartholomew's, *n* = 11) and 33% (NCIC, *n* = 24). A multicenter confirmatory Phase II trial is ongoing in the United States. However, additional schedules and integration with other therapy are necessary.

There have been anecdotal reports of thalidomide inducing remissions in patients with refractory MCL.^{241,242} Based on the rationale that thalidomide might target the microenvironment and rituximab the tumor, investigators from Austria examined the combination in patients with MCL.²⁴³ Sixteen patients were treated with rituximab 375 mg/m² weekly × 4 with thalidomide 200 mg po/day for 2 weeks, then increased to 400 mg po/day until progression or relapse. Thirteen (81%) of the patients responded, with CR in 31%. Median PFS was 20.4 months, with an estimated 3-year OS of 75%. Toxicity was primarily related to the thalidomide, with thromboembolic events in 2 patients and grade IV neutropenia in 1.

Summary

The clinical management of MCL remains a major challenge. Early-stage disease is uncommon, and other than small retrospective cases series, there is no high-level evidence to guide the management of these patients. These patients should be extensively evaluated for occult sites of extranodal disease with inclusion of gastrointestinal tract evaluation with blind biopsies (if not gross disease). It appears that involved-field radiation should be a component of the therapy. In advanced-stage disease, outside of a clinical trial, effective cytoreductive therapy (R-HyperCVAD/R-MA; R-CHOP) should be followed by HDT/ASCT in appropriate candidates. However, it should be cautioned that this is an effective palliative, and not a curative approach. For this reason, when possible patients with MCL should be referred for clinical trial. The effectiveness of HDT/ASCT at relapse is controversial, but most data suggest that it is not as effective for relapsed/refractory disease as it is for consolidation in first remission. Off study, the fludarabine-based FCM (±R) is

justified on the basis of the evidence presented, but the benefit is relatively brief. The data with investigational approaches, such as bortezomib, rituximab plus thalidomide, high-dose radioimmunotherapy, and allogeneic stem cell transplantation are all promising, but further trials are necessary to determine how these treatments fit into the management of MCL. Other agents, such as the MTOR inhibitor CCI779 and flavopiridol, also may have activity in MCL. Thus, patients with relapsed disease have no standard therapy and when possible should be referred for clinical trials.

Conclusions

The non-Hodgkin's lymphomas represent a clinically diverse array of diseases with some entities being incurable chronic illnesses and others progressing rapidly but having the potential for cure. Owing to the relative rarity of some of these entities, such as T-cell lymphoma, high-level evidence does not exist, and therapeutic decisions are based on small retrospective studies and the clinical impression of experts. In contrast, there is high-level evidence to guide the therapy of DLBCL in most clinical situations. Poor-risk young patients remain an area of controversy. Even in aggressive lymphoma relapse, randomized data support the use of HDT/ASCT. Among the indolent lymphomas, FL remains the greatest challenge in day-to-day practice because of the chronic nature of the disease and lack of clear guidance as to an optimal order of therapy. In these cases, it is important to extract the lessons learned from the high-level evidence and apply these to the particulars of the patient's clinical situation. FL is a disease, barring a major breakthrough resulting in curative outcomes, in which individual considerations will shape treatment choices. In MCL, much of the high-level evidence informs the clinician of what not to do. Despite intensive study over the past decade, consistent curative outcome has not been achieved. It remains very important that these patients be referred for clinical trials. Many lymphoma entities were not covered in this chapter because they are very uncommon. Regrettably, in many of these entities, high-level evidence may never exist to guide the management of these patients. In those circumstances, we must rely on the experience of highly specialized consultants who may be able to provide insight on a case-by-case basis.

Multiple Myeloma

Robert L. Schlossman

Multiple myeloma (MM) is an incurable plasma cell neoplasm characterized by the accumulation of malignant plasma cells in the bone marrow. In the vast majority of cases, this neoplastic proliferation of plasma cells produces a monoclonal protein or immunoglobulin fragment that can be detected in the blood, urine, or both. Signs and symptoms of MM can be related to the location of these cells as well as the excessive production of irrelevant monoclonal immunoglobulin. As the malignant plasma cells expand in the marrow, normal surrounding bone can dissolve as a result of stimulation of osteoclasts by a variety of cytokines. Damage to the bone can lead to pain, pathologic fractures, and hypercalcemia. Furthermore, normal bone marrow can be suppressed, in particular, erythropoiesis. Impairment of the immune system leads to decreased humoral immunity with increased risk of infection, particularly encapsulated organisms. The paraprotein itself can lead to problems, including hyperviscosity, amyloid, and renal damage. This disease typically occurs in individuals in the sixth or seventh decades, but can also be seen in younger people. Systemic therapy is palliative. For decades, chemotherapy was based on single agents or combinations of alkylating agents and steroids. Despite great enthusiasm, dose intensification is not curative in the majority of cases, but can prolong overall survival (OS) and event-free survival (EFS). Newer drugs, based on antiangiogenesis approaches and targeting cytokine pathways, have generated a great deal of interest.

Epidemiology and Etiology

The estimated number of new cases of MM in the United States for 2004 was 15,270, for an incidence rate of 4 per 100,000 per year. The estimated number of deaths from the disease in 2004 was 11,070.¹ The prevalence is approximately 50,000. Although not considered a common disease, MM does account for 20% of deaths caused by hematologic malignancies in the United States. Although MM represents 1% of all malignancies, it is the second most common hematologic malignancy after non-Hodgkin's lymphomas. The disease does appear to be increasing slowly in incidence. This increase may be in part due to increased screening by routine blood work and more sensitive tests. One hypothesis is that the increased incidence may be real and the results of increasing environmental toxins known and unknown.^{2,3}

Increased risk of developing MM may be related to the interaction of genetic and environmental factors, neither of

which alone is enough to lead to disease. Environmental risk factors associated with an increased incidence of MM, include excessive exposure to petroleum products, organic solvents, pesticides, herbicides, Agent Orange, and radiation. Groups particularly at increased risk of exposure to these compounds include farmers, woodworkers, and paper producers.^{4,5} An increased risk of MM was also noted in atomic bomb survivors exposed to more than 50Gy radiation.⁶ Although the genetic predisposition to the disease is not so strong as seen in other related lymphoproliferative disorders, MM has been described in first-degree relatives. Whether these associations represent a true genetic predisposition or a common environmental exposure remains unclear.

The Biology of MM

A process of immunoglobulin gene rearrangement characterizes normal B-cell development. As the B cell matures from a naïve pre-B to memory B cell and plasma cell, a number of genetic events occur. This process involves immunoglobulin VDJ rearrangement, somatic mutation, and immunoglobulin class switching.⁷ The hypermutated sequences of joining regions of the VDJ can provide molecular markers for identifying the presence of clonotypic myeloma cells even in low numbers. Using CDR3 polymerase chain reaction technology, the malignant clone can be identified with greater sensitivity.⁸

MM is characterized by sheets of mature-looking plasma cells. The malignant cell is a B lymphocyte with a plasma cell morphology. These malignant plasma cells are cIg+, CD38+, CD56+, and BB-4+ (CD138+). MM cells can aberrantly express CD10, HLA-DR, and CD20.^{7,9} The final oncogenic event leading to the development of MM appears to occur late in B-cell development based on immunoglobulin gene sequence analysis. The MM cell is postfollicular with the mutated homogeneous clonal sequences indicating no continuing exposure to somatic hypermutation.⁹

Chromosomal abnormalities occur in the range of 30% to 80%, but the true incidence is difficult to ascertain because of the low proliferative potential of MM cells and the methodology used to perform the analysis. Conventional cytogenetic analysis demonstrates abnormal karyotypes in 30% to 40% of patients,¹⁰ whereas fluorescence in situ hybridization (FISH) analysis increases this figure to 80%.¹¹ Spectral karyotyping (SKY) purportedly detects chromosomal abnormalities in almost 100% of MM cells.¹²

The most common chromosomal abnormalities involve 14q32, which is the heavy-chain locus. In many cases, the translocation involves genes on the partner chromosome that encode growth or transcription factors. These nonimmunoglobulin chromosomes include 11q13, 4p16, 8q24, 16q23, and 6p25.⁷ Deletions of the short arm of chromosome 13 correlate with a poorer outcome, although the associated genes remain to be identified.

The Bone Marrow Microenvironment

In addition to intrinsic genetic abnormalities, the role of the bone marrow environment in the pathogenesis of MM has come to be appreciated. Both normal and neoplastic plasma cells are attracted to the bone marrow via adhesion molecules and ligands. Once these cells enter the bone marrow microenvironment, they are exposed to a variety of cytokines that promote growth, migration, and survival. Specifically, bone marrow stromal cells (BMSC) secrete a variety of cytokines, including interleukin 6 (IL-6), vascular endothelial growth factor (VEGF), stromal cell-derived growth factor (SDF-1), and insulin growth factor (IGF-1).¹³⁻¹⁵ In addition to attracting MM cells to the bone marrow, adhesion of MM cells to BMSCs results in paracrine secretion of IL-6 as well as VEGF. IL-6 is secreted via a NF- κ B dependent pathway. IL-6 is a major growth factor for MM cells and results in increased survival and resistance to dexamethasone-induced apoptosis via a number of signaling pathways.

Another cytokine that plays an important role in MM is tumor necrosis factor- α (TNF- α). Although TNF- α does not act directly on MM cells, it does increase expression of cell-surface adhesion molecules via an NF- κ B-dependent pathway. The adhesion molecules ICAM-1 and VCAM-1 are found on both BMSC and MM cells. Increased expression of these adhesion molecules results in binding of the MM cells to the bone marrow and secretion of IL-6.¹⁶

Clinical Presentation

The majority of symptomatic patients present with a combination of bone pain, fatigue, and recurrent infections. Cortical bone destruction leads to pain in the back and chest. The pain worsens with weight bearing and typically does not involve the joints. Compression fractures of the vertebral bodies can lead to neurologic complications, including weakness, neuropathies, muscle spasm, and the signs and symptoms of cord compression. Loss of height can occur if multiple vertebrae are compressed. Often, back pain is present for weeks to months before a patient seeks medical evaluation. Extensive bone involvement can result in hypercalcemia, which in turn can result in weakness, constipation, confusion, and arrhythmias and potentiate renal dysfunction. Other complications include anemia caused by marrow suppression, immune dysfunction, and end-organ toxicity secondary to paraprotein deposition. The paraprotein can be directly nephrotoxic as well as neurotoxic and can be deposited in a variety of tissues as amyloid. Fevers and night sweats are rare but occasionally seen. Organomegaly is also rarely seen as a presented symptom. A subset of patients are diagnosed while asymptomatic when laboratory abnormali-

ties are noted incidentally on annual physicals or during the course of a workup to evaluate other issues.

Bone Disease

One of the dreaded complications of MM is cortical bone destruction, which leads to bone pain and pathologic fractures. Bone damage appears to be mediated by osteoclast activation by a host of cytokines released by MM cells and bone marrow stromal cells (BMSC). These cytokines include lymphotoxin (LT), TNF- α , hepatocyte growth factor (HGF), IL-6, metalloproteinases, and insulin-like growth factor-binding protein 4.¹⁷⁻²¹ Excessive production of these cytokines upsets the normal balance of bone modeling and favors bone reabsorption.

Approximately 70% to 80% of patients will experience bone pain during the course of their disease. The bone survey remains the standard imaging study. The classic abnormality is a punched-out lytic lesion typically seen in the axial skeleton, including the vertebrae, calvarium, ribs, and proximal long bones. Additional studies include computed tomography (CT) scans (although the risk of renal dysfunction due to contrast dye makes this imaging modality problematic), magnetic resonance imaging (MRI), and positron emission tomography (PET) scans. Extensive lytic bone disease is associated with hypercalcemia, which in turn can lead to constipation, weakness, and confusion. Bone scans are of limited use because of the pure lytic nature of these lesions. Osteosclerosis is uncommon and represents callus formation in healing of the POEMS variant of MM.

Another feared complication of MM is renal failure. Up to 25% of MM patients may experience some degree of renal dysfunction. The etiology of renal damage can be multifactorial and includes myeloma kidney, light-chain deposition disease, uric acid nephropathy, infection, hypercalcemia, dehydration, medication toxicity, and amyloid. In myeloma kidney, monoclonal light chains and intact immunoglobulin precipitate in the distal and collecting renal tubules, resulting in waxy casts. In light-chain deposition disease, monoclonal light chains deposit on the glomerular membrane. Another pattern of renal damage is due to the deposition of amyloid. These mechanisms of damage can be potentiated by dehydration. Also contributing to the damage caused by these mechanisms is hyperuricemia and medications. Nonsteroidal antiinflammatory agents can potentiate renal damage by modulating afferent blood flow into the glomerulus.

Anemia is common and can result in profound fatigue. Factors that contribute to anemia, include bone marrow infiltration by MM, suppressed erythropoietin production in part caused by renal dysfunction, and chemotherapy. In some cases, anemia may be a consequence of iron deficiency, which may in turn be caused by chronic gastrointestinal blood loss from nonsteroidal antiinflammatory drugs (NSAIDs) or steroid-induced gastritis. Also contributing may be the anemia of chronic disease.

Sensorimotor neuropathies are common in MM. Neurotoxic agents used in the therapy of myeloma exacerbate these neuropathies. Neurotoxic agents commonly used in the therapy of MM, include vinca alkaloids, steroids, thalidomide, and bortezomib. Sensory neuropathy is a common presenting symptom in POEMS. The mechanism of nerve

damage includes amyloid deposition, paraprotein directed against myelin,²² and nerve root damage secondary to compression fractures. Other causes of neurologic involvement include carpal tunnel syndrome due to amyloid.

Recurrent infections with encapsulated organisms are common and result from compromised humoral-mediated immunity. In advanced disease, further immunosuppression can be caused by steroid use and neutropenia. Aggressive antibiotic therapy for bacterial, viral, and fungal infections is essential in reducing the risk of life-threatening sepsis. All patients should receive pneumococcal vaccine at diagnosis and influenza vaccines annually. Prophylaxis for *Pneumocystis carinii* pneumonia should be considered for all patients on steroid-based regimens. In addition, antiviral therapy is advised for patients at increased risk of reactivation of varicella zoster virus. This prophylaxis is particularly important following high-dose therapy. For individuals with recurrent life-threatening or debilitating infections, intravenous immunoglobulin infusions may be indicated for passive immunization and to help clear existing infections.

Less common complications include hepatomegaly, malignant pleural effusions, subcutaneous plasmacytomas, and blood clots. Hyperviscosity symptoms can occur in patients with IgM paraproteins, or rarely, in those with hyperviscosity are seen extremely high IgG levels (IgG subclass 3).

Laboratory Findings: Diagnostic Tests

- Complete blood count
- Measurement of electrolytes, BUN, creatinine, calcium, LDH
- Serum protein electrophoresis
- Serum protein immunoelectrophoresis
- Metastatic series
- Bone marrow aspirate and biopsy
- 24-hour urine collection for urine immunoelectrophoresis
- Free serum light chains
- B2 microglobulin, C-reactive protein, plasma cell labeling index

The evaluation proceeds in a stepwise fashion and includes routine blood work and radiographic studies. A normocytic normochromic anemia is seen in 62% of cases.²³ Usually the remainder of the complete blood count (CBC) is normal. On peripheral blood smear, rouleaux formation is common and can account for a falsely elevated mean corpuscular volume (MCV) on automated CBC determinations. Approximately 55% of patients have some degree of renal insufficiency, and 76% have a monoclonal spike of serum electrophoresis.²³ If the preliminary workup is suspicious, then a more detailed workup is undertaken to establish the diagnosis and estimate tumor burden. Additional tests can be utilized to evaluate the biologic aggressiveness of the disease. Patients with more aggressive appearing disease at initial diagnosis can then be counseled about the need for sooner intervention and the possible benefit of more aggressive therapy.

Establishing the diagnosis is the first step in evaluating a patient suspected of having MM. Combinations of major or minor criteria are then evaluated.²⁴ This evaluation includes

defining a monoclonal protein in the serum, urine or both, presence of depressed normal immunoglobulins, presence of monotypic plasma cells, and lytic bone lesions. These diagnostic tests include a serum protein electrophoresis and urine immunoelectrophoresis to evaluate for a monoclonal protein in the blood, urine, or both. Quantitative immunoglobulins with immunofixation can further identify and quantitate the paraprotein. A monoclonal spike in the blood, urine, or both is found in 99% of patients with only 0.3% being nonsecretory.²³ While it remains unclear whether different types of monoclonal spikes are associated with different survival, they are associated with different complications. IgM and IgA myeloma have a higher association with hyperviscosity syndromes, whereas light chains have a higher association with renal dysfunction and amyloid.

Essential to the diagnosis is the demonstration of increased numbers of clonogenic plasma cell cells in the bone marrow. MM cells usually make up at least 10% to 30% of the bone marrow cellularity. Further identification of the plasma cell can be made with immunoperoxidase studies demonstrating light-chain restriction. In early-stage disease and some cases, involvement of the marrow can be patchy. Sampling error can lead to falsely elevated or reduced estimates of involvement when looking only at the percentage involvement in the marrow.

Once the diagnosis is established, other tests are performed to evaluate the extent of disease. Other tests used in staging, include a complete blood count (CBC) and chemistry panel, including blood urea nitrogen (BUN), creatinine, and calcium. For evaluating bone damage in MM, a skeletal survey remains the standard of care. Although the classic finding is a punched-out lytic lesion, other patterns can include diffuse osteopenia or a normal appearance to the bones. Typically, MM lesions involve the axial skeleton but can also be seen in the long bones. Other imaging studies useful in the evaluation of MM, include MRI. MRIs are particularly useful in evaluating bone damage that is not readily apparent on plain films. In addition, MRI is particularly sensitive for evaluating disease in the spine and defining the anatomy of the spinal cord and nerve roots. Myeloma lesions are commonly dark on T₁-weighted images and bright on T₂ images. Positron emission tomography (PET) is less well defined in MM. It may play a role in whole-body imaging of patients with nonsecretory disease and to evaluate extramedullary disease.

Differential Diagnosis

Although the diagnosis of MM is often clear once the tests are performed, monoclonal proteins can be associated with other disorders. The differential diagnosis for a monoclonal gammopathy includes monoclonal gammopathy of unknown significance (MGUS), smoldering myeloma, non-Hodgkin's lymphoma, chronic lymphocytic leukemia, primary amyloidosis, light-chain deposition disease, and Waldenstrom's macroglobulinemia. All but the MGUS, smoldering myeloma, and primary amyloid are fairly easy to distinguish when additional workup is pursued, including CT scans and flow cytometry.

The distinction between MGUS and smoldering MM is based on the amount of paraprotein and extent of bone

marrow involvement. These disorders represent steps leading to the development of symptomatic MM, whereas primary amyloid represents a complication related to the biochemical properties of the paraprotein itself. Amyloid can develop in the context of both MGUS and MM. A MGUS is characterized by a M-spike of less than 3g/dL and minimal involvement of the bone marrow by plasma cells. This disorder affects approximately 2% to 3% of individuals over 50 years old and increases in incidence with age. Commonly, the bone marrow looks normal but can have up to 10% involvement by plasma cells. Given the low number of plasma cells, a metastatic series should be normal, as well as the blood work, with the exception of the M-component. The diagnosis of a MGUS is associated with an increased risk of evolving into a malignant lymphoproliferative disorder. This risk is 24% overall and 1% per year in a large series from the Mayo Clinic.²⁵ Increasing paraprotein, elevated erythrocyte sedimentation rate (ESR), and presence of light chains are associated with an increased risk of transformation.⁵ Thus, MGUS represents a premalignant B-cell disorder.

Smoldering MM may represent the next step in the evolution of a MGUS into MM. In smoldering MM, the M-component is more than 3g/dL, and there is a greater degree of involvement on the bone marrow with more than 10% activity.²⁶ The development of smoldering MM from MGUS, may reflect changes occurring in the bone marrow that result in increased stimulation of plasma cells by cytokines and paracrine signaling.

Additional laboratory evaluation can be used to define how aggressive a particular patient's myeloma cells may behave. These factors include the B₂-microglobulin (β 2M), level chromosome 13 abnormalities, C-reactive protein (CRP), IL-6 levels, plasma cell labeling index (PCLI), lactate dehydrogenase (LDH), plasmablastic morphology, and presence of circulating plasma cells in the peripheral blood. Of these tests, the β 2M is the single most important prognostic factor. The β 2M represents the light chain of the major histocompatibility complex of the cell membrane on lymphocytes. Increased plasma cell turnover, associated with a rapid growth fraction, results in increased β 2M being shed into the serum. An elevated β 2M in a patient with normal renal function is associated with poorer survival and a rising level is associated with disease progression.²⁷ Because β 2M is renal excreted, renal insufficiency can falsely elevate the value.

Recently, chromosome 13 abnormalities have been shown to be an adverse prognostic factor. Deletions of the short arm of chromosome 13 (13q-) have been shown by FISH in approximately 40% of patients, and are associated with survivals of 27 months, compared to 65 months in patients without the deletion (*P* less than 0.001).^{12,28,29} An elevated CRP correlates with shorter survival and elevated IL-6 levels.³⁰ As in NHL, an elevated LDH is also a predictor of poorer outcome.³¹ The PCLI is a measure of plasma cell turnover in the bone marrow. Normally, plasma cells have a low mitotic fraction of less than 1%. A PCLI of 1% or greater is associated with more aggressive disease.³¹ Plasmablastic morphology also correlates with more aggressive disease and shorter survival.³²

For 30 years, MM has been classified based on the Durie-Salmon staging system.³³ This system was based on tumor burden and complications based on the evaluation. While this staging system was predictive of survival, it was not based on biologic features. The International Staging

System for MM attempts to correct the deficiencies of the Durie-Salmon Staging system by utilizing only the beta-2 microglobulin and albumin.³⁴

Initial Management

Once the diagnosis of MM is made, the next step is to initiate supportive care and decide whether systemic chemotherapy is warranted. Additional interventions include patient education, establishing a follow-up routine, and determining suitability for clinical trials. Supportive care includes reviewing the patient's history and updating immunizations, particularly for encapsulated organisms. These patients should be immunized against pneumococcal pneumonia and *Hemophilus influenzae* as well as influenza.

Newly diagnosed patients should be offered bisphosphonate therapy with either pamidronate or zoledronic acid as prophylaxis against bone disease. Bisphosphonates are analogues of normal pyrophosphonates involved in bone formation. These side-group substitutions allow pamidronate and zoledronic acid to be incorporated into bone but to prevent hydrolysis by osteoclasts. Pamidronate reduces the risk of skeletal-related events in patients undergoing chemotherapy from 42% to 24%, based on results from a randomized trial.³⁵ In this study, skeletal-related events were defined as pathologic fractures, bone pain, and bone damage requiring intervention. Based on this study and others, pamidronate has been approved for use in patients who meet diagnostic criteria for MM, demonstrate bone disease, and who are being started on systemic therapy. Bisphosphonate therapy in patients not requiring systemic therapy is controversial. Pre-clinical studies have demonstrated an antimyeloma effect for bisphosphonates in cell culture. This activity has been hard to demonstrate in the clinical setting. The newer bisphosphonate, zoledronic acid, has gained widespread use. While zoledronic acid is a more potent bisphosphonate in the laboratory, it has not been demonstrated to be superior to pamidronate in the clinical setting. Zoledronic acid is typically given over 20 minutes rather than the 2 hours recommended for pamidronate.

Although well tolerated, bisphosphonates have a number of potential side effects. The main concern is the risk of renal dysfunction. In patients with multiple risk factors for renal dysfunction, the relative contributions are not always apparent. This risk is low and may be related to rate of infusion. Initially, the incidence of renal dysfunction was believed to be higher with zoledronic acid than pamidronate, although some concerns did not materialize into a real problem. With more experience, this increased risk does not appear to be borne out. Possible explanations for the increased incidence of renal dysfunction associated with zoledronic acid, include rapid infusion rates and higher doses. When zoledronic acid was first evaluated, it was given in higher doses and over shorter periods. The current dosing recommendations of 4 mg over 20 minutes appear to be safe. In renal dysfunction due to pamidronate, patients sometimes develop an asymptomatic proteinuria. With zoledronic acid, this warning sign is not typically seen.

Other side effects seen with bisphosphonate therapy, include low-grade temperatures and bone pain. These complaints can begin within 24 to 48 hours of the infusion and

are often self-limited. When these symptoms occur, prophylactic Tylenol can be useful. Another risk associated with pamidronate, in particular, is thrombophlebitis. This complication typically occurs at the site of a peripheral intravenous catheter and can be avoided with central lines. Hypocalcemia is another potential risk of bisphosphonate use. Given that many of these patients are normocalcemic at initiation of the therapy, it is common for calcium levels to run in the 8.0–8.4 range. In patients with renal insufficiency who are not receiving adequate calcium repletion, clinically significant hypocalcemia may occur. For patients with stable to responding disease, cautious calcium repletion is reasonable.

Duration of Therapy

Initially, there was much enthusiasm for bisphosphonates and the consensus recommendation is to continue therapy so long as the patient benefits.³⁶ This initial enthusiasm has been tempered by the recognition of long-term complications. Osteonecrosis of the jaw (ONJ) presents as pain in the maxilla or mandible. This pain can be associated with a draining sinus. Initial workup should include MRI or detailed radiographic studies. These lesions are frequently biopsied to distinguish between abscess, plasmacytoma, and osteomyelitis. Pathology is consistent with bone necrosis and superinfection. Intervention typically focuses on antibiotic therapy but can include debridement and reconstruction in more advanced cases. In patients with suspected ONJ, the bisphosphonate should be stopped immediately and the patient referred to a dentist or oral surgeon familiar with the complication.

Other Interventions

Newly diagnosed patients or those already receiving care may benefit from further interventions. Lytic bone disease is a particularly dreaded complication. In addition to systemic therapy, patients may benefit from more-localized interventions. These approaches can include surgical stabilization, kyphoplasty/vertebroplasty, and radiation therapy (XRT). XRT can be used to reduce the risk of a pathologic fracture, as well as palliatively to treat pain. In addition, it can be used with curative intent in the setting of an isolated osseous or extraosseous plasmacytoma. MM is sensitive to even low doses of XRT. Indications for XRT include palliation of an impending pathologic fracture of a weight-bearing bone or intractable pain in a non-weight-bearing bone. For patients with a solitary osseous plasmacytoma, definitive XRT can result in long-term disease-free survival in up to 50% of patients.³⁷ In these patients, the XRT is given with curative intent at higher doses. The typical palliative dose is 2,500 to 3,000 cGy, whereas in curative intent the goal is 4,250 cGy.

Indications for invasive stabilization of bones include pathologic fractures, impending pathologic fracture of a weight-bearing bone, or intractable pain in a non-weight-bearing bone. Interventions are most successful before a fracture occurs. Surgical stabilization of a long bone can often be accomplished via rodding and relatively small incisions. Once a long bone is fractured, then the surgery becomes more extensive. Vertebroplasty and kyphoplasty are less invasive

interventions directed at stabilizing vertebral compression fractures. Indications include significant pain at a neurologic level and a compression fracture documented by MRI. Furthermore, the endplates of the vertebra must be intact with adequate space to insert the needles. Finally, the lesion must be relatively recent to avoid excessive calcification. If these requirements are met, then large-bore needles are inserted into the space between the endplates, avoiding the spinal cord. Balloon catheters are then inserted and inflated. The catheters are then removed and methyl methacrylate injected. A vertebroplasty differs only in omitting the balloon catheter step.

For patients not amenable to noninvasive intervention, then surgical stabilization is an option. Concerns about extensive surgery, include bleeding, inadequate anchoring of the devices, delayed wound healing, and increased risk of infection.

Other interventions considered supportive care, include hemodialysis (HD), plasmapheresis, and leukapheresis. The latter technique is reserved for patients with plasma cell leukemia (PCL) and the therapy of leukostasis. For patients with life-threatening complications of renal failure, HD is essential. Duration and etiology of renal failure can be predictive of which patients may recover function. The longer the duration of renal failure, the less likely patients are to recover. If patients are treated aggressively and promptly, the renal dysfunction may to some extent reverse over time. Plasmapheresis is controversial but does play a role in the treatment of hyperviscosity. It is most effective in IgA and IgM MM, because the majority of paraprotein is intravascular. Effective plasmapheresis can remove up to approximately 90% of circulating paraprotein and relieve the symptoms of hyperviscosity. The diagnosis is made clinically in a patient with more than 3 g paraprotein and appropriate symptoms, such as fatigue disproportionate to the degree of anemia, epis-taxis, bruising, renal dysfunction, blurred vision, headaches, and pain. IgG paraproteins are less successfully managed with this strategy owing to a much larger volume of distribution. The role of plasmapheresis in the management of renal dysfunction and neuropathies caused by IgG or light-chain MM is much more controversial. Studies show both benefit and no advantage to plasmapheresis in this setting. Given that IgG and light-chain paraproteins have a much larger volume of distribution with a significant extravascular component, plasmapheresis should be accompanied by aggressive systemic therapy. Timing of chemotherapy with plasmapheresis is always difficult.

Conventional Therapy

Initial Treatment for Nontransplant Candidates

An important distinction to be made when initiating chemotherapy is whether the patient is a transplant candidate or not. For patients more than 70 years old or with significant comorbid illness, an alkylating agent is a reasonable choice. The combination of oral melphalan and prednisone (MP) has been used for three decades. MP is associated with a response rate of 50% to 60%,^{38,39} is well tolerated, and is convenient. Typically, therapy is continued for 6 to 12 months until the monoclonal proteins stabilize in a plateau.

Once the patient enters a plateau, the therapy is discontinued and the patient monitored. Typical oral doses are 6 to 12 mg/m² by mouth each day for 4 days, repeated every 4 to 6 weeks. Other dosing schema include 0.15 mg/kg daily for 7 days. The prednisone is dosed at a fixed dose of 40 mg per day for 4 to 7 days to 40 to 60 mg/m². Because absorption of melphalan is unpredictable, the dose is often adjusted based on the degree of neutropenia at 3 weeks. Even in the absence of objective paraprotein response, patients may benefit in terms of symptoms and progression-free survival.

Although patients clearly benefited from MP, it was clear that other forms of therapy were needed. For patients with stable to responsive disease, median survival was of the order of 4 years. In patients with progressive disease, survival dropped to approximately 1 year. In an attempt to salvage MP failures and improve response rates, a number of combination chemotherapy regimens (CCT) were developed for MM. In single-institution trials, response rates in excess of 80% were reported. Popular regimens included vincristine, adriamycin, and dexamethasone (VAD),⁴⁰ as well as vincristine, BCNU, melphalan, cytoxan, and prednisone (VBMCP or M2).⁴¹ Multiple other regimens were developed, including alternating regimens. When these combination regimens were compared to MP, no difference was seen in efficacy. Gregory and colleagues conducted a meta-analysis of 18 randomized controlled trials comparing CCT with MP that showed no difference in response rates.⁴² Further analysis suggested that patients with high-risk disease did benefit in terms of survival with CCT but that patients with standard-risk disease did not benefit.

Initial Treatment for Transplant Candidates

For patients being considered for transplant, induction therapy ideally should be effective and have minimal stem cell toxicity. Although many patients have received induction chemotherapy containing alkylating agents, there is evidence that this approach has quantitative and qualitative implications concerning the ability to collect stem cells. For individuals failing initial therapy based on thalidomide or dexamethasone, up to several cycles of cyclophosphamide-based therapy is a reasonable strategy. Before the widespread adoption of front-line thalidomide-based therapy, induction therapy was often accomplished using VAD. Typically, the VAD was administered for 4 months or up to 6 to 8 months until the patient entered a plateau. Risks associated with VAD include neutropenia, alopecia, hyperpigmentation, myocardial injury, neuropathies, and constipation. In addition to the side effects associated with chemotherapy, are those of clotting and infections due to an indwelling catheter. Another approach is single-agent dexamethasone. While the response rate may be lower with single-agent dexamethasone (Webber), this strategy is convenient and avoids the toxicity of vincristine and adriamycin, as well as the need for placement of an indwelling catheter.

Over the past several years, the antiangiogenic drug thalidomide has gained widespread use. Single-agent thalidomide was first shown to have activity in heavily pretreated patients.⁴³ Recently, studies evaluating the combination of thalidomide and dexamethasone in newly diagnosed patients have revealed it to be highly active with response rates of 80%.⁴⁴ Importantly, the combination does not appear to com-

promise the ability to collect adequate numbers of stem cells to perform single or tandem transplants. The common risks include sedation, constipation, neuropathies, and hypercoagulability. There are several dosing schedules using thalidomide in doses of 100 to 200 mg orally each night and dexamethasone 40 mg orally once a week to days 1 to 4, 9 to 12, and 17 to 20.

The toxicity of thalidomide and dexamethasone appears to be dose related. Lower doses in general are associated with fewer side effects. Sedation is addressed by using reduced doses and instructing the patient take the drug at night. Sedation occurs within 1 to 2 hours of taking the drug and can last for 8 to 10 hours. To reduce the incidence of constipation, patients are advised to take a combination of stool softeners and laxatives; more aggressive interventions may be necessary. Neuropathies are inevitable with thalidomide. The risk appears to be related to dose and duration of exposure. The neuropathy typically occurs as a sensorimotor neuropathy that occurs in a stocking-and-glove distribution. This complication can take weeks to months to develop and often begins as intermittent paresthesias. The sensations can progress to become constant, severe in intensity, and progress proximally. Anecdotal evidence suggests that B vitamin supplementation may ameliorate the symptoms in some patients. In addition, nutritional supplements and electrolyte repletion may benefit selected patients. Other side effects include tachyarrhythmias, bradyarrhythmias, drug rashes including toxic epidermal necrolysis, and Stevens-Johnson syndrome, visceral neuropathies, and fatigue.

Should patients not plateau in a minimal disease state following thalidomide-based therapy, options include single-agent cyclophosphamide, bortomizomib, infusional doxorubicin-based therapy, or investigational studies. Once a patient achieves adequate disease control, then there are three options. These options include observation, maintenance therapy, and consolidation with dose intensification and stem cell support. The argument for observation is based on the sense that the disease is incurable and that the response seen with initial therapy can last for 6 to 12 months without further intervention. Continuing initial therapy longer can be associated with increased treatment-related toxicity, stem cell damage, and the selection of a greater number of resistant MM cells. Any of these options requires ongoing observation and supportive care, including bisphosphonates and monitoring by blood work, urine studies, radiographic studies, and bone marrows when warranted. Should there be consistent evidence of disease progression, therapy can be reinstated. If the relapse occurs more than 6 to 12 months after discontinuing therapy, then there can be benefit to another trial of the same therapy. If the progression occurs within 6 to 12 months, then another therapeutic option is a reasonable next step.

Numerous studies have evaluated the role of a variety of medications for maintenance. The rationale behind maintenance is to continue therapy in a reduced dose or schedule to prolong the response seen with the initial combination. The majority of studies evaluating the role of aciclovir therapy, continue the chemotherapy in full dose or reduced dose, or consider other agents, such as interferon-alpha-2 (IFN- α). Although the main benefit appears to be in terms of prolonging the progression-free survival, none of these studies

has shown a consistent benefit in terms of prolonging overall survival. When this modest benefit is weighed against the toxicity of some of these agents, the utility is questionable. Although IFN- α has been shown to prolong survival, the benefit was tempered by the decrement of quality of life in Quality Adjusted Time Without Symptoms of Toxicity (Q-TWIST) analysis.^{45,46} In an update of the tandem transplant experience, maintenance therapy with thalidomide and bisphosphonate therapy was associated with a prolongation in overall survival.

Maintenance therapy with low-dose thalidomide is appealing because it is well tolerated, oral, and does not damage stem cells. For patients who wish to be proactive but are ambivalent about transplant, thalidomide maintenance is a reasonable compromise. Newer forms of thalidomide will be even more appealing in this role given the reduced toxicity. Unfortunately, one of several outcomes is inevitable on thalidomide maintenance. Typically, thalidomide is discontinued because of disease progression or neurotoxicity. Maintenance therapy with steroids has also been evaluated. In a Southwest Oncology Group (SWOG) study, alternating-day prednisone was associated with improved overall and event-free survival.⁴⁷

Dose Intensification Followed by Stem Cell Rescue

High-dose therapy followed by infusion of autologous marrow or stem cells has become the standard of care in young and relatively healthy patients with MM. Despite high response rates and favorable side-effect profiles, MM remains an incurable illness. In addition, resistance can be overcome by dose intensification. As a consequence, the administration of alkylating agents in high doses with or without total-body irradiation, followed by infusion of allogeneic or autologous stem cells, is an appealing approach.

Autologous Stem Cell Transplantation

The rationale behind autologous transplantation is dose intensification to overcome resistance. Early studies performed at the Royal Marsden Hospital demonstrated that resistance to oral melphalan could be overcome by higher doses administered intravenously.⁴⁸ Unfortunately, this approach was associated with a high incidence of neutropenic complications. The addition of stem cell support was associated with shorter durations of neutropenia and a low risk of fatal infectious complications. Dose intensification is also associated with higher response rates when compared to conventional dose therapy. Although not curative, randomized studies demonstrate that patients treated with transplant have a prolonged overall and event-free survival compared to patients receiving conventional chemotherapy.

The first randomized study to demonstrate the benefits of autologous transplantation was the Intergroupe Francophone du Myelome 90 study, which enrolled 200 patients.⁴⁹ These patients received four to six cycles of vincristine, melphalan, cyclophosphamide, and prednisone (VMCP) alternating with carmustine, vincristin, doxorubicin, and prednisone (BVAP) for cytoreduction. They were then randomized to eight more cycles of VMCP/BVAP or autologous bone marrow transplant using melphalan and total-body irradiation (TBI). The results demonstrated a statistically significant prolongation in event-

free and overall survival in those receiving transplant. Estimated overall survival at 5 years was 52% for the transplant arm versus 12% on the chemotherapy arm ($P = 0.03$). Another randomized study demonstrating the benefits of autologous transplantation is the Medical Research Council Myeloma VII study.⁵⁰ This study also demonstrated a superior outcome in terms of overall and event-free survival. The median survival was 54 months with transplantation versus 42 months with chemotherapy ($P = 0.04$). Additional Phase II and Phase III studies of single transplants have at best shown no benefit in survival or only an advantage in terms of response rates or progression-free survival.⁵¹⁻⁵³ Interpreting these studies is difficult. Although few if any patients are cured, at a minimum, transplant appears to improve response rates, prolong progression-free survival, and in some patients, prolong overall survival. The benefit appears to be on the order of 1 to 2 years at best. Importantly, this benefit must be weighed against the substantial toxicity of the process itself. It also appears that patients who may derive the most benefit are those who are less heavily pretreated and who have sensitive disease.

Strategies to Improve Outcome

Timing

Although there are an increasing number of therapeutic options for treating MM utilizing newer drugs and combinations, the emphasis remains to perform the transplant earlier in the disease course rather than later. The strategy to transplant in first or second remission is based on subset analysis of transplant trials, which suggested that the sooner patients were transplanted, the better the outcome. Ease and speed in bringing a patient to transplant selects for those who have sensitive disease and who are in a minimal disease state. Heavily treated patients are more likely not to achieve a minimal disease state and to have more resistant disease. The recommendation for earlier transplant is also a consequence of therapeutic options before the availability of thalidomide and velcade. Before these agents, first-line therapy consisted of dexamethasone-based therapy whereas cyclophosphamide-based therapy was utilized in second-line regimens. Obtaining a third remission and preserving stem cell function was not always possible. Only one large randomized study addresses the issue of timing. The Myelome Autogreffe study compared transplant in first remission versus second remission.⁵⁴ In this study, no difference was seen in survival. The overall survival was 64 months in both groups. The main benefit to early transplant in this study was in terms of quality of life analysis. Quality Adjusted Time Without Symptoms and Toxicity (Q-TWIST) analysis as reported by the early-transplant group was superior compared to the late-transplant arm. One explanation for this finding is that, although the patients in the second remission arm received milder upfront therapy, because of the relapse they required combination chemotherapy and transplant.

Conditioning

A variety of regimens are used in conditioning patients for high-dose therapy. These regimens typically rely on alkylating agents with or without TBI. TBI was included because of

the radiosensitive nature of myeloma and different mechanism of action. Moreau et al., in an Intergroupe Francophone du Myelome (IFM) study, evaluated the role of TBI and determined that, although response rates were comparable, there was increased toxicity associated with melphalan plus TBI versus melphalan alone.⁵⁵

Purging of Bone Marrow or Stem Cells

One explanation for relapses following autologous transplantation, is reintroduction of tumor cells at the time of stem cell reinfusion. Several strategies have been employed to reduce contamination of the bone marrow or stem cell product by tumor cells. First, patients are not even evaluated for transplant until they have demonstrated a clinically significant response to conventional therapy. An indirect benefit of using peripheral blood stem cells as compared to bone marrow is that there may be less contamination by tumor cells. Using polymerase chain reaction (PCR) analysis of the hypervariable joining regions of the immunoglobulin heavy-chain gene (CDR3 PCR), sensitive probes can be created to measure minimal disease.⁸ CDR3 PCR analysis has demonstrated significantly less tumor cell contamination in the peripheral blood versus the bone marrow. Another approach taken to reduce contamination of the stem cell product by tumor cells is further manipulation to remove tumor cells or to select the normal stem cells. One approach was to use a cocktail of monoclonal antibodies directed at B-cell antigens combined with rabbit complement⁵⁶⁻⁵⁸ to kill contaminating tumor cells. Another approach was to select for normal hematopoietic stem cells using an anti-CD34 monoclonal antibody combined with a biotin and avidin system.⁵⁹ Unfortunately, these approaches do not address residual systemic disease and did not translate into improved response rates or survival.

Multiple Transplants

In an attempt to improve outcome following single transplants, a number of strategies have evolved to do multiple transplants. These approaches range from performing second or even third transplants as salvage for relapsed disease to planning second transplants in a sequential fashion. A further refinement to this approach is an autologous transplant followed by allogeneic transplant. A number of studies have demonstrated that multiple transplants can result in higher response rates when compared to single transplants and conventional dose chemotherapy.⁶⁰⁻⁶² A number of groups have published studies suggesting improved outcome with tandem transplants.⁶³⁻⁶⁵ While the Myeloma Autogreffe 95⁶⁵ fails to show a benefit and the Bologna 96 trial⁶⁴ only shows an event-free survival benefit of 44 versus 27 months ($P = 0.005$), the Intergroupe Francophone du Myeloma 94⁶⁶ does show both an event-free and overall survival benefit for the tandem transplant arm versus the single arm. The authors concluded that the survival benefit required at least 5 years of follow-up to reach statistical significance. At 7 years, the tandem arm demonstrated an overall survival of 42% versus 21% of the single-transplant arm ($P = 0.01$). This benefit becomes more impressive in patients who have a poorer response to the first transplant. In patients with less than a very good partial response within 3 months of the first transplant, the probability of surviving 7 years was 11% in the single-transplant

group and 43% in the double-transplant group (P less than 0.001). This study illustrates several points. The most important message is that it may take longer follow-up to see a benefit from tandem transplants. Although it is early, a substantial number of patients still relapse. Although the transplant-related mortality is comparable between the two groups, the tandem arms may experience increased morbidity. Finally, the single arm in the study received less dose intensity than many single transplants use.

Allogeneic Stem Cell Transplantation

Allogeneic transplant has a number of theoretical advantages over autologous transplantation. Using stem cells from a normal donor avoids the risk of contamination by tumor cells and concerns of stem cell function resulting from exposure to chemotherapy. Importantly, donor stem cell products contain immunocompetent lymphocytes that can initiate a graft-versus-myeloma effect. These benefits come at a cost in terms of increased morbidity and mortality. The 1-year transplant-related mortality of an autologous peripheral blood stem cell transplant is approximately 0.5% to 2% in large centers. The transplant-related mortality of an allogeneic transplant depends on the source of the stem cells and the degree of match but ranges from 8% to an excess of 50%. This increased risk is due to a greater degree of immunosuppression and complications associated with graft-versus-host disease (GVHD) and its therapy. There is no larger randomized, prospective trial comparing autologous to allogeneic transplantation. Allowing for the initial increase in transplant-related mortality, survival curves appear similar.⁶⁷

The single largest allogeneic transplant experience comes from the European Bone Marrow Transplant Group (EBMT).⁶⁸ For the 44% of patients who achieved a complete remission to allogeneic transplant, the overall survival was 32% at 4 years and 28% at 7 years. Overall progression-free survival was 36% at 6 years with only a handful of patients in continuing CR more than 4 years after transplant. The transplant-related mortality was 41%. In this study, favorable prognostic factors included being in a CR before transplant, fewer lines of conventional therapy, earlier stage at diagnosis, female, low β_2m , and IgA isotype. In another large allogeneic experience from Seattle,⁶⁹ the transplant-related mortality was 44%. For the 36% of patients achieving a CR, the overall survival and event-free survival at 54 months were 20% and 24%, respectively. A smaller experience using T-cell depletion as the GVHD is from the Dana Farber Cancer Institute.⁷⁰ In this study, the early treatment-related mortality was 5%, with a CR rate of 28%; overall survival at 36 months was 40% and event-free survival at 38 months was 20%.

Donor Lymphocyte Infusion

The existence of a significant graft-versus-myeloma (GVM) effect was inferred from the increased incidence of CRs in allogeneic transplant, as well as delayed responses in some cases.⁷¹⁻⁷³ Donor lymphocyte infusion (DLI) has been used to treat relapsed disease as well as being used prophylactically posttransplant before a documented relapse. The use of DLI

was particularly appealing in the setting of T-cell depletion for GVHD prophylaxis because of the reduced GVM effect resulting from T-cell depletion.⁷⁴ In this study, CD8-depleted DLI was utilized to further reduce the risk of GVHD. The DLI was performed at 6 months following a T-cell-depleted matched related donor transplant. In this setting, DLI accounted for addition responses but could only be performed in 58% of patients because of treatment-related mortality (TRM) and active GVHD.

Nonmyeloablative Transplants

The rationale behind a nonmyeloablative transplant is to reduce the toxicity of the transplant while maintaining a GVM effect. The reduced-dose conditioning therapy essentially represents immunosuppression to reduce the risk of graft rejection although melphalan-containing regimens have antimyeloma activity. The goal of this approach is to establish a chimera and to rely on the GVM for long-term disease control. In this setting, the use of DLI is even more appealing. Because of the reduced cytoreduction, nonmyeloablative transplants may be more appropriate for patients with indolent low-volume disease. Patients with aggressive high-volume disease may progress long before a GVM effect can be established. Preliminary results have demonstrated that nonmyeloablative transplants are associated with reduced immediate transplant-related morbidity and mortality.⁷⁵⁻⁷⁷ These studies also demonstrate substantial acute and chronic GVHD.

Related Disorders

Osteosclerotic MM

Osteosclerotic MM is characterized by a polyneuropathy, organomegaly, endocrinopathy, M-spike, and skin changes (POEMS syndrome).⁷⁸ It is rare to see all these features present at once. These patients usually seek medical attention because of a progressive motor neuropathy. Renal dysfunction is rare, as is a significant anemia. Gynecomastia and testicular atrophy can be seen. The M-spike is often relatively low given the degree of symptoms. These patients respond to therapy although rarely does the neuropathy resolve.

Nonsecretory MM

Approximately 2% to 5% of patients with MM have no measurable M-spike. Prognosis does not appear to be different compared to patients with a M-spike.⁷⁹ Monitoring of the disease can be challenging but is not impossible. Disease response and progression can be measured following the anemia, change in reciprocal depressions of the serum immunoglobulins, and B2M. In addition, serial bone marrow examinations can add useful information. Free serum light-chain tests may be sensitive enough to detect free light chains not seen on 24-hour urine immunoelectrophoresis.

Plasma Cell Leukemia

Plasma cell leukemia (PCL) can occur during the course of therapy or be the presenting diagnosis. PCL is defined as a

peripheral plasmacytosis of more than 20% or an absolute plasma cell count greater than $2 \times 10^9/L$. PCL is associated with a poor prognosis, although the median survival of patients with primary PCL may be better than those with secondary PCL. Median survivals are of the order of a year; although rare, patients can survive longer.

Solitary Plasmacytomas

Solitary plasmacytomas consist of isolated collections of plasma cells in bone or extramedullary tissues. Extramedullary plasmacytomas are associated with a median survival of 100.8 months versus 86.4 months for solitary osseous plasmacytomas.⁸⁰ Involved-field XRT is indicated and can be curative in selected patients.^{37,81} Disappearance of the M-spike following XRT predicts for long-term disease-free survival.

Primary Amyloidosis

Primary amyloidosis is characterized by the accumulation of a homogeneous amorphous material consisting of the variable portion of light chains. Free lambda light chains predominate, and the formation of amyloid is associated with the degradation of light chains, which then form beta pleated sheets. The clinical manifestation of the disease correlates to the extent of end-organ damage.^{82,83} Amyloid is relatively rare and can be divided into five categories. Primary amyloid is associated with lymphoproliferative disorders. Secondary amyloid is seen with chronic inflammation or infection. The other types are associated with inherited disorders, aging, and other malignancies. The clinical manifestations of amyloid include cardiac involvement with congestive heart failure and conduction disturbances, renal failure, and gastrointestinal involvement with malabsorption. The prognosis is dismal, and therapy is limited by organ toxicity. Therapy is palliative, and melphalan and prednisone remain the standard of care.⁸⁴ In selected patients, transplant is feasible and may improve symptoms.^{85,86}

New Therapies

The treatment of MM has been revolutionized by the development of new drugs and combinations. At the root of this activity has been a growing understanding of the biology of MM cells and their complex interactions with the bone marrow microenvironment. This knowledge has led to new paradigms of drug development. Despite these developments, no drug appears to be curative. Rather than replacing the older agents, newer approaches allow additional lines of therapy and prolongation of survival. Although an old drug, thalidomide has been resurrected with MM. Based on an appreciation of the increased density of blood vessels in the bone marrow in myeloma and novel approach of attacking angiogenesis, thalidomide was evaluated in MM.^{43,87} The mechanism of action does not appear to be suppression of neovascularization but rather, induction of apoptosis, inhibition of cytokine production and angiogenesis, and immunomodulation.^{14,88,89} Response rates in relapsed patients were 25% to 30%.^{43,87} In newly diagnosed patients in combi-

nation with dexamethasone, RR are in excess of 63% to 72%.^{44,90}

Bortezomib is a proteasome inhibitor approved for second-line therapy in MM. Proteasomes play an important role in the regulation of intracellular proteins vital to cell function. In addition to dysregulation of cell-cycling proteins, bortezomib has been shown to have several other effects on both myeloma cells and stromal cells in the bone marrow. By inhibiting degradation of regulatory proteins that have been targeted for destruction by ubiquitination, the cell can no longer remain viable. Molecular effects include stabilization of the inhibitory protein of the nuclear factor kappaB (NF-kB).⁹¹ This effect blocks downstream activities of proliferation, survival, and angiogenesis. Bortezomib as a single agent in relapsed refractory patients has a response rate of 27%.⁹² Studies combining bortezomib with other agents show even higher response rates.

Based on a growing understanding of the interactions between MM cells and the bone marrow microenvironment, new molecular targets are being identified. Novel agents are being evaluated that target the MM cell by interrupting MM cell growth, survival, drug resistance, and migration. These approaches include combining available drugs as well as novel drugs and analogues of thalidomide.

Superior Vena Cava Syndrome

Michael S. Kent and Jeffrey L. Port

Obstruction of the superior vena cava (SVC) is a common complication of thoracic malignancy and of bronchogenic cancer in particular. Although the condition was first described in 1757,¹ little progress had been made in the treatment of these patients until the first report of surgical reconstruction in 1951.² However, over the past decade there has been a remarkable evolution in the successful management of this disease, in large measure as a result of the refinement of endovascular techniques, such as stent placement and thrombolysis.

Superior vena cava obstruction is a disease with a wide range of clinical presentation and treatment. Caval obstruction may be an incidental finding on computed tomography (CT), with the development of collateral venous channels, or may be the fulminant, initial presentation of a malignancy. Furthermore, SVC obstruction may also arise as a consequence of benign conditions, such as mediastinal fibrosis or thrombosis related to indwelling central catheters. The successful management of this disease requires a familiarity with the wide variety of treatment options available and an appreciation of the significant disparity in prognosis between those with benign and malignant causes of SVC obstruction.

This chapter reviews the relevant anatomy and pathophysiology of SVC obstruction and discusses the current treatment options, including surgical reconstruction, radiation and/or chemotherapy, and endovascular therapies. Unfortunately, the majority of reports are single-institution case series. When available, data from clinical trials in which treatment modalities are directly compared are emphasized.

Clinical Presentation

The first reported case of SVC obstruction, by William Hunter in 1757, described a patient with an aneurysm of the ascending aorta. Although such benign causes of SVC obstruction were common in the 19th century, the increasing incidence of bronchogenic cancer has led to the overwhelming association of this condition with malignancy. For example, nearly 40% of cases reported in the first half of the 20th century were associated with infectious conditions, such as mycotic aortic aneurysms, tuberculosis, or syphilis.³ In contrast, malignant causes of SVC obstruction now account for more than 90% of cases.⁴ Bronchogenic carcinomas, both small cell (SCLC) and non-small cell (NSCLC) histologies, are responsible for 65% to 80% of these cases. Mediastinal tumors, particularly thymoma and thyroid cancer, account for 20% of

malignant cases, and metastatic solid tumors are responsible for the remainder.⁵ Although far less common, benign etiologies of SVC obstruction must also be considered. Thrombosis of the SVC from central venous catheters or pacemaker leads has been well described.^{6,7} Rare causes of SVC occlusion include mediastinal fibrosis and late effects of external-beam radiation therapy (Table 70.1).⁸

Superior vena cava obstruction is not an uncommon condition when all causes are considered. The disease is estimated to affect as many as 15,000 patients in the United States annually.⁹ Although only 3% of all patients with lung cancer develop SVC obstruction, the condition may develop in up to 10% of those with right-sided malignancies.¹⁰ SVC obstruction is especially common in small cell lung cancer, with a reported prevalence as high as 11%.¹¹

The pathogenesis of SVC occlusion is typically one of extraluminal compression. Direct extension of a malignancy, classically a non-small cell lung cancer arising from the right upper lobe, may lead to circumferential involvement of the cava and obstruction of venous return to the heart. The compressibility of the SVC and its central location within the mediastinum render it particularly susceptible to this process. SVC occlusion may also develop from mediastinal lymphadenopathy, particularly metastases from a NSCLC to the right paratracheal lymph node stations. Similarly, the central lymphadenopathy associated with small cell lung cancer leads to the high prevalence of SVC obstruction with this disease. A final mechanism of SVC occlusion is that of intraluminal thrombosis. The presence of indwelling central catheters has been shown to induce endothelial damage and turbulent blood flow, leading to catheter encapsulation and venous thrombosis.¹² In cases of malignant disease, a tumor that invades into the lumen of the cava may serve as the nidus for thrombus formation.

The development of SVC occlusion leads to a characteristic syndrome of facial and upper extremity edema, along with the development of tortuous collateral veins on the anterior chest wall. Headache, dizziness, and nausea are not infrequent. Rare signs of SVC occlusion include obtundation from cerebral edema and airway compromise from edema of the epiglottis (Table 70.2). Patients rarely present with acute symptoms; more commonly, they describe the gradual onset of symptoms over several weeks.¹³ The symptoms of SVC occlusion may be quite distressing for the patient and affect quality of life significantly. Fortunately, life-threatening symptoms are extremely rare. Severe neurologic symptoms and airway compromise have been reported to occur in less

than 5% of patients.¹⁴ Furthermore, central nervous system (CNS) symptoms may be secondary to cerebral metastases rather than SVC occlusion, and should be ruled out by CT or magnetic resonance imaging (MRI).

The belief that SVC syndrome represents an oncologic emergency has not been supported by modern series. Early reports suggested a high mortality associated with SVC occlusion; however, the majority of patients from these series had end-stage disease and the cause of death was not clear.¹⁵ Recent series have documented an early mortality of 2% or less.^{11,13,16} Furthermore, diagnostic studies may be safely performed in patients with SVC obstruction, and thus, adequate information may be obtained before embarking upon therapy.^{17,18}

Although patients rarely die as a direct consequence of SVC occlusion, the overall prognosis for these patients is quite poor, especially for those with lung cancer. In a review of 337 patients with malignant causes of SVC obstruction, patients with lung cancer had an overall 5-year survival of only 2%, compared with a 10% survival for those with breast cancer and a 40% survival for patients with lymphoma.¹⁴ Median survival is typically only 6 to 9 months following treatment.¹⁹ In contrast, the majority of patients with SVC syndrome from nonmalignant causes can anticipate a normal life expectancy.

Evaluation

The appropriate treatment of SVC obstruction depends greatly on the underlying cause of the syndrome. Often, patients with malignant causes of SVC obstruction have a known cancer diagnosis. However, SVC obstruction may be the presenting sign of a malignancy in up to 10% of patients with SCLC and 2% of those with NSCLC.¹⁹ In these situations, a tissue biopsy is necessary to clarify the diagnosis. In older series, fear of uncontrollable hemorrhage led to empiric treatment of patients without a tissue diagnosis. However, noninvasive techniques, such as sputum cytology, can yield a diagnosis in two-thirds of patients.²⁰ Furthermore, invasive procedures have been shown to be safe in patients with SVC obstruction. For instance, in a series of 88 patients who underwent a variety of sampling techniques, including CT-guided

TABLE 70.2. Symptoms of SVC obstruction.

<i>Symptoms</i>	<i>Frequency</i>
Facial swelling	72%
Dyspnea	60%

biopsy and mediastinoscopy, no mortalities and only 1 treatment-related morbidity were reported.¹⁸ Although mediastinoscopy has been shown to be safe in this patient population, the incidence of complications is indeed higher than in those without SVC obstruction. Clinical series have documented the need for salvage sternotomy because of bleeding to be between 1% and 3%,^{18,21,22} compared with the 0.3% sternotomy rate reported for patients without SVC obstruction.²³

Physical examination is sufficient to establish the diagnosis of SVC obstruction. Radiologic assessment, such as CT and venography, is not necessary to confirm the diagnosis but is valuable in treatment planning. CT defines the anatomic extent of the mass, determines whether the obstruction is from a primary tumor or malignant lymphadenopathy, and allows for a CT-guided biopsy (Figure 70.1). Rarely, patients with malignant tumors and SVC invasion may be resected for cure.^{24,25} CT in this setting would be essential for operative planning.

In addition, both CT and venography provide anatomic detail of the venous system that can define the severity of the SVC obstruction. In the presence of SVC obstruction, the major pathway for collateral flow to the heart is the azygos vein. The azygos vein runs parallel to the superior and infe-

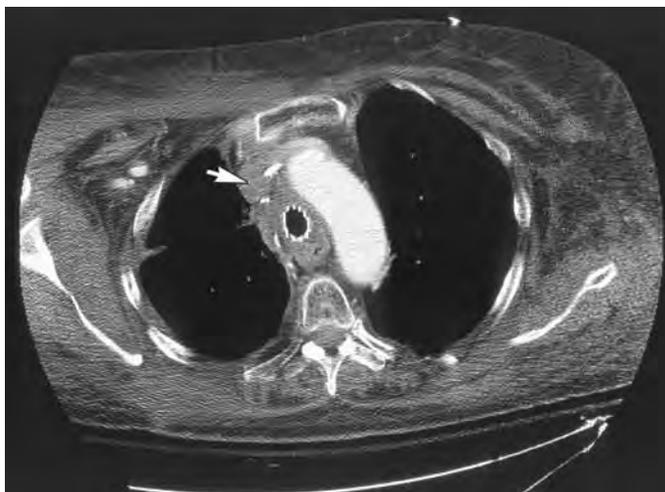

FIGURE 70.1. Computed tomography (CT) scan of a patient with recurrent non-small cell (NSCLC) and superior vena cava (SVC) obstruction. The tip of a subclavian catheter is seen within the thrombosed SVC (arrow). A tracheal stent and adjacent paratracheal lymphadenopathy are also appreciated.

TABLE 70.3. Classification of SVC obstruction by computed tomography (CT) and venography.

	<i>Finding</i>
CT classification	
Type IA	Moderate SVC narrowing without collateral flow
Type IB	Severe SVC narrowing with retrograde flow in azygos vein
Type II	SVC obstruction above azygos with retrograde flow into thoracic, vertebral, or other collateral channels
Type III	SVC obstruction below azygos with retrograde flow through azygos into the inferior vena cava (IVC)
Type IV	SVC obstruction at azygos vein with multiple small peripheral collaterals
Venogram classification	
Type I	Partial obstruction of the SVC with patency of the azygos vein
Type 2	Near-complete to complete obstruction of the SVC with antegrade flow in the azygos vein
Type 3	Near-complete to complete obstruction of the SVC with retrograde flow in the azygos vein to the IVC
Type 4	Complete obstruction of the SVC and azygos vein

rior vena cavae and drains into both the right common iliac vein and SVC just above the pericardial reflection. Obstruction of the SVC below the insertion of the azygos vein leads to retrograde flow through the azygos vein, into the inferior vena cava, and ultimately into the right atrium. When the obstruction is above the azygos vein, collateral venous beds, such as the cervical and paravertebral plexuses dilate. These collateral vessels then drain into the azygos vein. The most severe cases of SVC syndrome occur when the obstruction is at the level of the azygos vein. In these cases, small vessels overlying the thoracic wall dilate and serve to return venous blood to the inferior vena cava. Dilation of these vessels only occurs over a period of several weeks. Consequently, obstruction at the azygo-caval junction that occurs acutely may lead to severe symptoms.

Evaluation of the azygos vein is therefore critical in documenting the severity of SVC obstruction. Higher grades of SVC obstruction in current classification systems are those in which the azygos vein is not visualized. The schemes developed by Stanford and Doty for venography²⁶ and Raptopoulos for CT²⁷ are those most commonly referenced (Table 70.3).

Unfortunately, a similar classification of clinical symptoms has not been universally accepted. Such a scheme would allow for the means to objectively compare the degree of symptomatic relief between different methods of treatment. An illustrative scoring system is presented in Table 70.4; however, this scale has not been validated in a prospective fashion.²⁸

TABLE 70.4. Clinical scoring system for SVC obstruction.

<i>Symptom</i>	<i>Points</i>
Arm/head/extremity swelling	1
Neck or chest vein distension	1
Cough	1
Blurred vision	1
Tinnitus	1
Headache	1
Dizziness	1
Dyspnea	1
Plethora	1
Vocal cord paralysis	1
Total	Up to 10 points

Treatment

Historically, the treatment of SVC occlusion has included head elevation and the administration of steroids and diuretics. These measures are largely ineffective,⁴ and the standard treatment for patients with malignant causes of SVC obstruction has been radiation therapy and/or chemotherapy. Surgical bypass is an option for those who fail medical therapy, although the morbidity of such a procedure in patients with a limited life expectancy was often thought to be prohibitive. Endovascular stenting of SVC was first reported in 1992²⁹ and has gained increasing popularity since then. Many now consider stenting to be the mainstay of treatment for patients with malignant SVC obstruction. For benign causes of SVC occlusion, the most appropriate role for stenting or surgical bypass has not been well defined. As no standard treatment exists for all patients with SVC occlusion, a review of all the methods of available therapy is appropriate.

Chemotherapy and Radiotherapy

Chemotherapy and radiation therapy (CRT) have been the first-line therapy for patients with SVC occlusion of malignant etiology. The majority of reports of CRT are retrospective and include patients who undergo therapy for a variety of tumor subtypes, making a direct comparison of different protocols extremely difficult. Analysis is further complicated by the fact that patients are often treated with both radiotherapy and chemotherapy, so the two modalities cannot be directly compared.

Recently, a review of current therapy for SVC obstruction caused by bronchogenic cancer was published.¹⁹ In this review, 22 studies of CRT that included 746 patients were analyzed, and the results were stratified by small cell or non-small cell histology. For SCLC, 77% of patients experienced symptomatic relief of SVC obstruction after chemotherapy or radiation therapy. For NSCLC, the rates of symptomatic relief were lower: 59% for chemotherapy alone and 63% for radiotherapy alone. The rapidity of symptom relief after CRT was not well documented. Overall, a clinical response generally occurred within 2 to 3 weeks after the initiation of therapy. However, one study found that 25% of clinical responses occurred 3 weeks after starting treatment.¹¹ Data regarding relapse were provided in a smaller subset of series. Overall, clinical relapse occurred in 17% of patients with SCLC and 19% of those with NSCLC.

Endovascular Therapy

The entire spectrum of endovascular technology, including thrombolysis, angioplasty, and stenting, has found an application in the management of patients with SVC obstruction. The era of endovascular therapy for this condition began in 1986. In that year, the first successful angioplasty of SVC stenosis caused by a transvenous pacemaker was reported.³⁰ In that same year, the first patient with malignant SVC obstruction was treated by placement of an SVC stent.³¹ Since these early reports, endovascular therapy has essentially replaced surgery as the treatment for patients with malignant SVC obstruction who fail CRT. The role of endovascular technology as first-line therapy remains controversial, although many centers have recently adopted this approach.

Thrombolysis is rarely the sole method of treatment of SVC obstruction, because the majority of patients have external compression of the cava, for which thrombolysis alone is ineffective.³² On occasion, patients may have thrombosis of the SVC from benign causes, most often indwelling central lines, for which thrombolytic therapy may be effective. In this case, infusion of agents, such as tissue plasminogen activator (tPA), has been shown to be 88% successful if used within 5 days of the occlusion, but only 25% successful if used thereafter.³³ Thus, for subacute or long-standing thrombosis, pharmacologic therapy alone is insufficient. Similarly, angioplasty alone has a high rate of restenosis and failure because of the elastic nature of the cava.³⁴ Therefore, stenting in combination with angioplasty or thrombolysis is the more common treatment paradigm.

A wide variety of stents designed for peripheral vascular disease may be deployed within the SVC. Stents may be categorized as self-expanding or balloon-expanding. Most authors prefer to use self-expanding stents in the venous system. Self-expanding stents typically are more flexible and have greater radial force than balloon-expanding stents. In addition, the diameter of the cava often increases after successful stenting. Balloon-mounted stents that lack self-expansion are more likely to migrate in this circumstance.³⁶ Some of the more commonly used self-expanding stents include the Gianturco Z-stent, the Wallstent, and the Smartstent. The Z-stent was the first device used to stent the SVC; however, it has a relatively large profile compared to more recent devices. In addition, the Z-stent has a propensity to migrate or fracture.³⁶ The Wallstent is less likely to migrate; however, it has a tendency to shorten after deployment, which makes precise placement of the stent difficult. Fore-shortening of the stent may be significant to the point of uncovering the point of obstruction, leading to restenosis.³⁷ The Smartstent is a further evolution of stent technology based on nitinol (Figure 70.2). Nitinol is a nickel-titanium alloy that assumes a predetermined shape at a certain temperature. It has been found to have a high radial strength, a very low risk of fracture, and is not prone to foreshortening.

Access for stent deployment is usually obtained from the basilic vein. If larger sheaths are required or access via the brachial route is not possible, then the femoral vein may be cannulated. A guidewire is then passed beyond the obstruction under fluoroscopic guidance. A venogram is then obtained to document the areas of stenosis and thrombus formation within the cava (Figure 70.3). Thrombus formation is associated with SVC obstruction in up to 37% of cases³⁸;

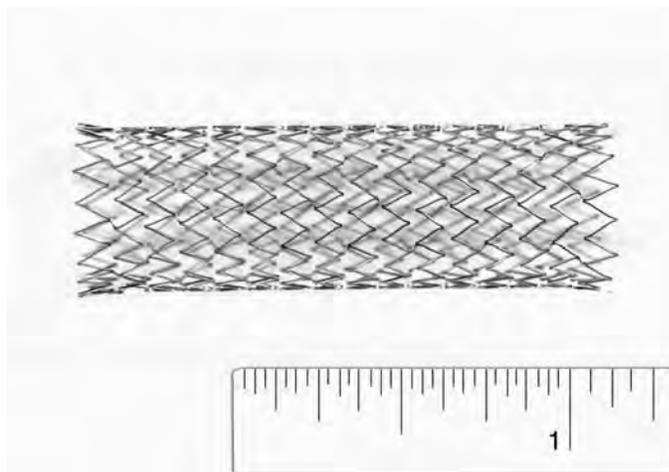

FIGURE 70.2. Self-expanding nitinol stent used for SVC obstruction.

however, the majority of patients have a nonocclusive clot that does not require thrombolysis. Given the risk of bleeding complications, thrombolytic therapy is usually reserved for patients with extensive thrombus within the caval system. Angioplasty is occasionally performed if the stenosis is significant enough to prevent stent deployment. In general, however, angioplasty is avoided and immediate stenting is performed (Figure 70.4). This practice results from the concern that angioplasty may dislodge a thrombus along the caval wall and lead to distant embolism.³⁵ Patients who require thrombolysis are routinely placed on intravenous heparin and then warfarin for a period of 3 to 6 months. Many authors recommend coumadin or antiplatelet therapy for all

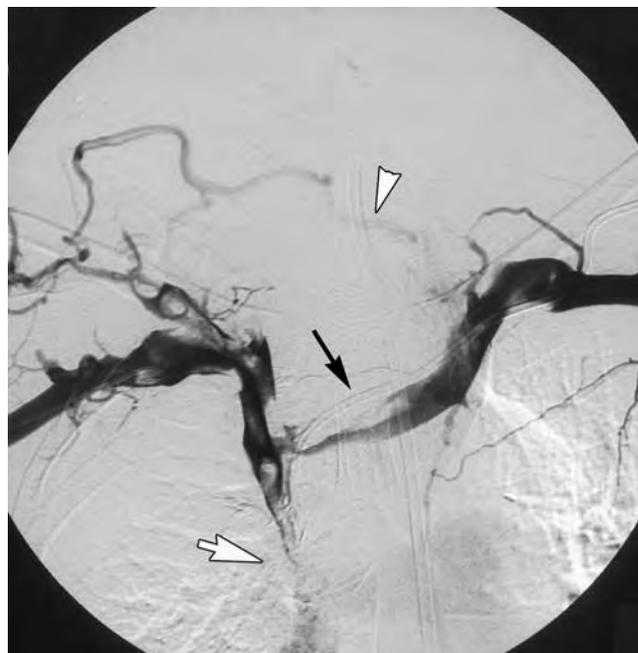

FIGURE 70.3. Pretreatment angiogram of a patient with SVC obstruction (*white arrow*) from NSCLC. A catheter with surrounding thrombus is visible within the left brachiocephalic vein (*black arrow*). Also present are small collateral channels (*white arrowhead*) that cross the midline.

FIGURE 70.4. Completion angiography in the same patient after thrombolysis and placement of an SVC stent. A tracheal stent (*arrow*) is also seen.

patients after SVC stenting,^{39,40} although there is no clear justification for this practice.

Stent deployment is technically successful in 95% of cases¹⁹ (Table 70.5). The majority of patients report immediate relief of headache.⁴¹ Other symptoms, such as arm and facial edema, usually resolve within 72 hours. Dyspnea is the most resistant symptom to improvement after stent placement and may persist in up to 40% of patients.³⁹ The rate of relapse following stent placement is also quite low. In a review of 23 series of SVC stenting in patients with lung cancer, the relapse rate was 11%.¹⁹ The majority of patients with recurrent symptoms may be treated with additional stent placement or thrombolysis. Given the success of subsequent interventions, the secondary patency rate after stenting in this review was 93%. The median survival for these patients, however, was less than 1 year, and thus the long-term patency of SVC stenting could not be determined.

Although uncommon, several complications have been associated with SVC stenting. Transient chest pain is often

seen with stent deployment. Bleeding complications, such as puncture site hematoma, melena, and epistaxis, have also been reported in those who require thrombolysis. Other complications, such as stent fracture or migration, were reported in earlier studies. Dislodged stents have even been documented to migrate to the pulmonary artery,⁴² although this is extremely rare. SVC rupture with pericardial tamponade has also been reported.⁴² Thankfully, these mechanical complications are uncommon in more recent series. No deaths have been recently reported with SVC stent deployment.¹⁹

Surgery

Surgery is rarely indicated for patients with SVC occlusion. Infrequently, patients may require contiguous resection of the SVC in the context of a malignancy that is otherwise resectable. However, the majority of patients with symptomatic SVC occlusion have locally advanced or distant disease and are not resectable for cure. Thus, surgery is often performed as a purely palliative procedure.

Venocavography is essential before undertaking surgical reconstruction; this allows for a precise determination of the proximal degree of obstruction and the presence of intraluminal thrombus. Usually the bypass is constructed between a single vein, such as the right or left brachiocephalic vein, and the right atrium (Figure 70.5). Bilateral bypasses are rarely required because collateral channels that cross the midline are sufficient to drain the contralateral side.

Several conduits are available to bypass the SVC. Conduits may be autologous vein, such as the saphenous or common femoral vein, or synthetic material, such as polytetrafluoroethylene (PTFE). The femoral vein was the first conduit used to relieve SVC obstruction³⁴; however, its use has declined significantly since the description of the technique in 1951. The size discrepancy between the femoral vein and SVC is significant, and removal of the femoral vein may lead to venous insufficiency of the leg. However, composite grafts of the smaller saphenous vein have found widespread applicability. In the initial report, the saphenous vein was incised along its length and “panels” of vein were sewn together to create a conduit of larger diameter.⁴³ A subsequent modification of the technique was the creation of a “spiral graft” in which the vein was sewn to itself in a spiral fashion around a chest tube or other stent.⁴⁴ The disadvantage of autologous vein, however, is its easy compressibility; this may lead to early occlusion, especially if the cause is a thoracic malignancy that may continue to progress. For this reason, some authors have preferred to use ringed PTFE, which has an intrinsic skeleton that renders it relatively resistant to external compression. Ringed PTFE has a 5-year patency of 86%,²⁵ which is comparable to that of spiral saphenous vein.⁴⁴ The equivalent long-term patency and the simplicity of the technique have led to a preference for synthetic grafts among many authors.^{25,45}

Surgical bypass for SVC obstruction is performed through a median sternotomy. Although bypass procedures using the azygos vein have been reported through a right thoracotomy,²² a sternotomy provides superior exposure to structures within the anterior mediastinum. The innominate vein is mobilized to the origin of the interior jugular vein and is encircled with tourniquets. After the patient has been systemically heparinized, a small venotomy is made. If present, thrombus within the vein is removed using a Fogarty catheter. Next, the conduit is sutured to the vein in an end-to-side fashion. The graft is flushed with heparinized saline, and an anastomosis is constructed to either the right atrial appendage or the right atrium.

It should be noted that patients who undergo caval resection and replacement (Figure 70.6), as opposed to surgical bypass, require a more-complex procedure. In this setting, the SVC is rarely occluded and clamping of the vein may lead to significant hemodynamic instability.⁴⁶ Techniques, such as intraluminal shunting or cardiopulmonary bypass, may be required; these are outside the scope of this chapter.

Although patients with SVC obstruction are often moribund, the operative mortality has been low (Table 70.6). In the largest report of 43 patients who underwent bypass for

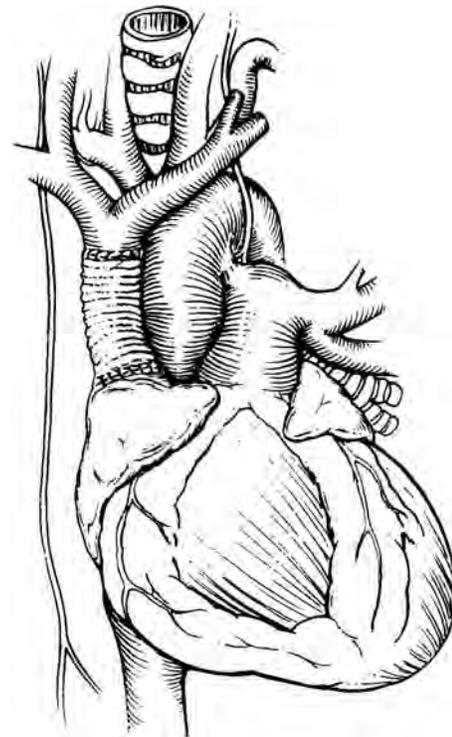

FIGURE 70.6. Resection of the SVC and replacement with an interposition PTFE graft. (Reprinted with permission from Nesbitt J. Surgical management of superior vena cava syndrome. In: Lung Cancer: Principles and Practice. Philadelphia: Lippincott-Raven, 1996.¹⁴)

malignant SVC obstruction, the operative mortality was only 4%.⁴⁷ Furthermore, relief of symptoms is nearly immediate and early thrombosis of the graft is uncommon. For patients with SVC obstruction from benign causes, the long-term patency of the bypass is critical. The largest series of SVC bypass for nonmalignant disease documented an overall 5-year patency of 80%.⁴⁸ Among the 29 patients, 5 required reoperation for early graft failure. Eight patients required additional interventions for late graft failure. The majority of these interventions were endovascular, although 3 patients required surgical revision. In this series, spiral saphenous vein had a superior patency and was preferred over PTFE conduits.

Management Controversies

There are no randomized studies that compare treatment options for patients with SVC obstruction. Nonetheless, the

TABLE 70.6. Results of open surgical bypass for SVC obstruction.

NS, not stated.

high success rate of stenting reported in case series, has led to a reduction in open surgical bypass, at least for patients with malignant SVC occlusion. However, two areas of controversy still exist in the management of this syndrome. The first is whether stenting should be first-line therapy for patients with malignant SVC obstruction, or reserved for those who fail radiation or chemotherapy. The second relates to the proper role of stenting versus open surgery for patients with benign causes of SVC obstruction.

Despite the lack of prospective data, there is evidence to support the use of stenting as primary therapy for patients with malignant SVC obstruction. Stenting has clearly demonstrated superiority over CRT in terms of the initial response to therapy. Stenting relieved symptoms in 95% of patients with bronchogenic cancer compared with 59% (for NSCLC) and 77% (for SCLC) of those treated with radiation or chemotherapy. Furthermore, relief of symptoms with stenting was nearly immediate, compared to days to weeks with chemotherapy. This difference is particularly significant in a patient population whose median survival is less than 1 year. Perhaps most important, fewer patients developed a recurrence of symptoms when treated with stenting. Thus, the relapse-free rate, defined as the response rate minus the recurrence rate, was estimated at 84% for stenting, compared with 41% (NSCLC) to 60% (SCLC) among those treated with radiation or chemotherapy.¹⁹ Certainly, for patients with NSCLC, these data would support the use of stenting as primary therapy. Although the response to CRT is somewhat higher for those with SCLC, stenting would still be justifiable as primary therapy in this patient population.

Additional data support stenting as primary therapy for malignant SVC syndrome. First, stenting in no way precludes further administration of CRT.⁴⁹ In fact, stenting may allow for the easier administration of intravenous fluids required for chemotherapy. Second, stenting has been estimated to incur only a marginal increase in the cost of treating these patients due to the expense of end-of-life care.^{37,41} Finally, most patients who develop a recurrence after stenting may be retreated, either with thrombolytics or additional stenting, leading to a secondary patency rate of nearly 100%.^{39,40}

The long-term results of stenting are not as well documented, and for this reason, the best treatment for patients with benign SVC occlusion remains controversial. In comparison with stenting, surgical bypass has been shown to yield excellent long-term results. For example, Doty reported on a series of 16 patients who underwent spiral saphenous vein bypass for benign SVC obstruction, most commonly caused by fibrosing mediastinitis. With a mean follow-up of nearly 11 years, 14 of the 16 grafts were patent. Only 3 patients had early graft occlusion, and reoperation restored flow in all but 1.⁴⁴ The only other large series of patients treated for benign SVC obstruction was from the Mayo Clinic. This report described similar results, with a 5-year patency of 80%.⁴⁸

The durability of stenting the SVC for benign disease does not seem to be as impressive. For example, in the Mayo Clinic series 3, additional patients were described who underwent stenting as primary therapy. All 3 patients required repeat interventions for restenosis, and 1 patient ultimately required open surgical bypass. Similarly, a recent report from Toulouse, described 14 patients who underwent stenting for benign disease, the majority related to venous access for hemodialysis.³⁵ Stenting *failed* to restore patency in 11 of these patients.

After repeat interventions, only 9 patients had restoration of flow. Furthermore, the follow-up of these patients was only 14 months, and so the rate of late restenosis is not known.

For several reasons, stenting will remain an option for patients with benign disease. First, it is certain that refinements in stent technology will improve on these relatively poor early results. Second, patients may prefer a minimally invasive therapy, even though the rate of early failure and the need for repeat intervention will be high. Perhaps most important, few centers have a large enough experience with open bypass to achieve long-term success. As experience with SVC stenting for malignancy increases, it may become the first option for benign disease as well, simply because of ease of insertion and familiarity with the technique.

Central Nervous System Emergencies

Kevin P. McMullen, Edward G. Shaw,
and Volker W. Stieber

Emergency management of central nervous system malignancies is an unfortunate reality facing the oncologist. Although expeditious treatment is certainly the cornerstone of management, the astute clinician should carefully weigh a combination of multidisciplinary therapeutic options to ensure optimal outcome for the patient, with an eye toward both treatment sequelae and anticipation of future need for further treatment.

Malignant Spinal Cord Compression

Epidemiology and Pathology

Malignant spinal cord compression (MSCC) is a medical emergency, with incidence second only to brain metastases for cancer emergencies in the central nervous system. Spinal cord compression from epidural metastases occurs in 5% to 10% of cancer patients, and in up to 40% of patients with preexisting nonspinal bone metastases.¹⁻⁴ Of those with bony spinal disease, 10% to 20% develop symptomatic spinal cord compression, resulting in more than 25,000 cases per year.^{5,6} Symptoms depend on location of the compression and can involve the spinal cord at any level. If not rapidly diagnosed and treated, paralysis, incontinence, and severe chronic pain may be the inevitable result.

The spine is the most common site of bony metastases overall, with a reported incidence in cancer patients of 40%.⁴ It has been estimated that the incidence of MSCC in the United States is approximately 25,000 cases annually.^{5,6} Approximately 5% to 10% of patients who die of their malignancy experience an MSCC.^{6,7} A recent population-based cohort study of cancer patients in Ontario, Canada, from 1990 to 1995, is the most comprehensive study available in the peer-reviewed literature on epidemiology for MSCC.⁸ In this study, overall incidence of MSCC within 5 years of death from cancer was 2.5% overall. Based on the American Cancer Society estimate of 563,700 cancer deaths expected in 2004,⁹ and assuming this population cohort is similar to the U.S. population, then an overall incidence for MSCC of 2.5% or 5% would estimate the number of cases of MSCC in 2004 to be between 14,100 and 28,200.

MSCC is slightly more common in male patients than in female patients (60:40 ratio).¹⁰ This difference may reflect the relative incidence of primary breast cancer compared with

primary prostate cancer. All ages of patients may be affected, but the period of highest prevalence coincides with the relatively high cancer risk period that occurs between 40 and 65 years of age.⁹

The histology of MSCC follows the incidence patterns of malignant disease, with the most common histologic diagnoses (breast, lung, and prostate) accounting for approximately half of all cases.^{4,9} Approximately 25% of all patients with MSCC have breast cancer, 15% have lung cancer, and 10% have prostate carcinomas. In the Ontario study, the overall incidence of MSCC ranged from 0.2% to 7.9%, depending on primary disease site.⁸ Overall, 5.5% of breast cancer patients, 2.6% of lung cancer patients, 7.2% of prostate cancer patients, and 0.8% of colorectal cancer patients experienced a MSCC. Other commonly reported histologic diagnoses in adults include, by order of cumulative incidence, multiple myeloma, nasopharynx, renal cell, melanoma, small cell lung, lymphoma, and cervix.^{4,8,11}

Seventy percent of cases occur at the thoracic level, 20% at the lumbar region, and 10% at the cervical region, approximately corresponding to the vertebral body bone volume in each region of the spine.^{12,13} Metastatic lesions present initially at multiple, noncontiguous levels in 10% to 38% of cases.^{12,14,15} In a recent prospective trial of surgical decompression and radiation therapy, the incidence of MSCC by vertebral level was 10% to 16% cervical, 35% to 40% in T1–T6, and 44% to 55% in T7–T12.¹⁶ By vertebral location, 56% to 64% were in the anterior vertebral body, 18% to 22% in the lateral elements, and 14% to 26% in the posterior elements, with a spine instability rate of 35% to 40% at the time of presentation.

Pathophysiology

A complicated cascade of events occurs with compression of the spinal cord and nerve roots. Epidural venous plexus compression can lead to cord edema and the secondary increase in inflammatory mediators, such as prostaglandin E₂ and interleukins 1 and 6. This cascade of events, if left unchecked, will eventually lead to ischemia, neuronal death, and permanent neurologic injury.^{4,17}

Anterior tumors can cause compression by growing posteriorly from the vertebral body into the epidural space, or by vertebral body collapse, causing tumor/bone retropulsion into the spinal canal. Lateral and posterior elements are less com-

monly, sites of origin for tumor that causes MSCC. Paravertebral tumors can cause compression by entering the spinal canal through the intervertebral foramina, and in rare instances, metastases can be intramedullary or in the epidural space without bony involvement.^{4,18} If not addressed rapidly upon the appearance of suspicious symptoms, it has been reported that roughly only 10% to 25% of patients who are not ambulatory before treatment will regain the ability to walk, as pretreatment ambulatory function is the main determinant for posttreatment gait function.¹⁹⁻²¹ In addition, patients who have a slow loss of function are significantly more likely to ambulate again after treatment than those with rapid decline when treated with radiation therapy.²²

Clinical Presentation and Diagnosis

The clinical presentation of tumors metastatic to the spinal axis is a function of the local anatomy.²³ Within the spinal canal there exists a well-defined extradural space containing epidural fat and blood vessels. Metastatic lesions are most commonly found in the extradural space. The extradural space communicates with adjacent extraspinal compartments via the intervertebral foramina. A spinal cord tumor produces local and distal symptoms and signs; the latter reflect involvement of motor and sensory long tracts within the spinal cord. These signs allow localization of the level of the lesion based on clinical findings.²³ However, the clinical presentation of a spinal tumor rarely indicates if it is extradural or intradural. Loss of sphincter control and ambulation before initiation of treatment are poor prognostic factors for recovery of function, so expeditious imaging and subsequent treatment must be initiated without delay when MSCC is suspected. Ninety percent or more of patients present with local and/or radicular pain.^{4,20,24,25} Weakness (76%) and sensory findings (51%) are common at diagnosis but are rarely, if ever, a presenting symptom.¹²

Lesions at the conus medullaris can produce several symptoms, including saddle anesthesia, acute urinary retention, incontinence of bowel and bladder, and impotence. If the lesion remains confined to the conus, it will not cause paralysis of the lower limbs and the ankle reflexes are preserved. However, rarely is a conus tumor diagnosed when it is this small, but rather, when some extension upward has occurred and there are additional cord signs.

Flaccid weakness, atrophy, fasciculations, and reduced deep tendon reflexes are seen in corresponding myotomes, with involvement of the anterior horn cells and the ventral roots (lower motor neuron lesions). A tumor involving the lateral corticospinal tracts can cause weakness, spasticity, hyperreflexia, and an extensor plantar response (Babinski's sign). Motor weakness and spasticity are seen with tumors above the conus medullaris. Weakness and flaccidity are seen with tumors below the conus. A tumor restricted to the conus should not cause weakness, although one also involving the cauda equina will.

Sensory impairment often helps to localize the level of the tumor based on loss of dermatome function, although the upper level of impaired long tract function may be several segments below the actual tumor. A lesion involving the lateral spinothalamic tract will cause numbness, paresthesias, and decreased temperature sensation over the contralateral limb or trunk below the lesion; this produces the classic finding of

a sensory level, which is best demonstrated with a pin observation for absence of perspiration or of temperature (cold) sensation. A lesion in the posterior column can cause gait ataxia. Standing posture is affected with the eyes closed (Romberg's sign). Paresthesias can occur below the level of the lesion.

Because pain and temperature pathways cross over in the spinal cord and proprioceptive and motor pathways do not, a unilateral spinal cord lesion can result in ipsilateral paralysis and proprioceptive loss, as well as contralateral pain-temperature loss below the level of the lesion. Because light touch travels in two pathways, one that crosses in the spinal cord (spinothalamic tract) and one that does not (posterior columns), it is usually spared in unilateral lesions. This combination of findings is known as the Brown-Sequard syndrome.

Both bladder and bowel symptoms can result from a spinal cord tumor. Bladder symptoms include hesitancy, dribbling, incontinence, urgency with incontinence, or acute retention. Most of the time, if the bowel is affected, constipation rather than incontinence occurs. Loss of bladder control is seen early in the presentation of tumors in or below the conus and later in tumors above the conus. Cord lesions above L1 can lead to impotence or reflex priapism. Lesions involving S2-S4 may produce loss of erection and ejaculation ability. Decreased genital sensation can occur from lesions affecting the S2 nerve roots.

Pain from spinal canal tumors can be either radicular, midline, or central. Radicular pain is secondary to involvement of the posterior roots and is typically described as shooting pain in a dermatomal distribution. The nerve can be compressed inside or outside the dura. Midline spinal pain causes discomfort localized to the area of the tumor and is thought to arise from pain-sensitive structures in the dura and extradural tissues. Characteristically, pain is more severe in extradural lesions. Sometimes, with spinal cord compression, a dull or burning pain, more widespread than segmental spinal or radicular pain, occurs. This type of pain, although relatively rare, has numerous designations, including central pain, causalgia, and deafferentation pain; it involves a limb or trunk below the lesion.

Cauda equina lesions can cause radicular pain in the thigh, weakness, and atrophy of muscles, including the glutei, hamstrings, gastrocnemius, and the anterior tibialis. Saddle anesthesia, absent ankle reflexes, impotence, urinary urgency, or acute retention and constipation are also commonly seen. Depending upon the location of the lesion, other reflexes may be affected.

Intramedullary metastases are exceedingly rare. In this location, they can cause a characteristic neurologic syndrome. Early on, decreased temperature and pain sensation occurs in the dermatomes of the spinal segments occupied by the tumor and two to three segments caudal to the lesion. No other sensory modality is affected while the tumor is confined to the central cord. This "dissociated" sensory loss is rarely seen with extramedullary tumors. Additionally, weakness and atrophy are early findings in the myotomes of the corresponding cord segments involved by tumor. As the tumor grows transversely, reflexes produced at the level of the tumor disappear, and spastic paralysis with hyperreflexia develops below the lesion. Eventually, all sensory modalities are affected. Cervical tumors can produce Horner's syndrome by interrupting unilateral autonomic pathways.

Magnetic Resonance Imaging of The Spine: Evidence Level III, Recommendation Grade A

The most important modality in the workup of suspected MSCC is magnetic resonance imaging (MRI) of the entire spinal axis with gadolinium enhancement. With the exception of a primary paraspinal or neuraxis tumor, MSCC occurs most often in the setting of disseminated disease from a distant primary site. A potential pitfall in the initial evaluation of a patient with suspected spinal cord compression, is imaging only the symptomatic area of the spine. Frequently, patients with lower body or extremity symptoms, and/or radicular pain in the lumbar distribution, present for evaluation and management with only partial spine imaging. Helweg-Larson et al. reported on a series of patients with MSCC diagnosed by myelography.²⁶ Their data showed that 35% of patients with MSCC had multiple metastases at presentation, and 7.5% developed a second episode of MSCC in an untreated portion of the spine during follow-up. Today, myelography has been replaced by magnetic resonance imaging. Husband et al. published a prospective study evaluating the value of MRI of the entire spine in the workup of suspected MSCC.²⁷ In this study of 201 patients, 25% of patients evaluated had spinal cord compression verified at multiple levels, and approximately two-thirds of these had involvement of different regions of the spine. The authors determined that when a sensory level was present on patient evaluation, it was two or more segments different from the actual lesion on MRI in 28% of patients, and four or more levels distant from the lesion in 21%. These data confirm that the entire spine must be imaged with MRI with gadolinium enhancement to make early diagnosis of occult lesions in other segments of the spinal axis.

Treatment

MEDICAL MANAGEMENT

USE OF STEROIDS: EVIDENCE LEVEL II, RECOMMENDATION GRADE A

Dexamethasone is the most commonly used agent. Maranzano et al. reported on a consecutive series of 209 patients who received different steroid regimens based on pretreatment clinical assessment of extent of motor deficit.²⁸ All patients received 30Gy radiation therapy, but paraparetic and paraplegic patients received 1g/day methylprednisolone, whereas patients with better motor function received 16mg/day dexamethasone, with results comparing favorably across the literature. No direct comparison has ever been attempted with methylprednisolone and dexamethasone.

Dexamethasone is typically given at an initial dosage of 16mg divided into four daily doses, with a subsequent taper lasting a few weeks to several months (usually a dose reduction of 2mg every 3–7 days), as guided by the patient's symptoms.^{29,30} The lowest possible dose should be used. Patients not on corticosteroids at the beginning of radiation may be observed and dexamethasone added if they become symptomatic. Side effects of intermediate- to long-term steroid use include hyperglycemia, insomnia, emotional lability, thrush, gastric irritation and intestinal ulceration, proximal muscle wasting, weight gain and adiposity (moon facies, buffalo

hump, centripetal obesity), osteoporotic compression fractures, and aseptic necrosis of the hip joints.³¹

The efficacy of steroids has been well demonstrated. In a single blind, randomized trial of 57 patients by Sorenson et al., patients with MSCC from solid tumors, were assigned to radiation therapy with or without high-dose dexamethasone (96mg bolus; 96mg per day given orally in qid dosing for 3 days, followed by a 10-day taper).¹⁹ The primary endpoint was maintaining pretreatment gait function and/or the recovery of lost function. Radiation therapy to both groups was 28Gy in 7 consecutive days of 4Gy per day. Results showed improved rates of surviving with intact gait function at 3 months (81% versus 63%), 6 months (59% versus 33%), and 1 year (30% versus 20%).³²

The optimal dose of steroids has not been completely defined. The concern with the use of high-dose steroids is the associated toxicity, and some data exist that moderate-dose steroids in the treatment of MSCC may be just as effective as a high dose. A small randomized trial by Vecht et al., comparing high (100mg) and modest (10mg) initial bolus dose dexamethasone in patients with MSCC, reported no difference between the two regimens in terms of continence, ambulation, or pain.³³ However, the number of patients was small and there was no stratification by pretreatment motor function.¹⁸ In the trial by Sorenson et al., 11% of patients suffered significant toxicity in the high-dose steroid treatment arm.¹⁹ Heimdal et al. reported overall steroid-related toxicity of 28.6%, 14.3% of which was rated as serious.^{19,34} When these authors abandoned higher-dose steroids for moderate dose (16mg/day tapered over 2 weeks), there were no serious steroid-related side effects reported. On the other hand, Greenberg et al. reported only 1 of 89 patients on a high-dose regimen of dexamethasone with RT who suffered a serious steroid-related complication.²⁵

Select patients may not require steroids during treatment. Maranzano et al. reported a Phase II trial of 20 consecutive patients with good baseline motor function and without major invasion of the spinal cord.³⁵ Of the 20 patients, 80% were ambulatory without need for support, and 20% needed support for ambulation as a result of radiculopathy or pain. Patients received 3,000cGy in 10 fractions initiated within 24 hours of diagnosis, and no steroids were given. All 16 ambulatory patients retained gait function, and the other 4 patients regained the ability to walk. This study suggests that some patients with good performance status who have rapid local treatment may be considered candidates to manage without steroids, although the majority of published data with radiation therapy are in combination with steroids. This management strategy may be considered reasonable if a patient is at high risk of complication from steroids because of underlying medical comorbidities, such as peptic ulcer disease, uncontrolled diabetes, or other medical problems that may cause severe or life-threatening problems if steroids are initiated.

SURGERY

SURGICAL DECOMPRESSION: EVIDENCE LEVEL II, RECOMMENDATION GRADE A

Laminectomy has historically been the standard surgery for MSCC, with most series in the literature showing no benefit to laminectomy-treated patients over patients managed with radiation therapy.^{4,12,36,37} Laminectomy traditionally had not

only failed to show a benefit but also was reported to have high rates of spinal instability and postoperative morbidity.^{4,8} Because most spinal cord compression is from sources anterior to the spinal canal, it stands to reason that simply enlarging the spinal canal with laminectomy would usually fail. Vertebral body resection offers the possibility of truly decompressing the spine and resecting tumor and bone fragments. No studies have ever compared these two modalities, but the morbidity is greater in vertebral body resection series (10%–54%) than in laminectomy series (0%–10%).⁸ Figure 71.1 shows an example of an anterior vertebral body resection of MSCC with surgical stabilization.

Despite the risk of morbidity, emergency surgery is not without support as initial management for MSCC. Harris et al. reported retrospectively on 84 patients with MSCC and compared outcomes based on whether the patient received emergent decompressive surgery or routine surgery (within 24 hours).³⁸ There were no reported postoperative deaths, and most of the surgical procedures were laminectomy or laminectomy with fusion (98%). Functional improvement, as defined by continence and/or mobility, was more commonly seen in patients who underwent emergency decompression (62% versus 25%). In this series, almost half (49%) of 35 incontinent and immobile patients regained function, with most of those regaining function (77%) being in the emergency surgery group. Furthermore, Sundaresan et al. retrospectively reviewed 110 surgical patients, 78% of whom underwent higher-risk surgery of anterior or anterior/posterior resection with instrumentation. The overall success rate, measured as maintaining or regaining ambulatory function, was 82% with decompressive surgery.³⁹ Strikingly, 67% of nonambulatory patients recovered gait, and in a subgroup of patients rated as having severe paresis, 55% regained gait function.

RADIATION THERAPY

RADIATION THERAPY ALONE: EVIDENCE LEVEL II, RECOMMENDATION GRADE A

In reality, many patients with spinal cord compression are not surgical candidates and are best treated with steroids and radiation therapy as their primary modality. Even patients with very poor initial performance or mobility/continence status can be helped by receiving emergent radiation therapy. Although no randomized trials exist comparing radiotherapy to best supportive care or medical therapy alone, every published radiotherapy series for MSCC has shown efficacy of radiation therapy in helping patients to retain or regain lost function and to relieve pain. Steroids are always initiated at the time of diagnosis, and as already discussed, the strongest evidence suggests that high-dose dexamethasone is the preferred regimen.

SELECTION OF RADIATION THERAPY DOSE: EVIDENCE LEVEL III, RECOMMENDATION GRADE B

Treatment outcomes reported in the literature vary only a small amount from series to series, regardless of fractionation schedule. Multiple fractionation schedules, ranging from 8Gy \times 1 to 2Gy \times 20, have been proposed and evaluated both prospectively and retrospectively^{21,25,28,40–42} (Table 71.1). Morbidity is generally low and is well tolerated even by patients with a poor performance status. Approximately 89% of patients who are ambulatory before radiation therapy can expect to retain gait function, while an average of 39% of paretic patients and 10% of paraplegic patients can expect to see an improvement after treatment.⁸ Although 30Gy in 10 fractions and 37.50Gy in 15 fractions are commonly used regimens, no compelling data are available to point to poorer outcomes with hypofractionated regimens.⁴⁰ Most recently,

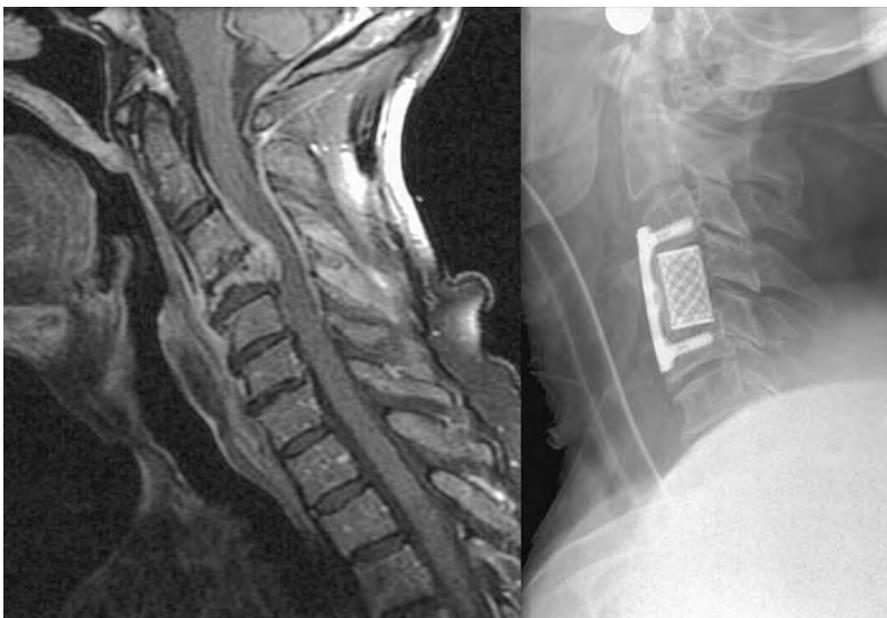

FIGURE 71.1. This patient presented with upper extremity weakness and numbness, and magnetic resonance imaging (MRI) revealed tumor with vertebral body collapse and a spinal cord compression at the C4 level. Surgery was recommended, and the patient's vertebral column was stabilized with resection of the gross tumor.

TABLE 71.1. Typical fractionation schedules for treatment of spinal cord compression and subsequent functional outcomes.

Author	Total dose	Fraction size	Overall percentage of patients ambulatory after irradiation
Greenberg ²⁵ Maranzano ⁹⁷	15 Gy, followed by 15 Gy for responders	5 Gy, followed by 3 Gy for responders	57%–75%
Helweg-Larson ²¹ Sorensen ¹⁹	28 Gy	4 Gy	61%–72%
Hoskin ⁴²	8 Gy 20 Gy	8 Gy 4 Gy	71%
Maranzano ⁹⁸	16 Gy (1 week split)	8 Gy	63%
Maranzano ²⁸	15 Gy, then 15 Gy 30 Gy	5 Gy, then 3 Gy 3 Gy	76%
Rades ⁹⁹	30 Gy 40 Gy	3 Gy 2 Gy	56%–60%

Gy, gray.

Maranzano et al. have reported preliminary data of a randomized trial comparing 16 Gy in 2 fractions to a 30-Gy split-course regimen (15 Gy in 3 fractions followed by 15 Gy in 5 fractions for responders), showing no difference in efficacy or toxicity.⁴³

Reirradiation of a spinal metastasis may be necessary in some long-term survivors with recurrent disease. Schiff et al. reviewed 54 reirradiated patients with at least two courses of radiation therapy to the same segment of the spine for the risk of radiation-induced myelopathy.⁴⁴ The median initial dose was 3,000 cGy in 10 fractions and the median reirradiation dose was 2,200 cGy in 11 fractions, with a median time of 9.1 months elapsing between treatment courses. Ninety percent of ambulatory patients retained gait function by the end of treatment, 43% regained ambulatory status, and 88% of ambulatory patients at the end of reirradiation were still ambulatory at the last documented follow-up.

TREATMENT TECHNIQUES

Common treatment approaches include a single posterior field (PA), opposed lateral fields, a PA field with opposed laterals, opposed anteroposterior/posteroanterior (AP/PA) fields, and oblique wedge-pair fields.^{45,46} Normal tissue constraints and potential toxicity must be considered when defining field arrangements. For tumors in the cervical region, an opposed lateral-beam approach can be employed to minimize dose to the anterior neck. For tumors in the cervicolumbar region, a split-beam technique can be employed with the central axis placed above the upper limit of the shoulders. Opposed lateral beams are used to treat the upper spine, whereas a PA field is used for the area of the spine below the central axis. Tumors in the thoracic region can be treated with opposed lateral beams: a three-field approach using a PA field and opposed lateral beams, a two-field approach using anteroposterior beams, or a posterior beam prescribed to an appropriate depth. The tolerance of dose-limiting organs, most commonly, the spinal cord and esophagus, may need to be taken into account by the radiation oncologist, depending upon the clinical scenario. In the lumbar region, care should be taken to minimize dose to the kidneys; AP/PA or PA fields are often used here, but a four-field approach using AP/PA and opposed lateral beams with the AP/PA beams preferentially weighted may be useful.

TOLERANCE OF THE SPINAL CORD AND LUMBOSACRAL NERVE ROOTS: EVIDENCE LEVEL II, RECOMMENDATION GRADE A

Radiation myelopathy may present as a transient early delayed or as a late delayed reaction. Transient radiation myelopathy is clinically manifested by momentary, electrical shocklike paresthesias or numbness radiating from the neck to the extremities, precipitated by neck flexion (Lhermitte's sign).⁴⁷ The syndrome typically develops 3 to 4 months after treatment and spontaneously resolves over the following 3 to 6 months without therapy. It is attributed to transient demyelination caused by radiation-induced inhibition of myelin-producing oligodendroglial cells in the irradiated spinal cord segment.⁴⁷⁻⁴⁹

Irreversible radiation myelopathy typically is not seen earlier than 6 to 12 months after completion of treatment. It is thought to be multifactorial, involving demyelination and white matter necrosis ultimately caused by oligodendroglial cell depletion and microvascular injury. The signs and symptoms are typically progressive over several months, but acute onset of plegia over several hours or a few days is possible. The diagnosis of radiation myelopathy is one of exclusion that first requires a history of radiation therapy in doses sufficient to result in injury. The region of the irradiated cord must lie slightly above the dermatome level of expression of the lesion; the latent period from the completion of treatment to the onset of injury must be consistent with that observed in radiation myelopathy, and local tumor progression must be ruled out. There are no pathognomonic laboratory tests or imaging studies that conclusively diagnose radiation myelopathy. MRI findings include swelling of the spinal cord with hyperintensity on the T₂-weighted images with or without areas of contrast enhancement.^{49,50} There is no known consistently effective treatment for radiation myelitis.^{51,52} The probability of dying of radiation myelopathy is approximately 70% in cervical lesions and 30% with thoracic spinal cord injury.⁵³ Figure 71.2 shows the characteristic MRI findings of radiation-induced myelitis.

There is no convincing evidence that the cervical and thoracic cord differ in their radiosensitivity, and there appears to be little change in tolerance with variations in the length of cord irradiated.⁵⁴ Typically, half the patients who develop radiation-induced myelopathy in the cervical or thoracic cord region will do so within 20 months of treatment and 75% of

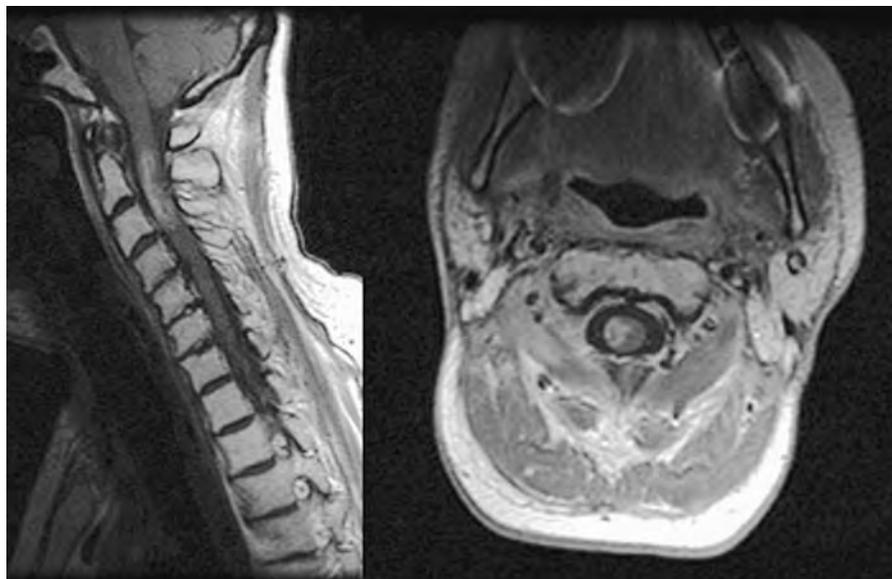

FIGURE 71.2. This patient received 50Gy (at 200cGy per fraction) of radiation therapy to the cervical spine. His expected risk of myelitis was less than 5%. At 2.5 years after treatment, he developed pain, extremity weakness, and numbness, and eventually urinary retention. The patient's imaging revealed increased T2 signal with an expansile region showing poorly defined gadolinium enhancement. These findings, along with the clinical history and symptoms, were consistent with radiation myelitis.

the cases will occur within 30 months.⁵⁵ Table 71.2 shows a range of iso-morbid fractionation schemes, all of which carry a 5% risk of radiation myelopathy.⁵⁶⁻⁶⁵ The tolerance of the lumbosacral nerve roots appears to be somewhat higher than that of the spinal cord.⁶⁶⁻⁶⁸ Given that the overall survival of patients presenting with MSCC is 6 months or less, selecting the shortest feasible fractionation schedule may be reasonable for the majority of patients.

MULTIMODALITY THERAPY

SURGICAL DECOMPRESSION FOLLOWED BY ADJUVANT RADIATION THERAPY: EVIDENCE LEVEL I, RECOMMENDATION GRADE A

Randomized and retrospective data historically have shown the benefit of surgery before radiation therapy to be of questionable benefit.^{12,36} Because the most common surgical procedure in the past for decompression of MSCC has been laminectomy, it stands to reason that most of the time the tumor is not adequately debulked. This is purely an anatomic issue, because a laminectomy will merely remove the posterior elements of the spinal column, and in most cases, the

tumor is growing posteriorly toward the spinal cord from a tumor burden within the vertebral body. Thus, a posterior approach would not ordinarily lend itself to removal of tumor in these cases and would only allow the cord to be displaced posteriorly without compression by the posterior rim of the bony spinal canal.

Patchell et al. recently reported the results of a randomized trial evaluating the benefit of adding surgical decompression to the radiotherapeutic management of metastatic spinal cord compression.¹⁶ Patients with symptomatic malignant spinal cord compression documented by clinical examination and MRI, were randomized to decompressive surgery with high-dose dexamethasone and adjuvant radiation therapy or the same radiation therapy and steroids without surgery. Dexamethasone dose was 100mg on day 1 followed by 24mg per day thereafter. Surgery was a decompressive procedure of the surgeon's discretion, and radiation therapy was given as 30Gy in 10 fractions over 2 weeks. Patients treated with radiation alone were allowed to undergo surgery if they had a significant decrease in neurologic function; this did not apply to patients who were completely paraplegic at the start of treatment. The primary endpoint of the trial was the length of time patients maintained their ambulatory status after treatment. Secondary endpoints were the length of time patients were able to maintain continence, overall survival, and narcotic and steroid dose requirements. The trial initially was planned to accrue approximately 200 patients, but a planned interim analysis forced an early stoppage of the trial after accruing the first 100 patients when an improvement in gait maintenance was demonstrated in the surgery arm ($P = 0.0045$). Patients who underwent decompressive surgery had a median time of gait retention of 126 days versus 35 days for those receiving only radiation therapy. More strikingly, 56% of surgical patients who were not ambulatory at the start of treatment regained gait function, but only 19% in the radiation-alone arm regained gait function, and 30% of those who underwent surgical salvage walked again. Continence was

Gilbert et al. ¹²	No	235	Ambulatory posttreatment Percent alive and ambulatory (at 6 months/12 months) At 6 months At 12 months	49% 78% 46%	46% 75% 54%	(n/a)

RT, radiation therapy; Sx, surgery.

maintained for 142 versus 12 days, favoring the surgery arm. Overall survival was not significantly different at 129 (surgery) versus 100 days ($P = 0.08$). The median steroid dose given to patients who received only radiation therapy was one-third of that given to those who underwent surgery (0.0093), and narcotic dosages were 12-fold less in surgical patients (0.002). The surgical complication rate was 12% among those patients who underwent planned surgery but 40% for those who received surgery because of treatment failure after radiation therapy alone. Overall, this trial suggests that all patients presenting with MSCC of short duration should undergo decompressive surgery, if feasible. Table 71.3 compares these outcomes to older historical data.

Emergent Management of Brain Tumors and Their Sequelae

Epidemiology and Pathology

Patients with primary brain tumors or brain metastases may occasionally present with potentially life-threatening symptoms requiring emergent management. Although either primary or metastatic tumors can cause symptoms requiring emergent management, this scenario is most commonly associated with metastatic lesions because of the 10:1 ratio of incidence each year of metastatic tumors compared to primary brain tumors.⁶⁹ Besides brain metastases, similar problems can also be encountered with posterior fossa tumors, such as medulloblastoma or ependymoma, tumors with a tendency to sudden hemorrhage with subsequent rapid enlargement, such as metastatic melanoma or choriocarcinoma, leukemic involvement of the central nervous system, and highly infiltrative tumors that commonly exhibit significant surrounding brain edema, such as glioblastoma multiforme. Primary brain tumors can frequently be distinguished from brain metastases based on imaging characteristics, location, number of lesions, and a previous diagnosis of extracranial malignancy. Primary brain tumors, once resected and the patient stabilized, are managed according to accepted treatment pathways and/or clinical trials that are not specifically the subject of the following review.

Pathophysiology

A tumor can obstruct cerebrospinal fluid (CSF) flow directly by sheer size and location or indirectly, as a result of secondary edema in the normal brain tissue that then leads to mass effect and subsequent CSF obstruction. Obstruction of normal CSF flow and cerebral edema can lead rapidly to increased intracranial pressure, which in turn results in headaches, nausea, vomiting, and, ultimately, lethargy, coma, and death.

Clinical Presentation and Diagnosis

Presenting signs and symptoms of an intracranial mass include headache (70%), miscellaneous focal neurologic deficits, seizures (30%–60%), cognitive impairment (30%), papilledema (8%), and intracranial hemorrhage, among others.^{11,18} Patients may develop obstructive hydrocephalus, particularly those with lesions in proximity to crucial areas of narrow CSF flow, such as the third or fourth ventricle or the foramen of Munro.

Diagnostic Workup

Patients with signs and symptoms of an intracranial emergency need rapid evaluation to assess the cause (Figure 71.3). Among the possible causes of central nervous system (CNS) intracranial emergency in cancer patients, are metastases or primary brain tumor, hemorrhage, infarction, as well as infectious, inflammatory, drug-related, or metabolic etiologies.¹⁸ Computed tomography (CT) gives inferior imaging of brain parenchyma but can give good baseline information initially and can be done quickly in a tenuously stable patient or a patient in whom a hemorrhage is suspected. Once the patient's condition has stabilized, the brain imaging modality of choice is MRI of the brain with and without gadolinium enhancement. Lumbar puncture should be avoided if at all possible until intracranial pressure has normalized because of the risk of herniation and death.

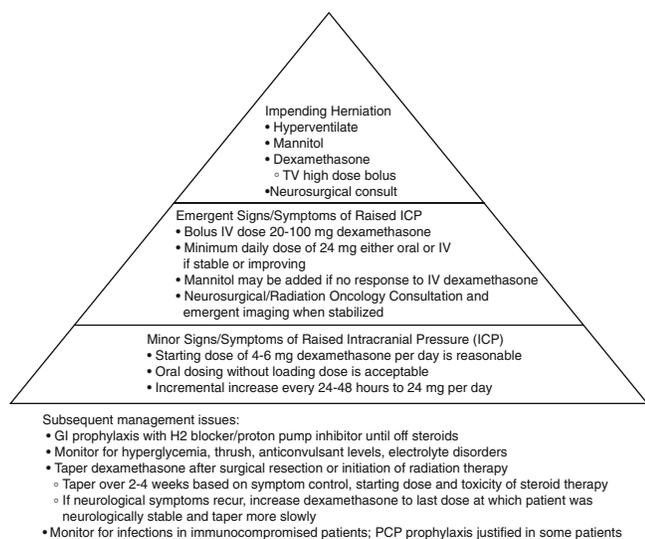

FIGURE 71.3. Recommended management of raised intracranial pressure (ICP) from emergent (*top*) to minor (*bottom*).

Treatment

MEDICAL MANAGEMENT

The initial emergent management consists of hyperventilation, which, through a series of changes induced by decreased partial pressure of CO_2 , leads to vasoconstriction and a subsequent transient drop in intracranial pressure (ICP).^{11,18} Because of the potentially deleterious effects of prolonged hyperventilation, namely, acidosis and potential ischemic brain injury due to vasoconstriction, other medical measures to decrease ICP must be rapidly employed.

STEROIDS/OSMOTIC AGENTS: EVIDENCE LEVEL I, RECOMMENDATION GRADE A

Medical decompressive therapy (MDT) generally consists of steroids with or without mannitol.⁷⁰ Mannitol functions by decreasing peritumoral brain edema, whereas dexamethasone does not, indicating different pathways in their mechanism of action in reducing the effects of cerebral edema.⁷¹ Mannitol has been shown to be of value for decreasing cerebral edema from sources other than brain tumors (head injury, hepatic failure).^{72,73} The only randomized data evaluating the combined usage of mannitol and dexamethasone for cerebral edema are from Canalese et al. for patients with cerebral edema from fulminant hepatic failure.⁷³ In this study, 44 patients were randomized to mannitol, dexamethasone, both drugs, or no treatment when they developed or presented with encephalopathy. Patients given mannitol had significantly better response in the presence of cerebral edema than those who did not. A common regimen of mannitol is 20% to 25% solution given intravenously over approximately 30 minutes dosed at 0.5 to 2.0 g/kg.¹⁸

The general value of dexamethasone has been discussed in the section on spinal cord compression. For obvious ethical reasons, no randomized data exist comparing steroids with placebo in patients with emergent symptoms from intracranial malignancy. The first large experience demonstrating the effectiveness of dexamethasone in decreasing cerebral edema in the setting of intracranial malignancies, came from the

University of Minnesota.^{74,75} Here, 249 patients with intracranial neoplasms were treated with steroids, with 212 having clinical signs of ICP and 31 being comatose. A response to therapy was noted within 12 to 18 hours of administration and more than 80% of patients showed dramatic improvement by 3 to 4 days after initiation of therapy.

Prospective data do exist evaluating the relative risks and benefits of varying dosing regimens of dexamethasone in the emergent management of cranial emergencies.^{76,77} Wolfson et al. published a small trial of 12 patients receiving 30 Gy cranial radiation and dexamethasone.⁷⁷ All patients received high-dose dexamethasone (24 mg IV every 6 hours) for 48 hours and were then randomized to further steroids (4 mg po every 6 hours) or no further steroids. The study could not confirm a clear benefit to either arm in terms of performance status or neurologic functional status, although the study had a surprisingly low rate of only 33% of patients having any clear response to the high-dose therapy.

Vecht et al. performed two separate randomized trials investigating different dose regimens of dexamethasone in patients with brain metastases who had an impaired performance status.⁷⁶ In addition to radiation therapy, all patients received oral dosing of dexamethasone with patients in the first trial randomized to 8 versus 16 mg/day. A tapering schedule with dexamethasone dose reductions every 4 days was initiated at day 7 of steroid therapy. Although the patients did not show a difference in Karnofsky Performance Status (KPS) after 1 week, after 28 days, the low-dose group had a lower rate of KPS improvement (53% versus 81%). The authors hypothesized that the tapering schedule may have been started too early to allow the low-dose patients to maintain their KPS as the tapering schedule was initiated before radiation therapy. They therefore initiated a second study substituting 4 mg per day as the low-dose arm, but continued the steroid dosing unchanged in both arms for the full 28 days before tapering. The results of this trial showed no improvement in KPS for the high-dose arm so long as the steroids were given over a longer period before tapering. A higher percentage of patients (41%) in the 4-mg arm had to have their tapering schedules extended due to recurrence of neurologic symptoms during or after tapering. The authors also found that the incidence of side effects was higher in the high-dose arm, significantly, the development of cushingoid features, peripheral edema, and steroid myopathy. The authors concluded that 4 mg dosing per day of steroids was adequate for treatment of symptomatic edema from brain metastases provided that the patients were tapered over a 28-day period. The outcomes for all treatment groups in these two trials are summarized in Table 71.4. Other studies have raised concerns also over the incidence of steroid-induced toxicity with steroid dosing longer than 21 days in duration.⁷⁸ Higher doses and longer tapering schedules should be based on physician assessment of response.

The frequency of dexamethasone dosing is controversial. The plasma half-life in both humans and animal models is relatively short, on the order of 3 to 6 hours, but the biologic half-life may be twice that, and drug-related effects last much longer.^{79,80} The most common dosing regimen of dexamethasone is every 6 hours, but a pilot study of twice-daily dexamethasone with radiation therapy, showed good responses with acceptable toxicity.⁷⁸ No randomized study comparing the common qid dosing to less-frequent daily dose regimens has been published. An excellent evidence-based review of

TABLE 71.4. The results of two randomized trials investigating different dose regimens of dexamethasone in patients with brain metastases who had an impaired performance status.

medical decompressive therapy and dosing literature, including the aforementioned Dutch trial, was published by Sarin and Murthy.⁷⁰ This review provides recommendations for starting doses, dose escalation, and tapering schedules based on symptoms and response. Based on this publication and our own review of the peer-reviewed literature, we propose a management scheme as depicted in Figure 71.4.

ANTICONVULSANTS: EVIDENCE LEVEL I, RECOMMENDATION GRADE A

The routine use of prophylactic anticonvulsants for patients diagnosed with a brain mass is not recommended based on Level 1 evidence. Glantz et al. reported on a randomized, double-blind placebo-controlled study of 74 patients with newly diagnosed brain mass and no history of seizures.⁸¹ Patients received either divalproex sodium or placebo, with an equivalent risk of a first seizure. In addition, Forsyth et al. reported on a prospective, randomized, nonblinded study of 100 patients newly diagnosed with a brain tumor and having no history of prior seizures.⁸² Patients were randomized to prophylactic anticonvulsants or placebo and followed for incidence of seizures, seizure-free interval, and survival. Although the study was truncated early for statistical reasons, there was no significant difference between the groups for any of these endpoints.

Stabilization of the patient in status epilepticus to perform imaging and make management decisions is critical.⁸³ After securing the airway and stabilizing the patient, seizure activity must be terminated as rapidly as possible. Phenytoin and rapid-onset/short-acting benzodiazepines are commonly used to quickly control seizure activity. Recommended initial regimens include 0.1 mg/kg at 2 mg/min lorazepam or diazepam at 0.2 mg/kg at 5 mg/min. Phenytoin infusion of 15 to 20 mg/kg at 50 mg/min or less in adults is indicated for seizure activity refractory to benzodiazepines or after truncation of seizures with diazepam.⁸³ Failure to control seizures can potentially lead to physical injuries, airway compromise, and secondary brain hypoxia/injury, or coma.¹⁸ From a practical standpoint, no randomized data exist comparing emergent medical treatment of seizure activity to observation because failure to treat is unacceptable.

There is Level 1 evidence for optimization of phenytoin dosing from a recent randomized study investigating the most rapid method of achieving therapeutic phenytoin levels in the emergency setting.⁸⁴ This study compared rapid intravenous infusion of fosphenytoin versus traditional phenytoin infusion. Fosphenytoin, a prodrug of phenytoin without the polyethylene glycol (PEG) vehicle, could be infused at a faster rate and was shown to more rapidly achieve therapeutic phenytoin serum levels.

SURGERY

DECOMPRESSIVE SURGERY: EVIDENCE LEVEL I, RECOMMENDATION GRADE A

Surgical resection and/or placement of a shunt is often required for emergent management of brain masses causing life-threatening hydrocephalus, mass effect, or profound neurologic impairment. In all instances, attempts at patient stabilization before surgery with the use of high-dose glucocorticoids with or without mannitol should be made. Patients often exhibit rapid recovery of neurologic and/or cognitive function, which may allow time for more effective diagnostic studies. Medical decompression, in many cases, may also relieve symptoms enough that other modalities such as whole-brain radiation therapy or radiosurgery may be considered as alternate management strategies. Good imaging also can better define the lesion(s) in question to allow stereotactic planning for more accurate surgery. Symptoms are usually related to mass effect, so resection or debulking are often the only logical choices if medical therapy fails to provide improvement in neurologic symptoms. Rapid surgical decompression is the treatment of choice for such prob-

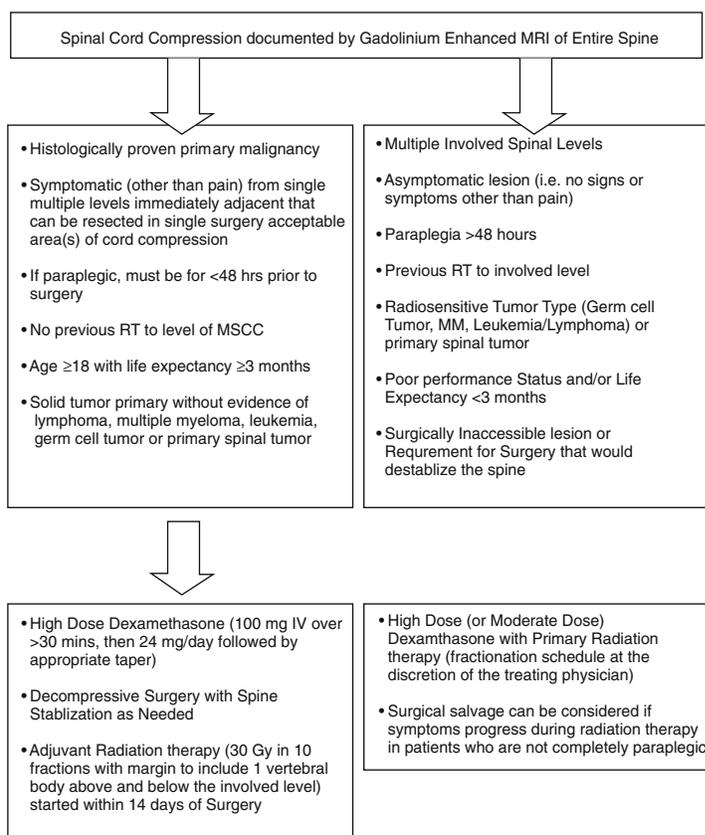

FIGURE 71.4. Evidence-based decision tree graph for malignant spinal cord compression.

lems when surgery can be performed safely based on patient performance status or tumor location. If no neurosurgical team is available, transfer of the patient should be initiated while medical measures are undertaken to stabilize the patient.

RADIATION THERAPY

PALLIATIVE RADIATION THERAPY: EVIDENCE LEVEL I, RECOMMENDATION GRADE A

Multimodality therapy for emergent brain tumors routinely takes the form of medical decompression followed by radiation therapy or surgery if there is no response to medical therapy or for most single, bulky resectable lesions. Patients who are medically inoperable, refuse surgery, or have multiple and/or unresectable lesions typically receive whole-brain radiation therapy for palliation of their symptoms. The fact that 60% to 70% of patients who present with brain metastases have multiple lesions makes radiotherapy the primary modality for palliation in the majority of cases.^{69,85} Many patients will respond dramatically to medical therapy and radiation in the emergent setting with an improvement in their performance status, particularly if their symptoms are largely caused by edema or rapidly correctable problems, such as electrolyte abnormalities. With this in mind, radiation therapy dosing schedules for the treatment of emergent patients can be tailored to patient parameters, such as initial response to steroids, extent of extracranial disease, primary site, and purported response of primary to systemic therapy.

The Radiation Therapy Oncology Group (RTOG) has reported on several large trials with differing fractionation schedules of whole-brain radiotherapy (Table 71.5). In the specific setting of emergent management, however, there are no randomized trials to specifically address the issues of dose; 50Gy in conventional fractionation has been used for postoperative treatment,⁶⁹ but in the emergent setting, larger daily fraction sizes are typically used to achieve a more rapid response. Doses of 30 to 37.5Gy using fraction sizes in the range of 2.5 to 3Gy per day are commonly used but may be adjusted based on patient response. One should keep in mind that larger fraction sizes do seem to predict for a higher incidence of radiation-induced dementia if the patient survives for an extended period of time.^{18,69}

MULTIMODALITY THERAPY

ADJUVANT TREATMENT AFTER SURGERY: LEVEL 1 EVIDENCE, RECOMMENDATION GRADE A

In the context of truly emergent management, there are no randomized data for emergent surgery. If surgery is recom-

Gy, gray; bid, twice daily.

mended, this routinely addresses the emergent situation; postoperative radiation therapy as already described is then added on a routine basis once the patient has recovered.^{86,87} However, because the treatment of brain metastases is for all practical purposes palliative in its nature, the preservation of functional independence is a valid and strong argument for patients with a solitary metastasis to undergo surgery, if such a benefit can be clearly demonstrated. In this regard, the issue of surgery for patients with solitary brain metastases who have been medically stabilized with MDT remains somewhat controversial. Hazuka et al. retrospectively reviewed patients with one or more metastases who underwent surgery and radiation therapy.⁸⁵ Patients with one lesion had excellent median, 1-, and 2-year survivals. Level 1 evidence from two randomized trials comparing radiotherapy with or without surgical resection in the management of solitary brain metastases has documented a survival advantage with the addition of surgery over radiation alone.^{86,88} However, another randomized trial failed to show any survival advantage for surgery in addition to radiotherapy alone, the reason for which remains unclear.⁸⁹ Table 71.6 summarizes the pertinent data from these three randomized trials. There is no Level 1 evidence demonstrating any survival benefit from operating on patients with multiple metastases. Retrospective data from M.D. Anderson suggest that patients with two or three metastases benefit from having them all resected, even when requiring multiple craniotomies.⁹⁰ However, conflicting retrospective data have not been able to confirm this conclusion.⁸⁵ Patients with multiple lesions and severe neurologic symptoms from a dominant metastasis that is unresponsive to medical decompressive therapy may benefit from a craniotomy for the reasons just described. An improvement in the patient's performance status may then allow further aggressive therapy with external-beam radiation therapy and/or radiosurgery.

CHEMOTHERAPY: NO EVIDENCE

There is currently no role for chemotherapy in the emergent management of brain tumors. A Japanese trial evaluated the use of whole-brain radiotherapy with or without chemotherapy after surgical resection, but demonstrated no compelling benefit from the additional therapy.⁹¹

Nonmetastatic Intracranial Disease

Patients with malignant glioma who require emergent treatment are typically treated with regimens similar to those used for brain metastases. Surgical debulking is the mainstay of emergent treatment, as is the initiation of steroid therapy. Patients who are unable to undergo surgical debulking may be treated with a short course of whole-brain radiation similar to that used for brain metastases. Varying fractionation schedules ranging from 30 Gy in 6 fractions to 50 Gy in 20 fractions have been described in the palliative setting.⁹²⁻⁹⁵ Typically, the prognosis for these patients is quite poor; if they survive long enough to complete their initial course of treatment, their survival time typically ranges from 3 to 9 months under the most favorable circumstances.

Leukemic brain infiltration causing acute mental status changes and/or impending herniation is a rare entity. There are virtually no data in the literature defining the optimal radiation therapy dosing for treatment of this uncommon problem. Most data describing the treatment of CNS leukemia with radiation therapy are from the pediatric experience and typically describe nonemergent craniospinal axis irradiation. One series from M.D. Anderson described the management of recurrent CNS leukemia in adults.⁹⁶ The median dose to the cranium was 24 Gy in 1.8-Gy fractions, with a median dose of 18 Gy given to the spine. Most patients also received chemotherapy in some form. The median times to progression and to death from CNS relapse were 7 and 9 months, respectively. Based on this experience, patients presenting with leukemic brain involvement requiring emergent palliative therapy could be treated with total doses ranging from 24 to 30 Gy in 1.8- to 3.0-Gy fractions.

Conclusion

Fortunately, reasonable data exist to guide the oncologist in the therapeutic management of most CNS emergencies. For both malignant spinal cord compression and brain metastases, emergent therapy typically consists of initiation of steroid therapy, evaluation for emergent decompressive surgery, and a relatively short course of palliative radiation therapy. In addition, the astute clinician will learn to recognize the nuances of each case that will require therapeutic decisions based not on randomized trials, but on hindsight and foresight, that is, past clinical experience and anticipation of future problems.

Metabolic Emergencies in Oncology

Daniel J. De Angelo

Tumor Lysis Syndrome

Tumor lysis syndrome (TLS) refers to the constellation of electrolyte abnormalities that occur as a result of the rapid and immediate release of intracellular contents into the bloodstream. The syndrome is characterized by hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia (Table 72.1).¹⁻⁴ Metabolic acidosis and acute renal failure may also occur. The release of intracellular potassium and organic, as well as inorganic, phosphate into the bloodstream from cells undergoing apoptosis, results in the development of hyperkalemia and hyperphosphatemia, respectively.^{5,6} Prolonged and severe hyperphosphatemia may result in a marked decrease of the serum calcium concentration, but symptomatic hypocalcemia rarely develops. It is the rapid breakdown of nucleic acids that leads to hyperuricemia.⁷ TLS may develop before the administration of chemotherapy in patients with rapidly proliferating hematologic neoplasms; however, TLS usually occurs after the administration of high doses of chemotherapy, which results in the rapid destruction of tumor cells.⁸⁻¹¹

Patients with large tumor burdens are at an increased risk for TLS (Table 72.2), especially if the malignancy is sensitive to chemotherapy. These disorders include acute myelogenous and lymphoblastic leukemias, especially those with high circulating blast counts.^{4,12,13} In addition, TLS is commonly seen in patients with acute lymphoblastic and Burkitt's lymphomas or other high-grade lymphoproliferative disorders (Table 72.3).¹⁴ Large bulky solid tumors that undergo rapid cellular destruction also place patients at a significant risk for the development of TLS.¹⁵⁻²⁰ TLS is more common in patients with elevated lactate dehydrogenase (LDH) levels. Elevated LDH levels are usually caused by ongoing cell lysis and are most commonly seen in patients with aggressive hematologic malignancies. TLS has also been described after the use of nonchemotherapy agents, such as α -interferon or with hormonal therapy for breast cancer.^{21,22} The risk of developing TLS is greater in older patients or patients with poor renal function at baseline. These patients have a lower glomerular filtration rate and are more susceptible to electrolyte disturbances as compared to patients with normal renal function.

Hyperuricemia

Purine nucleotides and deoxynucleotides are broken down within the liver. Xanthine oxidase catalyzes the breakdown of hypoxanthine and xanthine to uric acid²³ (Figure 72.1).

With the exception of primates, all other mammals convert uric acid to allantoin, which is 10 times more soluble than uric acid. The pK_a of uric acid is approximately 5.75 at 37°C. Therefore, in the serum where the pH is higher, uric acid is usually present in the acid-soluble form. Within the acidic environment of the renal tubules, uric acid is present in the nonionized and therefore less soluble form.²⁴ Hyperuricemia can be present as an isolated abnormality without the other characteristic metabolic findings associated with TLS (Table 72.4).^{6,9,25} Renal insufficiency develops when the urine becomes supersaturated with urate, which is caused by the development of uric acid crystals in the renal tubules and the distal renal collecting system.^{26,27} The development of uric acid stones is uncommon and usually develops only in patients with chronic hyperuricemia. Before the development of renal failure, patients with hyperuricemia may develop nausea, vomiting, diarrhea, and anorexia. As renal function declines, patients may develop edema and lethargy. In addition to renal failure, gouty arthritis is the other most important consequence of both acute and chronic hyperuricemia. It is important to recognize that certain medications, namely, diuretics, such as thiazides, as well as antituberculous drugs and certain cytotoxic agents, can aggravate hyperuricemia.

The single most important factor in the treatment of hyperuricemia is first to recognize the patients who are most at risk for its development and then initiate appropriate prophylactic measures (Figure 72.2). Drugs that elevate serum uric acid levels should be discontinued if at all possible. Intravenous hydration should be initiated, preferably before the start of chemotherapy.²⁸ It is important to correct any preexisting intravascular volume deficits. By increasing urinary outflow, the concentration of uric acid is substantially decreased, thereby decreasing the problems typically associated with its poor solubility. The main focus in the treatment of hyperuricemia is to attempt to maintain adequate urinary volume. Alkalinization of the urine will further decrease uric acid solubility, which can usually be achieved with the addition of sodium bicarbonate (50–100 mmol/L) to the intravenous fluids. The admixture can be adjusted so that the urine pH is maintained above 7.0 without overalkalinizing the serum.²⁹⁻³¹ This latter complication may further complicate hypocalcemia when present.²⁵ Acetazolamide is a carbonic anhydrase inhibitor that may be added to increase the effects of alkalinization. Nevertheless, the most important factor in decreasing uric acid levels is the maintenance of adequate urine output, and alkalinization remains a secondary factor. Although furosemide increases the renal tubular reab-

TABLE 72.1. Tumor lysis syndrome.

Metabolic complications
Hyperuricemia
Hyperkalemia
Hyperphosphatemia
Hypocalcemia
Metabolic acidosis
Acute renal failure may also result

sorption of uric acid, this is offset by the preservation of increased urinary flow rates. Therefore, furosemide can be used safely to maintain a proper total body fluid balance.

Allopurinol (Zyloprim, Alopriam) is the standard medical treatment for both the prevention and treatment of hyperuricemia.³² Allopurinol is an inhibitor of xanthine oxidase and is extremely well tolerated. The most common adverse reaction is an erythematous skin rash due to a hypersensitivity reaction. Fortunately, this reaction is usually delayed by several days, and allopurinol can be given safely during the most critical period for patients who are at a high risk for the development of TLS. There have been rare reports of interstitial nephritis developing after the administration of allopurinol. Allopurinol will increase the serum levels of both hypoxanthine and xanthine; however, this has rarely been associated with the development of acute renal failure.³³⁻³⁵ Allopurinol (Zyloprim) is usually administered orally at a dose of 200 to 300 mg/m²/day. For patients who receive a dose greater than 300 mg/day, allopurinol should be administered in divided doses. Typical doses of allopurinol range from 300 to 600 mg/day with a maximum oral dose of 800 mg/day. Allopurinol is cleared renally, and the dose should be adjusted in older patients or patients with chronic renal failure. In addition, allopurinol is now available intravenously (Aloprim).³⁶ The typical dose of intravenous allopurinol is 200 to 400 mg/m²/day as either a single infusion or in divided doses with a maximum adult dose of 600 mg/day. The starting dose of intravenous allopurinol in pediatric patients is slightly lower at 200 mg/m²/day. Both azathioprine (Imuran) and 6-mercaptopurine (Purinthol) are metabolized by xanthine oxidase, therefore, the dose of these agents must be reduced by one-third to one-fourth during treatment with allopurinol.²³

Rasburicase (Elitek), a recombinant urate oxidase enzyme, catalyzes the enzymatic oxidation of uric acid into the inactive, water-soluble metabolite, allantoin (see Figure 72.2).³⁷⁻⁴⁰ Rasburicase is well tolerated and has a rapid onset of action as a uricolytic agent. The typical dose of rasburicase is 0.15 to 0.2 mg/kg IV over 30 minutes daily for 1 to 5 days. The

High tumor growth fraction
Tumors highly sensitive to chemotherapy
Markedly elevated lactate dehydrogenase (LDH)
Baseline renal insufficiency

TABLE 72.3. Risk for tumor lysis syndrome by tumor type.

Frequent cases
Acute myelogenous leukemia
Acute lymphoblastic leukemia or lymphoma
Burkitt's and other high-grade lymphomas
Less frequent occurrences
Diffuse large B-cell lymphoma
Chronic myelogenous leukemia
Low-grade lymphoma
Small-cell lung cancer
Breast cancer
Germ cell tumor
Non-seminoma, seminoma, mediastinal, ovarian
Rare case reports
Merkel's cell carcinoma
Adenocarcinoma
Medulloblastoma

safety and efficacy of rasburicase dosing beyond 5 days or for more than one course has not been well established and this should not be recommended. Rasburicase is contraindicated in patients with glucose-6-phosphatase dehydrogenase (G6PD) deficiency.

Rasburicase is effective in both the prophylaxis and treatment of hyperuricemia associated with malignancy.^{41,42} With regard to prophylaxis, chemotherapy should begin 4 to 24 hours after the first dose of rasburicase. In patients at high risk of TLS, that is, when uric acid is greater than 8 mg/dL or other criteria consistent with TLS, rasburicase may be substituted for allopurinol. Rasburicase is usually administered at a dose of 0.2 mg/kg IV every 24 hours and is typically required for approximately 1 to 3 doses over a 72-hour period. Allopurinol should not be administered concomitantly with rasburicase. Intravenous hydration should be administered at 3,000 mL/m²/day during the initial few days of therapy. Alkalinization is not necessary with recombinant urate oxidase therapy.

It is important to evaluate patients who develop oliguria or acute renal failure with ultrasonography or computed tomography (CT) scans to rule out ureteral obstruction caused by uric acid stones. Intravenous contrast agents should be avoided because of the risk of developing acute tubular necrosis.⁴³ Hemodialysis and continuous venous-venous hemofiltration (CVVH) are both effective in reversing severe uric acid nephropathy and states of fluid overload.⁴⁴ Rapid and early

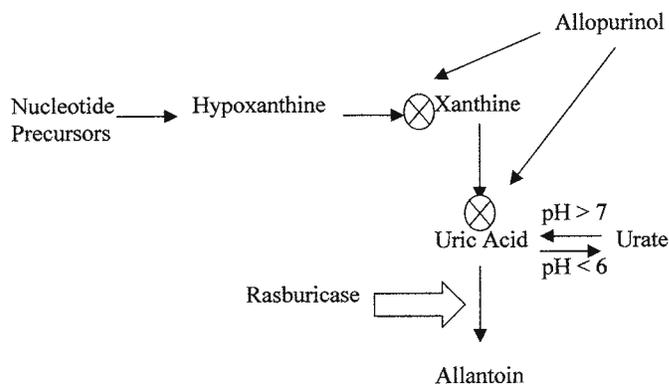

FIGURE 72.1. The oxidation of nucleotide precursors.

TABLE 72.4. Signs and symptoms of tumor lysis syndrome.

<i>Laboratory abnormality</i>	<i>Clinical symptoms</i>
Hyperuricemia	Nausea, vomiting, diarrhea, joint pain, oliguria, anuria, azotemia, flank pain, hematuria, crystalluria
Hyperkalemia	Muscle cramps, nausea, weakness, paresthesias, paralysis, EKG changes, bradyarrhythmias, tachyarrhythmias, cardiac arrest
Hyperphosphatemia	Oliguria, anuria, azotemia, renal failure
Hypocalcemia	Muscle twitching, tetany, laryngospasm, paresthesias, hypotension, ventricular arrhythmias, heart block

consultation of the nephrology team should be initiated once the renal function starts to deteriorate or in the case of severe hypervolemia that is not responsive to loop diuretics.

Hyperkalemia

Hyperkalemia is the principal life-threatening electrolyte abnormality that develops during tumor lysis syndrome.⁴⁵⁻⁴⁷ Hyperkalemia, defined as plasma concentration greater than 5.0 mmol/L, results from the release of large intracellular

stores due to cell lysis. Iatrogenic causes, which result from administration of potassium, especially in patients with renal insufficiency, must be excluded. Pseudohyperkalemia may result from poor phlebotomy technique, hemolysis, or marked leukocytosis or thrombocytosis. The latter two are caused by the release of intracellular potassium into the serum following clot formation. Measuring the plasma potassium using a heparinized tube may be required in the setting of a markedly elevated platelet count.

The intracellular and extracellular potassium ion concentrations maintain the resting membrane potential.⁴⁸ Hyperkalemia will cause a partial depolarization of the resting membrane potential, and prolonged depolarization will eventually lead to impaired excitability, resulting in muscular weakness, which may progress to flaccid paralysis.

The most serious and life-threatening manifestation of hyperkalemia is ventricular arrhythmia (see Table 72.4). Unfortunately, cardiac toxicity does not necessarily correlate with the degree of hyperkalemia. The initial electrocardiographic abnormalities include increased amplitude of the T-waves, which are often referred to as “peaked” T-waves. Subsequent EKG changes include prolongation of the PR and QRS intervals, A-V conduction blocks, and flattening of the P-waves. Eventually the QRS complex will merge with the T-wave, resulting in a sine wave pattern, which will often terminate in ventricular fibrillation or asystole. Fatal

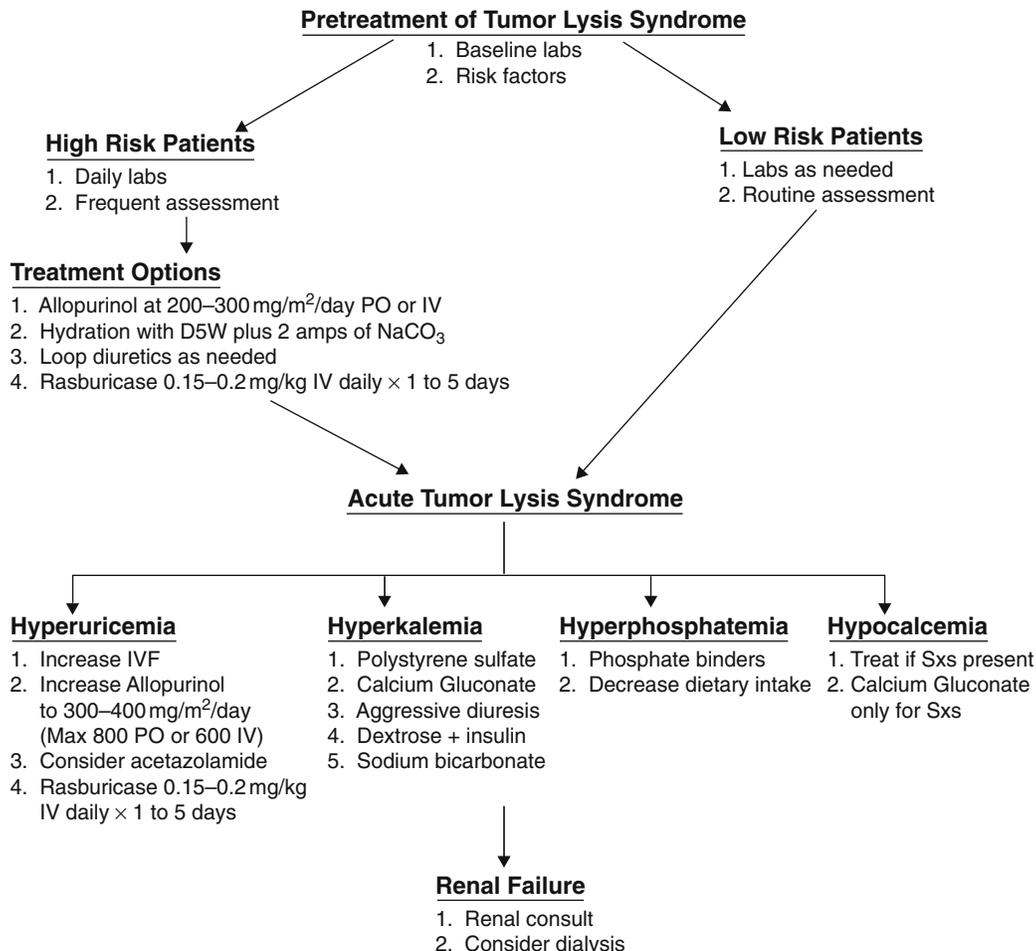

FIGURE 72.2. The treatment of tumor lysis syndrome.

hyperkalemia rarely occurs at a plasma potassium concentration less than 7.5 mmol/L.

The treatment of hyperkalemia largely depends upon the potassium serum concentration (see Figure 72.2). All patients with hyperkalemia, regardless of the degree of elevation, require an electrocardiogram. Furthermore, medications that interfere with potassium metabolism, such as nonsteroidal antiinflammatory drugs (NSAIDs) and angiotensin-converting enzyme inhibitors (ACEI), should be discontinued. Oral cation-exchange resins promote the exchange of potassium and sodium ions within the lumen of the gastrointestinal (GI) tract; this is an easy and effective initial strategy for patients with mild asymptomatic hyperkalemia. A dose of 15 to 30 g sodium polystyrene sulfonate (Kayexalate) will generally lower the serum potassium concentration by 0.5 to 1.0 mmol/L within 1 to 2 hours and last for about 4 hours.

Severe hyperkalemia requires more emergent treatment. Calcium gluconate should be given to decrease cellular membrane excitability. The usual dose is 10 mL 10% solution administered over 1 to 3 minutes. The effect, which can be seen in minutes, is unfortunately short-lived. The administration of insulin with glucose will cause potassium to shift into cells. The usual combination is 10 to 20 units of regular insulin with 25 to 50 g glucose. Glucose should be avoided if the patient is already severely hyperglycemic. This method typically results in the lowering of the serum potassium concentration by 0.5 to 1.5 mmol/L and will last for several hours. Alkalinization of the serum with bicarbonate will also lead to a shift of potassium into cells. Hemodialysis and continuous venous-venous hemofiltration (CVVH) are the most effective methods for effectively lowering the serum potassium levels, especially in patients with either preexisting or acute renal failure. Peritoneal dialysis is not as effective as hemodialysis in lowering the serum potassium level, and its initiation should be avoided in patients receiving chemotherapy.

Hyperphosphatemia

Similar to hyperkalemia, hyperphosphatemia results from the release of intracellular phosphate stores into the serum as a result of cell lysis.³⁰ Hyperphosphatemia is defined as a serum phosphate level above 1.67 mmol/L (5.0 mg/dL). Spurious hyperphosphatemia may occur in patients with a marked thrombocytosis, and the phosphorus levels should be confirmed in a heparinized tube. In addition, positively charged paraproteins, as in plasma cell dyscrasias, may cause marked elevations in the serum phosphate levels.

Hyperphosphatemia is a potentially dangerous condition because of extraosseous calcification. Although it should only serve as a guideline, a calcium-phosphorus product [serum Ca (mg/dL) \times serum P (mg/dL)] greater than 70, suggests a potential risk of metastatic calcification.⁴⁹ Prolonged hyperphosphatemia may result in lowering the serum calcium levels. Except in those patients with renal failure, the initial treatment of hyperphosphatemia includes volume expansion (see Figure 72.2), which effectively results in the increase of the fractional clearance of phosphorus by the kidney. Aluminum-based antacids bind to phosphorus in the gut and prevents further absorption. Although the chronic use of these agents may lead to aluminum toxicity, they are safe and effective for short-term use. Other phosphate binders, such as calcium

acetate (PhosLo) or sevelamer (Renagel) may also be used. Calcium acetate is dispensed as two tablets or gelscaps (667 mg) with each meal, and the dose can be increased so long as hypercalcemia does not develop. Sevelamer, a cross-linked polyallylamine hydrochloride, is a cationic polymer that binds intestinal phosphate. The recommended starting dose of sevelamer is 800 to 1,000 mg three times daily. The treatment of hyperphosphatemia in the setting of renal failure often requires hemodialysis.

Hypocalcemia

Unlike the other metabolic alterations resulting from TLS, hypocalcemia is a direct manifestation of hyperphosphatemia.^{1-3,6} Many oncology patients have hypocalcemia, defined as a serum calcium level less than 2.1 mmol/L (8.5 mg/dL); however, only 10% of these patients will have a reduction in ionized calcium.⁵⁰ Hypoalbuminemia is the principal cause of a reduced total serum calcium level in severely ill patients. Overalkalinization of the serum will increase the binding of calcium to proteins and result in a further reduction of the serum calcium level. In these cases, an ionized calcium level should be measured. Transient hypocalcemia also may arise from repeated transfusions of blood products due to the use of citrate as an anticoagulant. Although parathyroid hormone (PTH) is responsible for the regulation of serum calcium levels, it is overwhelmed in patients with TLS by the excessive loss of calcium from the extracellular fluid. Transient hypocalcemia is seldom clinically significant, but if long-standing, it can lead to several serious clinical manifestations (see Table 72.4); these include muscle spasms, carpopedal spasms, and in severe cases, tetany, laryngeal spasms, or convulsions. The QT interval on the EKG can become prolonged, which may lead to serious ventricular arrhythmias. Rarely, patients may become irritable, depressed, or psychotic as a consequence of severe prolonged hypocalcemia.

The principal focus on correcting the hypocalcemia of TLS revolves around the treatment of the hyperphosphatemia (see Figure 72.2). Calcium supplementation with oral calcium or calcium gluconate in severe symptomatic cases must be taken with caution, especially if the calcium-phosphate product is greater than 70 (see above). In general, calcium should not be given in asymptomatic patients, as this may precipitate calcium phosphate deposition. The correction of serum phosphate levels will usually improve the serum calcium levels. For patients who have persistent hypocalcemia, calcitriol may be used until the serum calcium level normalizes.⁵¹

Hypercalcemia

The single most common metabolic disorder in patients with cancer is hypercalcemia.⁵² Hypercalcemia caused by an underlying malignancy must be differentiated from hypercalcemia as a result of primary hyperparathyroidism. Patients who present with cancer-related hypercalcemia often have signs and symptoms of the underlying malignant tumor that include the recent onset of weight loss and is associated with a shortened median survival.⁵³ Patients with primary hyperparathyroidism are often asymptomatic or present with recurrent nephrolithiasis.⁵⁴ The association of elevated serum

TABLE 72.5. Signs and symptoms of hypercalcemia.

Category	Clinical symptoms
Constitutional	Weight loss, anorexia, polydipsia
Neurologic	Fatigue, lethargy, muscle weakness, confusion, seizure, coma
Gastrointestinal	Nausea, vomiting, constipation, ileus, abdominal pain, obstipation
Renal	Polyuria, azotemia, renal failure
Cardiac	Bradycardia, prolonged PR interval, shortened QT interval, wide T wave, arrhythmias

calcium with a low or normal parathyroid hormone (PTH) level excludes the diagnosis of primary hyperparathyroidism.

Serum calcium is highly bound to albumin; therefore, the total serum concentration will vary depending on serum protein concentrations.⁵⁵ Measurement of the ionized calcium level can often assist in sorting out difficult cases.^{56,57} An adjustment for the total serum calcium concentration based on the serum albumin concentration can be made as follows:

$$\text{Corrected calcium (mg/dL)} = \text{measured calcium (mg/dL)} - \text{albumin (g/dL)} + 4.0$$

Clinical symptoms that arise from hypercalcemia are a direct result of both the rate of rise and the absolute serum calcium level (Table 72.5).⁵⁸ The most common constitutional symptoms include weight loss, anorexia, polydipsia, which may progress into nausea, vomiting, polyuria, azotemia, renal failure, constipation, ileus, abdominal pain, and even obstipation. With continued rise, patients may begin to experience neurologic symptoms, such as fatigue, lethargy, muscle weakness, confusion, seizure, and even coma. Cardiac symptoms are rare, but when they occur, can lead to fatal arrhythmias. The initial electrocardiographic changes include bradycardia, prolonged PR interval, shortened QT interval, and widening of the T-wave.

Most patients remain asymptomatic even with a serum calcium level as high as 14 mg/dL. However, if the serum calcium levels remain at a level of 13 mg/dL for an extended period of time, dehydration, renal insufficiency, and calcifications may begin to occur, especially if the serum phosphate levels are also elevated. When the serum calcium level exceeds 16 mg/dL, severe neurologic and cardiac changes begin to occur that may prove life threatening, and should be treated as a medical emergency, with prompt hospitalization and immediate initiation of appropriate therapy to correct the electrolyte abnormalities.

The cause of cancer-related hypercalcemia depends marginally upon the underlying malignancy. In patients with widespread bone metastasis, hypercalcemia is believed to be associated with direct bone destruction by the cancer cells⁵⁹; this is referred to as local osteolytic hypercalcemia. More commonly however, are the various humorally mediated causes for hypercalcemia.⁶⁰⁻⁶² Even in patients with extensive bone metastasis, humorally mediated factors often are most important. In many cases of cancer-related hypercalcemia, PTH stimulation induces significant biochemical changes. These changes include increased renal tubular reabsorption of calcium and the development of hypophosphatemia, as well

as an increase in urinary output of phosphate.^{63,64} The predominant cause of the cancer-related hypercalcemia in these cases is ectopic PTH production with a PTH-related protein (PTH-RP). The genes encoding PTH-RP have been mapped to the short arm of chromosome 12.^{65,66} Authentic human PTH has been mapped to the short arm of chromosome 11. Both the authentic PTH, as well as the PTH-RP, have much in common. The most important similarity is within the amino terminal portion where 8 of the first 13 of the amino acids are homologous. This portion of PTH corresponds to the receptor-binding domain. PTH-RP is the most common cause of cancer-related hypercalcemia and is found in many patients with solid tumors, particularly those with squamous cell carcinomas.^{67,68} In addition, high levels of PTH-RP have been reported in the human T-cell leukemia/lymphoma virus (HTLV)-1-associated adult T-cell leukemia/lymphoma syndrome (ATLL).⁶⁹ In this case, it is thought that the viral TAX activates the PTH-RP gene promoter. PTH-RP has also been associated with patients with cancer-related hypercalcemia and patients with bone metastasis from breast carcinoma⁷⁰ and prostate cancer.⁷¹ Patients with high levels of PTH-RP in the primary tumor seem more likely to develop bone metastasis. PTH-RP does not seem to be involved in most hematologic cancers, such as multiple myeloma or lymphoma.⁶⁷

Elevated serum levels of 1,25-(OH)₂-vitamin D₃ have been reported in patients with Hodgkin's disease, non-Hodgkin's lymphoma, and multiple myeloma.^{72,73} The increase of the vitamin D₃ level results from an increase in 1- α -vitamin D-hydroxylase, thereby increasing enzymatic conversion to vitamin D₃.

Osteoclast-activating factors are important molecules that induce bone reabsorption. For example, interleukin 6 (IL-6) is an autocytochrome growth factor in patients with multiple myeloma and has been shown to increase bone reabsorption in vitro.^{74,75} IL-6 administration can induce remarkably high levels of serum calcium, which can be blocked by specific neutralizing antibodies. Other cytokines can also serve as osteoclast-activating factors, such as interleukin-1, tumor-derived hematopoietic colony-stimulating factor (CSF), tumor necrosis factor, and transforming growth factors (TGFs).⁷⁶⁻⁷⁸

It is important to know that the treatment of cancer-related hypercalcemia should be directed at the underlying malignancy. Hypercalcemia most commonly affects older patients, as well as patients with an underlying renal insufficiency, and those patients with advanced disease. It is important to take note of several supportive issues that can exacerbate hypercalcemia, such as immobilization, as well as to review the patient's medication list to avoid drugs that inhibit the usual calcium excretion, such as thiazide diuretics, nonsteroidal antiinflammatory agents, and histamine receptor antagonists.⁵²

Most patients with hypercalcemia present with marked dehydration resulting from anorexia, nausea, and vomiting, as well as polyuria caused by calciuresis. Therefore, aggressive fluid repletion with normal saline is the first line of therapy. Appropriate volume expansion not only increases renal blood flow but will also improve calcium excretion. The rate of fluid administration will depend upon the clinical situation, keeping in mind many patients may have renal and cardiac dysfunction at baseline. Once euvoolemia has been established, forced diuresis with furosemide can be initiated. One must be extremely careful because furosemide can reestablish a

volume-depleted state. The effect of calcium reduction with forced diuresis is only minimal and therefore, the use of furosemide should be limited to balancing fluid intake and urine output, as patients are volume depleted.

Bisphosphonates form the basis of most therapeutic endeavors in the treatment of cancer-related hypercalcemia.⁷⁹ Older agents, such as etidronate,⁸⁰ and clodronate⁸¹ have been largely replaced with pamidronate (Aredia)^{82,83} and zoledronic acid (Zometa).⁸⁴⁻⁸⁷ The typical onset of action is within 24 to 48 hours. Bisphosphonates work by absorbing to the surface of hydroxyapatite, thereby inhibiting calcium released from bone. Bisphosphonates also interfere with the metabolic activity of osteoclasts. Interestingly, bisphosphonates may not be as effective in the management of cancer-related hypercalcemia in patients and those mediated by PTH-RP.

Both pamidronate and zoledronic acid should be administered intravenously. Pamidronate is typically infused at a dose of 60 to 90 mg over 2 to 4 hours, and zoledronic acid is administered at a dose of 4 mg in patients with normal renal function. Peak levels of both pamidronate and zoledronic acid have been associated with renal tubular dysfunction.^{84,88,89} Although zoledronic acid was initially infused at a rate of less than 15 minutes, infusion rates between 30 and 45 minutes are now being recommended, and zoledronic acid should be dose reduced in patients with renal insufficiency.

Gallium nitrate is a potent inhibitor of bone absorption.⁹⁰ Gallium is incorporated into the bone, thereby rendering hydroxyapatite resistant to cell-mediated reabsorption. Calcitonin (Miacalcin) is particularly advantageous, given its rapid onset of action, 2 to 4 hours.^{91,92} Calcitonin reduces serum calcium by increasing renal calcium excretion and also by inhibiting bone reabsorption. Unfortunately, the hypocalcemic effect of calcitonin is relatively weak, and the acute response peaks at approximately 48 hours even with continued treatment. Randomized clinical trials have demonstrated the superiority of gallium nitrate over calcitonin for the treatment of resistant hypercalcemia.⁹³

The use of corticosteroids is most useful in patients with malignancies that respond to cortical steroid therapy^{91,94}; these include multiple myeloma, lymphoma, and acute lymphoblastic leukemia. Unfortunately, corticosteroids do not seem to have a consistent effect on serum calcium levels in other malignancies.

Hyponatremia

Hyponatremia is a potentially life-threatening abnormality that has many causes. One must first differentiate between true hyponatremia and pseudohyponatremia, which is a lowering of the measured serum sodium level that is not physiologic.⁹⁵ Because sodium ions are dissolved in plasma, any increase in the nonaqueous phase will artificially lower the serum sodium concentration. This point is important, as the plasma osmolality typically remains normal. The most common cause of pseudohyponatremia is hyperproteinemia or hyperlipidemia. Other causes of pseudohyponatremia as a result of increased plasma osmolality, include hyperglycemia and mannitol administration.

The differential diagnosis of hyponatremia cannot be made until the patient's volume status is accurately determined.^{96,97} Hypotonic hyponatremia is typically caused either

by a primary water gain or as a result of primary or secondary sodium loss. In the absence of water intake, it is important to realize that hyponatremia is not a disease, but a manifestation of a variety of underlying clinical disorders. To ascertain the cause of hyponatremia, it is important also to measure the plasma osmolality, the urine osmolality, and the urine sodium concentration, as well as the urine potassium concentration.

In patients with hyponatremia, who are volume overloaded, the expanded extracellular fluid (ECF) status is typically caused by a decrease in the effective circulating volume, as in patients with congestive heart failure, hepatic cirrhosis, or nephrotic syndrome. Patients with hyponatremia that occurs as a result of a reduced ECF volume or dehydration, include those with significant sodium losses from sweating, large body area burns, or gastrointestinal losses due to vomiting, fistula or visceral tube drainage, or diarrhea. Diuretic-induced hyponatremia is usually as a result of thiazide-type diuretics, as the loop diuretics impair maximal urinary concentrating capacity.

The syndrome of inappropriate antidiuretic hormone secretion (SIADH) is the most common cause of hyponatremia that occurs in the euvolemic state.⁹⁷⁻⁹⁹ SIADH is a result of the nonphysiologic release of arginine vasopressin (AVP) either secreted from the posterior pituitary or an ectopic source. SIADH is usually caused by the production of an ADH-like substance through ectopic production, although nonmalignant causes must be excluded (Table 72.6). Although only approximately 10% to 15% of patients with small cell lung cancer present with SIADH, the majority of patients with small cell lung tumors stain positively for AVP. SIADH can be caused by a variety of other tumors, including non-small cell lung cancer, head and neck tumors, brain tumors, and rarely, hematologic malignancies, such as leukemia and lymphoma (Table 72.7).

In addition to malignant cause for SIADH, there are several nonmalignant causes that must be excluded; these include central nervous system infections or vasculitis. Rarely, head injury or benign tumors can also cause SIADH, and numerous pulmonary infections and a variety of drugs have been implicated in causing SIADH. It is important to remember that tumor-associated SIADH remains a diagnosis of exclusion; however, the treatment of both tumor-related SIADH and SIADH from other causes is similar.

The clinical manifestations of hyponatremia are a direct relationship to the rate of change in the serum plasma sodium concentration.¹⁰⁰ Plasma sodium concentrations that fall

slowly over long periods of time are often well tolerated and patients usually remain asymptomatic. As the plasma sodium concentration falls to below 120mmol/L, patients may develop neurologic symptoms. These symptoms include headache, lethargy, and confusion, and if left uncorrected, may develop into seizures and coma.

The goal of therapy is to increase the serum sodium concentration. In patients with mild to moderate hyponatremia, this can be efficiently corrected by restricting the patient's free water intake.^{97,98,101} In the event that free water restriction is ineffective in raising the sodium level, demeclocycline can be used. Demeclocycline (Declomycin) has a modest effect on inhibiting the effect of arginine vasopressin (AVP) on the kidneys. The typical dose of demeclocycline is 600 mg/day. However, one must be cognizant that the overall goal of therapy, specifically in a patient with SIADH, is to effectively treat the underlying malignancy. In patients who have hypovolemia, restoration of normal volume status typically initiates AVP release, allowing free water excretion. In patients with severe hyponatremia that results in the development of neurologic symptoms, it may be necessary to administer hypertonic saline. One must be extremely careful with the administration of hypertonic saline to avoid central pontine myelinolysis.¹⁰² This devastating neurologic syndrome can be avoided by ensuring that the plasma sodium concentration is raised by no more than 1 to 2mmol/L per hour.

Adrenal Failure

Adrenal failure as a result of destruction of adrenal cortical tissue by metastatic tumor is extremely uncommon.^{103–105} Bilateral adrenal hemorrhage may also result in severe adrenal insufficiency, and patients with the antiphospholipid antibody syndrome are at high risk of adrenal hemorrhage and infarction.^{106,107} In autopsy series, metastases to the pituitary or hypothalamus are found in up to 5% of patients with cancer, but associated adrenal insufficiency is rarely reported. Other causes of adrenal failure include the long-term use of chronic corticosteroid therapy. Patients on long-term corticosteroids may develop suppression of adrenal cortical function and require a taper of their corticosteroids to maintain baseline adrenal function. Patients at the highest risk for adrenal failure caused by chronic corticosteroid therapy are those patients with central nervous system tumors or spinal column tumors or patients undergoing treatment for acute lymphoblastic leukemia, non-Hodgkin's lymphoma, or

Hodgkin's disease. Chemotherapeutics that may result in adrenal failure include mitotane (Lysodren), ketoconazole (Nizoral), and aminoglutethimide (Cytadren); the latter inhibits adrenal steroid synthesis.¹⁰⁸

Symptoms of adrenal insufficiency are rather insidious. Classic signs include weakness, weight loss, and anorexia. In patients with long-standing adrenal insufficiency, hyperpigmentation as well as postural hypertension may also develop. Shock as a result of circulatory collapse is extremely uncommon and may develop in the setting of clinical infection. Laboratory abnormalities include nonanion gap metabolic acidosis, mild hyponatremia, and hypokalemia.

To make the diagnosis of adrenal insufficiency, patients should receive an injection of cosyntropin (Cortrosyn) at a dose of 0.25mg intravenously with measurement of serum cortisone levels at baseline and at 30 minutes and 1 hour after injection. An increase of the serum cortisone level of 5 to 7mg/dL over baseline is considered normal. In patients who are suspected to have adrenal insufficiency based on clinical symptoms, stress-dose steroid replacement should be initiated immediately; this is typically administered as hydrocortisone 100mg intravenously every 8 hours and tapered as tolerated. Physiologic cortisol replacement is administered as prednisone at a dose of 25mg in the morning and 12.5mg in the evening. During periods of stress, such as infection and or an operation, the doses may need to be increased substantially. Occasionally, the addition of a mineralocorticoid, such as fludrocortisone at a dose of 0.1mg/day is required.

Disorders of Blood Glucose

Hypoglycemia as a result of an underlying malignancy is extremely rare. The most frequent cause is as a result of an insulin-producing islet cell tumor. However, several cases of hypoglycemia as a result of non-islet cell tumors have also been reported.¹⁰⁹ Non-islet cell tumors that are associated with hypoglycemia tend to be extremely large and are often mesenchymal in origin, such as fibrosarcomas, leiomyomas, rhabdomyosarcomas, liposarcomas, and even mesotheliomas.¹⁰⁹ There have also been reports of hepatomas causing tumor-related hypoglycemia.

Patients with hypoglycemia usually present with symptoms of tachycardia, diaphoresis, nausea, weakness, and dizziness; these are extremely nonspecific findings, and only if the clinician is extremely compulsive will a diagnosis of hypoglycemia be entertained. For most patients, symptoms are usually worse early in the morning after an overnight fast and improve only after a meal. In patients with severe hypoglycemia, mental status changes may develop that can result in focal neurologic deficits, which may lead to the development of a seizure or coma. Islet cell tumors induce hypoglycemia as a result of abundant ectopic insulin secretion. In most patients with non-islet cell tumor-induced hypoglycemia, the secretion of substances with nonsuppressible insulin-like activity has been detected; these are usually a result of a secretion of insulin-like growth factors, such as IGF-1, IGF-2, somatomedin A, and somatomedin C.^{109,110} The IGF proteins are similar to pro-insulin but have only 1% of its biologic activity. Similar to pro-insulin, IGFs are bound by circulating proteins and induce specific biologic activities only after binding to cell-surface receptors.^{110–117}

Increased glucose utilization by large tumors may also account for several episodes of cancer-related hypoglycemia. Tumor sizes greater than 1 kg may utilize 50 to 200 g glucose per day.¹¹⁸ In a healthy patient, the liver can produce approximately 700 g of glucose per day; however, patients with cancer-related hypoglycemia have tumors that weigh several kilograms and may also have extensive hepatic metastasis, which impairs hepatic glucose production. In addition, patients with cancer-related hypoglycemia may have dysfunctional counterregulatory mechanisms that induce hypoglycemia.¹¹⁸ For example, impaired hepatic function can lead to a decrease in both glycogenolysis and gluconeogenesis.

The treatment of severe hypoglycemia is the immediate infusion of 50 mL 50% dextrose (D50). In patients who have a serum glucose level less than 40 mg/dL, the administration of continuous glucose after an infusion of D50 may prove beneficial. Patients with mild hypoglycemia can usually be managed by increasing the frequency of their meals. In addition, the coadministration of corticosteroids may provide some symptomatic relief, and the use of a continuous infusion of glucagon via a portable pump has met with some success.¹¹⁹

The most common glycemic abnormality in patients with cancer is hyperglycemia. Hyperglycemia may result from long-term corticosteroid administration, especially in patients with underlying glucose intolerance or diabetes mellitus.¹²⁰ Patients at highest risk are those patients who receive high-dose corticosteroids as part of their chemotherapy or antiemetic regimen, such as those patients with non-Hodgkin's lymphoma, Hodgkin's disease, acute lymphoblastic leukemia, or lymphoma, as well as those patients with metastatic tumors to the central nervous system and spinal column. Long-term corticosteroid administration may result in dysregulated glucose utilization, leading to states of hyperglycemia. For most patients, hyperglycemia is mild and the only metabolic abnormality, but in other patients long-term hyperglycemia may result in hyperosmolar states requiring insulin administration. Rarely will hyperglycemia lead to ketoacidosis unless the patient already has an underlying type 1 diabetes mellitus that is either poorly controlled or inappropriately monitored.¹²¹

Surgical Emergencies

David A. August, Thomas Kearney,
and Roderich E. Schwarz

Most surgical problems in cancer patients are not urgent. Tumors rarely grow or metastasize rapidly. Surgical evaluation can usually proceed at a measured pace over a number of weeks to accurately assess the patient's underlying cancer, to define associated comorbidities that may modify treatment decisions, to consult various disciplines to devise multimodal therapies, and to work with patients and families to create care plans that account for patient preferences and family needs. In light of this panoply of issues that affect surgical decision making in cancer patients, the presence of a surgical emergency requiring prompt evaluation and intervention is especially problematic. Thorough evaluation of cardiac, pulmonary, and other comorbidities may not be feasible. Discussions with medical and radiation oncologists and other consultants may be constrained by time and availability. Attempts to inform and understand patient and family wishes may be confounded by changes in emotional state and cognitive ability caused by pain, anxiety, fear, and the need to intervene promptly.

This chapter discusses the evaluation and treatment of general surgery oncologic emergencies. Attention is focused upon those problems likely to be treated by a general surgeon or general surgical oncologist, including the acute abdomen; surgical complications of radiation therapy and chemotherapy; gastrointestinal obstruction, bleeding, and perforation; abdominal and anorectal emergencies in the setting of neutropenia; and problems peculiar to bone marrow transplant patients.

For the purposes of this chapter, a surgical emergency is defined as an acute medical problem necessitating surgical evaluation for urgent intervention; by this definition, many "surgical emergencies" do not require surgery. The term acute abdomen implies the presence of a life-threatening situation causing abdominal signs and/or symptoms that needs to be evaluated for potential surgical intervention.¹ In many instances, patients with an acute abdomen do not require immediate surgery (e.g., abdominal pain resulting from an evolving inferior wall myocardial infarction or lower lobe pneumonia, or free air introduced by transmigration during an otherwise uncomplicated colonoscopy). All cancer patients may be considered immunocompromised. Especially problematic are those patients with absolute neutropenia (absolute neutrophil count less than 1,000 cells/mm³) secondary to bone marrow suppression from chemotherapy, radiation therapy, and/or the underlying malignancy. They may fail to exhibit the classic signs of an emergent surgical

problem, such as pain, tenderness, fever, and leukocytosis. Often, more subtle manifestations such as intolerance of oral intake, abdominal distension, diarrhea, changes in mental status, or isolated hyperbilirubinemia may be the only indications of an evolving, life-threatening situation.

General Considerations

An initial diagnosis of cancer is made in less than 1% of cases seen in a typical emergency department.² Such a presentation, however, is ominous. The prognosis of patients newly diagnosed with cancer during an emergency room evaluation is poor. In comparison with other newly diagnosed cancer patients, they are more likely to have metastatic disease and they are more likely to die during their initial hospital admission. Median survival for these patients is less than 1 year.³⁻⁵ This poorer prognosis likely relates to poor access to medical care in these patients (resulting in inadequate screening and fewer opportunities to recognize signs and symptoms early), increased morbidity and mortality frequently observed in patients presenting with any type of emergency problem, and advanced stage of disease at presentation.⁶ Overall, approximately 5% of cancer cases are initially diagnosed in an emergency room setting.⁴ This number may be significantly higher for certain sites, such as the gastrointestinal tract.⁵

In patients being treated for cancer, surgical emergencies may arise as a consequence of their antitumor therapy. In a review of 213 cancer patients requiring exploration for an acute abdomen, approximately one-third had problems relating directly to chemotherapy or the cancer itself (Table 73.1).^{7,8} It has been observed that emergent abdominal complications are more likely to arise in patients with acute leukemia during or immediately following treatment with chemotherapy.⁹ Corticosteroids administered as part of a chemotherapy regimen are also a common offender.¹⁰ Radiation therapy may contribute to the development of surgical emergencies. Injury to irradiated tissues may lead to necrosis or vascular catastrophes (thrombosis or rupture) requiring acute intervention. Radiotherapy is implicated in approximately one-third of enterocutaneous fistulae.¹¹ As many as 15% of patients receiving abdominal irradiation may experience related complications, although most will not require an operation.¹² Most radiation-induced surgical emergencies arise well after the therapy is completed. With increased fractionation and a greater number of ports used, the less likely it is that normal tissue injury will occur.¹³

TABLE 73.1. The spectrum of diagnoses in 213 cancer patients requiring emergency laparotomy.

<i>Diagnosis</i>	<i>Location</i>	<i>% (n)</i>
Obstruction	Not specified	39% (83)
Hemorrhage	Intraabdominal tumor	4% (8)
	Gastrointestinal (stomach, 6; duodenum, 5; small bowel, 3; colon, 9)	11% (23)
Perforation	Stomach, 7; duodenum, 9; small bowel, 11; colon, 20	22% (47)
Infection	Cholecystitis, 7; appendicitis, 5; bile peritonitis, 4; cholangitis, 3; ascites, 1; neutropenic enterocolitis, 1; other, 1	10% (22)
Incarcerated hernia	Not specified	3% (6)
Vascular occlusion	Mesenteric	3% (6)
Other	Not specified	1% (3)
Negative laparotomy	Not specified	7% (15)

Source: From Turnbull.⁷

Abdominal pain is a common presenting complaint for a variety of illnesses. Distension of hollow organs, bowel or organ ischemia, and irritation of the peritoneum by infection or gastrointestinal contents can cause abdominal pain. For all patients presenting to an emergency room with abdominal pain, the most common diagnosis is nonspecific pain (35%). Appendicitis (17%), bowel obstruction (15%), renal calculi (6%), and gallstones (5%) are the most common specific diagnoses.¹⁴

Evaluation of patients with an initial or known diagnosis of cancer who present with a potential surgical emergency may be difficult. Neutropenia, corticosteroids, narcotic analgesics, and malnutrition may all blunt the signs and symptoms of a surgical emergency. Pain may be obscured, the patient's ability to mount an inflammatory response may be muted, and preexisting poor performance status may hide functional consequences of an evolving catastrophe. Conversely, cytokine support [granulocyte colony-stimulating factor (G-CSF) and granulocyte macrophage colony-stimulating factor (GM-CSF)] may confound the interpretation of standard laboratory tests, such as a complete blood count.

These factors notwithstanding, pain is usually the most important symptom heralding a surgical emergency. Particularly in the setting of a preexisting malignancy, pain and other complaints, such as vomiting, abdominal distension, fever, anorexia, constipation, melena/hematochezia, perianal symptoms, and even subtle stigmata of soft tissue infections, must be evaluated promptly and thoroughly. Although the need for emergent operations in cancer patients is relatively uncommon, failure to intervene in a timely fashion can increase morbidity and mortality in these compromised hosts.¹⁵

Physical examination remains the mainstay of diagnosis. Constitutional signs, such as fever, tachypnea, and tachycardia, on occasion, are the only objective findings present. Their presence is significant, because they represent a systemic reaction, connoting a more generalized process. Although immunocompromised hosts may not demonstrate localized tenderness, more diffuse abdominal or soft tissue tenderness is usually present. Paradoxically, it may be easier to palpate organomegaly or an abdominal mass in these patients because of the blunting of involuntary guarding. Care must be taken when examining open wounds or considering digital rectal or vaginal examination in neutropenic patients, as these examinations may result in transient bacteremia. Given the prevalence of anorectal and soft tissue infections in these patients, however, a careful visual inspection of the perineum, vaginal introitus, anoderm, and anal canal, and of soft tissue wounds, is mandatory.

Laboratory and imaging studies are also helpful. A complete blood count with differential is necessary to determine whether absolute neutropenia or leukocytosis is present. It will also demonstrate the presence of thrombocytopenia, which is important in bleeding patients and in those in whom an operation is considered. Liver function tests and serum amylase and lipase often help to direct evaluation of the acute abdomen. Standard laboratory studies are also necessary to direct preoperative resuscitation and operative risk assessment. Because of the immunocompromised status of these patients, plain X-rays (chest X-ray and abdominal films to look for pneumonia, pleural effusion, intestinal obstruction, pneumoperitoneum, and soft tissue air) and cross-sectional imaging with ultrasound, computed tomography (CT), and/or magnetic resonance imaging (MRI) are usually indicated, even though immune compromise may blunt some of the subtle inflammatory findings that can be helpful with these imaging modalities. Localization of a bleeding source in patients with gastrointestinal or other hemorrhage using endoscopy or arteriography is important and may even be therapeutic. The roles of these studies are discussed here in relationship to specific clinical situations. Critical care issues in cancer patients undergoing emergency operations are important but are beyond the scope of this chapter.¹⁶

When Is Operative Therapy Not Appropriate?

Acute surgical interventions in cancer patients should improve patients' well-being. In patients being treated for cancer with curative intent, decisions to operate should be guided by the medical circumstances. Although an operation may be high risk, successful acute intervention can result in long-term survival.

More problematic are surgical emergencies in a patient in whom cancer cure is not possible (Table 73.2).¹⁷ It is important that the patient's definition and assessment of well-being be understood by the treating clinicians and incorporated into medical decision making. If an operation is unlikely to improve the patient's well-being according to his or her definition, even though it may be technically indicated (e.g., plication of a perforated duodenal ulcer in a patient with metastatic melanoma), it may be inappropriate.¹⁷ In this circumstance, likelihood of survival to discharge (although often difficult to predict) can be an important parameter. Futile procedures that are unlikely to have a beneficial outcome are contraindicated, although few data exist to assist with these decisions.¹⁷ There are some data concerning the efficacy of

TABLE 73.2. Factors that identify situations in which surgical treatment may not be appropriate.

<i>Factor</i>	<i>Comment</i>
Surgical indication vs. palliation	Operations undertaken in patients with potentially curable acute complications and potentially curable cancers are more likely to be beneficial. Operations undertaken to palliate symptoms should be carefully considered in light of potential nonoperative alternatives and in accordance with patients' preferences and values.
Likely outcome	Procedures should not be undertaken when the likelihood of survival to discharge is low (e.g., cardiopulmonary resuscitation in patients with metastatic disease, emergency laparotomy in patients with widespread metastatic disease).
Futility	When therapy is as unlikely to lead to a desirable outcome as supportive care, the latter is preferred. It is not the physician's duty to attempt to do "everything possible."

cardiopulmonary resuscitation in patients with metastatic cancer. In one review, fewer than 3% of patients with metastatic cancer survived to actually be discharged from the hospital.¹⁸ Emergency abdominal operations in patients with metastatic cancer may be equally futile. In a series of 21 such patients receiving chemotherapy, 17 died in the immediate postoperative period. Only 3 survived to discharge, and only 1 lived beyond 5 months.¹⁹ Generally, invasive treatments are not appropriate when the patient's definition of well-being is unlikely to be achieved, or when the intervention is doomed to failure because of its inherent medical futility. In this light, decisions to treat or not treat must be made using the medical knowledge and experience of the treating clinicians (surgeons, medical oncologists, primary care physicians, nurses, and other involved clinicians and support staff) in combination with the values and wishes of the patient and family.

Gastrointestinal Obstruction

Gastrointestinal obstruction is the most common problem that requires urgent surgical evaluation in cancer patients, and this is especially true in patients with solid tumors of intraabdominal and pelvic origin. At one institution, 39% of cancer patients requiring emergency abdominal operation suffered from intestinal obstruction.^{8,20} In most patients, cancer is the cause of the obstruction. However, obstruction is secondary to a benign process in approximately 30% of cases; most often, this occurs as a result of adhesions that develop after a previous operation. Cancer-related obstruction is seen most often in patients with a history of gastrointestinal cancer, followed by gynecologic malignancy. Obstruction from metastases is less common. Acute intestinal obstruction may be the initial presentation of gastrointestinal cancer, comprising up to 30% of cases of malignant bowel obstruction.¹⁶ In patients with primary small bowel neoplasms, as many as 64% require emergency treatment; obstruction is the most common presenting finding (22%), followed by bleeding in 17%, and perforation in 6%.²¹

Clinical Presentation, Evaluation, and Stabilization

Crampy abdominal pain, nausea, and vomiting are characteristic symptoms of intestinal obstruction. Dysphagia or early postprandial vomiting suggest esophagogastric obstruction. Bilious vomiting is encountered when small bowel or proximal colon are involved. More distal large bowel obstruction usually presents with distension, pain, and constipation before vomiting occurs. So-called paralytic ileus and intesti-

nal pseudoobstruction (Ogilvie's syndrome) are the main differential diagnoses; they are usually characterized by the absence of bowel sounds, which is only a late finding in patients with true gastrointestinal obstruction. Peritonitis in the setting of obstruction is ominous and is associated with bacterial translocation, perforation, or bowel necrosis.

Laboratory tests are often nonspecific. Leukocytosis can reflect the degree of inflammation or infection associated with obstruction but may not be present in immunocompromised hosts. Sometimes, a subtle left shift alone may be the only laboratory finding. Metabolic acidosis, especially if not correctable, should raise concern over tissue ischemia or necrosis. Plain abdominal radiographs can confirm a clinical diagnosis of obstruction and help define the anatomic site. Upper gastrointestinal (GI) contrast studies should be avoided except when esophageal or gastric obstruction is suspected. If these studies are performed, aspiration precautions must be implemented. A water-soluble contrast diagnostic enema study can be very helpful to rule out colon obstruction and to facilitate intraoperative decision making. For example, a water-soluble contrast enema can assess left-sided colorectal patency and may avoid the need for a colostomy in a patient explored for small bowel obstruction with peritoneal carcinomatosis. In addition, it may differentiate a true obstruction from a pseudoobstructive process.²² CT is almost always helpful to assess the extent of the underlying malignancy. This information can inform decisions of whether to operate and whether the goal of an operation should be palliation or cure.

Initial management of the cancer patient with intestinal obstruction should include cessation of oral intake, intravenous hydration, nasogastric decompression, pain management, and nutrition status assessment. If signs of peritonitis or sepsis (fever, tachycardia, leukocytosis, acidosis, peritoneal signs on abdominal examination) are absent, most patients can be stabilized and undergo deliberate evaluation. Emergency operations, necessitated by the presence of infection or compromised bowel, are accompanied by greater morbidity and mortality.^{23,24} Avoidance of emergency operations, when possible, also allows assessment of potentially curative resection options and of palliative nonoperative approaches for incurable tumors.

Treatment

Endoscopic ablation techniques can provide temporary control of localized obstruction caused by large tumor masses, especially in cases of esophageal or distal colorectal obstruction.²⁵⁻²⁷ Endoscopic or interventional intestinal stent

placement offer additional nonoperative options. With judicious use of these techniques, operations for partial esophago-gastric, duodenal, and colorectal obstruction can frequently be avoided in patients with advanced disease. Unfortunately, most patients with small bowel obstruction who fail to respond to hydration and nasogastric decompression, or those with complete intestinal obstruction at any level, require operative therapy (Figure 73.1). Nasogastric decompression and supportive care alone may succeed in 25% to 35% of cancer patients with intestinal obstruction; unfortunately, as many as 50% of these patients will develop subsequent recurrent bowel obstruction. An exception is those situations in which intestinal obstruction is caused by a malignancy that is likely to respond well to either chemotherapy and/or radiation therapy, such as lymphoma and testicular cancer; operations are best avoided in this setting, in favor of cytotoxic treatment.

Operative techniques include resection of the obstructed intestinal segment, intestinal bypass, and external diversion (ileostomy, colostomy, esophageal spit fistula). The decision

whether to stage decompression, resection, and/or reconstruction, or combine these steps within a one-stage procedure, must be individualized. Patient physiologic status (hemodynamic stability, organ function, presence of ascites, nutrition status, performance status, and presence of comorbidities) and operative factors (tissue viability, contamination, extent of cancer) must be considered.²⁸

There is ongoing controversy over whether a colon resection with primary anastomosis should be performed in cases of left-sided large bowel obstruction. When the primary presentation of colon cancer is obstruction, and resection for cure is possible, it may be considered, but available trial-based evidence is sparse.²⁹ Intraoperative bowel cleansing can be performed and may reduce the risk of anastomotic leak.³⁰ Alternatively, subtotal colectomy with ileorectal anastomosis apparently can be performed with acceptable morbidity and functional outcome.^{31,32} Alternatively, an endoscopic colon stent may achieve decompression, after which a definitive resection can be performed electively.³³⁻³⁵

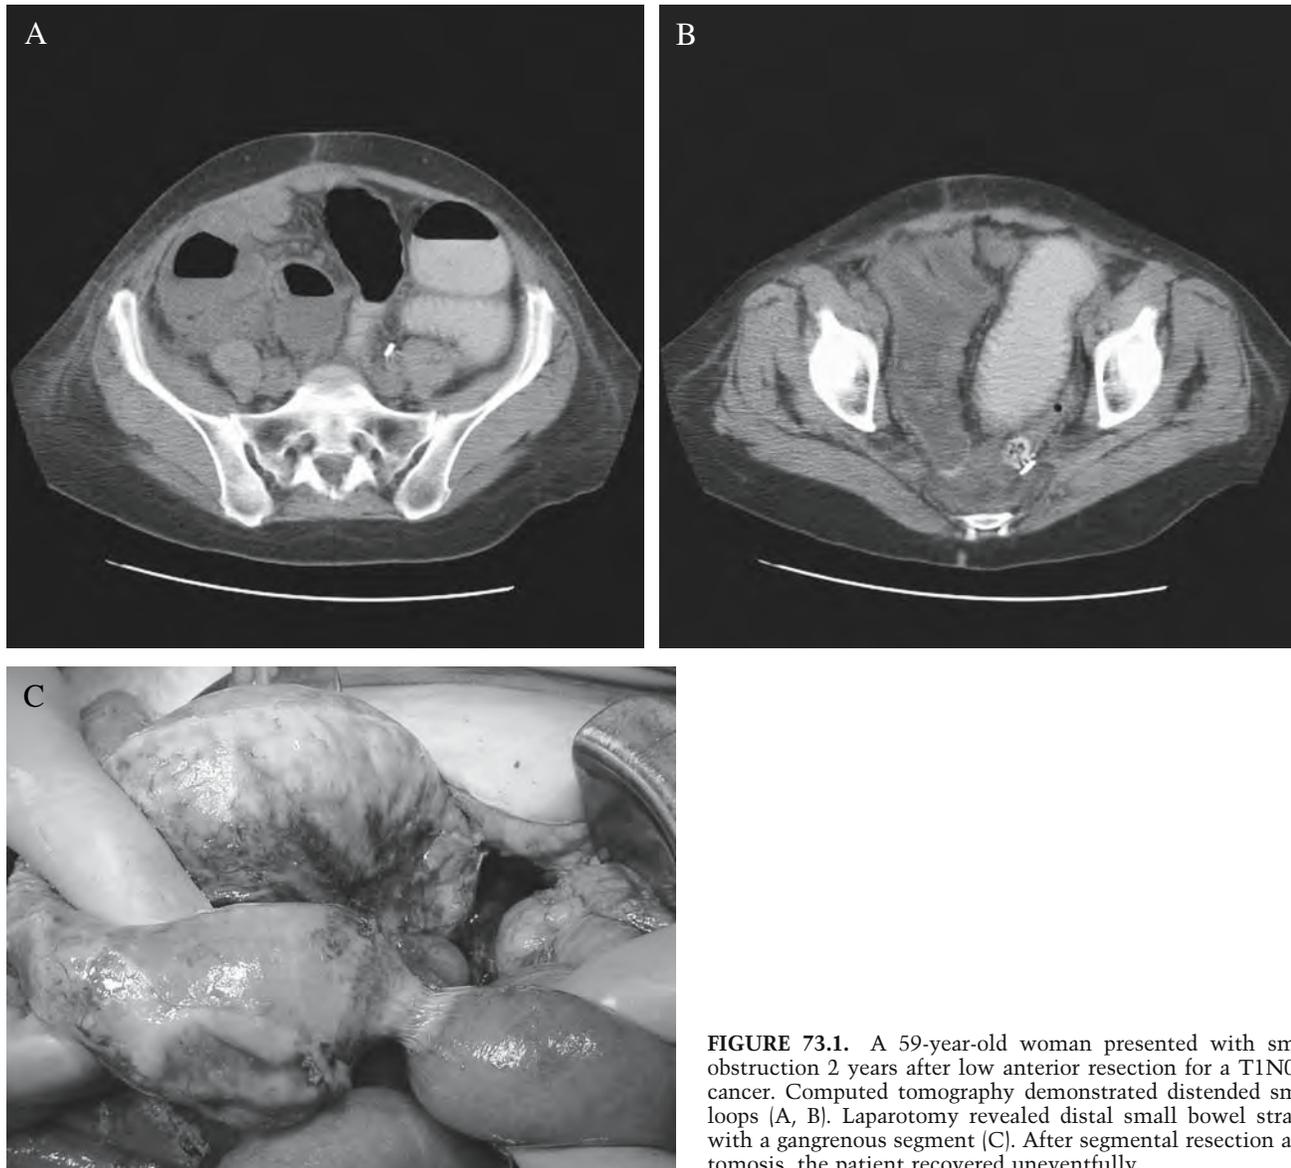

FIGURE 73.1. A 59-year-old woman presented with small bowel obstruction 2 years after low anterior resection for a T1N0M0 rectal cancer. Computed tomography demonstrated distended small bowel loops (A, B). Laparotomy revealed distal small bowel strangulation, with a gangrenous segment (C). After segmental resection and reanastomosis, the patient recovered uneventfully.

Source: From Blair et al.¹⁶

Tube gastrostomy may be helpful in patients with extensive peritoneal carcinomatosis, or those at risk for recurrence of obstruction. In patients with inoperable malignant bowel obstruction, operative or percutaneous endoscopic gastrostomy can avoid the need for prolonged or even lifelong nasogastric tube decompression. A feeding jejunostomy tube can assist the management of patients with proximal gastrointestinal dysfunction or if sufficient oral food tolerance remains unlikely. Feeding tubes, however, should be reserved for those patients with active treatment options (chemotherapy or radiation therapy).

Outcomes after operations for malignant bowel obstruction vary considerably, based on the patient's physiologic and functional status and extent of underlying disease. In general, however, mortality rates are high (10% to 25%). Postoperative complications may occur in as many as 50% of patients. Success rates for palliative operations are rarely reported. The median survival for these patients ranges between 3 and 7 months. A systematic review of available clinical trials concludes that surgical therapy for malignant bowel obstruction remains problematic: symptom control is achieved in only 40% to 80% of patients; reobstruction occurs frequently (10% to 50% of the time); and perioperative morbidity and mortality are formidable. Especially disappointing is the lack of validated outcome.^{36,37} A recent review reported outcomes of palliative operations in 63 patients with malignant bowel obstruction. The complication rate was 44%, with a 15% mortality rate, and a median length of hospital stay of 12 days.

Patients with colorectal primaries had somewhat better survival. Absence of ascites, obstruction site outside of the small bowel, and a serum albumin greater than 3 mg/dL correlated with the ability to tolerate solid food postoperatively. Prolonged successful palliation was observed in only one-third of patients.¹⁶ Comparable outcomes in patients with peritoneal carcinomatosis and malignant bowel obstruction have been reported in other operative series (Table 73.3). Emergency gastrectomy for gastric obstruction as compared to acute bleeding is rare.^{43,44}

Nonoperative therapy of bowel obstruction beyond that of general supportive care may be indicated, especially in patients with advanced-stage disease, or without specific anticancer therapy options, or whose physiologic status will not permit a safe operation. Corticosteroid treatment has been advocated to improve intestinal obstruction and alleviate associated symptoms. Outcome data are limited.³⁷ In several prospective trials, octreotide has been effective, controlling vomiting or reducing the volume of nasogastric drainage.^{45–48} Symptomatic improvement has also been described in a series of 20 patients with inoperable intestinal obstruction with the combined use of morphine sulfate, scopolamine, and haloperidol.⁴⁹

Colonoscopic placement of self-expanding metallic stents for large bowel obstruction is safe and effective (perforation rate less than 5%; 17% need for subsequent intestinal stoma) (Table 73.4).⁵⁰ Stent reobstruction (29%) and migration (9%) have been reported, but may be managed with further endo-

scopic manipulation.⁵⁸ The majority of patients stented with palliative intent achieve long-term relief of obstruction.³⁵ Experience with stents for gastric outlet obstruction is more limited (Table 73.5).⁶⁶⁻⁷⁰ Even with simultaneous biliary stenting in many patients, immediate success rates are reported as high as 95%, with 70% of patients remaining free of gastrointestinal symptoms during their remaining lifetime.⁷⁰ Among positive effects are: ability to tolerate solid food (77%), weight gain (71%), and improvement of reflux esophagitis (92%).⁶⁷ Late complications include tumor ingrowth and stent occlusion in about 20% of patients, but restenting is possible and often successful.^{66,68} In all series, median survival is limited to around 4 months.⁷¹ A small retrospective series suggests patients who undergo endoscopic stenting may achieve oral intake and hospital discharge sooner than those who undergo open or laparoscopic gastrojejunostomy for gastroduodenal obstruction.⁷²

Biliary Tract Obstruction

Biliary obstruction in patients with cancer is rarely an emergency and is not discussed here in detail. Obstructive jaundice itself does not require urgent treatment. Secondary cholangitis is an emergency, but rarely, if ever, occurs absent prior manipulation of the biliary tree either surgically or by endoscopic or transhepatic maneuvers.⁷³⁻⁷⁵ In most cases of painless obstructive jaundice, primary or recurrent neoplasms of the pancreatic head, extrahepatic biliary tree, or other periampullary tissues are identified; secondary lesions in retroperitoneal lymph nodes causing biliary obstruction most often metastasize, in decreasing order of frequency, from gastric, colonic, breast, or lung cancer primaries.⁷³ Endoscopic retrograde cholangiopancreatography (ERCP) or transhepatic imaging or stent placement upon initial presentation in a patient without signs of infection is rarely indicated, especially because preoperative biliary manipulation may increase operative mortality.⁷⁴ Biliary sepsis in the setting of biliary obstruction does necessitate emergent biliary decompression. Under these circumstances, endoscopic stenting via ERCP, when feasible, appears preferable to percutaneous transhepatic stent placement. For patients with metastatic disease, endoscopic stents should always be considered first.⁷⁶

Gastrointestinal Hemorrhage

Acute gastrointestinal hemorrhage is the third most frequent problem requiring emergency abdominal operation in cancer patients.^{7,8} Both benign causes and tumor-related etiologies occur in patients with cancer.

Clinical Presentation, Evaluation, and Stabilization

In a review of five case series encompassing 121 cancer patients, the most common causes for upper gastrointestinal hemorrhage were gastritis (36%), ulcer disease (26%), and tumor-related bleeding (23%).⁷⁷ Other reports support these findings, and they are true even today despite a dramatic decrease in the need for emergency operations for benign peptic disease in noncancer patients with the advent of H2 blockers and proton pump inhibitors.⁷⁸⁻⁸⁰ It is unusual for upper GI bleeding to require operative intervention (11%), and in only one-fourth of cases is the need for operation a true emergency.⁸¹

Lower gastrointestinal hemorrhage resulting from non-cancerous conditions has an 80% likelihood of stopping spontaneously, but the rebleeding rate is 50%. Colonoscopy or scintigraphic bleeding scan alone fail to localize a bleeding site in up to 50% of cases, but they complement each other.⁸² Angiographic localization succeeds in more than 80% of patients.^{83,84} The prevalence of lower GI bleeding and of both benign and malignant lesions that may cause lower GI hemorrhage increase with greater age. Arteriovenous malformation, diverticulosis, hemorrhoids, and cancer are therefore the most common causes of lower gastrointestinal bleeding.⁸⁵

In a study of 377 patients with advanced malignancy receiving palliative care at home, 18 developed gastrointestinal bleeding, resulting in 3 deaths. Metastatic liver disease was common in these patients.⁸⁶ Many factors present in cancer patients may increase the risk of a bleeding diathesis. Direct tumor growth and/or invasion can cause mucosal ulceration and vascular invasion. Intestinal ulceration and bleeding can also be caused by chemotherapy or corticosteroids. Chemotherapy-induced thrombocytopenia, coagulation disturbances from tumor- or treatment-induced hepatopathy, and use of aspirin, other nonnarcotic analgesics, and therapeutic anticoagulants in patients with cancer-

related thromboembolic complications can all predispose to and exacerbate GI hemorrhage. Gastrointestinal hemorrhage can result from *Candida*, cytomegalovirus, or *Clostridium difficile* infections in the GI tract, or from systemic sepsis resulting from immunosuppressive side effects of cancer and systemic cancer therapy. Direct chemical or physical injury to the GI tract by chemotherapy and radiation therapy can cause bleeding. Radiation-related bleeding risk is directly related to the dose administered.⁸⁷ Other factors increasing the bleeding risk in cancer patients relate to underlying conditions, such as variceal bleeds in cirrhotic patients with hepatocellular cancer.⁸⁸

Postoperative gastrointestinal hemorrhage can occur after visceral resection, as well as GI bypass procedures.⁸⁹ Acute hemorrhage by far outweighs obstruction among the indications for urgent reoperations after previous gastrectomy.⁴⁴ Massive GI hemorrhage, occurring in 3.2% of patients with previous abdominal cancer operations, can result from arterial erosions related to anastomotic leaks or from anastomotic mucosal suture line bleeding, at roughly equal frequency.⁹⁰ The mortality for anastomotic leak-associated hemorrhage may approach 50%, but is much lower for suture line bleeds. Hemorrhage can also be encountered postoperatively in the presence of uncontrolled infection or sepsis, although these are rare events even after major visceral resections for cancer.⁹¹⁻⁹³

Treatment

Immediate therapeutic efforts must focus on hemodynamic resuscitation and correction of coagulopathy. Venous access, fluid resuscitation, and transfusion of blood products (including packed red blood cells, platelets, and plasma to optimize coagulation) must be accomplished rapidly. As always, disease extent, patient physiologic and performance status, and advanced directives must be considered before complex treatment decisions are made. When the patient is stabilized, diagnostic studies should be initiated without delay, for reactivation of bleeding is common. These studies may include upper or lower gastrointestinal endoscopy, or contrast arteriography, based on the suspected site, bleeding rate, and underlying mechanism. Both endoscopy and angiography may also be therapeutic. Endoscopic variceal ligation is more effective for acute upper gastrointestinal bleeding in patients with hepatocellular cancer than conservative therapy.⁹⁴ For other sites, less-rapid bleeding from the intestinal mucosal surface suggests initial attempt at control by endoscopy. Techniques include argon beam plasma coagulation or laser application.^{25,26} Bleeding from radiation proctitis has been effectively controlled with topical formalin application.⁹⁵ More rapid bleeds in the presence of a larger tumor mass, or other local tissue compromise, such as infection, are more likely to respond to angiographic embolization.⁹⁶ If less-rapid bleeding originates from tumor tissue, especially large, unresectable lesions with gastrointestinal erosion, external-beam radiation therapy may be effective. For example, a single fraction of 10 Gy to patients with advanced uterine cancer controls pelvic bleeding in 90% of cases.⁹⁷ Similarly, rectal bleeding can be controlled in 85% of patients with ovarian cancer and tumor erosion with the use of radiation therapy.^{98,99}

Operative treatment for cancer-related hemorrhage should be considered only when tumor bleeding can be

treated by complete resection, when less-invasive therapeutic modalities have failed, or when endoscopy, angiography, and radiation are unlikely to be effective. It is imperative that the source of bleeding be unambiguously identified and localized before laparotomy. In cases of tumor bleeding, preoperative understanding of organ resectability is of great help as well, but obtaining the desirable imaging study may not always be feasible.

In a review of 427 patients with gastric cancer, 36 presented with upper gastrointestinal bleeding; among these, hemorrhage was self-limited in 44%, but an emergency operation was required in 56%; the resulting mortality after gastrectomy was 28%.¹⁰⁰ Bleeding gastric cancers tend to be larger in size, but resection is indicated whenever technically and physiologically feasible.¹⁰¹ Most emergency gastrectomies in cancer patients are performed for massive, intractable bleeding. The majority of these patients do not have adenocarcinoma; lymphomas, gastrointestinal stromal tumors, and other soft tissue neoplasms are the more frequent cause of massive neoplastic gastric hemorrhage. The mortality rate for emergency gastrectomy under these circumstances is 50% compared to 4% for nonemergent procedures.²³ Mortality among elderly cancer patients requiring emergency gastrectomy is reported to be as high as 67%.⁴³

Bleeding is not as common an indication as obstruction for small bowel resection in cancer patients, as both primary neoplasms and metastases to the small intestine cause hemorrhage in fewer than 20% of cases.¹⁰²⁻¹⁰⁴ An exception seems to be melanoma metastatic to the small intestine; equal numbers of patients require emergency resection for hemorrhage and for obstruction.¹⁰⁵⁻¹⁰⁷ Emergency abdominal colectomy for bleeding is associated with a high mortality rate. In one series, 5 of 11 patients undergoing emergency colectomy died, primarily of infectious complications.¹⁰⁸ In a larger series of emergency colectomies, only 6% (10 of 170) were indicated because of bleeding. Overall mortality after a one-stage procedure was 11%.¹⁰⁹ Massive gastrointestinal bleeding as first presentation of other visceral tumors is rare, but has been reported for pancreatic cancers and others.¹¹⁰

In rare cases of bleeding arteriodigestive fistulae, usually related to previous operations and/or radiation therapy, selective angiography, if feasible, can be both diagnostic and therapeutic.¹¹¹ When bleeding is massive, immediate operation with intrathoracic aortic inflow control, temporizing suture hemostasis, and subsequent vascularized tissue flap coverage may lead to a rare treatment success.¹¹² Similarly, visceral parenchymal hemorrhage from tumor is infrequent. Perhaps the most common occurrence of this rare event is from the liver secondary to intraparenchymal or intraperitoneal rupture of a hepatocellular carcinoma. Mortality is high. Angiographic embolization seems to offer the best chance for initial control and stabilization, followed by subsequent resection.^{113,114} Rarely, emergency surgery with resection is successful, but cancer recurrence is likely.¹¹⁵

Gastrointestinal Perforation

Perforations of the gastrointestinal tract constitute the second most common indication for urgent abdominal surgical intervention in cancer patients. In a series of 47 patients, the sites of perforation were located in the colon ($n = 20$),

small intestine ($n = 11$), duodenum ($n = 9$), and stomach ($n = 7$) patients.^{7,8} Primary small bowel tumors often present with an emergent problem. In a series of 32 patients with emergent presentations, 8 were perforated, 7 were bleeding, and 17 were obstructed.¹⁰⁷ Gastrointestinal perforation in cancer patients occurs by various mechanisms. Tumor may erode through the wall of the GI tract. Treatment-related perforations may occur after endoscopic or operative procedures. They may also result from rapid tumor regression following administration of chemotherapy or radiation therapy; these types of perforations, although rare, are seen most often during treatment of bulky, chemotherapy-sensitive tumors (i.e., lymphoma, testicular cancer, germ cell tumors) involving the gastrointestinal tract. Perforations may also occur secondary to treatment-related toxicity, such as nonsteroidal antiinflammatory drug (NSAID)- or corticosteroid-induced ulcer diatheses, immunosuppression-induced cytomegalovirus or other infections, inadvertent embolization of arteries that supply the bowel during chemoembolization angiographic procedures, and inadvertent perfusion of gastrointestinal mucosa with cytotoxic drugs during hepatic artery infusion therapy. Finally, other causes altogether unrelated to the underlying malignancy, such as peptic ulcer disease or diverticular perforation, can occur as well. Iatrogenic perforations relating to endoscopic procedures are probably underreported; they may occur during colonic or duodenal stent placement (1%–4%) and esophageal photodynamic therapy procedures (2%).^{27,50,70}

Clinical Presentation, Evaluation, and Stabilization

Cancer patients with gastrointestinal perforation may present with as little sign as subtle abdominal discomfort or with overwhelming signs of peritonitis, including sepsis and shock. Acute pain from a perforation may be masked by medications.¹¹⁶ Findings on physical examination may include abdominal wall crepitus, distension, firmness, and rebound tenderness. Clinical findings and laboratory studies reflect the severity of infection, systemic inflammatory response, and compromise of organ function only in patients who are not immunocompromised. Chest and abdominal X-rays can detect free air, the most accurate sign of visceral perforation (Figure 73.2). CT is a more sensitive test to detect extraluminal air; it can define the extent of the underlying cancer and assess local resectability of the diseased bowel at the same time. Tissue pneumatosis or intravenous air can be the result of an intestinal perforation due to cancer.¹¹⁷ As noted for obstruction and hemorrhage, initial therapy should include establishment of adequate venous access and hemodynamic monitoring, vigorous hydration, initiation of antibiotics, and assessment of the patient's overall physiologic and oncologic status.

Treatment

Intestinal perforation almost always requires operative therapy to remediate, in contradistinction to obstruction or bleeding. Whether a patient is a candidate for an operation is determined by the presence of comorbidities, the overall cancer burden, and the patient's values and goals (cure, palliation, comfort). These issues must be addressed early in the presentation. The prognosis for a meaningful postoperative recovery is influenced by the patient's underlying immune

function, nutrition status, and performance status, as well as his/her physiologic and oncologic status. Even in patients without cancer, operations for "benign" ulcer perforations are attended by significant morbidity and mortality.⁷⁸ In a report of 170 urgent surgical procedures for colorectal conditions, not specifically limited to cancer patients, 71% were performed for obstruction, 23% for perforation, and 6% for massive bleeding, with an overall mortality rate of 18%.¹⁰⁹ In cancer patients, the choice of surgical procedure to treat a perforation largely depends on the patient's acute physiologic status, the technical resectability of the diseased bowel, and the extent of the cancer. In general, resection of the site of perforation is preferable to suture repair or simple drainage. Intestinal resection may be followed by anastomotic reconstruction, if the severity of the associated peritonitis and physiologic and nutrition status permit.²⁸ Otherwise, intestinal diversion with a stoma or enterostomy is necessary.

The mortality of spontaneous gastrointestinal perforation in cancer patients is high. In one series of 36 patients, 84% died. Factors responsible for this high mortality include delayed diagnosis, perforation through tumor, advanced stage of disease, and multiple organ failure. Even in patients able to undergo surgery, only 32% survived.¹¹⁸ In a subsequent review of 30 cancer patients with gastrointestinal perforation treated operatively, steroid therapy was implicated in 77% and chemotherapy in 23%. Sites of perforation were almost evenly divided between the small and large bowel. In half the patients, cancer was identified at the perforation site. Operative mortality was 53%.¹¹⁹ Tumor involvement at the perforation site appears to be especially ominous.

Spontaneous gastroduodenal perforations in patients with various cancers, but mostly without tumor at the perforation site, are amenable to nonresectional surgical treatment, such as simple closure, omental patch, vagotomy, and pyloroplasty. In this setting, mortality may be as low as 10% to 20%.¹²⁰ Surgical treatment of gynecologic cancers presenting with intestinal pneumatosis or perforation has been reported to be associated with 67% mortality. Again, tumor involvement appears crucial. In this series, cancer was not present in any of the survivors.¹²¹ Not surprisingly, patients with spontaneous perforations of gastric cancer are likely to present with advanced disease. Good outcomes can be achieved if the perforation and associated cancer are amenable to complete resection.^{23,101} Tumors metastatic to the intestines rarely cause perforation. One of 32 patients with melanoma metastases to the small bowel presented with a perforation.¹⁰⁶ Among 24 patients with melanoma metastatic to the large intestine, perforation and obstruction predicted poor median survival (less than 10 months).¹²² Gastrointestinal lymphomas have been linked to perforation as a result of treatment-induced tumor necrosis. However, the perception that this is a common problem is probably not true. Upon initial presentation of gastrointestinal lymphomas, perforation is seen in 2% (gastric non-Hodgkin's lymphoma, NHL) to 9% of cases (intestinal NHL), compared to bleeding rates of 19% and 6%, respectively.¹²³ Among intestinal NHLs, T-cell lymphomas appear to present more frequently with perforation (37% versus 5%) or bleeding (17% versus 10%) than B-cell lymphomas.¹²⁴ In the same series, the rate of emergency operations upon presentation of the intestinal NHL was 46% for T-cell lymphomas, compared to 14% for B-cell lymphomas. However, actual treatment-induced perforation is seen in only 4% of patients (Table 73.6).

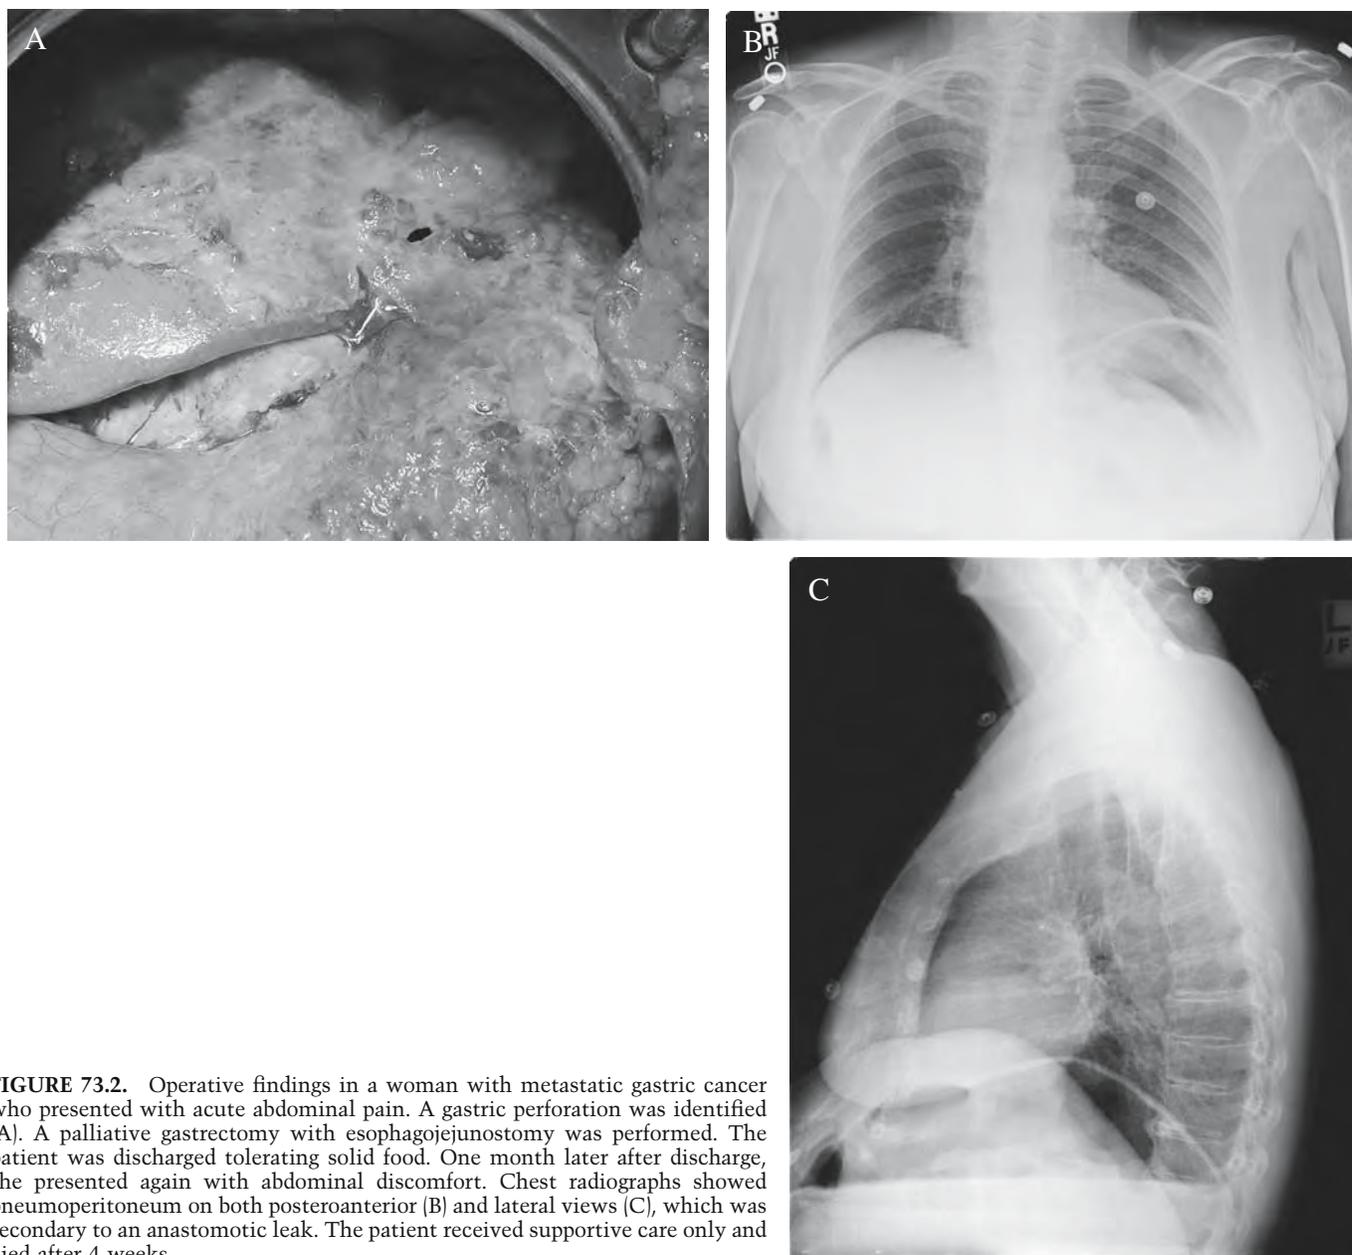

FIGURE 73.2. Operative findings in a woman with metastatic gastric cancer who presented with acute abdominal pain. A gastric perforation was identified (A). A palliative gastrectomy with esophagojejunostomy was performed. The patient was discharged tolerating solid food. One month later after discharge, she presented again with abdominal discomfort. Chest radiographs showed pneumoperitoneum on both posteroanterior (B) and lateral views (C), which was secondary to an anastomotic leak. The patient received supportive care only and died after 4 weeks.

TABLE 73.6. Complications of gastrointestinal lymphomas: frequency of perforation and hemorrhage when surgical resection is not performed before initiation of cytotoxic therapy.

Neutropenic Patients

Abdominal Pain

In the oncology setting, surgeons are frequently asked to evaluate patients with abdominal pain who are neutropenic. The neutropenia is often a side effect of the patient's therapy. Most commonly, this occurs in patients with leukemia or other hematologic malignancies, although it also may be seen in patients with solid tumors.¹²⁵ The neutropenia in patients with hematologic malignancies can be quite profound and prolonged, especially following autologous or allogeneic stem cell or bone marrow transplant (BMT).¹²⁶ The potential for graft-versus-host disease (GVHD) in patients undergoing allogeneic transplant may make evaluation and management of abdominal pain particularly difficult. It must be remembered that common problems occur commonly and the neutropenic patient may be suffering from a common problem, such as cholecystitis or appendicitis.

After a detailed history is obtained and the patient is examined, imaging studies are useful. Because patients with neutropenia often fail to exhibit the classic signs and symptoms of an acute abdomen, CT is almost always indicated. Plain abdominal films may also be helpful.

The abdominal pain may be caused by obstruction or ileus; vascular problems, such as infarct or ischemia; infectious or inflammatory conditions; or other miscellaneous causes. Ileus is occasionally seen secondary to chemotherapeutic agents. Vincristine is classically linked with ileus; more than 40% of patients receiving the drug describe abdominal pain and constipation. Fortunately, this complication is almost always self-limited. Hydration, bowel rest, and decompression usually suffice. Arterial insufficiency causing bowel ischemia or infarct can occur in neutropenic patients but is not common. Venous thrombosis is associated with cancer as a result of the hypercoagulable state that is present, often coupled with dehydration. Infectious or inflammatory problems causing abdominal pain in neutropenic patients are the major focus of the rest of this section. These conditions can be divided into problems unique to the neutropenic cancer patient, those that affect the general population, and posttransplant complications.

Causes of Abdominal Pain Unique to Neutropenic Cancer Patients

Neutropenic enterocolitis (NE) is the most common cause of abdominal pain in neutropenic cancer patients.^{127,128} This syndrome has many synonyms, including typhlitis, necrotizing or neutropenic enteropathy, and ileocecal syndrome. The syndrome was initially described in 1970 as a complication of leukemia treatment in children.¹²⁹ NE is characterized by fever, abdominal pain (usually right-sided), nausea, and vomiting, occurring in the setting of a low or falling neutrophil count. Adult patients are usually neutropenic secondary to myeloablative chemotherapy for leukemia or other hematologic malignancy.^{130,131} Occasionally, NE can be seen in adult patients being treated for solid tumors, particularly when high-dose chemotherapy is used with BMT.^{126,132} Although NE is probably the most common cause of abdominal pain requiring surgical intervention in neutropenic patients, few neutropenic patients develop NE and even fewer require operation (Table 73.7).^{128,133} In case series of several hundred adult leukemias, the incidence of NE ranged between 2% and 6%.^{127,128,134-136} In childhood leukemia, the incidence appears to be lower.¹³⁷⁻¹³⁹

The site of inflammation is usually the right colon, cecum, and terminal ileum. The cecum is usually the area most severely affected. The pathologic basis for this anatomic location is unclear. Proposed reasons include relative ischemia, greater distensibility, and stasis of GI contents. Infection with bacterial pathogens plays some role as evidenced by frequent recovery of enteric bacteria from blood cultures in NE patients. Commonly cultured organisms include *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, *Escherichia coli*, and *Candida* species as well as *Clostridia* species.^{138,140} The most likely inciting factor is mucosal injury with ulceration and subsequent invasion of the bowel wall with enteric bacteria and/or opportunistic pathogens¹²⁶; this sets the stage for breakdown of gut mucosal barrier function, further invasion, and (rarely) perforation.

The clinical picture of abdominal pain, fever, and neutropenia usually suggests NE, although other conditions can be present. The symptoms usually appear a few days to weeks after the onset of neutropenia. Laboratory evaluation reveals

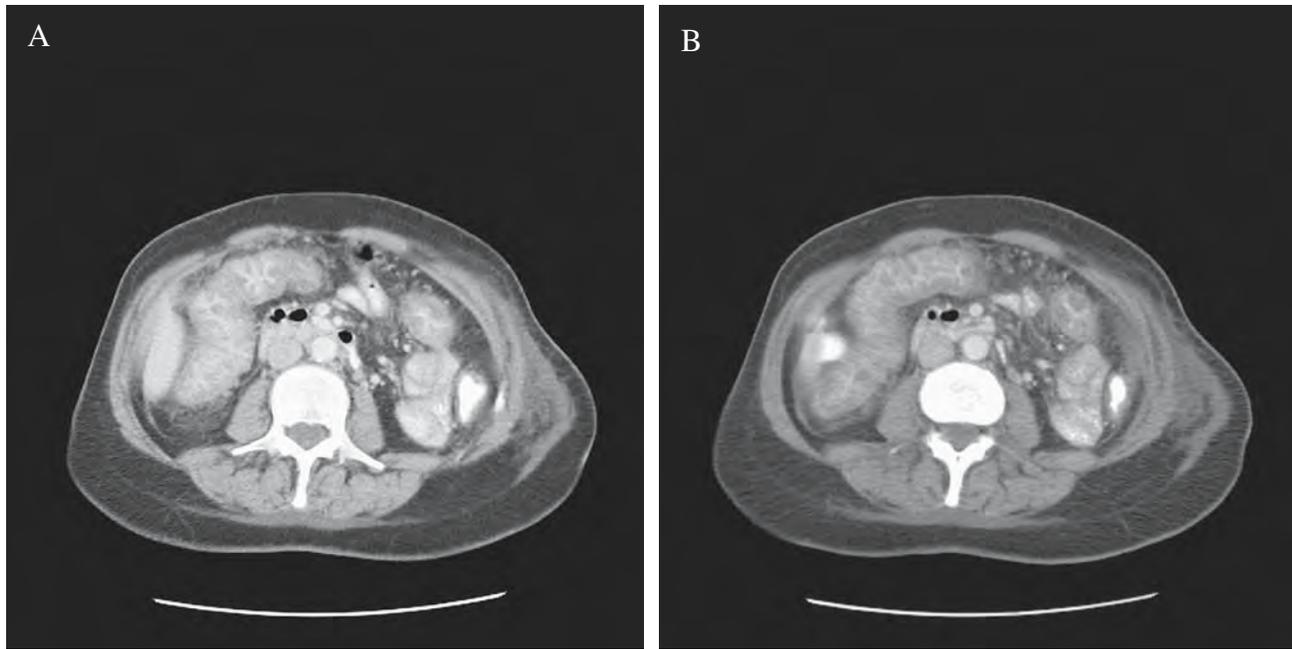

FIGURE 73.3. Computed tomography (CT) scan panels (A, B) show marked bowel wall edema in the terminal ileum in a patient with neutropenic colitis.

absolute neutropenia as well as anemia and thrombocytopenia.¹³⁸ The total bilirubin can be elevated and probably reflects ongoing sepsis and hepatic dysfunction. Positive blood cultures are associated with higher mortality.¹³⁵ Stool cultures can be positive for *Clostridium difficile*, *E. coli*, *Pseudomonas*, and adenovirus.^{125,138} In the past, plain radiographs were usually obtained and signs of bowel wall thickening, such as thumb printing, were associated with the diagnosis of NE. However, only 50% of patients have this radiologic sign.¹³⁵ Pneumatosis can be seen as well as distension and cecal fluid. Free air is a sign of perforation and an indication for surgery.¹⁴¹ CT scan with intravenous and oral contrast is the study of choice to evaluate patients with suspected NE. In a review of 289 neutropenic patients undergoing abdominal CT scan, 76 had abnormal scans. NE was present in 53 patients. *C. difficile* colitis was seen in 14 and 7 had GVHD.¹⁴² Bowel wall thickening was seen in all NE patients, and also in all *C. difficile* colitis patients and 86% of the GVHD patients (Figure 73.3). Pneumatosis intestinalis was seen only in NE and occurred in 21% of the patients. Abnormalities in the cecum alone were only seen in NE although entire right colon involvement was seen with the other conditions. *C. difficile* colitis was characterized by the most wall thickening, more pancolitis, and wall nodularity. Ultrasound has been used to evaluate NE. In a review of 88 leukemic patients with clinical signs of NE, 50% had bowel wall thickening on ultrasound; this was associated with higher mortality (29% versus 0%) and longer duration of symptoms (7.9 days versus 3.8 days).¹³⁶ In another study, ultrasonic bowel wall thickening was observed in 6 of 36 patients (16%). Three patients had acute cholecystitis diagnosed by ultrasound.¹⁴³

The treatment of NE is controversial. There are no prospective randomized trials. Varying criteria for diagnosis make comparisons between reports difficult. Some series

include both adult and pediatric patients. Some reports focus solely on NE.^{125,131,135-138,144} Other reports discuss all abdominal problems in neutropenic patients.^{127,128,142,143} These caveats notwithstanding, recommendations have changed over the past decade. Initial reports emphasized prohibitive surgical mortality and recommended medical management.^{145,146} Nonoperative therapy usually includes broad-spectrum antibiotics, hydration, bowel rest with or without nasogastric decompression, and frequent clinical reevaluation. Subsequent investigators recommended operative management.^{125,128,135} More recent reports once again emphasize nonoperative treatment. Gomez et al. reported on 29 cases from two institutions between 1992 and 1996,¹²⁵ of which 18 had definite NE while 11 had possible NE, and 28 patients received nonoperative management. One patient underwent exploratory laparotomy for suspected intussusception; NE was found, no resection was performed, and the patient was treated medically. Overall mortality was 17%. Cartoni et al. reported on 88 patients. All were managed medically except one who underwent right colectomy after neutropenia resolved. Mortality was 14%.¹³⁶

Current recommendations for patients with suspected NE include initial evaluation by physical examination, routine laboratory tests, stool cultures, and CT imaging. Patients with clearly defined surgical problems other than NE, such as cholecystitis or appendicitis, should have surgery. Patients with clearly defined medical problems other than NE, such as *C. difficile* or fungal colitis should receive specific appropriate medical management. Patients with presumed NE without clear surgical indications should be managed medically. Indications for surgery include evidence of free perforation, pneumoperitoneum, pneumatosis, associated hemorrhage, or clinical progression despite maximum medical therapy. When surgery is performed and NE is discovered, most authors recommend resection of grossly

involved colon and small bowel because of the degree of necrosis typically seen. Anastomosis is risky and should be avoided through use of a stoma.

Causes of Abdominal Pain in Bone Marrow Transplant Patients

Autologous bone marrow or stem cell transplantation (BMT) following high-dose chemotherapy is a treatment modality for many hematologic malignancies. The role of BMT in the treatment of solid tumors remains controversial. Patients undergoing autologous transplant are profoundly neutropenic at the initiation of their therapy and are subject to all the complications seen in the typical neutropenic patient. Marrow recovery secondary to reinfusion of stem cells eventually resolves the neutropenia. Allogeneic bone marrow transplant has been used to treat a variety of hematologic malignancies, aplastic anemia, immunodeficiencies, and other congenital disorders. Allogeneic transplant patients are subject to profound neutropenia but have additional problems related to the infusion of donor marrow or stem cells. Pharmacologic immunosuppression is required after transplant to control rejection. Approximately 50% of BMT patients experience abdominal pain during their treatment. It is helpful to consider three phases of BMT in relation to the etiology of abdominal pain in these patients.¹⁴⁷

The marrow ablative chemotherapy and radiation therapy that are used during the induction phase of BMT is toxic to gastrointestinal mucosa and often causes diarrhea and colicky pain. Nausea, vomiting, and dysphagia are also common. These symptoms are usually present starting 3 to 7 days following induction therapy and may last as long as 2 weeks.¹⁴⁸ Overt GI bleeding occurs in about 8% of patients, with gastritis and esophagitis being the most common endoscopic findings.¹⁴⁹ When neutropenia evolves 7 to 10 days following induction therapy, patients are subject to all the causes of abdominal pain previously discussed, including neutropenic enterocolitis, fungal or viral enteritis, and more run-of-the-mill entities, such as pancreatitis or cholecystitis; this represents the second phase of BMT-related abdominal pain. As in non-BMT patients with NE, management is usually conservative, but surgery may be required for perforation or hemorrhage.¹²⁶

After 2 to 10 weeks, bone marrow engraftment with resolution of neutropenia occurs. The patient enters the third phase of BMT-related abdominal pain. This phase is characterized by the possibility of the presence of graft-versus-host disease (GVHD) in patients undergoing allogeneic transplant (although GVHD may be seen as soon as 7 days posttransplant).^{2,148} In acute GVHD, donor T cells attack the host. The presence and course of the disease is determined by the degree of histocompatibility mismatch between the donor and the recipient and the extent of immunosuppression in the recipient. Patients with acute GVHD may experience diarrhea, abdominal pain, and GI bleeding along with skin rash and hepatopathy characterized by hyperbilirubinemia.¹⁴⁹ It is occasionally difficult to differentiate GVHD from infectious complications. Biopsy of the gastric or rectal mucosa or the skin can be helpful. GVHD is thought to occur in 30% to 80% of BMT patients.^{148,150} Despite the frequency with which GVHD appears, most patients do not require surgical intervention. Severe bleeding, obstruction, or perforation are the

most common indications for operation.¹⁴⁹⁻¹⁵¹ Pneumatosis intestinalis has been reported in up to 20% of BMT patients with acute GVHD.¹⁵² In this setting, associated pneumoperitoneum may be managed nonoperatively, as a frank bowel perforation or necrosis may not be present; persistent evidence of peritonitis, hemodynamic instability, sepsis, or acidosis necessitate surgery.^{153,154} Chronic GVHD appears several months to a year after transplant and is usually preceded by acute GVHD; it is seen in 20% to 40% of BMT patients. Most patients with chronic GVHD have liver function abnormalities, as well as chronic abdominal pain, diarrhea, and malnutrition.

Veno-occlusive disease (VOD) is another condition specific to BMT patients. It is seen in 20% to 50% of BMT patients and usually occurs several weeks posttransplant secondary to the intense chemoradiation preparative regimen.¹⁵⁵ In 15% of patients the VOD is severe, with mortality approaching 100%. The pathogenesis is thought to be secondary to hepatic endothelial damage from chemotherapy and radiation therapy with resulting postsinusoidal obstruction. Patients with preexisting liver disease have a higher incidence. Patients may experience fluid retention, weight gain, hepatomegaly, ascites, jaundice, and encephalopathy. The diagnosis can be confirmed with liver biopsy that reveals centrilobular necrosis with obliteration of the sinusoids and terminal venules. VOD resolves in most patients but can lead to multisystem organ failure. Treatment is primarily supportive with attention to maintaining fluid volume and renal function. There are case reports of successful liver transplantation to salvage patients dying of severe VOD.¹⁵⁶ Anticoagulant and thrombolytic agents have also been used to treat VOD. Tissue plasminogen activator was used to treat 42 patients with VOD and was successful in 29%. However, therapy had to be started before multiorgan failure appeared and was associated with a significant risk of hemorrhage.¹⁵⁷ In a small study with historical controls, antithrombin III concentrate was associated with clinical improvement and increased survival in patients with severe VOD.¹⁵⁸ VOD is not treated surgically but may be confused with surgical diagnoses. It can mimic myriad other entities, including cholecystitis, hepatitis, cholangitis, sepsis, and GVHD. The ultrasound findings in patients with VOD may suggest the presence of cholecystitis.¹⁵⁹ As noted previously, in cases of suspected VOD, liver biopsy is confirmatory. It is worth noting that jaundice is observed in as many as one-fourth of all patients undergoing BMT and is rarely the result of a problem requiring surgery.¹⁶⁰

Perianal Problems in Neutropenic Patients

Perianal problems occur with some frequency in neutropenic patients. The incidence of perianal problems among patients with leukemia ranges from 5% to 8%.¹⁶¹⁻¹⁶³ The diagnosis and management of these disorders in neutropenic patients must be modified because of their immunocompromised status. Patients present with perirectal pain, pain with defecation, and fever in 70% of cases.¹⁶¹ The most common physical findings are tenderness, erythema, and induration; they are present in almost all patients.¹⁶³ Most common is perirectal infection (what would otherwise be an abscess in an immunocompetent host), seen in 30% of neutropenic patients with perianal problems, followed by fissures and hemorrhoids.¹⁶¹

^aDeath from leukemia versus death from perianal sepsis may not be specified in the article.

^bIncludes noninfectious perianal problems.

Fistula in ano is much less common. In advanced cases of perianal infection, tissue necrosis and fasciitis (Fournier's gangrene) can develop. Most perianal infections are polymicrobial, based on the results of needle aspiration for culture or surgical incision and drainage. Common organisms include *Pseudomonas aeruginosa*, *Escherichia coli*, *Streptococcus*, and *Klebsiella*. Anaerobic organisms and *Candida* may also be involved.^{161,162,164}

The etiology of these perianal problems is not definitively known but probably involves the translocation of normal microbial flora through physiologically and immunologically compromised mucosal and dermal barriers on the perineum. The diarrhea often seen in neutropenic patients can lead to breakdown of perianal skin and transitional epithelium in the anal canal, forming a nidus that is particularly problematic in the setting of compromised immune function. Once established, an infection can spread through the perirectal tissue planes. Although historically observed in patients with hematologic malignancies, solid tumor patients are increasingly prone to these problems, perhaps reflecting the use of more aggressive chemotherapeutic regimens.¹⁶⁵

Upon initial evaluation, examination of the perianal area is often limited by tenderness. Historically, digital rectal examination and instrumentation with anoscopes has been avoided because of concern over traumatic microbial seeding. More recent studies suggest this may not be the case.^{163,166} There is little information concerning the use of CT scans or other imaging modalities in the evaluation of perianal infections. Radiographic as well as physical examination findings are often limited by the absence of the usual stigmata of inflammation and infection.^{163,166} The host is simply incapable of mounting an effective immune response. Aspiration of an indurated area may be performed with culture results used to guide antibiotic coverage. One report suggested this practice leads to modification of the antibiotic regimen in up to 50% of cases.¹⁶⁵ Antibiotic treatment alone is usually adequate, as return of immunocompetence with resolution of the neutropenia almost always clears the process. Specific antibiotics targeted to anaerobic infection are beneficial, increasing resolution from 55% to 88% in cases that do not require surgery.¹⁶⁴ Symptomatic treatment with sitz baths, stool softeners, and analgesia is usually also recommended.

Despite adequate antibiotic coverage, in some patients infection will progress. Surgical intervention may be required, although the need is less common in more recent series (Table 73.8). Absolute indications for surgery include fluctuance, worsening sepsis, extension of erythema, soft tissue necrosis, and crepitus. Fluctuance indicates the presence of pus in the perianal tissues. Incision and drainage is the most common

procedure performed in all studies reviewed. In severe cases, debridement of tissue and diverting colostomy may be necessary. Overall mortality appears to be lower currently in comparison to older studies,^{164,165} which may be the result of earlier recognition of perianal sepsis, improved antibiotic therapy, and more prompt surgical intervention when indicated. It is important to undertake a more thorough examination when the neutropenia resolves. At that time, patients can be evaluated for hemorrhoids or fissures that may require therapy, particularly if further chemotherapy is planned.

Oral Complications of Cancer Therapy

Mark S. Chambers and Adam S. Garden

Many patients receive cytotoxic therapies that result in complications to the oral mucosa. Other patients receive either radiation or surgery as treatment of malignancies involving the head and neck region, with resultant consequences to the normal structures of the oral cavity and pharynx.

Strategies for managing these sequelae of therapy include a combination of preventive measures, treatment directed at reversal of the insults to the oral tissues, and supportive care interventions. Few objective scales on oral morbidity have been reliably evaluated in clinical measure studies.

General Considerations

Overview

Evaluation, treatment, and prevention of any oral and dental preexisting pathology is an important aspect of the overall treatment outcome for cancer patients.^{1,2} Patients undergoing aggressive anticancer treatment encounter preventable, if not treatable, oral mucosal and dental sequelae that could produce morbid events.³ Complications vary with each patient, depending on the individual's oral and dental status, the type of malignancy, and the therapeutic approach (i.e., surgery, radiation therapy, chemotherapy, or a combination of these treatments).⁴

Oral complications associated with cancer therapy can be classified into seven general types: stomatitis, infection, bleeding, mucositis, pain, loss of function, and xerostomia.⁵ Such complications arise primarily in three anatomic sites: the mucosa, periodontium, and teeth.⁴ Management algorithms for these complications are reviewed in the following sections dedicated to the causative modalities.

Pretherapy Evaluation and Management

An oral and dental consultation before chemotherapy, radiation therapy, or head and neck surgery is extremely important in the oral management of cancer patients.^{2,6-11} Addressing the dental needs at the outset allows for more careful planning of the timing of the overall treatment; as with regard to nonsurgical therapies, timing can influence outcome. Necessary dental work can be managed at the same time as the surgery, and in the immediate postsurgical period, the oral cavity should be prepared for appropriate prosthetic rehabilitation to correct postsurgical deficits. The following

sections describe methods of integrating dental and oral treatment into specific oncologic therapies.

Radiation Therapy

Radiation-Induced Oral Complications

The complications from radiation therapy are categorized as either acute (e.g., mucositis, infectious stomatitis, alteration of taste or smell acuity, dermatitis, pain, inflammation, and difficulty swallowing) or late (e.g., xerostomia, caries, abnormal development, fibrosis, trismus, osteoradionecrosis, and pain).^{2,12,13} The term *late* refers to effects that either affect slowly responding tissues, such as muscles and bone, or effects that persist and are generally irreversible, such as xerostomia.

The severity of treatment-induced morbidity depends on multiple factors, such as the radiation dose, energy source, volume of tissue treated, pretreatment performance status, and pretreatment periodontal condition.¹⁴ In addition, treatment intensification by altered fractionation or the use of concurrent chemotherapy can increase the morbidity to the oral mucosa. The volume of tissue irradiated is susceptible to dermatitis and mucositis, which are often accompanied by salivary gland hypofunction, dysgeusia, dysphagia, odynophagia, hypovascularity of soft and hard tissues, fibrosis, or trismus.^{2,14-16} Widespread oral melanotic hyperpigmentation and hypopigmentation have been reported.¹⁷ Developmental abnormalities of the dentition and jaws may occur in children undergoing head and neck radiation therapy.¹⁷⁻²⁵ In patients of all ages, altered tissues within the volume of tissue irradiated are highly susceptible to infectious processes, especially with fungal organisms (*Candida* species)^{26,27}; bacterial infections, especially with streptococci and staphylococci; and viral infections, especially with herpes simplex virus (HSV).^{28,29}

Mucositis

Oral mucositis generally occurs 5 to 7 days after initiation of external-beam radiation therapy by accelerating the rate of destruction of the basal cell layer compared with the proliferation of new cells. Subepithelial edema can provoke an epithelial breakdown, beginning with erythema of the involved mucosa in the second week of therapy. As treatment continues, the epithelial surface cells shed, but their replace-

ment by cells from the basal level does not occur. The mucosa becomes thin and superficially ulcerated, appearing as white patches, commonly mistaken for a yeast infection. As radiation progresses, the patches coalesce, forming large fields of superficial ulceration, referred to as *confluent mucositis*. Infrequently, radiation-induced mucositis can form deep ulceration with necrosis and hemorrhage. By the end of treatment, diffuse erythema, ulceration, spontaneous bleeding, and white or yellow pseudomembrane formation may be present.³⁰⁻³² Following a course of fractionated radiation, the mucositis heals, generally in 6 weeks after therapy, but ulceration can last for 2 or 3 months and occasionally longer.^{33,34}

The definitions of the degree and intensity of mucositis are quite varied. Numerous scoring systems, none universally accepted, have been proposed and are used in clinical trials.³⁵ The most common are the World Health Organization (WHO) system that incorporates subjective symptoms (dysphagia) into the scores, and the NCI CTC system, a simple 0-4 system based on the observed degree of mucositis. This lack of uniformity, as well as the question of the validity of these systems despite their common usage, further compounds the difficulty in assessing trials exploring mucositis.

Management of mucositis is twofold. Agents are used or are being developed to either prevent or delay both the onset and severity of mucositis. The primary mode of mucositis management, however, is on symptom management. These agents are being used or tested for mucositis, but they fall into one of three categories: drugs designed to protect damage to the proliferating cells, drugs that are antiinflammatory, or drugs that are antiinfective.

MUCOSAL PROTECTORS

Amifostine (WR-2721), a radioprotector, is a phosphorylated aminothiol pro-drug.³⁶ In tissue, membrane-bound alkaline phosphatase dephosphorylates the drug to its active metabolite, the free thiol WR-1065. The postulated mechanism of action of WR-1065 is scavenging of free radicals created by the action of radiation. The drug is currently approved for the prevention of radiation-induced xerostomia, but investigators have also been interested in using the drug to prevent or reduce the severity of mucositis.

To date, the impact of amifostine on mucositis is controversial. In more than 300 patients randomized in a trial whose primary endpoint was xerostomia, amifostine did not reduce the incidence of mucositis.³⁷ Mucositis grade 3 occurred in 35% of the amifostine group and in 39% of the radiotherapy-alone patients. The median duration of mucositis was also similar in the two groups of patients (41 days versus 38 days, respectively).

Several smaller randomized trials have also investigated the role of amifostine for patients with head and neck cancer, with mucositis as a primary endpoint. Bourhis and colleagues randomized 26 patients treated with an extremely accelerated course of radiation.³⁸ Patients randomized to amifostine had a lower incidence of grade 4 mucositis and required their feeding tubes for a shorter duration. Buntzel et al. investigated the role of amifostine with concurrent chemotherapy and radiation. Randomizing 28 patients, they report a significant reduction in mucositis, as none of the patients receiving amifostine had grade 3 or 4 mucositis, compared with 86% of patients treated with radiation alone.³⁹ Despite the conflict-

ing reports, the question is likely moot; as amifostine has been demonstrated to reduce xerostomia, it will be administered to many patients undergoing radiation for head and neck cancers.

Growth factors and/or cytokines can either stimulate or suppress proliferation, including interleukin 11 and transforming growth factor-beta.⁴⁰⁻⁴³ Some, through a variety of mechanisms, may reduce mucositis either by interfering with epithelial proliferation or through other effects. Clinical use of these agents for radiation-induced mucositis remains highly investigational.

Keratinocyte growth factor (KGF) is another growth factor speculated to have a role in prevention of mucositis. KGF has stem cell stimulatory properties. Recombinant human keratinocyte growth factor (rHuKGF)⁴⁴ has been demonstrated to cause a marked increase in oral mucosal radiation tolerance in mice. However, preliminary reports of a Phase 2 testing rHuKGF in patients receiving head and neck irradiation are mixed, and Phase 3 trials still are to be conducted.⁴⁵

Preclinical data have demonstrated granulocyte macrophage colony-stimulating factor (GM-CSF) can influence the proliferation of keratinocytes.⁴⁶ Clinical observations that patients receiving GM-CSF, with myeloablative chemotherapy for hematologic malignancies, appeared to have a lower incidence of grade 3 and 4 mucositis, compared with placebo controls⁴⁷ have also garnered interest. However, small trials using this agent via a subcutaneous route that have been conducted^{48,49} have not demonstrated a benefit with regard to mucositis reduction. Topical administration of GM-CSF is also under investigation. Despite encouraging results in single-arm trials testing topical GM-CSF,⁵⁰ a trial randomizing patients receiving concurrent chemoradiation to topical administration of GM-CSF or a control solution, was discontinued when preliminary results did not demonstrate any benefit.⁵¹

Sucralfate, an agent that has little systemic absorption and adheres to ulcer bases, has been postulated to be of use in the prevention or amelioration of mucositis. It is believed that the coating action provides some protection from injury and also promotes healing. The majority of studies (Table 74.1), including double-blinded, placebo-controlled randomized trials, show little if any benefit of sucralfate in reducing radiation-induced oral side effects.⁵²⁻⁵⁹

ANTIINFLAMMATORY AGENTS

Despite the recognition that a severe inflammatory response ensues following radiation injury, few investigations and few data support the use of classic (steroids and nonsteroidal) antiinflammatory agents. Topical prostaglandins are believed to have antiinflammatory properties that may benefit patients who develop radiation-induced mucositis. However, both prostaglandin E₁ (misoprostol), and prostaglandin E₂ (prostin) have been evaluated in small trials, and neither has been demonstrated to either prevent or reduce the severity of radiation-induced mucositis.^{60,61}

Benzylamine hydrochloride (HCl) is a topical agent that has been studied for preventing or alleviating radiation-induced mucositis. The primary mode of action is believed to be antiinflammatory, and it has been demonstrated⁶² that benzylamine HCl inhibits the production and effects of inflammatory cytokines.

TABLE 74.1. Randomized trials evaluating sucralfate versus placebo for the prevention or alleviation of mucositis secondary to radiation therapy to the head and neck.

Authors	No. of patients	Endpoint(s) ^a	Results	P value

S, sucralfate; Pl, placebo; ND, not described; NS, not significant [value(s) not provided].

^aSeveral studies evaluated more than two endpoints; in those cases, only two are provided for the table.

^bIn general, scoring systems and descriptions of mucositis were study specific.

In a randomized trial of nearly 150 patients,⁶³ for conventionally fractionated radiation up to cumulative doses of 50 Gy, benzydamine significantly ($P = 0.006$) reduced erythema and ulceration by approximately 30% compared with the placebo, and more than 33% of benzydamine subjects remained ulcer free compared with 18% of placebo subjects ($P = 0.037$). However, benzydamine was not effective in subjects receiving accelerated radiation doses. Further studies are under way.

TARGETING INFECTION

It has been theorized that the formation of ulcerative mucositis, combined with changes in the pH of the oral cavity caused by effects of radiation on salivary glands, creates a favorable environment for microbials and local infections. These infections create additional stress on the tissues and thereby intensify the severity of mucositis. Based on this theory, topical antimicrobials have been studied as a strategy to minimize mucositis.

Chlorhexidine, a broad-spectrum rinse effective against both gram-positive and gram-negative bacilli and yeast, has been tested in several randomized trials for preventing or alleviating oral mucositis. No trial has demonstrated it to be efficacious,^{64,65} and it may even be detrimental for some patients undergoing radiation for head and neck cancer.⁶⁶

Several centers have studied rinses or pastilles using a combination of agents. Typically, the combinations have included an antifungal (amphotericin B or clotrimazole) and antibacterials, particularly those to combat gram-negative organisms. PTA, a combination of polymyxin B, tobramycin, and amphotericin B,⁶⁷ has been tested in several centers as an antimicrobial strategy for mucositis prevention, with both randomized placebo-controlled trials having mixed results, using either a lozenge or pastille.^{68,69} Differences in several measured secondary endpoints including a lower incidence of

worse reported grade of mucositis, dysphagia, and weight loss in patients treated with the drug have been reported. Wijers et al. also tested a PTA paste in a randomized placebo-controlled double-blind study and did not find that PTA reduced the incidence of mucositis.⁷⁰ El-Sayed et al. randomized patients to either a lozenge of bacitracin, clotrimazole, and gentamicin, or placebo, and found no differences in the severity of mucositis in patients receiving conventionally fractionated radiation between the two groups.⁷¹

A trial investigating iseganan HCl, a broad-spectrum antimicrobial rinse, randomized patients in a Phase III multi-institutional trial to active drug, placebo rinse, or best standard of care. There was no benefit to the active drug compared with placebo.⁷² A summary of randomized trials testing antibiotic therapy is shown in Table 74.2.

Mucositis Symptom Management

The management of radiation-induced mucositis primarily involves managing pain. Mucositis that is not severe can be managed with topical agents, although their efficacy has not been proven. Baking soda rinses, with or without salt, are advocated, although they too have not been proven to alleviate mucositis. However, they are important in maintaining good oral hygiene.

Lidocaine gel (2%) is occasionally useful particularly for anterior oral sores. Diluting lidocaine in *magic mouthwashes* is a common practice. These mouthwashes combine aluminum hydroxide antacid, benadryl, and lidocaine. Although prophylactic antifungal agents are not needed, some practices include nystatin in the mouthwash. Again, it should be emphasized that no significant evidence-based studies exist to support the use of these mouthwashes.⁷³

Other topical agents with soothing properties, including aloe vera and the bioadherent Gelclair, have not demon-

strated benefit in randomized trials. Neither aloe vera nor Gelclair has been shown in randomized Phase III trials to benefit patients with radiation-induced mucositis.

Ultimately, mucositis is managed with analgesics including acetaminophen or nonsteroidal antiinflammatory agents and, eventually, narcotics. Our pain regimens begin with codeine-based products, then progress to morphine-based products, primarily hydromorphone or morphine sulfate or methadone. Recently, we have found fentanyl transdermal patches are effective for many patients, as they are long-acting and avoid contact with oral mucous membranes.

Osteoradionecrosis

Radiation can permanently destroy cellular elements of bone and thus limit the potential for wound maintenance and the ability to heal after infection or trauma (e.g., dental extraction, alveoloplasty).^{74,75} Further, the risk of complications following trauma or oral surgical procedures in an irradiated field can be highly significant, depending on a predetermined threshold of irradiation, and result in osteoradionecrosis (ORN).^{14,16,75,76} For these reasons, elective oral surgical procedures, such as extractions or soft tissue surgery, are contraindicated within an irradiated field owing to hypovascularity, hypocellularity, and hypoxia.² However, nonsurgical dental procedures that can safely be performed include routine restorative procedures, oral prophylaxis, radiography, endodontic, and prosthodontic procedures.^{2,12,13}

If oral or periodontal surgical intervention is required after radiation therapy, the clinician should discuss the volume of tissue radiated and specific treatment parameters with the treating radiation therapist and should request a copy of the simulation or port films and treatment summary. Preoperative hyperbaric oxygen (HBO) therapy may increase the potential of wound healing while minimizing the risk of ORN by promoting angiogenesis and osteogenesis.⁷⁷⁻⁷⁹ HBO therapy must be used as an adjunct to debridement (sequestrectomy),

wound care, parenteral antibiotics (as dictated by bone culture results), and composite bone and muscle grafts by free tissue transfer (subject to the availability of the requisite microvascular skills).^{78,79}

Optimal oral health must be maintained during and after radiation therapy. However, to avoid soft tissue injury during the postradiation healing period, patients must curtail all but the most basic oral hygiene procedures (i.e., brushing, flossing, and fluoride therapy). Conventional oral physiotherapy (oral opening exercises) can be performed during and after radiation treatment, especially if the pterygoid regions are involved in the radiation treatment fields, resulting in increased fibrosis of masticatory musculature and trismus.⁸⁰⁻⁸² Trismus is a challenging problem and may prove to be irreversible. Therefore, patients should be encouraged to perform mouth-stretching exercises before, during, and after radiation therapy.^{2,6,80,83,84} Sophisticated means of oral opening exercises may need to be employed with opening devices. In addition to exercising, other supportive care adjuncts should include nutritional counseling and smoking cessation therapy, as indicated.

Following initial recovery from radiation effects, nonsurgical periodontal therapy, usually with prophylactic antibiotic coverage, is appropriate for treatment of the periodontium within the radiation field. It is important to detect and treat dental caries or traumatic dental injury that could lead to pathosis. However, ORN can occur spontaneously if wound healing is compromised.⁸⁵⁻⁸⁹ If postradiation extractions are necessary, HBO therapy, along with a specific oral care regimen, is indicated to augment wound healing. In such cases, tissues should be managed gently, and antibiotic coverage is required. Local anesthetics containing epinephrine should be avoided, when possible, to prevent further vascular constriction.¹¹ Workers have reported successful placement of endosseous implants in irradiated fields, with a pretreatment regimen of hyperbaric oxygen.^{90,91} In contrast, ORN has been initiated by such elective surgical intervention.^{86,88,91}

Xerostomia

When the major salivary glands are involved in the volume of tissue irradiated, the quality and quantity of salivary secretions decrease.^{2,92,93} Serous cells, found predominantly in the parotid glands, are extremely radiosensitive, and undergo apoptosis when exposed to low doses of radiation.⁹⁴ Salivary gland dysfunction to the direct effects of radiation on the vascular and connective tissues of the glands^{92,93} may account for the effects on the submandibular glands, which have a high proportion of mucinous cells and are essential for resting saliva.

Radiation damage to the major glands results in either a transient or permanent decreased salivary flow.⁹² Saliva is a complex bodily fluid that consists of multiple small organic molecules, electrolytes, and immunoglobulins that defend the oral cavity from contamination and promote healing. Salivary hypofunction can increase the risk for dental caries and compromise mucosal integrity.² Dryness of the mucosal tissues may increase the susceptibility to oral infections and lead to difficulty in chewing, swallowing, and speech.^{76,93} Therefore, when the salivary glands are within the radiation field, irreversible damage due to the cytotoxic effects of the radiation is imminent, as are the clinical manifestations of xerostomia.

Dental caries is a common postradiation morbid sequela that is often exacerbated by xerostomia.⁹⁵ Irradiation of major salivary glands leads to qualitative and quantitative changes in salivary secretions, thus increasing plaque and mucoid debris accumulation, reducing the salivary pH, and reducing the buffering capacity of saliva.⁹⁶ This sequence creates a cariogenic oral environment, particularly in patients ingesting a diet high in carbohydrates or sucrose. Susceptibility to caries is not limited to the dentition within the volume of tissue irradiated. Because of the harmful effect of postradiation caries, patients who have undergone radiation should be treated with a specific prophylactic regimen consisting of flossing, brushing, and fluoride therapy. An effective combination of oral hygiene, frequent dental follow-up examinations, and appropriate prophylactic treatment procedures are essential to caries prevention, as is fluoride treatment consisting of a daily application of 0.4% stannous fluoride or 1.1% sodium fluoride to the dentition using a brush-on technique or gel-filled trays (i.e., fluoride carriers).^{2,14,96,97} In adults with xerostomia, fluoride leaches out of the enamel within 24 hours; thus, the fluoride regimen must be performed daily for optimal protection. The most efficient method of fluoride application is to use a custom-made polypropylene fluoride carrier that completely covers, and extends slightly beyond, the tooth surface.¹⁴ Patients who receive low doses of radiation and are expected to have a slight degree of xerostomia can use a toothbrush to apply the fluoride gel.⁹⁸ Sensitivity and pain are common side effects of fluoride and may necessitate a change in the fluoride concentration or the method of application. A daily fluoride program can decrease postradiation dentinal hypersensitivity, remineralize cavitated enamel matrices, and, more importantly, inhibit caries-forming organisms.^{2,14}

MANAGING XEROSTOMIA

Radiation-induced reductions in salivary flow are worrisome because saliva protects the oral mucosa from dehydration and

assists in the mechanical lavage of food and microbial debris from the oral cavity.⁹³ To avoid oral infections and to reduce the mucositis that may arise during radiation therapy, patients must frequently rinse the oral cavity to reduce oral microorganisms and to maintain mucosal hydration. Such oral lavage can be performed by rinsing with a solution of 1 tsp sodium bicarbonate dissolved in 1 quart water several times each day to alkalinize the oral cavity and keep the oral and oropharyngeal tissues moist.^{2,12}

The traditional treatment for radiation-induced xerostomia and mucositis is inadequate, as no effective salivary substitute for patients with these conditions can replicate natural salivary mucin and protective salivary components.^{14,99} Mouth rinses, saliva substitutes, and gustatory stimulants have not been tested in Phase III trials to clearly demonstrate their efficacy. Oral Balance or Biotene were found to have palliative effects superior to the effects of a placebo.¹⁰⁰

Sialogogue therapy, such as with cholinergic agonists (e.g., pilocarpine hydrochloride and cevimeline), has been shown to provide clinically significant relief of symptoms of postradiation xerostomia in randomized trials.¹⁰¹⁻¹⁰³

PREVENTING XEROSTOMIA

Cholinergic agonists, primarily pilocarpine, have been tested in the postradiation setting, and the evidence is fairly convincing that they have a palliative benefit in a subset of patients who experience radiation-induced xerostomia. Pilocarpine has also been tested during radiation to determine if stimulation of salivary glands can result in either improvement in quality of life during radiation or long-term benefits.

Two randomized trials conducted in North America tested pilocarpine compared with placebo administered during radiotherapy. Warde et al. found no improvement in quality of life measures or differences in subjective measures of xerostomia or mucositis.¹⁰⁴ The Radiation Therapy Oncology Group (RTOG) did find objective measures of increased salivary flow when pilocarpine was administered during radiation, but this finding did not translate into improved subjective scores.¹⁰⁵ The authors concluded that during and immediately following radiation, mucositis plays such a dominant role in patient quality of life that xerostomia was not a critical issue. Rode et al. not only studied the effects of salivary stimulation during radiation but also salivary inhibition with biperiden.¹⁰⁶ In a small randomized trial, the authors concluded that patients benefited the most from salivary inhibition with biperiden during radiation followed by stimulation with pilocarpine following radiation treatment. In conclusion, the evidence for prevention of xerostomia by salivary stimulation is weak. Table 74.3 summarizes randomized trials evaluating agents tested for prevention or alleviation of xerostomia.

The main efforts for prevention of xerostomia are either with drugs that are true radioprotectors or by using methods to limit the dose to some of the major glands. When administered intravenously, during radiation therapy, amifostine, a free radical scavenger, has been shown to diminish toxic effects of irradiation on salivary glands.³⁷ Amifostine, described in the mucositis section, has been tested in several randomized trials. Brizel et al. demonstrated an absolute reduction of grade 2 xerostomia in approximately 20% of patients treated with amifostine daily before delivery of fractionated radiation. Quality of life measures were also

TABLE 74.3. Randomized trials evaluating agents for prevention or alleviation of xerostomia.

Authors	No. of patients	Drug and timing	Endpoint(s)	Differences detected between regimen and placebo ^a	P value

^aAmifostine trials with no treatment rather than placebo arm.

improved in the amifostine-treated patients.¹⁰⁷ The study, however, was neither blinded nor placebo controlled.

When administered intravenously, amifostine has a modest toxicity profile, with a small incidence of hypotension that can potentially be severe and a high incidence of drug-induced nausea. To decrease the toxicity, the drug can be administered subcutaneously,¹⁰⁸ and smaller trials have suggested it is efficacious when delivered via this route with a lower incidence of both nausea and severe hypotension.^{109,110} Preliminary results of a randomized trial comparing the two routes of administration suggest that the subcutaneous route is safer with a lower incidence of hypotension, and to date, it is as efficacious with respect to xerostomia.¹¹¹

An intriguing method to prevent xerostomia is to transfer surgically one gland away from the proposed radiation field. Jha et al. have conducted a Phase II trial.¹¹² During patients' oncologic surgery, one submandibular gland was transferred into the submental space, an area that routinely is not irradiated. The gland was not transferred in 20% of patients and was not shielded in an additional 16% of patients. In those patients in whom the gland was transferred and shielded from radiation, only 20% experienced severe late xerostomia. Further evaluation of this technique is planned in a multiinstitutional setting.

Conformal radiation, and, in particular, intensity-modulated radiation, are radiation techniques that potentially can minimize the dose to salivary glands and thereby decrease the incidence of xerostomia. Unfortunately, the threshold dose for salivary gland sparing is unclear. It is recognized that high doses (50 Gy and above) result in a high incidence of xerostomia, but the effects of intermediate doses (between 15 and 35 Gy) are less clear. Eisbruch et al., using conformal techniques, stated that keeping the mean parotid dose below 26 Gy minimized the incidence of xerostomia,¹¹³ whereas Chao and colleagues, using complex mathematical modeling, have stated the threshold dose is 32 Gy, and each gray results in a 4% reduction in salivary flow.¹¹⁴

Eisbruch et al. have used conformal techniques with parotid gland sparing in their treatment of patients with head and neck cancer and report a reduction in the incidence of xerostomia.¹¹⁵ Similarly, Chao et al. have reported similar results with the use of intensity-modulated radiation.¹¹⁶ Lee et al. analyzed the results of intensity-modulated radiation in the treatment of patients with nasopharynx cancer.¹¹⁷

Although the goal of the technique was improved tumor coverage, a by-product has been lower doses to the parotid glands, and the group described a low incidence of grade 2 or greater xerostomia. The RTOG is now testing intensity-modulated radiation in the multiinstitutional setting.

Chemotherapy and Bone Marrow Transplantation

Most cytotoxic drugs are effective in destroying cancer cells because they interfere, through various mechanisms, with the synthesis or function of DNA.¹¹⁸ Thus, it is not surprising that these drugs are in general more toxic to proliferating cells than to those incapable of replication and are most effective against tumors with high growth fractions.¹² Chemotherapeutic agents have gained a certain notoriety for damaging normal tissue, resulting in such effects as hematologic suppression, mucositis, and hair loss. In many patients, these drugs also cause nausea and vomiting with marked oral effects.

Malignancy coupled with aggressive chemotherapeutic regimens profoundly compromises the immune system, leading to multiple serious infections with varying potential to involve the oral cavity. Empirical use of prophylactic antimicrobial agents may substantially alter the risk of infection of the oral cavity and the presenting signs and symptoms of infection during chemotherapy.^{12,119,120} Oncologic physicians and treatment centers vary in their treatment philosophies on the use of such antiinfectious agents.

The dentoalveolar complex should be thoroughly evaluated for microbial reservoirs or sanctuaries (e.g., plaque, calculus, or periodontal pockets), and these infectious foci should be eliminated before the start of chemotherapy.^{12,119-121} A compromised periodontal status presents a risk of infection.^{122,123} Clinically, however, the risk of infection depends on multiple interacting factors, such as oral hygiene, immunosuppressive status, chemotherapeutic agents used, prophylactic or therapeutic antimicrobial agents used, and the degree of periodontal pathology.

To minimize the risks of periodontal infection, it is important to develop simple and practical guidelines for maintaining periodontal health and for diagnosing, prevent-

ing, and treating periodontal infections during therapy.^{2,12} Cancer patients should make regular dental visits for overall dental and periodontal assessment. Patients receiving chemotherapy can undergo a dental cleaning, provided that they meet the following hematologic conditions: first, an absolute neutrophil count of approximately $1,000/\text{mm}^3$ (white blood cell count times % neutrophils equals the absolute neutrophil count), a level at which the risk of developing an infection is minimal, and second, a platelet count greater than $50,000/\text{mm}^3$ with a normal coagulation profile.¹²⁴ The administration of prophylactic antibiotics is essential, owing to the induced bacteremia, immunocompromised status, and potential for hypofunctioning white blood cells introduced by chemotherapy.

Patients with an uninfected dentition and good periodontal health do not pose a diagnostic treatment challenge, nor do patients with advanced periodontal disease that mandates immediate surgical intervention. However, patients with increased loss of attachment, with bone loss at the junction of the roots of molar dentition and frank bone exposure without gingival coverage (furcation) or periodontal pocket formation with furcation involvement, pose a treatment dilemma.¹² Patients in whom the soft tissue parallels the bone loss and in whom pocket depth is normal can be treated with regular periodontal care and maintenance. Extraction should be considered only for patients with pathologic mobility of dentition or with a fulminant periapical abscess.^{2,12} Patients with moderate to advanced periodontal disease, present a greater challenge and would, under usual circumstances, receive instructions for infection prophylaxis and dental hygiene, as well as surgical correction. However, the feasibility of such comprehensive therapy during chemotherapy can be limited by several factors, including performance status, type of malignant disease, cycling of chemotherapy, and hematologic competence. The clinician should strive to provide a thorough scaling and to encourage maintenance through exceptional plaque control (i.e., brushing, flossing, and use of chlorhexidine gluconate).^{12,125-130} To reduce the risk of a septic foci, extractions should be considered for patients with any exacerbated acute periodontal infection. This oral surgical correction should be performed at the appropriate time in the treatment cycle (beginning of cycle or during recovery phase with hematological/chemistry stability) or when the patient's cancer is in complete remission. If chemotherapy is on hold, oral surgical intervention could be considered provided that the hematologic status is appropriate. The oral surgeon must discuss with the treating medical oncologist the patient's oral status, treatment plan, and contraindications to surgical intervention, as well as the appropriate timing of oral treatment intervention.^{12,118,131}

Toothbrushing and flossing should be the standard of dental care for patients who routinely brush and floss. However, as in the general population, many patients with cancer either do not floss or floss only infrequently. Thus, clinicians either may instruct patients to floss or may stress brushing techniques only. In most cases, patient factors and limited time parameters do not permit the patient to become proficient in flossing techniques. However, if the clinician identifies an area where food continually lodges, the patient should be encouraged to floss the area to reduce the risk of gingival inflammation.^{13,132-136} Patients who floss on a regular

basis are instructed to modify the flossing technique in certain clinical situations. First, patients are instructed to floss gently when the lining of the oral cavity starts to become sensitive to thermal changes or food substances, indicating mucosal thinning caused by suppressive effects of chemotherapy on the normally proliferative epithelium.^{134,136} Second, patients are instructed to floss only to the gingiva when the platelet count falls below $50,000/\text{mm}^3$. This technique removes most of the debris from this area.¹²

Toothbrushing is imperative for plaque control. The patient should be instructed to always brush after each meal. In certain clinical situations, such as increased mucosal sensitivity to food or thermal changes, increased sensitivity to toothbrush bristles, irritation of the gingival tissues by the toothbrush, or profound thrombocytopenia (less than $20,000/\text{mm}^3$), patients should change from a soft to an ultra-soft-bristled or sensitive-bristled toothbrush.^{2,12,13,29} In controlling plaque accumulation, it is important to minimize the risk of gingival inflammation, the oral bacterial load, and the potential for infection.¹³⁷ Along with routine brushing and flossing, rinsing with chlorhexidine gluconate should be initiated when patients begin chemotherapy. Such rinsing is an adjunct to ideal oral periodontal care and can also be used when indications arise, such as oral mucosal changes secondary to chemotherapy and subsequent increased soft tissue sensitivity.^{12,125-130,138} Patients undergoing chemotherapy should be encouraged to rinse with a dilute saline and sodium bicarbonate solution (5%) to reduce adherent mucoid debris on oral soft tissues, lubricate oral mucosal and oropharyngeal tissues, and elevate the pH of oral fluids.^{13,139} Patients encountering nausea and anorexia should be encouraged to rinse with the sodium bicarbonate and salt water solution several times throughout the day to reduce oral acidity and minimize the mucosal insult.^{140,141}

Another challenge cancer patients face is the risk of local infection or septicemia associated with dental implants. If an implant with its restorative component poses a risk of infection for patients under normal circumstances, this risk will be intensified during chemotherapy. Interventional antibiotics and aggressive hygiene have limited ability to control infection caused by a poorly integrated endosseous implant, whereas a well-integrated implant should not pose problems if its integrity is maintained with effective dental hygiene practices.¹⁴²⁻¹⁴⁴

Aggressive anticancer therapy severely undermines the integrity of the mucosal epithelium of the oral cavity. In addition, the oral cavity is a focused area for trauma from teeth, denture prostheses, and hot or cold dietary substances.⁴ Many patients are at risk for infection from resident microflora or opportunistic pathogens sequestered in sanctuary areas. Furthermore, cancer patients share with the general population common problems of the oral cavity, such as poor hygiene, poorly maintained dentition, periodontal disease, and prostheses in poor repair, with the associated mucosal pathology.¹² With all these interactive injurious influences in such close proximity, even small alterations in the area could cause a problem. Each course of chemotherapy introduces this threat of oral complication, and the risk of developing complications with subsequent courses increases as local or systematic resistance is challenged. Appropriate evaluation of the oral cavity and correction of existing oral and dental pathology can minimize, and in some cases eliminate, treat-

ment-limiting toxicities, such as mucositis, oral infections, and bleeding, that necessitate chemotherapy dose reduction or termination.^{12,118,145}

Mucositis

The oral mucosal response to cancer therapy is varied and unpredictable. Mucositis, the most common acute complication of chemotherapy, has a specific, defined mechanism of progression: mucosal erythema progresses to oral sensitivity and then to mucosal denudation.^{3,136,146} Several grading scales for oral mucositis have been developed to assess the severity of the mucosal reaction during each course of chemotherapy. These grading scales allow the clinicians to prescribe appropriate preventive or therapeutic measures to treat mucosal situations after chemotherapy or during subsequent treatment courses. Grading scales range from the simple to the complex.^{35,147,148}

Mucosal HSV infections occurring early in the chemotherapy cycle can mimic mucositis. Failure to collect diagnostic cultures with each mucosal reaction can lead to a misdiagnosis of mucositis, in which case the infection goes untreated.¹⁴⁹⁻¹⁵³ Culturing at this early stage of therapy is essential for differentiating mucositis from infectious stomatitis that can be caused by a bacterial, fungal, or viral agent and that is usually associated with low hematologic values (i.e., the nadir).^{2,12} Oral mucosal infectious agents must be correctly identified and treated, because the loss of mucosal integrity creates a portal of entry for systemic infection in immunocompromised patients.¹⁵⁴⁻¹⁵⁶

Unlike the approach to oral stomatitis, effective therapy for oral mucositis has not been standardized. All the interventional agents are aimed at either the prevention and reduction or the palliation of chemotherapy toxicity. The many agents used vary widely in their mechanisms of action.^{146,157} When mucositis can be controlled as a dose-limiting toxicity, chemotherapy agents, alone or in combination regimens, are escalated to higher doses to achieve the ultimate goal of cure. Chemotherapy-induced pancytopenia, combined with mucositis, can develop oral infection and bleeding events. Severe thrombocytopenia (less than 20,000/mm³) and neutropenia (less than 500/mm³) may exist with normal-appearing oral mucosa. Serious complications, such as hemorrhagic diathesis or sepsis, can occur if hematologic parameters are not considered in the treatment of the oral cavity. Thus, clinicians should conduct a benefit-versus-risk analysis of the intended therapy and should thoroughly assess the hematologic values before each treatment intervention. Treatment guidelines based on such assessments have been established.^{2,3,12,121,145}

Drug-related mucositis can be severe, with onset occurring within 7 days after initiation of chemotherapy and with duration varying from several days to weeks. Compared with single-agent therapy, combination drug therapy or chemoradiation therapy is more likely to induce intensified mucosal morbidity. Maximal myelosuppression can induce thrombocytopenia, thereby causing gingivitis and gingival bleeding. Drugs most frequently associated with mucositis and myelosuppression include cytoxan, etoposide, cyclophosphamide, doxorubicin, dactinomycin, daunorubicin, 5-fluorouracil, bleomycin, melphalan, and methotrexate.^{3,6,19,118,131,158-163}

Gingival hemorrhage can usually be controlled by such local measures as the application of pressure, cool water, periodontal dressings, topical thrombin, gelatin sponges, oxidized cellulose, prefabricated stents lined with a hemostatic agent, or tranexamic acid.² Persistent hemorrhage may require platelet support.^{6,11,12,139}

As previously mentioned, any emergent oral treatment given while patients undergo myelosuppressive chemotherapy requires prophylactic antibiotic coverage, and all patients with in-dwelling central venous catheters require prophylactic antibiotic coverage for procedures likely to induce bacteremia.^{13,164} The dental specialist should consult with the patient's treating oncologist to select the most appropriate antibiotic.

Although grossly overlooked, diet profoundly influences the stability of the oral tissues and can cause mucosal problems when a patient is undergoing cancer therapy.^{2,131} During the myelosuppressive phase of therapy or when the mucosa is thinned owing to chemotherapy, the diet should consist of nontraumatizing, soft foods that cannot puncture, abrade, or otherwise damage the compromised mucosal epithelium. Hard or abrasive food items can lead to increased pain, infection, or bleeding episodes as they interact with the oral mucosa.

Although all patients with cancer and on chemotherapy are at risk for oral complications, some patients are at a greater risk than others, depending primarily on the type of malignancy and the aggressiveness of the cancer treatment. Patients with hematologic malignancies (e.g., leukemia and lymphoma) have a greater risk than do patients with solid tumors (e.g., breast cancer, lung cancer, and sarcomas), because the protective elements that maintain bodily homeostasis are part of the malignant process of hematologic malignancies.^{14,131}

Viral reactivity may lead to severe oral or disseminated infections during periods of myeloimmunosuppression. In particular, HSV infections are often associated with severe, painful, and prolonged ulcerations atypical of those found in immunocompetent hosts.^{149-151,153,165,166} Suspected HSV lesions should be treated with antiviral agents, such as acyclovir administered orally or intravenously and managed as described previously for irradiated patients. The diagnosis should be established using viral cultures, direct immunofluorescence, or other rapid diagnostic tests, and the lesions.^{149-153,163,165}

Bacterial infections following chemotherapy can cause localized mucosal lesions, sialoadenitis, periodontal abscesses, pericoronitis, or acute necrotizing ulcerative gingivitis.^{12,158} Because systemic infection is a serious complication in neutropenic patients, constant vigilance must be maintained to prevent or manage oral infections of any type.^{2,12,13,163,167} Because antileukemic therapy is designed to achieve myelosuppression, this risk may be higher among patients with leukemia than among those with solid tumors.^{163,168} Oral infections should be treated with selected antibiotic combinations (broad-spectrum antibiotics), including an agent effective against anaerobic gram-negative bacilli such as *Pseudomonas*, *Klebsiella*, or enterobacteria, which are often found in the oral cavity of immunocompromised individuals.^{12,13,132,135,158,161} Oral microbial culture testing should be used to ensure antibiotic sensitivity and resistance selection and to assist in identification of the causative organisms.^{139,169}

Bone Marrow Transplant

The risk of oral complications from an autologous transplant is similar, possibly slightly higher, to that of conventional chemotherapy because patients receive their own cells after undergoing an intensified chemotherapy regimen. Thus, the risk is highest during immunosuppression and engraftment of the stem cells.¹⁷⁰⁻¹⁷³ In contrast, patients who undergo an allogeneic transplant face ponderous complications during the conditioning chemotherapy, infusion of the donor's stem cells, and engraftment. Allogeneic transplant patients, with all the interactive dynamic clinical signs and symptoms, patient factors, and topical and systemic medicines used to treat their conditions, challenge the diagnostic acumen of oral healthcare practitioners.

Patients with bone marrow transplantation (BMT) are at high risk for the development of candidiasis, viral infections (most commonly HSV, varicella zoster, and cytomegalovirus),^{29,138,174-179} and bacterial infections, including those associated with microorganisms of periodontal origin.^{123,180,181} Workers have reported hairy leukoplakia caused by Epstein-Barr viral infection in human immunodeficiency virus-negative BMT patients.¹⁸² Atypical, potentially life-threatening pathogenic organisms have been isolated in cultures from sites of preexisting periodontitis in patients with myelosuppression, a finding that emphasizes the importance of establishing periodontal health status before cancer therapy.^{12,13,183}

Graft-versus-host disease (GVHD)¹⁸⁴⁻¹⁸⁸ is associated with a spectrum of intraoral presentations, ranging from atrophy/erythema to lichenoid hyperkeratosis resembling lichen planus to ulceration-pseudomembrane reaction.¹⁴⁷ The associated symptoms vary widely depending on the mucosal changes, thus making oral care and dietary support difficult. Additional chemotherapeutic agents, such as methotrexate and cyclosporin, may be required to prevent severe GVHD following BMT.¹⁷⁵

For patients undergoing chemotherapy or BMT, proper oral care is imperative to preventing complications. Because of the varying clinical presentations, oral infections are exceedingly difficult to diagnose. Clinicians must constantly be vigilant and suspect any mucosal change or symptom as infection.^{176,189-191} Oral and dental care depend on the degree of mucosal sensitivity and the patient's tolerance to treatment. Exceptional plaque control with topical fluoride is imperative in the treatment of rampant caries. The use of typical steroid-containing rinses provides additional oral comfort when mucosal changes develop in BMT patients.¹²⁶⁻¹²⁸

Conclusion

The oral cavity should be thoroughly evaluated in all patients diagnosed with cancer, as well as in patients undergoing any immunosuppressive therapy. Preventing and treating the oral complications of cancer are important responsibilities of the treating physicians, and anticipating primary and secondary mucosal insults and recognizing oral complications promptly in this setting, can decrease the incidence of such complications or ameliorate their morbid side effects. By fostering communication and compliance among the mul-

tidisciplinary team, the cancer patient can receive optimal oral care while undergoing oncologic treatment.

Alopecia and Cutaneous Complications of Chemotherapy

Faith M. Durden and Paradi Mirmirani

Alopecia and Chemotherapy

The hair growth cycle is composed of three well-recognized phases: anagen (growth), catagen (deconstruction), and telogen (resting) phases. At any time, approximately 90% of the 100,000 to 150,000 scalp hairs are in the anagen phase. An in-depth discussion of hair cycling is beyond the scope of this chapter, but please refer to the referenced article for an excellent review on the current thinking on the subject.¹

Only the hair follicle has the unique ability to destruct via apoptosis, remodel, and reconstruct a hair shaft on a continuous, cyclic, and relatively rapid basis, occurring, in most cases, throughout the life of the individual. Remarkably, however, it does so with such precision that malignancies of the hair shaft are rare. This fact, coupled with the fact that the hair growth rate rivals many malignancies, makes the hair follicle an important organ to understand. In addition, despite perturbations, such as insult via chemotherapeutic agents, the hair frequently deconstructs, biding its time until the insult has ceased, before resuming its growth cycle once again.

Alopecia is the most common side effect of cancer chemotherapy. Known as anagen effluvium, or anagen arrest, this typically begins in the first 1 to 4 weeks after instituting cancer chemotherapy, becoming most noticeable 1 to 2 months after therapy begins. As the name implies, hairs in the anagen phase are predominantly affected. Long-term or repeated treatment often results in complete, but usually reversible, hair loss. It is because of the hair follicle epithelium's high replication rate that it is exquisitely susceptible to insult from chemotherapeutic agents. Although loss of scalp hair is more readily noted by the patient, loss of body hair, such as the axillae, pubic region, beard, and lashes and brows may occur as well. The hair loss occurs as a result of dystrophic hair shaft development, resulting in hair fragility and easy breakage proximal to the scalp.²

Transduction signals results in accelerated apoptotic activity in chemotherapy patients. This induced programmed cell death (cell suicide) results in a dystrophic hair. Apoptosis appears to occur either as a result of direct action of the drug on the cell or as a result of cell-cycle events resulting in delayed activation. The apoptosis regulatory gene, *bcl-2*, exhibits increased expression in mice treated with cyclophosphamide, promoting catagen and subsequent alopecia. *Bcl-2* is most strongly expressed during the anagen phase.³

p53 also plays a major role in chemotherapy-induced hair follicle apoptosis. The mechanism of p53 in inducing hair follicle apoptosis is unknown but may be secondary to upregulation of IGF-BP3, coupled with upregulation of Fas/Apo-1 and alteration of the *bcl-2/Bax* ratio, resulting in the presence of endonucleases and upregulation of interleukin 1-beta-converting enzyme.⁴⁻⁷

Microscopic evaluation of the affected hair shaft reveals a decrease in hair shaft diameter, with separation of the protective outer layer (cuticle) from the inner core (cortex). Depigmentation occurs frequently. Splaying of the hair shaft, swelling of the inner and outer root sheath, and cuticular fragmentation also occur.⁸

Although these findings are usually temporary, 58% of women found possible hair loss the most concerning side effect of chemotherapy, and in some cases, were at risk for not accepting therapy as a result of this potential complication. In addition, those who experience hair loss reported feelings of alienation, isolation, and embarrassment because of personal feelings and reactions from others. Others felt shame, loss of privacy while trying to cope with cancer therapy, and loss of self-esteem. Social interactions may become impaired or avoided altogether. Alopecia caused a significant number of women to exhibit evidence of poor body image and sexual dysfunction.⁹⁻¹⁶

Studies are being conducted to determine the validity of using computer-generated images to allow patients to view how they will look without hair as a modality to have patients adjust to the possibility of alopecia. The patient may also generate multiple images using wigs, scarves, and other coverings. This technique allows the patient to not only view herself as bald before this actually occurs but to have a plan of adaptive strategies before chemotherapy has begun.¹⁷

If treatment regimens have no differing efficacy, considerations of side effects, including potential for a regimen to induce alopecia, should be considered. However, one must keep in mind that the majority of patients adjust well to the hair loss, with appropriate counseling. Additionally, hair may even regrow during the course of long-term chemotherapy. Recovery typically occurs in 6 to 12 months after chemotherapy has ended. Occasionally, the hair may have an altered texture and/or color. The degree of hair loss is dependent on the type of drug used, its half-life, and the dose of the drug, as well as the duration of use, duration of infusion, and use

TABLE 75.1. Frequency of alopecia from various chemotherapeutic agents.

<i>Frequency of alopecia</i>	<i>Drug</i>
Common	Cyclophosphamide
	Daunorubicin
	Docetaxel
	Doxorubicin
	Idarubicin
	Ifosfamide
Often	Paclitaxel
	Bleomycin
	Etoposide
	Mechlorethamine
	Methotrexate
	Mitoxantrone
Infrequent	5-Fluorouracil
	Hydroxyurea
	Thiotepa
	Vinblastine
	Vincristine
	Vinorelbine
Rare	Procarbazine

Source: From Alley et al.,¹⁸ by permission of *Current Opinion in Oncology*.

of combination regimens. Chemotherapeutic agents typically producing alopecia are listed in Table 75.1.¹⁸

One study reviewed the incidence of irreversible alopecia in patients receiving high-dose chemotherapy using carboplatin, thiotepa, and cyclophosphamide. Although these patients had received previous chemotherapy and cyclophosphamide was also part of the regimen, it was thought that carboplatin and thiotepa may have played the principal role in the hair loss. Thus, it may be advisable to warn patients of the possibility of permanent alopecia if chemotherapy employing carboplatin and thiotepa is offered.¹⁹

By contrast, a study of 17 patients with Hodgkin's disease with ABVD or MOPP/ABV suggested that those who fail to experience alopecia may have a poorer response than those who do.²⁰

Unfortunately, there are currently no preventative treatments available in the United States to prevent the alopecia common to chemotherapy patients. Scalp hypothermia for prevention of alopecia, being investigated in other countries, is thought to work by limiting the follicular uptake of chemotherapy due to vasoconstriction. Factors influencing efficacy of hypothermic devices include rapidity, dose, type of chemotherapy, route of administration, and duration and degree of cooling of the scalp. Three recently studied devices used outside the United States are reviewed in Table 75.2. Previously used in the United States, scalp cooling has been banned by the U.S. Food and Drug Administration (FDA) secondary to reports of scalp metastases occurring in patients. However, benefits versus risks remain controversial. There may be an eventual role in using such a modality in patients receiving palliative therapy who are concerned about hair loss. However, should an indication receive approval, well-controlled studies will be required to determine optimal temperature, type of device to use, optimal cooling agent, duration of treatment, and objective measurement of the degree of alopecia.²¹⁻²⁵

Other modalities to prevent loss and/or induce growth have been studied as well. Preliminary studies suggest topical 2% minoxidil may decrease the duration of alopecia. It is well tolerated. Topical 1,25-dihydroxyvitamin D₃ was not effective in preventing hair loss in humans in one small series. However, murine models suggest that use of 1,25-dihydroxyvitamin D₃ may help accelerate the hair regrowth process. Further studies are necessary to evaluate these very safe options.²⁶ Antioxidants not only fail to prevent alopecia, they may actually impede response to chemotherapy.²⁷

On the horizon: The primary approach in preventing chemotherapy-induced alopecia has been to alter or manipulate the hair cycle either before or after a chemotherapeutic insult. Typically, candidate agents are those compounds known to affect the follicular cycle. The data presented here have been derived from animal models but may hold promise for future developments for viable treatment options (murine models predominating).

TABLE 75.2. Treatment modalities for prevention/treatment of chemotherapy-induced alopecia.

<i>Treatment</i>	<i>Reference</i>	<i>Year</i>	<i>No. of patients</i>	<i>Randomized</i>	<i>Placebo</i>	<i>Intervention/design</i>	<i>Median follow-up</i>	<i>Conclusions</i>
Hypothermia	21	2003	74	No	No	Digitized, scalp cooling system	15 months	100% prevention of hair loss in anthracycline-treated patients
Hypothermia	22	2002	83	No	No	MSC Cold Cap	Unknown	69%–88% effective in preventing alopecia from anthracycline, etoposide, or taxane
Hypothermia	23	2000	70	No	No	Cold cap system	Unknown	92% effective in prevention of alopecia from anthracycline and taxane
Minoxidil topical solution	26	1996	22	Yes	Yes	2% Minoxidil topical solution	N/A	Decreased duration of alopecia caused by chemotherapy
Topical calcitriol	27	1999	14	Yes	Yes	Topical topitriol (calcitriol, 1,25-dihydroxyvitamin D ₃) at various dosages 7 days before and 5 days after chemotherapy	30 days after chemotherapy	All patients developed grade 2 alopecia 20–30 days post-chemotherapy demonstrating lack of efficacy of calcitriol in this schedule of administration.

Murine studies suggest a role for a topical sonic hedgehog expression therapy, which appears to induce hair regrowth after treatment with cyclophosphamide. Similarly, the immunophilins cyclosporine A and tacrolimus were found to transiently induce anagen and to decrease cyclophosphamide-induced alopecia in mice. Although cyclosporine response was dose dependent, response to tacrolimus was not. In addition, tacrolimus was more effective in decreasing cyclophosphamide-induced hair loss. Importantly, however, hair loss occurred eventually. Further studies in humans are warranted.^{28,29}

Pretreatment with calcitriol decreased, but failed to completely inhibit, follicular apoptosis postcyclophosphamide therapy in mice. Although the exact mechanism of action of inhibition unknown, it may be secondary to calcium-dependent effects.³⁰⁻³²

The parathormone/parathormone receptor protein (PTH/PTHrP) antagonist aided in hair retention in cyclophosphamide-treated mice. In addition, the PTH/PTHrPR agonist resulted in hair growth promotion after chemotherapy. Similar findings of hair loss reduction have been reported in mice treated with topical p53 inhibitors, CDK2 antagonists, fas/fasL inhibitors, and caspase-3. These latter agents are known to impede apoptosis.^{33,34}

N-Acetylcysteine may provide a protective effect against alopecia in mice and rats receiving chemotherapy, as hair was retained.³⁵

Cutaneous Complications of Chemotherapy

The following section of this chapter is devoted to the common cutaneous side effects of chemotherapy.

Hypersensitivity Reactions

Fortunately, allergic reactions are relatively rare, but can be severe enough to change or alter the dose of the offending drug. Although type I hypersensitivity reactions (HSR) are most common, type II, III, and IV reactions may occur as well. Manifestations include urticaria, angioedema, anaphylaxis, eczematous dermatitis, vasculitis, and variants of erythema multiforme. Table 75.3 summarizes common chemotherapeutic agents causing hypersensitivity reactions.¹⁸

L-Asparaginase is the most common cause of type I hypersensitivity, followed by cisplatin, carboplatin (intravenous), docetaxel, and paclitaxel. The former has been reported mainly in children. Although rare, rasburicase, used to prevent tumor lysis syndrome, may cause hypersensitivity reactions, in some cases, severe. In addition, this medication is contraindicated in persons who are G6PD deficient.³⁶⁻³⁸

Using a test dose for taxanes has proven beneficial in decreasing the severity of hypersensitivity reactions, medication waste, and costs associated with managing patients suffering from such reactions. *Escherichia coli* asparaginase is generally well tolerated, but *Erwinia* asparaginase may be substituted in individuals sensitive to the *E. coli* derivative without sacrificing efficacy.³⁹

Of note, mechlorethamine ranks as one of the major causes of type IV hypersensitivity reaction. These eruptions are eczematous in presentation, resembling the eruption one might see with a nickel- or poison ivy-type rash.

TABLE 75.3. Common chemotherapeutic agents causing hypersensitivity reactions.

Drug	Type of reaction ^a
Alemtuzumab	Type I
<i>L</i> -Asparaginase	Type I
Bleomycin	Type I
Carboplatin	Type I
Cisplatin	Type I, II
Chlorambucil	Type I, II
Cyclophosphamide	Type I
Cytarabine	Type I
Docetaxel	Type I
Daunorubicin	Type I
Doxorubicin	Type I
Dacarbazine	Type I
Etoposide	Type I, III
5-Fluorouracil	Type I
Ifosfamide	Type I
Mechlorethamine (topical)	Type IV
Melphalan	Type I
Methotrexate	Type I, III
Mitomycin	Type I, III, IV
Mitoxantrone	Type I
Paclitaxel	Type I
Procarbazine	Type I, III
Pentostatin	Type I
Rituximab	Type I, III
Teniposide	Type I
Trastuzumab	Type I

^aType I, immediate hypersensitivity reaction (mediated by IgE antibody to specific antigens); type II, cytotoxic antibody reaction (mediated by IgG and IgM to specific antigens); type III, immune complex reaction (antigen-antibody complexes deposit in tissue); type IV, delayed-type hypersensitivity (mediated by T lymphocytes to specific antigens).

Source: From Alley et al.,¹⁸ by permission of *Current Opinion in Oncology*.

In summary, hypersensitivity reactions are idiosyncratic. However, if feasible, test doses may be given to try to identify patients who may be at risk for HSR type I. In those patients with a positive reaction, desensitization, prophylaxis, or use of an efficacious alternative may be employed. Indeed, prophylaxis is highly recommended before treatment with the aforementioned agents associated with HSR type I, using H₁ with H₂ blockers and systemic corticosteroids. Treatment of reactions include use of epinephrine, systemic corticosteroids, antihistamines, and stable maintenance of the patient's hemodynamic status. In some instances, cisplatin may be successfully substituted for carboplatin-hypersensitive individuals; again, skin testing should be performed first.⁴⁰

Extravasation Reactions

Extravasation reactions occur in approximately 0.1% to 6% of adults, and the rate is higher in children. The two types of reactions include irritant and vesicant reactions.⁴¹ Clinically, irritant reactions present with erythema, tenderness, and swelling at the infusion site, with associated phlebitis. Necro-

sis does not occur. Later, sclerosis and hyperpigmentation may occur. Treatment includes discontinuation of the drug and aspiration to remove as much residua as possible. The extremity should be elevated. Use of hot or cold compresses may prove beneficial; cold compresses help alleviate associated discomfort.

Extravasation with vesicating agents are typically similar to irritant extravasation reactions. They may occur days to weeks after exposure to an offending drug. In addition to erythema, pain, hyperpigmentation, and superficial desquamation, bullae may form. Extensive extravasation may result in ulcer formation. If small, these ulcers typically heal with routine wound management. By contrast, larger ulcers may remain indolent or enlarge. Thus, prompt management may help reduce the risk of involvement of tendons, nerves, and blood vessels, which, in turn, could further complicate wound healing and result in disabling outcomes, including joint contractures. Fortunately, secondary local and systemic infection is rare, even in persons with extensive ulceration.⁴²⁻⁴⁴

Common vesicants include the vinca alkaloids, the anthracyclines, nitrogen mustard, paclitaxel, and cisplatin. Reactions are treated with extremity elevation and cold compresses. The exception to this is in the case of the vinca alkaloid. As cold compresses have been associated with increased necrosis in animal models, hot compresses are preferred. Surgery is indicated only for failure to respond to conservative therapy or if ulceration and/or necrosis occur. Corticosteroids, lidocaine, hyaluronidase, and phentolamine are ineffective in preventing necrosis associated with extravasation of vesicating agents.⁴⁵⁻⁴⁷

Hyperpigmentation

Hyperpigmentation is common, occurring locally secondary to mechanical stress (i.e., electrodes, monitors, bandages), or diffusely. Increased pigmentation may be identified not only in the skin but in hair, mucous membranes, and nails as well.⁴⁸ The exact mechanism of diffuse hyperpigmentation is unknown. Serpiginous and linear streaks of hyperpigmentation have been associated with bleomycin therapy. Pigmentation will usually resolve spontaneously in 6 to 12 months after discontinuation of therapy. However, a single case report of permanent hyperpigmentation occurred in a patient treated with bleomycin and cisplatin. Serpentine supravenuous hyperpigmentation has been reported as well. Diffuse pigmentation may be seen with persons receiving busulfan, hence the term "busulfan tan."⁴⁸⁻⁵²

Acral Erythema

Also known as Burgdorf's syndrome, toxic erythema of the palms and soles, palmar-plantar erythema, palmoplantar erythrodysesthesia, and hand-foot syndrome, this condition occurs most commonly with cytarabine, doxorubicin, and fluorouracil, but may occur with many other chemotherapeutic agents, including tegafur, a derivative of fluorouracil. The frequency varies from 6% to 42% of patients, and it occurs almost exclusively in adults but may occur in children receiving high-dose methotrexate therapy. Lesions typically develop 1 to 90 days after chemotherapy.⁵³

Capecitabine, an oral derivative of fluorouracil, has a long tissue half-life. It is associated with acral erythema in up to 10% of treated patients, with 57% of patients having some symptomatology of acral erythema.

The patient typically complains of a burning sensation of the palms and soles, followed by exquisite tenderness and/or pruritus and swelling. Subsequently, discrete, intensely red plaques develop on the thenar and hypothenar eminence, and/or the lateral fingers, with occasional extension to the dorsum of the hands. Periungual erythema and erythematous bands over the joint surfaces may occur. The hands are affected more than the feet. A morbilliform eruption may occur on the head, neck, chest, and extremities; periorbital swelling may also occur. Symptoms resolve with discontinuation of the offending agent, but subsequent desquamation is not uncommon. Complete recovery occurs in approximately 1 month.⁵⁴⁻⁵⁶

The bullous variant, reported in persons receiving cytarabine and methotrexate, is associated with necrosis, sloughing, and subsequent reepithelialization. The exact cause is unknown but may be dose related. The condition is typically more severe with short-term bolus infusions compared with low-dose infusions.

Acral erythema resembles early graft-versus-host disease of the hands and feet and may be quite difficult to distinguish in patients who have undergone bone marrow transplant. Similarly, the two diseases may occur simultaneously. Serial biopsies, performed 3 to 5 days apart, will eventually elucidate the cause, allowing for appropriate management. There are no evidence-based protocols for treatment of acral erythema, but pyridoxine and corticosteroids have been reported beneficial anecdotally.

Pain management, elevation of the extremities, and cold compresses help relieve symptoms. Cold immersion of the hands and feet may also decrease the incidence and severity of the reaction, presumably secondary to vasoconstriction resulting in lower drug levels being delivered to the extremities. Acral erythema might also be prevented by using lower drug dosages, when feasible, coupled with use of pyridoxine. Some patients may resume their chemotherapy with subsequent decreased severity of the condition.

Inflammation of Keratosis

Precancerous actinic keratoses and, occasionally, benign seborrheic keratoses become inflamed when patients receive systemic fluorouracil (most common) and other types of chemotherapy. The reaction is thought to be secondary to the lesions' relative rapidly dividing nature, compared to uninvolved skin. The lesions are characterized by focal, scaly papules or plaques in sun-exposed areas that become inflamed and/or eroded. No intervention is necessary, unless the lesions become bothersome for the patient, as removal of actinic keratosis will prevent subsequent development of cutaneous squamous cell carcinoma, which might otherwise occur in these lesions. The patient may use low-potency topical corticosteroids if the lesions become symptomatic.

Graft-Versus-Host Disease

Although mild graft-versus-host disease (GVHD) may have a therapeutic effect against malignant cells, severe reactions

may result in significant morbidity and mortality. GVHD is divided into acute and chronic GVHD, occurring within and after 100 days posttransplant, respectively.

Acute GVHD estimates are 6% to 90%. Factors increasing risk include patient's age, prevention protocols, and HLA type. In HLA-matched adults, the incidence is approximately 35%. The selective epithelial inflammation typically affects the skin, digestive tract, and liver, with cutaneous involvement being the most common. Patients frequently complain of itching, but pain and tenderness may also occur. Patients develop a morbilliform eruption, often with folliculocentric prominence. Involvement of the palms, soles, and ears is common. In rare cases, a toxic epidermal necrolysis-type presentation may occur, presenting either with erythema with superficial desquamation, or in a vesicular pattern.^{57,58}

Lymphocytic infiltration and cytopathic changes of keratinocytes are the major features of acute GVHD. However, histopathologic diagnosis is difficult because of other factors that can cause a similar histopathologic picture in these patients, and thus the biopsy results must be interpreted in the context of the clinical findings in the patient, as well as other sites of presumed involvement, such as the liver and gut. Histologic signs are classified into four grades, as summarized in Table 75.4.

One school of thought suggests GVHD develops when the donor T lymphocytes are recognized as foreign, resulting in activation of recipient T cells and recipient IL-2 secretion. The recipient IL-2/donor IL-2 receptor binding results in expansion and proliferation of the T lymphocytes, and in release of tumor necrosis factor- α (TNF- α), which, in turn, recruits effector cells, including natural killer cells, macrophages, and mast cells, in concert with fas/fasL (the latter found only in TH-1 lymphocytes), perforingranzyme, and tumor necrosis factor. Interleukin (IL)-1, -2, and -6, as well as interferon- γ , may also play a role. Cellular apoptosis and tissue damage ensues, resulting in continued activation; thus, the cycle perpetuates itself. Acute GVHD is thought to be predominantly TH-1 mediated.

Conditioning regimens themselves cause release of cytokines, promoting GVHD; these are amplified in the "second phase" when the marrow or PBSCs are infused. Subsequently, the aforementioned mediators are released, potentiating the entire cascade. Patients with high IL-10 production have partial protection from GVHD.⁵⁹⁻⁶¹

Current treatment options include psoralens/UVA photochemotherapy (PUVA; improves cutaneous GVHD only). Other drugs used include oral and topical corticosteroids,

calcineurin inhibitors, and cyclosporine A. The role of extracorporeal photochemotherapy remains unclear.

On the horizon: One murine study demonstrated blockade if only the fas was associated with effective inhibition of GVHD without inducing graft versus leukemia. In addition, blockade of fasL in mouse models was associated with improvement of GVHD. Thus, further study into blockade of fas/fasL is warranted.⁶²⁻⁶⁴

Antithymocyte antibody improves the cutaneous stigmata of acute GVHD but not advanced internal GVHD. Thus, there was no difference in survival outcomes in those treated with antithymocyte globulin and those who were not.⁶⁵

"Mega-dose" CD34+ cells, coupled with a conditioning regimen of thiopeta, antithymocyte globulin, cyclophosphamide, and total-body irradiation, was well tolerated and appeared to allow for inhibition of GVHD without inhibiting a graft-versus-leukemia effect. Similar findings have been found in vitro.⁶⁶

Chronic graft-versus-host disease (c-GVHD) occurs in 60% to 80% of allogeneic hematopoietic stem cell transplant recipients, and is also associated with a high morbidity and mortality rate. It is unclear if it is TH-2 mediated. Chronic GVHD occurs more frequently in those with previous acute GVHD (a-GVHD) (11-fold increase, compared with those without a history of a-GVHD, older donor or recipients, males receiving alloimmune female donor marrow, and those receiving non-T-cell-depleted bone marrow). Because c-GVHD involving skin only is associated with only mild morbidity, some question the utility of treating under this scenario. Mortality is as high as 40% in those with visceral involvement, usually secondary to liver failure, infection, and/or wasting. Chronic GVHD may occur in a continuum of acute GVHD, de novo, or as an intermittent finding.⁶⁷⁻⁷²

The two types of c-GVHD are lichenoid and sclerodermatous. In early c-GVHD, the lichenoid form predominates, typically with involvement of the palms, soles, ears, and periorbital region, and occasionally the penis, foreskin, and vaginal mucosa. Again, the eruption may be folliculocentric. The sclerodermatous form occurs later and is characterized by erythematous plaques and papules occurring on the extremities, with progressive involvement of the trunk. Conjunctivitis, mucositis, esophageal, and genital strictures are associated findings also. Nail changes, including onycholysis, vertical ridging, and periungual telangiectasias, may occur as well. Secondary onychomycosis may develop. The sclerodermatous pattern is characterized by firm, indurated, pearl-white papules and plaques, often with a surrounding border of erythema. These lesions may remain localized but can become generalized and debilitating. As a result of the constriction associated with the sclerodermatous skin changes, patients are at risk for chronic leg ulcers, peripheral neuropathy, joint constriction and retraction, and lung constriction.^{73,74}

Treatment options include oral and topical tacrolimus (the latter for skin involvement only), cyclosporine A, corticosteroids, thalidomide, hydroxychloroquine, UVB and PUVA, and mycophenylate mofetil. Although thalidomide for c-GVHD may decrease the need for long-term corticosteroid therapy, it increases the risk of c-GVHD if used prophylactically. The dose ranges from 1,200 to 1,600 mg/day. Complete or partial response occurs in up to 20% of conventional therapy nonresponders. However, the side effects, including

TABLE 75.4. Histologic grading of cutaneous graft-versus-host disease (GVHD).

Grade	Histologic description
Grade I	Basal cell vacuolization
Grade II	Basal cell vacuolization and single necrotic keratinocytes
Grade III	Superepidermal clefts and numerous necrotic keratinocytes
Grade IV	Necrosis of the entire epidermis and complete separation from the dermis

Source: From Aractingi et al.,⁵⁷ by permission of *Archives of Dermatology*.

somnolence and neuropathy, are great.⁷⁵⁻⁸² The prognosis is poor in those with generalized sclerodermatous changes, due in great part to lung constriction.

On the horizon: TNF antagonists show promise, even in systemic disease. Depletion of cd20-positive B lymphocytes via monoclonal antibodies may prove beneficial as well.⁸³⁻⁸⁵

Radiation Recall

Radiation recall occurs in a previously irradiated site after receiving chemotherapy. It occurs most often after use of doxorubicin and dactinomycin but may occur in association with other chemotherapeutic agents as well.⁸⁶⁻⁸⁸

The condition usually occurs after the first 1 to 2 weeks after ionizing radiation therapy and hours to days after receiving the corresponding chemotherapeutic agent. Recall reactions occur after first exposure to the drug. Although erythema is present, symptoms vary from none to extreme pain. Pruritus and swelling may also occur. The erythema is well demarcated, corresponding to the radiation field. Rarely, ulcer formation and necrosis may occur.^{89,90}

There should be a reasonable interval between radiation therapy and chemotherapy. Elicitation of a reaction seems predicated on the time interval between radiation and administration of chemotherapy. Two case reports in the literature suggest that the magnitude of radiation therapy dictates the severity of the radiation recall reaction. The mechanism of action is unknown, but it may be secondary to defects associated with DNA repair mechanisms.^{91,92}

Recall reactions seem to occur more rapidly with infused medications, compared with oral agents. By contrast, recovery time is longer for oral medications, compared with infused agents. Resolution occurs with discontinuation of the drug and, in some cases, will resolve despite continuation of the offending agent. Additionally, recurrence on rechallenge is often associated with an attenuated reaction. Although dosages are often altered and/or systemic corticosteroids are used, this practice has not undergone scrutiny.

Standardization of reporting would help better delineate the pathophysiology of this phenomenon. Those radiation reactions occurring within 7 days after radiation therapy may represent radiation enhancement reactions; therefore, these would represent an insult to tissue undergoing repair and thus, should not be included with true radiation recall reactions.

Radiation Enhancement

In contrast to radiation recall, radiation enhancement represents the phenomenon associated with increased toxicity of radiation in a patient receiving chemotherapy than would be expected if radiation had been used alone. The effect may be additive or synergistic.

The radiation therapy and the chemotherapy occur within 7 days of one another; the reaction may occur in nearly any organ tissue. It is dose dependent, related to the time between chemotherapy and radiation therapy, the treated tissue, and the mechanism of action of the drug. The most common agents associated with this phenomenon are listed next.

Although radiation enhancement may have a beneficial effect on solid tumors, and may be part of the therapeutic

regimen, significant cutaneous side effects may occur. Erythema, swelling, blister formation, and erosions may develop; ulceration and necrosis may occur in severe cases. Although typically involving only the area irradiated, local extension may occur. Mucositis may occur if a mucous membrane is within the radiation port. Eventually, the eruption clears, with subsequent pigmentary changes, atrophy, scarring, and telangiectasias. Treatment is supportive, with avoidance of further injury to the involved area.

Ultraviolet/Photosensitivity

Photosensitivity reactions occur in patients receiving chemotherapy, followed by intentional or unintentional ultraviolet (UV) exposure. Most of these reactions resemble an exaggerated sunburn, with erythema, swelling, pruritus and/or pain, superficial desquamation, and occasionally, blister formation. Subsequent hyperpigmentation is not uncommon. Diagnosis is aided when the eruption occurs in areas typically receiving the greatest sun exposure, such as the face, posterior neck, the "V" of the chest (upper medial region), dorsum of the arms, and anterior legs.

Treatment consists of discontinuation of the offending agent and complete avoidance of UV light for 2 weeks. Physical sunblocks providing at least SPF 30 afford the greatest protection; these include those containing zinc oxide and titanium dioxide. Treatment is supportive, and includes systemic antihistamines, cold compresses, and topical immunomodulators, such as corticosteroids or calcineurin inhibitors (tacrolimus, pimecrolimus).⁹³

Porphyryns, used for photodynamic therapy in the treatment of solid tumors, are known cutaneous photosensitizers. Thus, patients treated with these compounds are at great risk for phototoxicity, even after taking the appropriate precautions to avoid UV exposure, including bright lights. The photosensitivity is of longer duration, lasting up to 6 weeks after discontinuing the porphyryns.

Nails can be affected in a process called photo-onycholysis in which the distal third of the nail plate separates from the nail bed. This effect has been reported in patients receiving mercaptopurine.

UV recall may occur with use of methotrexate, after a previous episode of recent phototoxicity, such as a sunburn (within 5 days). Similar reactions have been reported with use of suramin. In contrast to recall associated with methotrexate, however, often there is no history of previous sun exposure.⁹⁴

Cutaneous Eruption of Lymphocyte Recovery

This condition develops in some individuals receiving ablative chemotherapy for subsequent bone marrow transplant, typically 6 to 21 days after receiving chemotherapy. Peripheral lymphocytes in the skin recover, becoming immunocompetent once again and subsequently causing cutaneous toxicity, characterized by erythematous macules, papules, and possible erythroderma. Fever is common. The rash usually clears within 1 week, with desquamation and hyperpigmentation.

Histologic findings are nonspecific and may resemble GVHD.

The Role of Skin Biopsies in Therapeutic Outcomes

In a retrospective study performed by Chren et al., the outcomes of 123 adult hospital inpatients with 190 episodes of skin rashes were reviewed. The study revealed that although the utility of biopsy for diagnostic purposes might alter the clinical impression of the rash, it does little in altering management strategies. Interestingly, none of the patients receiving biopsy to evaluate for an infectious etiology for the rash required change in their management. In addition, even in cases when the prebiopsy and postbiopsy diagnosis differed, therapeutic changes occurred in only 22% of patients: Change of systemic management occurred in 14%. Comparatively, changes in systemic therapy occurred in 12% of individuals where the pre- and postbiopsy diagnoses were the same. Additionally, follow-up of patients not receiving biopsy revealed no incidence that later deemed a biopsy should have been performed. Nevertheless, the article points out that biopsy can prove beneficial for reasons other than planning therapeutic strategies.⁹⁵

Infectious Complications of Cancer Therapy

Nasia Safdar, Christopher J. Crnich,
and Dennis G. Maki

Advances in the management of cancer, particularly the development of new chemotherapeutic agents, have greatly improved the survival and outcome of patients with hematologic malignancies and solid tumors; overall 5-year survival rates in cancer patients have improved from 39% in the 1960s to 60% in the 1990s.¹ However, infection, caused by both the underlying malignancy and cancer chemotherapy, particularly myelosuppressive chemotherapy, remains a persistent challenge.²

Impairment of Immunity with Cancer and Treatment of Cancer

Infection occurs commonly during treatment of cancer; 80% of patients with acute leukemia, 40% to 60% of those with lung cancer, and 50% of those with lymphoma, develop an infection at some point in the course of the illness.³ A number of factors account for the increased risk of infection in the cancer patient: poor nutritional status, mechanical obstruction by the tumor, breach of anatomic barriers by surgery, intravascular devices (IVDs), or mucositis caused by cytotoxic chemotherapy, and defects of humoral and cell-mediated immunity that are either disease associated or follow myelosuppressive chemotherapy (Table 76.1).

Granulocytes are the most critical component of the host innate defense against infection. Granulocytopenia is defined as a neutrophil count less than 500 cells/mm³ or less than 1,000 cells/mm³ with expected decrease to less than 500 cells/mm³ within 48 hours, and it is the main immune defect of cancer patients following chemotherapy.⁴

The inverse relationship between the magnitude of granulocytopenia and subsequent infection was first delineated in the 1960s by Bodey et al., in patients with acute leukemia⁵: the incidence of infection was 14% if the absolute granulocyte count fell below 500 to 1,000/mm³ and 24% to 60% if it fell below 100/mm³ (Figure 76.1).⁵ Prolonged granulocytopenia, especially a rapid decline in circulating granulocytes, also increases the risk of deep fungal infection.⁵ Absolute granulocyte counts less than 500 cells/mm³ for more than 10 days is now viewed as the threshold for a greatly increased risk of severe infection.⁶ Common pathogens causing infection in granulocytopenia include a wide array of gram-negative and gram-positive bacteria, *Candida* species, and filamentous fungi, such as *Aspergillus* and *Fusarium*.¹

In general, with the exception of lymphoproliferative malignancies, defects of humoral immunity are not seen in most patients with cancer. However, globulin dysfunction or depletion is common in chronic lymphocytic leukemia (CLL) and nearly universal in multiple myeloma, predisposing to invasive infection with encapsulated organisms, particularly *Streptococcus pneumoniae*.⁷

Impairment of cell-mediated immunity (CMI) occurs with selected chemotherapeutic agents, such as the purine analogues,⁸ and has also been described with novel therapies for cancer, such as monoclonal antibodies. Pathogens typically associated with impaired CMI include *Pneumocystis jiroveci* (formerly *carinii*), the herpesviruses, especially cytomegalovirus (CMV) and varicella-zoster virus (VZV), and atypical mycobacteria, *Candida*, and *Nocardia*.

Infections Associated with Chemotherapeutic Agents

Purine Analogues

Purine analogues, particularly fludarabine, and to a lesser extent, cladribine (2-chlorodeoxyadenosine, 2-CdA) and pentostatin (2'-deoxycoformycin, 2'-DCF), are potent chemotherapeutic agents for the treatment of lymphoproliferative malignancies, such as CLL, Waldenstrom's macroglobulinemia, non-Hodgkin's lymphoma, T-cell leukemia, Sezary syndrome, and hairy cell leukemia (HCL). This class of drugs produces profound lymphocytopenia and a marked decrease in CD4 cells that can persist for several years following the discontinuation of treatment, which, in the case of fludarabine, has been associated with a high incidence of severe opportunistic infections, as high as 50% in some series, most occurring during the first 6 weeks of therapy.⁸

Early reports on the spectrum of infections associated with purine analogues emphasized, in addition to the usual bacterial pathogens causing infection in granulocytopenic patients, an increased incidence of infections caused by pathogens associated with impaired cell-mediated immunity (CMI), particularly *Listeria monocytogenes* and *Pneumocystis jiroveci* (*carinii*), occurring most often in patients who were heavily pretreated with alkylating agents and may also have received concomitant corticosteroids. Invasive infections with opportunistic pathogens, such as *Nocardia*,

TABLE 76.1. Defects in host defense mechanisms and common infections associated with malignant diseases.

Disease	Proportion (%) of patients developing infection	Predominant defect	Common infections
Acute leukemia, aplastic anemia	80	Granulocytopenia	Gram-positive cocci, gram-negative bacilli, <i>Candida</i> , <i>Aspergillus</i> , <i>Fusarium</i> , <i>Trichosporon</i>
Hairy cell leukemia	60	Granulocytopenia, impaired lymphocyte function, monocytopenia	Gram-negative bacilli, gram-positive cocci, mycobacteria (including nontuberculous)
Chronic lymphatic leukemia, multiple myeloma	50	Hypogammaglobulinemia	<i>Streptococcus pneumoniae</i> ; <i>Haemophilus influenzae</i> ; <i>Neisseria meningitidis</i>
Hodgkin's disease	75	Impaired T-lymphocyte response	<i>Pneumocystis</i> , <i>Cryptococcus</i> , mycobacteria, <i>Toxoplasma</i> , <i>Listeria</i> , <i>Cryptosporidium</i> , <i>Candida</i> , cytomegalovirus
Bone marrow transplant recipient	90	Granulocytopenia, increased activity of suppressor T lymphocytes	Gram-positive cocci, gram-negative bacilli, cytomegalovirus, <i>Candida</i> , <i>Aspergillus</i> , other herpes viruses
Breast cancer	35	Tissue necrosis	Staphylococci and gram-negative bacilli
Lung cancer	46–62	Local obstruction, tissue necrosis	Gram-positive cocci, gram-negative bacilli, anaerobic bacteria
Gynecologic malignancy	25	Local obstruction, tissue necrosis	Mixed aerobic and anaerobic enteric bacteria

Mycobacterium tuberculosis, and atypical mycobacteria and fungi have also been reported.⁹ The most frequent late infection has been herpes zoster, both localized and disseminated, with a median time to onset following treatment of 7 to 8 months.⁹

Factors that further increase the risk of infection with purine analogue therapy include organ damage, such as severe mucositis, renal or hepatic failure, prior therapy with antineoplastic agents, advanced stage of underlying cancer, advanced age and poor performance status, pretreatment pancytopenia, high doses of purine analogue therapy, and failure of the cancer to respond to purine analogue therapy.⁹

Strategies suggested to prevent opportunistic infection in patients receiving purine analogue therapy include prophylaxis against *P. jiroveci* (*carinii*). No placebo-controlled trials have been conducted to address the issue; however, some

authorities recommend trimethoprim-sulfamethoxazole (160/800 mg by mouth) thrice weekly for 2 months following fludarabine therapy.⁸

Immunotherapy

Monoclonal antibodies are a new class of biologic anticancer agents targeted at specific receptors on tumor cells. Five monoclonal antibodies—rituximab, trastuzumab, gemtuzumab, ozagamicin, alemtuzumab, and ibritumomab tiuxetan—are in clinical trials with a variety of hematologic malignancies, especially lymphomas and solid tumors.¹⁰ Infusion-related fever, chills, and hypotension may occur with any of the monoclonal antibodies. However, the incidence and microbiology of infections vary according to the cell line affected by the monoclonal antibody. The only commercially available monoclonal antibodies at the present time are rituximab (Rituxan), for the treatment of lymphoma and relapsed HCL, and alemtuzumab (Campath), for the treatment of CLL.

Rituximab, a chimeric monoclonal antibody, targets the B-cell antigen CD20, resulting in the depletion of peripheral B-lymphocyte counts by approximately 90% within 3 days; B-cell recovery occurs slowly, over 9 to 12 months. Mild transient reductions in granulocyte count may also be seen. Infections have been reported with the use of rituximab; however, the incidence of infections with rituximab appears to be no higher than that seen with conventional cytotoxic chemotherapy.¹¹

Alemtuzumab is a chimeric monoclonal antibody that binds to the CD52 antigen. Because this antigen is present on the surface of all lymphocytes, alemtuzumab significantly depletes both B and T cells and is associated with infections caused by organisms similar to those seen with purine analogue therapy, including *P. jiroveci* (*carinii*) pneumonia and invasive infection caused by *Candida*, *Aspergillus*, VZV, and

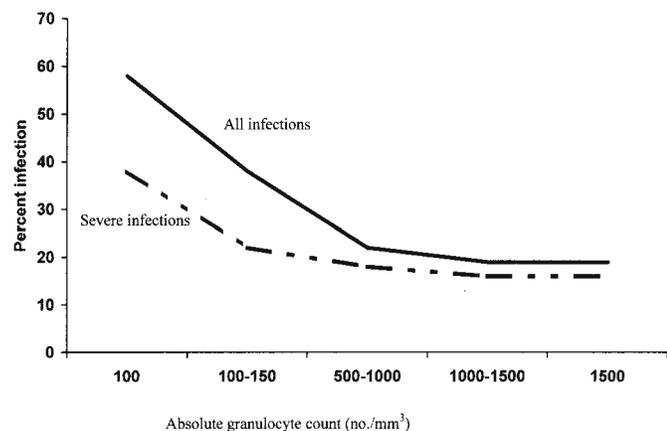

FIGURE 76.1. Relationship between granulocyte count and infection in patients with acute leukemia. The incidence of infection is inversely related to the level of circulating granulocytes. (Adapted from Bodey et al.,⁵ by permission of *Annals of Internal Medicine*.)

CMV. All patients receiving alemtuzumab should receive trimethoprim-sulfamethoxazole (TMP-SMZ) prophylaxis against *Pneumocystis carinii* pneumonia (PCP) and acyclovir for prevention of herpes simplex virus (HSV).

Myeloablative Chemotherapy and Bone Marrow Transplantation

An increasing number of cancers are now being treated with myeloablative chemotherapy, followed by autologous or allogeneic bone marrow transplantation.^{12,13} The intense immunosuppression incurred by this approach, which involves high-dose cytotoxic chemotherapy and total-body irradiation, places the cancer patient at extremely high risk of infection. Typically, profound marrow suppression lasts 2 to 3 weeks until the newly infused marrow engrafts. Severe granulocytopenia and mucositis during this period, often necessitating parenteral nutrition, are major risk factors for infection. Gram-negative bacilli, fungi including *Candida* spp. and *Aspergillus*, herpesviruses, and CMV are the major pathogens causing invasive infection following bone marrow transplantation. In allogeneic bone marrow transplantation, well-conducted studies have shown that acyclovir, given prophylactically for 3 months, almost completely prevents an otherwise very high incidence of severe HSV mucosal infection.¹⁴

Infection in the Granulocytopenic Patient

General Considerations

Infection remains the most frequent life-threatening complication in patients with hematologic malignancies or solid

tumors. Infection is the cause of death of 50% of patients with solid tumors and lymphomas and 75% of patients with leukemia.^{15,16}

Microbiology

The epidemiology and microbiology of infections in patients with granulocytopenia and malignancy has undergone a shift from predominantly gram-negative bacilli in the 1960s and 1970s, to a preponderance of gram-positive organisms in more recent years¹⁷ (Table 76.2). Between 30% and 50% of febrile episodes in granulocytopenic patients can be confirmed microbiologically, and of these, most represent bacteremia.⁶ Causes of fever in the granulocytopenic patient are shown in Figure 76.2.¹⁸

The emergence of gram-positive bacteria as pathogens in patients with granulocytopenia is most striking for bloodstream infections (BSIs) (see Table 76.2).¹⁹ This dramatic shift in the ecology of invasive infection reflects greatly increased use of IVDs for long-term access, the wide use of antibiotic prophylaxis against gram-negative infections, most often with TMP-sulfa or fluoroquinolones, intense antineoplastic therapy, which produces severe mucositis, and initiation of broad-spectrum empiric antiinfective therapy at the first sign of fever in the cancer patient.

Nevertheless, gram-negative bacilli continue to be associated with major morbidity and mortality in granulocytopenic patients, and the emergence of strains highly resistant to multiple antibiotics, such as *Acinetobacter* spp., *Stenotrophomonas maltophilia*, and *Alcaligenes xylosoxidans*, is of great concern. Resistance in all nosocomial gram-negative bacilli is increasing; data from the U.S. Centers for Disease Control and Prevention, show that nosocomial infections in intensive care unit (ICU) patients caused by gram-

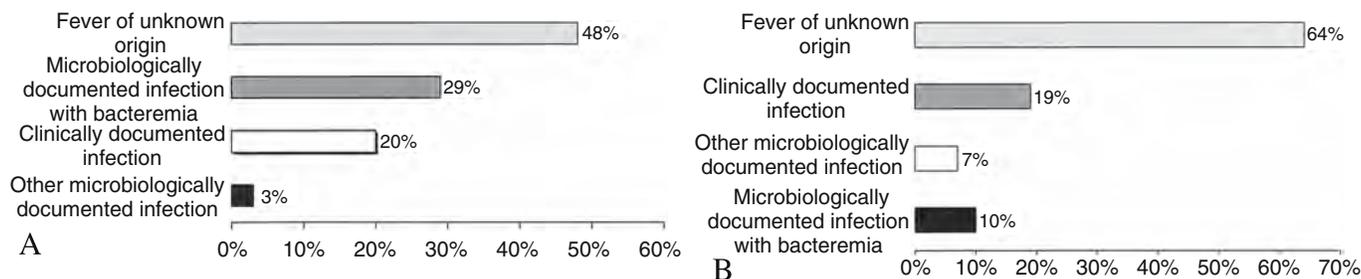

FIGURE 76.2. (A, B) Causes of fever in granulocytopenic patients with hematologic malignancies or solid tumors. Data derived from four consecutive European Organization for Research and Treatment of Cancer studies between 1991 and 2000, and from a North

American Study conducted between 1992 and 1997.^{212,293,294,303,304} [By permission of Marchetti O, Calandra T. Infections in the neutropenic cancer patient. In: Cohen J, Powderly WG (eds) *Infectious Diseases*, 2nd ed. St. Louis: Mosby, 2004:1083.]

negative bacilli resistant to third-generation cephalosporins, have risen to 32.2% of all *Enterobacter* infections and 14% of all *Klebsiella pneumoniae* infections.²⁰

Moreover, new and emerging pathogens, such as *Chryseobacterium meningosepticum*, *Aeromonas* spp., *Fusobacterium nucleatum*, *Burkholderia cepacia*, *Roseomonas*, *Agrobacterium radiobacter*, and *Sphingomonas paucimobilis*, many of which are associated with significant attributable mortality, are being increasingly encountered in granulocytopenic patients.²¹ The major pathogens that cause infection in granulocytopenic cancer patients are shown in Table 76.3.

Major Bacterial Pathogens in Patients with Granulocytopenia

ENTEROBACTERIACEAE

Enterobacteriaceae are the leading gram-negative pathogens implicated in bacteremia in granulocytopenic patients. Although in recent years the overall frequency of gram-negative infections has declined, the proportion of gram-negative infections caused by *Enterobacteriaceae* has remained remarkably unchanged. Data from several surveillance studies show that *Enterobacteriaceae* cause 65% to 80% of documented gram-negative infections in cancer patients, with *Escherichia coli* and *Klebsiella pneumoniae*

most commonly isolated. The bloodstream is the most frequent site of infection, followed by the urinary tract and the lung.

The recent widespread emergence of resistance to beta-lactams, mediated by inducible and extended-spectrum beta-lactamases, poses a major problem.²² Risk factors for infection caused by an extended-spectrum beta-lactamase-producing organism, include exposure to broad-spectrum cephalosporins, prolonged hospitalization, invasive devices, and immunocompromised state.²³ Although the majority of infections caused by *Enterobacteriaceae* can yet be treated with standard therapy, most often, a third-generation cephalosporin or a fluoroquinolone, a carbapenem should be used if infection with an extended-spectrum beta-lactamase-producing organism is suspected or confirmed.²⁴

PSEUDOMONAS AERUGINOSA

Historically, *Pseudomonas aeruginosa* has been the leading cause of life-threatening invasive infection and bacteremia in the granulocytopenic cancer patient.²⁵ In recent years, however, the incidence of bacteremia caused by *P. aeruginosa* has declined. A recent large retrospective cohort study of *P. aeruginosa* bacteremia in a cancer hospital, found that the incidence of BSI fell from 4.7 to 2.1 per 1,000 admissions in 1991 to 1995; however, no decline was noted in patients with acute leukemia, and *P. aeruginosa* accounted for 15% to 20% of gram-negative infections in leukemic patients.²⁶

Pseudomonas aeruginosa rarely causes serious infection in the normal host but is capable of causing devastating, invasive disease if host defenses are breached by mucositis or myelosuppression from chemotherapy or the underlying malignancy, IVDs, or other invasive devices. However, the most important risk factor for life-threatening *P. aeruginosa* infection in patients with cancer is granulocytopenia.^{26,27}

Pseudomonas aeruginosa causes a wide spectrum of infections in the granulocytopenic patient. Pneumonia and bacteremia are most common, but involvement of the urinary tract and skin also occurs. Skin lesions are present in approximately 20% of cancer patients with bacteremia. Ecthyma gangrenosum, the classic skin lesion historically associated with *P. aeruginosa* in patients with granulocytopenia, occurs most commonly in the axilla, groin, and perianal region²⁸ (Figure 76.3). Histologically, these lesions show a septic vasculitis with dense bacillary infiltration of the blood vessel walls. *P. aeruginosa* septicemia may also be associated with subcutaneous nodules, deep abscesses, cellulitis, vesicular or pustular lesions, bullae, or necrotizing fasciitis.²⁹

In general, treatment of *P. aeruginosa* sepsis represents a formidable challenge, because of the intrinsic resistance of the organism to most antimicrobials, and the capacity to rapidly develop resistance during therapy. Factors associated with an unfavorable outcome include persistent neutropenia, especially an absolute granulocyte count of less than 100 cells/mm³, septic shock, lung, skin, or soft tissue involvement, or unidentified source, renal failure, metastatic foci, rapidly or ultimately fatal underlying disease, and inappropriate antibiotic therapy.^{26,27,30} Most studies have found a higher mortality rate among patients with *P. aeruginosa* bacteremia compared with other bacteremias.^{26,27} It is not clear to what extent a higher mortality rate reflects the more severe underlying illnesses affecting patients susceptible to

FIGURE 76.3. Classic ecthyma gangrenosum secondary to *Pseudomonas aeruginosa* infection. [By permission of Fekety R. External manifestations of systemic infections. In: Mandell GL (ed). *Essential Atlas of Infectious Diseases for Primary Care*. Current Medicine, vol. 1. Philadelphia: Churchill-Livingstone, 1997:45.]

Pseudomonas bacteremia as contrasted with the greater inherent virulence of the organism.

It is absolutely essential that empiric antimicrobial therapy for granulocytopenic patients with fever always include a drug or drugs active against *P. aeruginosa*. The number and choice of antibiotics in this setting are controversial, however. In a recent meta-analysis of five studies of *P. aeruginosa* bacteremia, mortality was reduced with combination therapy [relative risk (RR), 0.65; *P* less than 0.05].³¹ The conventional approach to presumptive therapy in the face of granulocytopenia, or other settings in which *Pseudomonas* is a potential pathogen, is to combine treatment with an aminoglycoside or fluoroquinolone plus an extended-spectrum antipseudomonal penicillin (e.g., piperacillin-tazobactam or ticarcillin-clavulanate) or antipseudomonal cephalosporin (ceftazidime or cefepime) or a carbapenem (imipenem or meropenem). The specific choice of agents should be guided by institutional antibiotic susceptibility patterns and guidelines. Although the subject of intense debate, cohort studies and a recent meta-analysis suggest that, in patients with *P. aeruginosa* sepsis, there is a survival advantage with combination therapy as contrasted with treatment with one antimicrobial to which the infecting strain is susceptible.³¹

STAPHYLOCOCCAL INFECTIONS

Coagulase-negative staphylococci have emerged as major pathogens in granulocytopenic patients; two large multicenter studies in patients with hematologic malignancy or solid tumor, identified coagulase-negative staphylococci to be the most common cause of bacteremia in granulocytopenic cancer patients.¹⁹ This increase in incidence clearly reflects an ever increasing use of long-term IVDs in this population.

Although widely regarded as organisms of low virulence, recent studies have shown that infections caused by coagulase-negative staphylococci are associated with considerable morbidity and mortality in immunocompromised patients.³² Primary bacteremia is the major site of infection; complications, such as abscesses and septic phlebitis, have been well described.

Virtually all *Staphylococcus epidermidis* infections are health care associated and most are multiresistant, reflecting the selection pressure of widespread antibiotic use in that setting. Vancomycin remains the mainstay of therapy for coagulase-negative bacteremia.

Staphylococcus aureus is still a major pathogen causing intravascular device-related (IVDR) BSI in granulocytopenic patients and is associated with severe morbidity and mortality. Metastatic infection to distant sites, particularly endocarditis, always poses a threat. In the healthcare setting, approximately 50% of *S. aureus* isolates are resistant to methicillin (MRSA).³³ Until recently, vancomycin was the only available treatment for MRSA; however, recently, two new antimicrobials, linezolid and daptomycin, have been approved for treatment of MRSA infections. In two large randomized trials, linezolid has been shown to reduce mortality from MRSA pneumonia in ICU patients.³⁴ The optimal duration of therapy for *S. aureus* uncomplicated or complicated bacteremia has not been studied thus far; in most instances, a prolonged course (4–6 weeks) of parenteral antimicrobial therapy is desirable for complicated *S. aureus* bacteremia. An echocardiogram to rule out endocarditis in *S. aureus* bacteremia is highly recommended to determine whether prolonged therapy is necessary, as discussed next.

ALPHA-HEMOLYTIC (VIRIDANS) STREPTOCOCCI

Viridans streptococci have become increasingly important pathogens in cancer patients, particularly, patients with acute leukemia undergoing intensive chemotherapy and allogeneic bone marrow transplant recipients; *Streptococcus mitis*, *Streptococcus sanguis*, and *Streptococcus salivarius* are the predominant infecting species.^{35–37} Viridans streptococci are now a leading cause of bacteremia in febrile, neutropenic patients. At the M.D. Anderson Cancer Center in Houston, the incidence of streptococcal bacteremia increased from 1 case per 10,000 admissions in 1972 to 47 per 10,000 in 1989.

A number of studies have examined risk factors for viridans streptococcal bacteremia in patients with cancer.^{36–38} Bacteremia usually occurs in association with aggressive cytoreductive therapy for acute leukemia or allogeneic bone marrow transplantation, especially after treatment with high-dose cytosine arabinoside.³⁹ In a case-controlled study, the risk of viridans streptococcal bacteremia was reported to increase with profound neutropenia, prophylactic administration of trimethoprim-sulfamethoxazole or a fluoroquinolone, and use of antacids or histamine type 2 (H_2) receptor antagonists (e.g., cimetidine).³⁶ Another risk factor strongly implicated is the presence of mucositis^{38,40,41}; in one noncomparative study of 32 patients, 78% had oral inflammation or ulceration at the onset of infection.⁴⁰ Bostrom and Weisdorf reported an association of viridans streptococcal bacteremia with an increased radiation dose to the oral cavity,⁴² whereas Ringden and colleagues described an association with herpes simplex infection⁴³; prophylactic acy-

clovir reduced the frequency of all bacteremias following allogeneic bone marrow transplantation.

Although the most common clinical presentation of viridans streptococcal infection in patients with cancer is primary bacteremia, in many patients, the infection is fulminant, producing septic shock and acute respiratory distress syndrome (ARDS) akin to toxic shock syndrome, resulting in a 25% to 35% mortality, despite prompt and appropriate antimicrobial therapy.^{44,45}

Also of great concern is the fact that 20% to 60% of alpha-hemolytic streptococci now exhibit high-level penicillin resistance in some centers.^{46,47} All these strains remain susceptible to vancomycin, although tolerance to glycopeptides has been described, and the use of antibiotic combinations, such as vancomycin plus rifampin, with or without gentamicin, may be needed to control infections caused by resistant strains.³⁵

ENTEROCOCCI

Enterococcal infections, distinctly uncommon in cancer patients until the mid-1970s, are now the second most common gram-positive species, after coagulase-negative staphylococci, isolated from granulocytopenic patients. Their increased frequency almost certainly derives from the very heavy use of cephalosporins over the past 25 years, drugs to which all enterococci are intrinsically resistant. The most common infections caused by enterococci are bacteremias, urinary tract infections, and postoperative surgical site infections; endocarditis is seen only rarely in patients being treated for cancer.⁴⁸ *Enterococcus faecalis* is the predominant species, accounting for 75% to 80% of enterococcal infections; however, infections caused by *Enterococcus faecium* are rapidly rising. This finding is of great concern, because 25% of all enterococcal isolates in U.S. hospitals are now resistant to vancomycin, and most of the vancomycin-resistant strains

are *E. faecium*.⁴⁹ In the setting of granulocytopenia, bacteremia with vancomycin-resistant enterococci (VRE) has been associated with mortality greater than 70%.⁵⁰

Major Infectious Syndromes in the Granulocytopenic Patient

Numerous studies have shown that infection can be clinically or microbiologically documented in only 50% of patients with granulocytopenia and fever.⁵¹ A large multicenter study from 1985 to 1990 found, in 1,573 patients with granulocytopenic fever, that pulmonary infections were most frequent (17%), followed by BSI and fungemia; in only 5% of cases was an infection clinically and microbiologically diagnosed. The response to treatment was significantly poorer in documented infections than in unexplained fever, with the worse outcomes for pulmonary infections (crude mortality, 21%).

PERIANAL INFECTION

Perianal infections occur in 10% to 25% of patients with leukemia undergoing chemotherapy and are associated with a 15% to 35% mortality.⁵² Most patients with perirectal infection have underlying hematologic malignancy, although the incidence of these infections appears to be increasing in patients with solid tumors, probably because of more intensive myelosuppressive chemotherapy. Although fever is near universal, the predominant local presenting symptom is rectal pain; fewer than half of the patients, however, have frank fluctuance or drainage. Because hypotension or septic shock occurs in 10% of patients, a high index of suspicion for this condition is essential.

The majority of anorectal infections are caused by gram-negative bacilli, particularly, *P. aeruginosa* and *E. coli*; the role of anaerobes is much less clear (Table 76.4). Computed tomography (CT) imaging should be performed to ascertain

TABLE 76.4. Major infectious disease syndromes in patients with granulocytopenia.

Syndrome	Microbial etiology	Differential diagnosis	Diagnostic tests
Skin and soft tissue infection			
Perirectal infection	<i>Pseudomonas aeruginosa</i> <i>Aeromonas</i> spp.		Clinical; computed tomography to determine extent of infection
Complicated cellulitis	Staphylococci, streptococci, gram-negative bacilli		Percutaneous aspirate, biopsy; computed tomography
Pulmonary infections	<i>P. aeruginosa</i> , <i>Klebsiella</i> , <i>Escherichia coli</i> , <i>Enterobacteriaceae</i> , <i>Streptococcus pneumoniae</i> , <i>Staphylococcus aureus</i> , <i>Aspergillus</i> , <i>Fusarium</i> , <i>Mucor</i>	Aspiration Pulmonary edema Pulmonary embolus Atelectasis Alveolar hemorrhage Acute respiratory distress syndrome Pulmonary toxicity from chemotherapy	Chest radiograph, high-resolution computed tomography, sputum stains and cultures, bronchoalveolar lavage, biopsy if platelet count permits
Granulocytopenic typhlitis	Gram-negative bacilli	<i>C. difficile</i> infection	Plain films and computed tomography of abdomen
Intravascular device-related BSI	Coagulase-negative staphylococci, <i>S. aureus</i> , enterococci	Sepsis from another source	Paired quantitative or qualitative blood cultures
Antibiotic-associated colitis	<i>Clostridium difficile</i>	Typhlitis Peritonitis	Stool toxin A and B; cytotoxin B; flexible sigmoidoscopy
Oropharyngeal-esophageal mucositis	Herpes simplex <i>Candida</i> spp.	Aphthous ulceration	Biopsy, culture for herpes simplex virus (HSV) and <i>Candida</i>

BSI, bloodstream infection.

the extent of necrotic tissue and inflammation. Combination regimens with antipseudomonal drugs should be administered, including an agent with activity against anaerobic bacteria. Surgical intervention should be considered only if the disease progresses despite adequate antimicrobial therapy. With simple cellulitis, without fluctuance or abscess, most patients will do well without surgical debridement, if granulocyte function is returning or can be anticipated to return in the immediate future. The occurrence of severe gram-negative soft tissue infection in patients with refractory profound granulocytopenia may be an indication for allogeneic granulocyte transfusion therapy to keep the infection under control until granulocyte function returns. The main predictor of improvement is recovery of granulocyte function.

Patients with fissures or hemorrhoids should undergo fissurectomy or hemorrhoidectomy when their malignancy is in remission; failure to do so will result in an increased risk of perianal infection with myelosuppression.⁵²

OTHER SKIN AND SOFT TISSUE INFECTIONS

Skin infections in patients with cancer may also occur secondary to necrotic tumor masses, postoperative wound infection, extravasation of vesicant drugs, infected IVDs, folliculitis, infected pressure ulcers, or as a manifestation of systemic bacteremic infection. Bacterial cellulitis in granulocytopenic patients is most often caused by staphylococci or streptococci, the leading causes of cellulitis in immunocompetent patients. However, gram-negative bacilli, such as *P. aeruginosa*, which rarely cause de novo skin and soft tissue infection in normal hosts, commonly cause severe soft tissue infections in the granulocytopenic patient.

Antineoplastic therapy makes cancer patients more vulnerable to necrotizing soft tissue infections, "necrotizing fasciitis," which may involve underlying muscle. These infections are usually polymicrobial, caused by gram-positive bacteria, gram-negative bacilli, and anaerobic organisms. Bacteremia occurs in up to 40% of cases.⁵³ In contrast to uncomplicated monomicrobial gram-negative cellulitis in the granulocytopenic patient, which can usually be managed nonsurgically, with necrotizing polymicrobial soft tissue infections, early surgical debridement is imperative to avert otherwise very high mortality.⁵⁴

Any soft tissue inflammation occurring in patients at risk for complex cellulitis must be vigorously evaluated diagnostically, at the minimum with Gram stain and culture of percutaneous aspirates or biopsies⁵⁵; in most cases, the Gram stain will show the infecting organisms. If a grayish hue or frank necrosis is seen or gas is present in the deep tissues on radiographic examination, surgical debridement is imperative at the outset.

INTRAABDOMINAL INFECTIONS

Focal enterocolitis (typhlitis) is a life-threatening condition occurring primarily in granulocytopenic patients.⁵⁶ Although the pathogenesis is poorly understood, mucosal injury by cytotoxic drugs in the setting of profound granulocytopenia is thought to foster microbial invasion of the bowel wall, leading to necrosis. The cecum is almost always affected but the infection may involve the entire colon. This infection

is assumed to be polymicrobial; however, the presence of *Clostridium septicum*, in association with typhlitis, has been described.⁵⁷

Typhlitis must be considered in the differential diagnosis of any profoundly granulocytopenic patient (absolute granulocyte count less than 500/ μ L) who presents with fever and abdominal pain, usually in the right lower quadrant. More than 60% of patients have bloody diarrhea; two-thirds develop gram-negative bacteremia. Peritoneal signs and shock suggest full-thickness necrosis with perforation of the bowel wall. Stomatitis and pharyngitis, suggesting widespread mucositis, may be present. Symptoms typically appear 10 to 14 days after cytotoxic chemotherapy, at a time when granulocytopenia is most profound and the patient is febrile.

Computed tomography is the preferred diagnostic modality; findings include presence of a fluid-filled dilated and distended cecum, diffuse cecal wall thickening, or the presence of intramural edema, air, or hemorrhage; localized perforation with free air or a soft tissue mass, suggesting abscess formation, may also be seen.⁵⁸ Other diagnoses to be excluded, include appendicitis, cholecystitis, intraabdominal abscess, pseudomembranous colitis, and Ogilvie's syndrome (colonic pseudoobstruction). In patients with uncomplicated typhlitis, that is, without peritonitis, perforation, or bleeding, nonsurgical management, with combination antimicrobial therapy, bowel rest, nasogastric suction, and IV fluids, is usually effective if there is a return of granulocyte function; in one study, 70% of affected patients survived with medical therapy alone.⁵⁹

Surgical intervention is reserved for patients with generalized peritonitis, free perforation, persistent gastrointestinal bleeding despite correction of coagulopathy, or clinical deterioration despite medical treatment. If surgery is necessary, a two-stage right hemicolectomy is preferred, and further chemotherapy should be delayed until recovery. Resection of all necrotic tissue is essential; incomplete removal of necrotic tissue is almost always fatal.⁵⁶

PULMONARY INFECTIONS

Pulmonary infiltrates occur in 15% to 25% of all patients with profound granulocytopenia following intensive chemotherapy.⁶⁰ In approximately two-thirds of cases, they become apparent within the first 5 days after the onset of fever. Pulmonary infections in granulocytopenic patients are associated with the highest mortality and remain a formidable challenge, diagnostically and therapeutically.⁶⁰ Noninfectious causes of pulmonary infiltrates that mimic infectious pneumonitis include aspiration, alveolitis, fluid overload, alveolar hemorrhage, malignant infiltration, and pneumonitis caused by chemotherapy or radiotherapy. Although pneumonia has become less frequent in patients with granulocytopenia because of earlier initiation of empiric antibiotic therapy with the onset of fever, gram-negative pneumonia is still common, although there has been an increased incidence of gram-positive pneumonia caused by *Streptococcus pneumoniae*, viridans streptococci, and *Staphylococcus aureus*.⁶¹ Pneumonia caused by viridans streptococci has been encountered most commonly in patients with severe oropharyngeal mucositis following chemotherapy with high-dose ARA-C.³⁵ Hematogenous pneumonia occurs in 3% to 31% of patients

with bacteremia, whereas a fatal ARDS syndrome is noted with about the same incidence.

Accurate microbiologic diagnosis of pneumonia poses the greatest challenge to optimal management. In 20% to 30% of patients with gram-positive and gram-negative bacteremia, there is radiographic evidence of pneumonia, and it is usually assumed to be caused by the same organisms causing bacteremia; this is not necessarily the case, particularly with bacteremia caused by bacteria, such as enterococci, coagulase-negative staphylococci, *Bacillus* species, or *Corynebacterium jeikium*, which rarely cause pneumonia. Conventional chest radiographs show pulmonary infiltrates in less than 10% of patients who remain febrile despite antibacterial therapy, whereas CT, particularly the use of high-resolution scans, shows lung infiltrates in 50% of these patients.⁶² Microbiologic diagnosis is based on blood cultures and cultures of specimens obtained by bronchoscopy or bronchoalveolar lavage. However, the role of invasive diagnostic procedures in granulocytopenic patients remains controversial; moreover, many bronchoscopists are reluctant to perform bronchoscopy, especially transbronchial biopsy, in patients with severe thrombocytopenia. During the past decade, molecular diagnostic methods have become available for the diagnosis of pneumonia caused by *S. pneumoniae*, *Aspergillus*, and *Legionella*.⁶³ However, the predictive value of these tests in patients with granulocytopenia and pneumonia has not been adequately characterized at this time.

The initial step in the management of a patient with a focal infiltrate early in the granulocytopenic period begins with early intensive empiric antimicrobial therapy, providing coverage for gram-positive and gram-negative pathogens. In institutions where MRSA is a common pathogen in granulocytopenic patients, the initial regimen should include vancomycin or linezolid.³⁴ In our institution, a fourth-generation cephalosporin (cefepime), combined with a fluoroquinolone, is most often used, but a carbapenem is also acceptable. Patients who are clinically stable and have a small infiltrate may be observed for 48 hours. If the chest radiograph is suggestive of fluid overload, a trial of diuretics may be given, but continued observation of diffuse infiltrates is not recommended, as rapid clinical deterioration tends to occur when the problem is diffuse pneumonitis.⁶⁴

If rapid clinical improvement does not ensue, and the infiltrate has not changed, the patient may continue to be observed on therapy, and follow-up pulmonary imaging should be considered. If the infiltrate progresses on antimicrobial therapy, more aggressive diagnostic procedures are strongly recommended, preferably fiberoptic bronchoscopy with bronchoalveolar lavage (BAL).⁶⁴

In many centers, if no improvement is noted after 5 to 7 days of antibiotics, empiric therapy with amphotericin B is started. In general, fungal infections are rarely documented before the patient has received at least 5 days of therapy.

Finally, if an infiltrate appears during antimicrobial or antifungal therapy, the approach needs to be modified in favor of an early bronchoscopy because of the high likelihood of infection caused by a fungus or a bacteria resistant to the empiric therapy, or another process altogether, such as viral pneumonitis or a noninfectious process.

In a large prospective study conducted by the Paul Ehrlich Society, supplementation of antibiotics with amphotericin B in all persistently febrile granulocytopenic patients with pul-

monary lung infiltrates resulted in a favorable response rate of 78%.⁶⁵ This finding has led to the recommendation that empiric treatment with amphotericin B should be given early for all febrile granulocytopenic patients with pulmonary infiltrates, especially if there is not an early clinical response to empiric antimicrobial therapy.

CLOSTRIDIUM DIFFICILE-ASSOCIATED DIARRHEA

Clostridium difficile is the major infectious cause of nosocomial diarrhea⁶⁶ and is associated with prolonged hospitalization and increased hospital costs.⁶⁷ The incidence of infection with this organism is increasing in hospitals worldwide as a result of the widespread use of broad-spectrum antibiotics, with reported rates ranging from 1 to 10 cases per 1,000 discharges and 17 to 60 cases per 100,000 bed-days.⁶⁸

Patients with hematologic malignancies are at particularly high risk of developing *C. difficile*-associated diarrhea, and outbreaks have been reported.⁶⁹⁻⁷¹ The majority of these patients receive antimicrobial therapy; mucositis and surgical procedures also increase risk.²³ Studies have also implicated chemotherapeutic agents as independent risk factors for *C. difficile*-associated diarrhea, even in the absence of antibiotic therapy, presumably because of alteration of the normal bowel flora and extensive mucosal inflammation caused by chemotherapy, facilitating colonization by *C. difficile*.⁷¹ A recent case-control study in hematology and oncology patients showed that antineoplastic therapy was associated with a fivefold-greater risk of developing *C. difficile* colitis [adjusted odds ratio (OR) 5.1; $P = 0.01$].⁷²

Clostridium difficile infection encompasses a spectrum of conditions ranging from asymptomatic colonization to fulminant disease with toxic megacolon.⁷³ The usual presentation is acute watery diarrhea with lower abdominal pain and fever occurring during or shortly after beginning antimicrobial therapy. The antibiotics that most predispose to *C. difficile* infection are third- or fourth-generation cephalosporins, clindamycin, and penicillins⁷⁴; however, virtually any antimicrobial may trigger *C. difficile* infection.

Diagnosis of *C. difficile*-associated diarrhea can be reliably made by detection of *C. difficile* toxins A and/or B by enzyme-linked immunosorbent assay (ELISA) in a stool sample.⁷⁵ If this test is negative and *C. difficile* infection is strongly suspected, then cytotoxin testing, widely regarded as the reference standard, should be performed. This test, although 94% to 100% sensitive and 99% specific, takes at least 48 to 72 hours before results are available. In severely ill patients, flexible sigmoidoscopy provides a rapid means of diagnosis, because 90% of cases of pseudomembranous colitis involve the left side of the colon; the visualization of colonic pseudomembranes is essentially pathognomonic for *C. difficile* infection (Figure 76.4). CT of the abdomen, although useful for identifying bowel wall thickness, does not differentiate between *C. difficile* and other causes of bowel wall thickening, such as ischemic colitis.⁷⁶

The most important step in the treatment of *C. difficile* is discontinuation of the culpable antimicrobial, if possible; in approximately 25% of cases of antibiotic-associated diarrhea, this will prove sufficient to resolve the infection. However, discontinuation may not always be possible in a profoundly granulocytopenic patient who is infected or febrile. Modification of the regimen to exclude drugs with

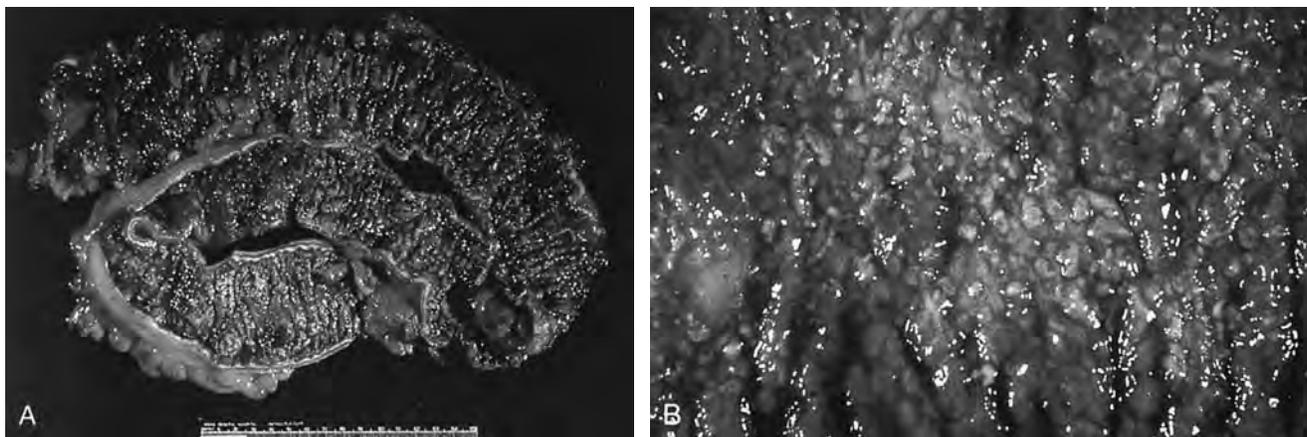

FIGURE 76.4. (A, B) Diffuse hemorrhagic colitis is seen in the resected colon. (B) Closeup reveals the diffuse mucosal irregularity and pseudomembrane formation seen with *Clostridium difficile*

infection. [By permission of Stone DR, Gorbach SL (eds) Atlas of Infectious Diseases. Philadelphia: Saunders, 2000.]

unnecessary antianaerobic activity is strongly recommended if antimicrobials cannot be discontinued.

Oral metronidazole in a dose of 500 mg three times daily for 7 to 10 days is the treatment of choice for symptomatic *C. difficile* infection; vancomycin given orally should be restricted to patients who fail to respond to metronidazole or who have had relapses.⁷⁷ In critically ill patients unable to take oral medications, intravenous metronidazole should be given in conjunction with vancomycin given either by intracolonic instillation or by enema.⁷⁸ *C. difficile* colitis cannot be treated with an agent that fails to achieve high intraluminal concentrations; vancomycin given intravenously is ineffective. In most clinical situations, it is not necessary to repeat stool toxin assays in patients who are responding satisfactorily to therapy.

Clostridium difficile has now become a major nosocomial pathogen widely prevalent in healthcare institutions, and control of nosocomial transmission is also essential. A growing body of literature suggests that the inanimate environment may contribute to nosocomial transmission of *C. difficile*. Commonly used hospital disinfectants are not germicidal against *C. difficile* spores, which may persist for very prolonged periods on surfaces. A recent before–after study using sodium hypochlorite solution to disinfect a bone marrow transplant ward found that rates of *C. difficile* infection decreased from 8.3 per 1,000 patient-days to 3.4 per 1,000 patient-days; when hypochlorite disinfection was discontinued, rates rose to the baseline level.⁷⁹

The Society for Healthcare Epidemiology of America has published a guideline for prevention and treatment of *C. difficile* infections (Table 76.5).⁸⁰ Patients with *C. difficile* should be placed in private rooms and gowns and gloves should be worn for all contacts with the patient. Hand hygiene with an antiseptic agent is essential. It is important to note that alcohol-based handrubs do *not* have activity against the spore form of *C. difficile*. Equipment, such as stethoscopes and sphygmomanometers, should be dedicated to the patient, and the environment should be terminally disinfected with an agent active against spores, such as sodium hypochlorite.

Intravascular Device-Related Bloodstream Infection

The use of IVDs has become an essential component of care to patients with cancer. Unfortunately, vascular access is associated with substantial and generally underappreciated potential for producing iatrogenic disease, particularly BSI originating from infection of the percutaneous device used for vascular access. Nearly 40% of all nosocomial bacteremias derive from vascular access in some form⁸¹ and are associated with excess mortality,⁸² increased length of hospitalization, and excess healthcare costs.⁸³ Different types of IVDs pose widely ranging risks of infection (Table 76.6).⁸⁴

Figure 76.5 summarizes the microbial profile of IVD-related BSIs from 159 published prospective studies.⁸⁵ As might be expected from knowledge of the pathogenesis of these infections, skin microorganisms account for the largest proportion of IVDR BSIs.

Recent evidence-based guidelines provide the best current information on the evaluation of the ICU patient with fever or other signs of sepsis (Table 76.7).⁸⁶ Before any decision regarding initiation of antimicrobial therapy or removal of an IVD, the patient must be thoroughly examined to identify *all* plausible sites of nosocomial infection, including pneumonia, urinary tract infection, surgical site infection, or antibiotic-associated colitis, as well as line sepsis.

Despite the challenge of identifying the source of a patient's signs of sepsis,⁸⁶ several clinical, epidemiologic, and microbiologic findings point strongly toward an IVD as the source of a fever: patients with abrupt onset of signs and symptoms of sepsis without any other identifiable source should prompt suspicion of infection of an IVD; the presence of inflammation or purulence at the catheter insertion site is now uncommon in patients with IVDR BSI⁸⁷; however, if purulence is seen, it is highly likely the patient has IVDR BSI, and this finding should prompt removal of the IVD. Finally, recovery of certain microorganisms in multiple blood cultures, such as staphylococci, *Corynebacterium* or *Bacillus* species, or *Candida* or *Malassezia* species, strongly suggests infection of the IVD.⁸¹

TABLE 76.5. Recommendations for prevention and treatment of *Clostridium difficile*-associated diarrhea (CDAD) in the healthcare institution.

<i>Recommendation</i>	<i>Strength of recommendation^a</i>
Surveillance and diagnosis	
Surveillance for CDAD should be performed in every institution	B-III
Appropriate and prompt diagnostic testing should be performed in patients with antibiotic-associated diarrhea	A-II
Diagnostic tests for <i>Clostridium difficile</i> should be performed only on diarrheal (soft or unformed) stool specimens, unless ileus is suspected	B-III
Testing of stool specimens from asymptomatic patients for <i>C. difficile</i> (including "test of cure" after treatment)	B-II
Treatment	
If possible, discontinuation of the offending antimicrobial agent is recommended	A-I
Oral metronidazole should be considered the treatment of choice for CDAD; oral vancomycin should be administered only if there has been failure to respond to metronidazole, or if the patient cannot tolerate or is allergic to metronidazole	A-I
Treatment of asymptomatic patients with <i>C. difficile</i> colonization is not recommended	A-I
First recurrences of CDAD following treatment of initial episode should be retreated as for the initial episode	B-III
Prevention and control	
Implement policies to ensure prudent antimicrobial use	A-II
Surveillance of antimicrobial utilization in the facility should be conducted	B-III
Healthcare providers in the facility should be educated about the epidemiology of CDAD	B-III
Patients with CDAD and fecal incontinence should be in a private room; if possible, all patients with CDAD should be in private rooms	B-III
Meticulous hand hygiene with soap or an antiseptic agent is recommended after contact with patients, their body substances, or their potentially contaminated environment	B-III
Healthcare providers should wear gloves for contact with patients with CDAD	A-I
Use of disposable, single-use thermometers (rather than shared electronic thermometers) is recommended	A-II
Patient care items, such as stethoscopes and sphygmomanometers should be dedicated; if they must be shared, they should be disinfected between patients	B-III
Disinfection of the environment of a patient with CDAD should be done using sporocidal agents, such as a diluted sodium hypochlorite solution	B-II
Patients with CDAD may be removed from contact isolation when their diarrhea has resolved	B-III

^aData in part from the 2002 Society for Healthcare Epidemiology of America guidelines for the prevention of *Clostridium difficile*-associated diarrhea; Simor et al.,⁸⁰ *Infection Control and Hospital Epidemiology* 2002;23:696–703; from the Infectious Diseases Society of America Guidelines for weighting recommendations based on the quality of scientific evidence.²⁸⁵ Category: A, good evidence to support a recommendation for use; B, moderate evidence to support a recommendation for use; C, poor evidence to support a recommendation for use. Quality of evidence: I, evidence from one or more properly randomized controlled trial; II, evidence from one or more well-designed observational study, multiple time-series, or dramatic results of uncontrolled experiments; III, expert opinion, descriptive studies.

It is indefensible to start antiinfective drugs for suspected or presumed infection in the critically ill patient without first obtaining blood cultures from two separate sites, at least one of which is drawn from a peripheral vein by percutaneous venipuncture. In adults, if at least 30mL blood is cultured,

99% of detectable BSIs should be identified.⁸⁸ Similar operating characteristics are achieved in the pediatric population using a weight-based graduated volume approach to blood cultures.⁸⁹ Standard blood cultures drawn through central venous catheters (CVCs) provide excellent sensitivity for diagnosis of

TABLE 76.6. Rates of bloodstream infection (BSI) caused by various types of devices used for vascular access.

<i>Device (number of prospective studies)</i>	<i>Rates of device-related BSI</i>			
	<i>Per 100 catheters</i>		<i>Per 1,000 catheter-days</i>

BSI but are less specific than cultures obtained from a peripheral vein.⁹⁰

Short-term IVDs should be removed from the outset in unstable patients with suspected IVDR BSI or if IVDR BSI is documented (see Table 76.7); however, it is difficult or, more often, unnecessary to arbitrarily remove surgically implanted IVDs, such as Hickman and Broviac catheters or central

venous ports. Only 15% to 45% of long-term IVDs that are removed for suspected infection are truly colonized or infected at the time of removal.^{91,92} To avoid unnecessary removal of IVDs, novel methods have been developed to identify IVDR BSI without removing the device: (1) paired quantitative blood cultures drawn from the IVD and percutaneously from a peripheral vein⁹³; (2) differential time-to-positivity (DTP) of paired standard blood cultures, one drawn from the IVD, the second from a peripheral vein⁹⁴; and (3) Gram stain⁹⁵ or acridine orange staining⁹⁶ of blood samples drawn through the IVD.

Quantitative blood cultures are labor intensive and cost almost twice as much as standard blood cultures. The differential-time-to-positivity (DTP) of paired blood cultures, one drawn through the IVD and the second concomitantly from a peripheral vein, has been shown to reliably identify IVDR BSI of long-term IVDs if the blood culture drawn from the IVD turns positive 2 or more hours before the culture drawn peripherally. In studies of patients with long-term IVDs, the sensitivity and specificity of DTP are 92% and 75%, respectively.⁹⁴

If a short-term vascular catheter is suspected of being infected because the patient has no obvious other source of infection to explain fever, there is inflammation at the insertion site, or cryptogenic staphylococcal bacteremia or candidemia has been documented, blood cultures should be obtained and the catheter should be removed and cultured (see Table 76.7). Failure to remove an infected IVD puts the patient at risk of developing septic thrombophlebitis with peripheral

TABLE 76.7. Algorithm for diagnosis and management of intravascular device (IVD)-related bloodstream infection.

- Examine the patient thoroughly to identify unrelated sources of infection.
- Carefully examine all catheter insertion sites; Gram stain and culture any expressible purulence from sites.
 - Obtain two 10- to 15-mL cultures:
 - If standard (nonquantitative) blood cultures, draw one by *percutaneous peripheral* venipuncture and one through the suspect IVD.
 - If quantitative blood culture techniques are available (e.g., the Isolator system), catheter-drawn cultures can enhance the diagnostic specificity of blood culturing in diagnosis of line sepsis. However, a peripheral percutaneous quantitative blood culture *must* be drawn *concomitantly*.
- Option regarding a peripheral IV or arterial catheter: *remove and culture catheter*.
- Options regarding a short-term central venous catheter:
 - Purulence at insertion site or no purulence, but patient floridly septic, without obvious source:*
 - Remove and culture catheter.*
 - Gram stain purulence.
 - Reestablish access at new site.
 - No purulence, patient not floridly septic:*
 - Leave catheter in place*, pending results of blood cultures.
 - or
 - Remove and culture catheter*, reestablish needed access at new site.
- Options regarding surgically implanted, cuffed Hickman-type catheters.
 - Remove at outset if:*
 - Infecting organism known to be *S. aureus*, *Bacillus* spp., JK *Diphtheroid*, *Mycobacterium* species, or filamentous fungus.
 - Refractory or progressive exit-site infection, despite antimicrobial therapy, especially with *Pseudomonas aeruginosa*.
 - Tunnel infected.
 - Evidence of septic thrombosis of cannulated central vein or septic pulmonary emboli.
 - Evidence of endocarditis.
 - Remove later on if:*
 - Any of the above become manifest.
 - BSI persists 3 days or more, despite IV antimicrobial therapy through catheter.
- Options regarding surgically implanted subcutaneous central ports (e.g., Portacath):
 - Cellulitis without documented bacteremia: begin antimicrobial therapy, *withhold removing port*.
- Aspirate from port shows organisms on Gram stain or heavy growth in quantitative culture, or documented port-related bacteremia:
 - remove port*.
- Decision on whether to begin antimicrobial therapy, before culture results available, based on clinical assessment and/or Gram stain of exit site or the blood drawn from a long-term IVD.
- With no microbiologic data to guide antimicrobial selection in a septic patient with suspected line sepsis, consider: *IV vancomycin and ciprofloxacin, cefepime, or imipenem/meropenem*.

Source: Adapted from Maki,²¹³ by permission of Lippincott Williams & Wilkins.

IV catheters, septic thrombosis of a great central vein with CVCs,⁹⁷ or even endocarditis. Continued access, if necessary, can be established with a new catheter inserted in a new site. Although small studies have found some utility in catheter exchange over a guidewire in the management of CVCs suspected of being infected,⁹⁸ we believe that, in the absence of randomized studies demonstrating its safety, guidewire exchange generally should not be performed if there is strong suspicion of IVDR BSI, especially if there are signs of local infection, such as purulence or erythema at the insertion site or signs of systemic sepsis without a source (see Table 76.7). In these cases, the old catheter should be removed and cultured, and a new catheter should be inserted in a new site.

Bloodstream infection that might have originated from a long-term IVD, such as a Hickman catheter or subcutaneous port, does not automatically mandate removal of the device, unless (see Table 76.7) there has been persistent exit site infection; the tunnel is obviously infected; there is evidence of complicating endocarditis, septic thrombosis, or septic pulmonary emboli; the infecting pathogen is *S. aureus*, *Corynebacterium* JK, a *Bacillus* species, *Stenotrophomonas* spp., *Burkholderia cepacia* and all pseudomonal species, a filamentous fungus or *Malassezia* species, or a mycobacterial species; or bacteremia or candidemia persists for more than 3 days despite adequate therapy.⁹⁹ Intravascular device-related BSI caused by *S. aureus* must always prompt removal of the IVD, even if signs of bacteremia have resolved following antimicrobial therapy, because of the significant risk of infectious endocarditis (IE) or other metastatic infection if bacteremia recurs.^{100,101} Similarly, we believe that patients with documented for presumed IVDR candidemia should have their catheter removed in most situations.¹⁰²⁻¹⁰⁴

In small, uncontrolled clinical trials of "antibiotic lock therapy" (ALT), usually in conjunction with systemic antibiotic therapy, cure rates of infected IVDs in excess of 90% have been reported.¹⁰⁵⁻¹⁰⁷ Most of the IVDs reported in these studies were infected with coagulase-negative staphylococci and fermenting gram-negative bacilli; therefore, at this time ALT cannot be recommended for the management of long-term IVDs infected by *S. aureus*, *Bacillus* sp., *Corynebacterium* JK, *Stenotrophomonas* spp., *B. cepacia*, all *Pseudomonas* species, fungi, or mycobacterial species. Obviously, if IVDR BSI recurs after an attempt to salvage an IVD with ALT, the device should be removed.

Infected surgically implanted subcutaneous central ports have rarely proven to be curable with medical therapy alone, especially if it is clear that the device is infected (e.g., an aspirate from the port shows heavy growth).¹⁰⁸ A recent study of patients with acquired immunodeficiency syndrome (AIDS), with surgically implanted ports who developed IVDR BSI, found that ALT, combined with systemic antibiotic therapy, resulted in 70% of the ports being salvaged; however, long-term follow-up data on surveillance cultures of the ports were not reported.¹⁰⁹ The only other clinical study of the utilization of ALT in subcutaneous central port infections achieved salvage rates less than 50%.¹¹⁰ Based on the marginal efficacy of ALT in these two studies and the historically poor cure rate achieved with systemic antibiotics alone, we believe that definitive therapy of infected subcutaneous central ports mandates removal of the infected device.

If IVDR BSI is suspected, after cultures have been obtained, the combination of IV vancomycin (for staphylo-

cocci resistant to methicillin, i.e., MRSA) with a fluoroquinolone, cefepime, or imipenem/meropenem (for multiresistant nosocomial gram-negative bacilli) (see Table 76.7), should prove effective against the bacterial pathogens most likely to be encountered (see Figure 76.5). Initial therapy can then be modified based on the ultimate microbiologic identification and susceptibilities of the infecting organisms.

How long to treat IVDR BSI will be influenced by the infecting microorganism, and by whether the patient has underlying valvular heart disease, already has evidence of endocarditis or septic thrombosis, or shows evidence of metastatic infection. If endocarditis is suspected, transesophageal echocardiography offers superior sensitivity and discrimination for detecting vegetations, as compared with transthoracic echocardiography.¹⁰¹ In patients with high-grade bacteremia or fungemia, but without clinical or echocardiographic evidence of endocarditis, septic thrombosis should be suspected.⁹⁷ Central venous thrombosis can now be diagnosed by venography, ultrasonography, magnetic resonance imaging, or CT.¹¹¹

Although there are no prospective studies to guide the optimal duration of antimicrobial therapy for IVDR BSIs, most coagulase-negative staphylococcal infections can be cured with 5 to 7 days of therapy,^{112,113} whereas most infections caused by other microorganisms are adequately treated with 10 to 14 days of antimicrobial therapy.¹¹³ These recommendations hold only as long as there are no complications related to the infection and the BSI clears within 72 hours of initiating therapy. Nosocomial enterococcal bacteremia deriving from an IVD is rarely associated with persistent endovascular infection, and unless there is clinical or echocardiographic evidence of endocarditis, treatment with IV ampicillin or vancomycin alone for 7 to 14 days should suffice.⁴⁸

The management of *S. aureus* device-related infection deserves special mention, as there have been no prospective studies to evaluate the optimal duration of therapy for IVDR BSIs caused by this ubiquitous human pathogen. Historically, high rates of associated IE and late complications led to a universal policy of 4 to 6 weeks of antimicrobial therapy for all patients with *S. aureus* bacteremia. Earlier diagnosis and initiation of bactericidal therapy of nosocomial *S. aureus* BSIs in recent years have been associated with lower rates of IE and metastatic complications, prompting suggestions that short-course therapy (i.e., 14 days) is effective and safe for most patients with *S. aureus* IVDR BSI, so long as the patient defervesces within 72 hours and there is no evidence of metastatic infection.¹¹⁴ In a study of transesophageal echocardiography (TEE) in 103 hospitalized patients with *S. aureus* bacteremia, 69 related to an IVD, Fowler et al. found a surprisingly high incidence of endocarditis, 23% with IVDR *S. aureus* BSI.¹⁰¹ In a more recent report, these authors have reported that the routine use of TEE with IVDR *S. aureus* BSI, as a means to stratify patients into short-course or long-course therapy, is cost-effective.¹¹⁵ However, at this time, there are no prospective studies to affirm this approach. Until more data are available, short-course therapy for IVDR *S. aureus* bacteremia therapy should be approached with caution, and used only when the TEE is unequivocally negative and the patient has defervesced within 72 hours of removing the IVD and starting anti-infective therapy.

All patients with an IVDR BSI must be monitored closely, for at least 6 weeks after completing therapy, especially if

they have had high-grade bacteremia or candidemia, to detect late-appearing endocarditis or other metastatic infection, such as vertebral osteomyelitis.

An updated guideline for the prevention of intravascular device-related bloodstream infections (IVDR BSIs) was published in 2002 by the CDC's Healthcare Infection Control Practices Advisory Committee.¹¹⁶ The use of antimicrobial lock solutions for prevention of BSIs caused by long-term IVDs has been of particular interest in cancer patients. Seven randomized, prospective trials have examined a vancomycin-containing antibiotic lock solution for the prevention of IVDR BSI,¹¹⁷ the largest of which found that use of a vancomycin or vancomycin/ciprofloxacin lock solution reduced the risk of IVDR BSI nearly 80% (P equal to or less than 0.005).¹¹⁸ Concern about the emergence of resistance with prophylactic antibiotic-containing lock solutions has limited their acceptance to date. Three of the seven studies performed serial surveillance cultures for vancomycin-resistant enterococcus; VRE was not found in any of these studies. However, the use of prophylactic antibiotic lock solution is considered acceptable in the HICPAC Guideline if a patient with an essential long-term IVD has continued to experience recurrent IVDR BSIs despite consistent application of recommended infection control practices.¹¹⁶

Viral Infections

Patients who have inherited or acquired impairment of cell-mediated immunity are at risk of opportunistic viral infections. Not surprisingly, patients who are treated with agents with potent activity against this arm of the immune system, such as glucocorticoids, calcineurin inhibitors (i.e., cyclosporine A and tacrolimus),¹¹⁹ alkylating agents (i.e., cyclophosphamide),¹²⁰ selected antimetabolites (i.e., azathioprine, methotrexate, and fludarabine),¹²¹ and monoclonal antibodies [i.e., alemtuzumab (anti-CD52) and basiliximab and daclizumab (anti-CD25)]¹²² are at greatest risk. In general, reactivation of latent herpesviruses account for the majority of viral infections in this population, although community- and nosocomial-acquired infections caused by other common viral pathogens occur at an increased frequency, compared to the general population, and may be associated with increased patient morbidity and mortality.

HERPESVIRUSES

Currently, there are eight herpesviruses that can infect humans and cause disease (Table 76.8). All members of this family demonstrate a tropism for human cells and share the

TABLE 76.8. The human herpesviruses.

Alphaherpesviruses	
Herpes simplex virus type 1 (HSV-1)	
Herpes simplex virus type 2 (HSV-2)	
Varicella-zoster virus (VZV)	
Betaherpesviruses	
Cytomegalovirus (CMV)	
Human herpesvirus type 6 (HHV-6)	
Human herpesvirus type 7 (HHV-7)	
Gammaherpesviruses	
Epstein-Barr virus (EBV)	
Human herpesvirus type 8 (HHV-8)

ability to establish themselves in a state of latency following acute infection. Reactivation of latent infection, characterized by viral replication and shedding, tends to occur most often during periods of immunosuppression, although there is variability in the clinical manifestations of reactivated infection, depending on the virus.

HERPES SIMPLEX VIRUS TYPE 1 AND 2

Herpes simplex virus type 1 and 2 (HSV-1 and HSV-2) are widely distributed in the population, seroprevalence in adults approaching 95% for HSV-1 and 25% for HSV-2. Upward of 70% to 80% of seropositive stem cell transplant (SCT) patients begin to shed HSV following transplantation,¹²³ a finding that has led to recommendations for routine acyclovir prophylaxis in bone marrow transplantation (BMT) and patients with hematologic malignancies who are receiving chemotherapy.¹²⁴

Herpes simplex virus infection typically manifests as localized mucocutaneous disease, most commonly involving the oral cavity, which can be necrotizing in the immunocompromised patient (Figure 76.6), less commonly the genital area. Extensive mucocutaneous disease involving the esophagus may occur in up to 10% of cancer patients with upper gastrointestinal symptoms.¹²³ Life-threatening disease is rare, even in this population; however, HSV pneumonia, hepatitis, encephalitis, and disseminated disease are seen, and are associated with a high mortality, despite appropriate antiviral therapy.

The diagnosis of HSV infection is usually made on clinical grounds in immunocompetent individuals; however, identification of HSV infection is complicated in cancer patients because extensive mucocutaneous disease can be caused by chemotherapeutic drugs, as well as a number of other opportunistic infections. It is thus important that the clinician strive to determine the etiology of the patient's mucocutaneous signs and symptoms.

In the case of acute mucocutaneous disease, viral culture of a swab of an unroofed vesicle or open ulcer offers the best method of confirming HSV infection, with results available

in most cases within 48 to 96 hours. Direct Giesma staining (Tzanck preparation) of fluid from an unroofed vesicle, seeking giant cells or intranuclear inclusions, cannot reliably differentiate between varicella-zoster virus (VZV) infection and HSV infection, is insensitive, and should *not* be used to rule out HSV infection. When feasible, every attempt should be made to obtain specimens for pathologic examination and viral culture or polymerase chain reaction (PCR) in patients with suspected HSV esophagitis or pneumonitis, although empiric treatment based on clinical symptoms may be necessary in patients in whom the risks of invasive tests are too high. In patients with suspected HSV encephalitis, PCR testing of cerebrospinal fluid (CSF) has shown sensitivity and specificity approaching 100%,¹²⁵ although the yield has been shown to be laboratory dependent.¹²⁶

The treatment of HSV infections is dependent on the location and severity of infection (Table 76.9).¹²³ Valaciclovir and famciclovir have an oral bioavailability three to five times that of oral acyclovir, making oral therapy of serious disease a technical feasibility. Nevertheless, the use of oral therapy from the outset should be restricted to immunocompromised patients who have limited mucocutaneous disease. In the presence of extensive mucocutaneous disease, esophagitis, pneumonitis, or disseminated disease, initial therapy should begin with intravenous acyclovir, 5 to 10 mg/kg every 8 hours, to ensure adequate tissue levels, particularly in patients in whom intestinal absorption is in question. Once the patient has shown a favorable response to therapy, therapy may be completed with a highly bioavailable oral agent such as valaciclovir or famciclovir.

VARICELLA-ZOSTER VIRUS

Primary varicella-zoster virus (VZV) infection, in the form of chicken pox, is a ubiquitous childhood infection, most commonly associated with a diffuse vesicular rash, and is associated with secondary reactivation later in life, in the form of a painful, localized eruption, herpes zoster. Primary infection usually occurs in children under the age of 13; however, morbidity and mortality related to primary infection occurs disproportionately in susceptible adults over the age of 23.

Immunocompromised persons are at high risk of primary and reactivation disease,¹²⁷ and these patients are more likely to experience visceral dissemination, with involvement of the lungs, liver, or brain.¹²⁷ Primary VZV infection usually occurs in children with hematologic malignancy where infection is associated with pneumonia in up to 32% of untreated cases.¹²⁸ In contrast, herpes zoster is a delayed reactivated infection that occurs most commonly in adults undergoing chemotherapy and is associated with visceral involvement in up to 13% of cases.¹²⁹

The diagnosis of varicella and herpes zoster infection is usually made on clinical grounds, with a generalized vesicular centripetal rash in lesions in varying stages of development seen in chicken pox and a unilateral dermatomal eruption with herpes zoster (Figure 76.7). Cutaneous dissemination can follow a dermatomal eruption in up to 35% of cancer patients, in contrast to only 4% in persons without cancer. Involvement of adjacent dermatomes is not unusual in immunocompetent patients and does not usually represent disseminated disease. Viral culture of lesions fails to detect the virus in 40% to 70% of cases.¹³⁰ Fluorescent antibody staining appears to be easier and far more sensitive diagnos-

tically. Amplification of VZV DNA is of limited value in the diagnosis of cutaneous disease, but PCR of bronchoalveolar lavage and cerebrospinal fluid can be a useful adjunct in the diagnosis of VZV pneumonia or meningoencephalitis.^{131,132}

Treatment of immunodeficient patients with varicella or herpes zoster is described in Table 76.9. Intravenous acyclovir, 10 mg/kg every 8 hours, is recommended for most patients; however, oral therapy with valaciclovir or famciclovir may be used in patients with mild to moderate immunosuppression who do not have evidence of disseminated or visceral disease. Resistance to acyclovir, mediated by mutation of the viral thymidine kinase, has been seen almost exclusively in patients with AIDS, but should be suspected in any patient not responding to therapy, in which case the use of foscarnet or cidofovir is recommended (see Table 76.9).¹²³

The median time to onset of herpes zoster in BMT patients is 5 months¹²³; as a result, preventive therapy with acyclovir or its congeners is not recommended. The use of varicella zoster-immunoglobulin (VZIG) can reduce the risk of primary infection and its attendant complications, but must be given to susceptible immunodeficient individuals within 96 hours of exposure at a dose of 125 U/10 kg (maximum dose, 625 U).¹³³ The use of live, attenuated varicella virus vaccine is contraindicated in immunocompromised adults at the present time, although a clinical trial of the vaccine is under way in susceptible children.¹³³ Household contacts of immunodeficient patients at risk should be vaccinated if they are known to be susceptible to varicella infection (i.e., children and adults with no known history of varicella).¹³⁴

CYTOMEGALOVIRUS

Cytomegalovirus (CMV) is a herpesvirus that may infect up to 50% to 70% of the population in developed countries.¹²³ Cytomegalovirus infection is seen mainly in patients undergoing BMT or solid organ transplantation,^{135,136} although there have been increasing reports of CMV infection among

TABLE 76.9. Treatment and prophylaxis of infections caused by viral pathogens.

<i>Indication</i>	<i>Drug</i>	<i>Route</i>	<i>Dosage</i>	<i>Duration</i>	
HSV 1 and 2					
Prophylaxis	Acyclovir	IV	5 mg/kg q12	For the period of the most severe immunosuppression (usually 2–3 months)	
		PO	200–400 mg q8 to 800 mg q12	Same	
Treatment	Valacyclovir	PO	500–1,000 q12	Same	
		PO	500 mg q12	Same	
	Famciclovir	PO	500 mg q12	Same	
		PO	500 mg q12	Same	
Mucocutaneous disease	Acyclovir	IV	5 mg/kg q8	7–10 days	
		PO	200–400 mg 5×/day	7–10 days	
	Valacyclovir	PO	500–1,000 mg q12	7 days	
		PO	500 mg q12 or 250 mg q8	7 days	
Esophageal disease	Acyclovir	IV	5 mg/kg q8	10 days	
Encephalitis or pneumonia	Acyclovir	IV	10–15 mg/kg q8	14–21 days	
Resistant infection	Foscarnet	IV	60 mg/kg q12 or 40 mg/kg q8	As above	
	Cidofovir	IV	5 mg/kg once weekly for 2 weeks	Continue every 2 weeks until healing	
VZV					
First prophylaxis (patient VZV seronegative)	VZIG immunoglobulin	IV	125 U/10 kg once	Must be given within 96 hours of exposure	
Second prophylaxis (patient VZV seropositive)	Not recommended				
Treatment	Disseminated or invasive disease	Acyclovir	IV	10 mg/kg q8	7–10 days
		Acyclovir	PO	800 mg 5×/day	7–10 days
Localized mucocutaneous disease	Valacyclovir	PO	1,000 mg q8	7–10 days	
		PO	500 mg q8	7–10 days	
Resistant infection	Foscarnet	IV	60 mg/kg q8–q12	7–14 days or until complete healing	
		IV	60 mg/kg q8–q12	7–14 days or until complete healing	
CMV					
Prophylaxis	Ganciclovir	IV	5 mg/kg q12 then 5 mg/kg daily	5 days From engraftment until day 100 after bone marrow transplantation (BMT)	
Preemptive therapy	Ganciclovir	IV	5 mg/kg q12 then 6 mg/kg daily 5 days per week	14 days Until CMV surveillance test negative	
		IV	60 mg/kg q12 then 90 mg/kg daily 5 days per week	14 days Until CMV surveillance test negative	
Treatment	Ganciclovir	IV	5 mg/kg q12 then 5–6 mg/kg daily	14 days 30 days or until complete recovery	
Resistant infection	Foscarnet	IV	90 mg/kg q12 or 60 mg/kg q8 for 2 weeks, then 90–120 mg/kg once daily	Until complete recovery	
Influenza A					
Prophylaxis	Amantidine	PO	200 mg daily	For duration of peak influenza activity in community	
Treatment	Rimantidine	PO	100 mg bid	For duration of peak influenza activity in community	
	Amantidine	PO	200 mg daily	4–5 days or until 24–48 hours after symptomatic improvement	
	Rimantidine	PO	100 mg bid	4–5 days or until 24–48 hours after symptomatic improvement	
Influenza A & B					
Prophylaxis	Oseltamivir	PO	75 qd	For duration of peak influenza activity in community	
Treatment	Oseltamivir	PO	75 mg bid	5 days	
	Zanamavir	inhaled	2 inhalations bid	5 days	
RSV					
	Ribavirin	Inhaled	55 mg/h for 12 hours	7–14 days	
	RSV IVIG	IV	1.5 g/kg	Once	

VZV, varicella-zoster virus; CMV, cytomegalovirus; RSV, respiratory syncytial virus.

patients with leukemia, as a result of exposure to powerful immunosuppressive drugs, such as fludarabine and cytoxan.¹³⁷ Seropositive patients undergoing BMT or those who receive marrow from a seropositive donor without preventive therapy, develop infection in 60% to 70% of cases.¹²³ The likelihood of CMV infection is greatly increased in patients who develop graft-versus-host disease, those who receive an HLA-mismatched transplant, or those who receive antithymocyte immunoglobulin.^{138,139}

Clinically, CMV infection in immunosuppressed patients can range from asymptomatic excretion to fulminant disseminated disease. Cytomegalovirus viremia often presents as unexplained fever without specific end-organ involvement but usually manifests as pneumonia or gastroenteritis. Without therapy, CMV pneumonia is fatal in up to 85% of cases.¹³⁹ Less common manifestations include esophagitis, myocarditis, hepatitis, encephalitis, and retinitis.

The diagnosis of CMV infection requires documentation of CMV in blood, tissue, or bronchoalveolar fluid specimens. Serologic, histopathologic, and direct culture methods have proven to be insensitive for diagnostic purposes, as highlighted in BMT patients where CMV cultures of blood may be negative in up to 30% of cases of proven invasive disease.¹⁴⁰ Newer molecular techniques, including pp65 CMV antigen detection, PCR, branched-chain DNA, and hybrid capture CMV DNA assay, have revolutionized the diagnosis of invasive CMV disease.¹⁴¹ Studies of quantitative CMV antigen assays and real-time PCR have found that these tests have negative predictive values that range from 90% to 95%, with positive predictive values ranging from 50% to 84%.^{141,142}

Ganciclovir should be used for the initial treatment of all suspected or established CMV disease in immunocompromised patients (see Table 76.9). Many transplant centers also use CMV immunoglobulin for the treatment of patients with CMV pneumonia; however, this recommendation is based on older studies utilizing historical controls,¹⁴³ and at least one contemporary study has failed to find additional benefit over ganciclovir therapy alone.¹⁴⁴ As a result, we do not recommend the adjunctive use of CMV immunoglobulin in the treatment of invasive CMV disease.

The prophylactic use of antivirals in patients at risk for developing invasive CMV disease is also another area of controversy. Many transplant centers routinely give prophylactic ganciclovir to patients who are CMV seropositive or who have received a transplant from a CMV-positive donor. Although this approach does lead to a reduction in documented episodes of invasive CMV, no study has shown a survival advantage.¹²³ An alternative approach, which relies on preemptive ganciclovir therapy in patients with documented CMV viremia, as determined by use of one or more of the molecular techniques already described, has been found to be associated with a survival advantage in several prospective trials.^{145,146} However, studies have found that up to 86% of patients with evidence of CMV shedding, based on molecular surveillance studies, ultimately do not require therapy.¹⁴⁷ As a result, whether to use a prophylactic or preemptive strategy remains controversial, and the approach used will be influenced by institutional rates of CMV infection. The prevention of primary CMV infection in susceptible (antibody-negative) patients is best approached by using CMV-negative marrow and blood products.

EPSTEIN-BARR VIRUS

Epstein-Barr virus (EBV) occurs in more than 90% of the population. In developed countries, primary infection occurs principally in adolescents and teenagers, and as a result primary infection is a rare phenomenon in adults with cancer. However, EBV-induced posttransplant lymphoproliferative disease (PTLD) is a threat to patients who have undergone solid organ or allogeneic BMT. The incidence of this disorder in patients with solid organ transplants varies by the degree of immunosuppression; renal transplant patients have an incidence of PTLD of 1%, whereas the incidence in small bowel transplant patients is as high as 14%.¹²³ In contrast, the incidence of PTLD in BMT patients appears to be lower, around 1.3%.¹⁴⁸ The mortality from PTLD ranges from 30% to 80%, although mortality in BMT patients approaches 90%.¹⁴⁹ Treatment of patients with PTLD is difficult and generally requires a reduction or, better, total cessation of immunosuppressive therapy.¹⁵⁰ Use of antiviral agents is generally of little benefit, although anecdotal success has been reported with infusions of donor-derived leukocytes and the use of anti-B-cell antibodies.¹⁴⁹

HUMAN HERPESVIRUS 6

Human herpesvirus 6 (HHV-6) causes exanthem subitum in children, and shedding of the virus may be seen in up to 60% of patients undergoing BMT.¹²³ Human herpesvirus 6 has been implicated as a cause of rejection, marrow suppression, encephalitis, and interstitial pneumonia in this population; however, clear evidence of a causal role has only been established clearly for encephalitis.¹⁵¹ There have been no prospective trials reported to evaluate the effectiveness of antiviral therapy in infections thought to be caused by HHV-6, although both foscarnet and ganciclovir exhibit in vitro activity, and successful treatment of patients with HHV-6 encephalitis with ganciclovir and foscarnet has been reported anecdotally.¹⁵²

COMMUNITY-ACQUIRED VIRAL RESPIRATORY PATHOGENS

Community-acquired viral respiratory pathogens (Table 76.10) are increasingly recognized causes of infection in immunocompromised patients. In one study at the M.D. Anderson Cancer Center, a respiratory virus was isolated from 33% of adult patients presenting with a respiratory illness, 31% caused by respiratory syncytial virus (RSV), 28% by rhinoviruses or picornaviruses, 18% by influenza A or B, and 23% by parainfluenza or adenoviruses.¹⁵³ Parainfluenza, rhinoviruses, and adenovirus infections occur year round, whereas infections caused by influenza A and B and RSV peak during the winter months. Although many respiratory viral infections are community acquired, several studies have clearly demonstrated the potential for nosocomial acquisi-

TABLE 76.10. Community-acquired respiratory pathogens.

Parainfluenza viruses 1, 2, & 3
Rhinoviruses
Adenoviruses
Coronaviruses

tion, most likely as a result of transmission from visitors or healthcare workers.^{154,155}

Mortality associated with these infections is difficult to establish, because many patients infected by these viruses die with, rather than of, their viral infection. Nevertheless, studies examining mortality in immunocompromised patients from whom a viral respiratory pathogen has been isolated have found case-fatality rates ranging from 22% to 44%.¹⁵³ Mortality appears to be higher for patients infected with RSV; Whimby et al. found that 60% of leukemic patients who developed RSV died of complications related to their infection.¹⁵⁶

Diagnostic tests for most of the major respiratory viral pathogens, such as influenza A and B, parainfluenza 1, 2, and 3, RSV, and adenovirus, are commercially available. A description of individual tests is beyond the scope of this text; however, a new rapid reverse transcriptase PCR test (Hexaplex; Prodesse, Waukesha, WI), which simultaneously tests for the presence of both influenza subtypes, the three parainfluenza subtypes, and the two RSV subtypes, has shown high diagnostic accuracy.¹⁵⁷

The treatment of most respiratory viral infections is supportive; however, there are viable treatment options for influenza and RSV.¹⁵⁸ The neuraminidase inhibitor, oseltamivir, is active against both influenza A and B, whereas amantadine and rimantidine possess activity only against influenza A; therapeutic impact appears to be negligible if the antiviral agent cannot be started within 48 to 72 hours of onset of clinical symptoms.¹⁵⁸ Aerosolized ribavirin has traditionally been used in patients with RSV; however, its benefit appears to be marginal in patients with established infection. The concomitant use of RSV immunoglobulin with aerosolized ribavirin has been shown to reduce mortality in leukemic adults by 30% compared to historical controls (70% to 50%).¹⁵⁵ The results from an ongoing randomized trial of aerosolized ribavirin versus ribavirin plus RSV immunoglobulin are still unavailable. The use of intravenous ribavirin does not appear to be of clinical benefit and can be associated with hemolysis, limiting its utility in this population.¹⁵⁹

The prevention of nosocomial transmission of community-acquired respiratory viral infections, such as influenza and RSV deserves mention, given the number of reports of institutional outbreaks.^{160,161} Minimum infection control practices to prevent nosocomial respiratory viral infections include (1) timely immunization of patients and staff against influenza¹⁶²; (2) prevention of patient contact with persons (friends, family, and healthcare staff) who have active respiratory symptoms; (3) use of rapid diagnostic tests to quickly identify symptomatic patients with potentially transmissible viral pathogens; (4) grouping patients with confirmed infection when single rooms are not available; and (5) placement of patients with suspected community-acquired respiratory viral infections in droplet isolation precautions. The use of more aggressive isolation procedures, such as contact and airborne isolation precautions, with or without the use of prophylactic antiviral agents, may require consideration with outbreaks among very high risk patients.

Fungal Pathogens

The growing problem of devastating fungal infections in cancer patients necessitates a major focus on the leading

fungal pathogens in patients with malignant disease. Most fungal infections occur in patients with hematologic malignancies as a result of the intrinsic nature of the disease and the chemotherapeutic regimens that result in severe and prolonged granulocytopenia, which correlate very strongly with an increased risk of infections caused by the filamentous fungi, such as *Aspergillus* and *Fusarium*. Filamentous fungal infections are far less common in patients with lymphoma and rare in patients with solid tumors. Regardless of the type of malignancy, all patients with cancer are at increased risk of infection caused by *Candida* spp., primarily as a result of the widespread use of IVDs and the intensive chemotherapeutic regimens used in this patient population.

CANDIDA

The risk of developing a *Candida* infection is closely associated with the type of cancer; candidiasis occurs in 9% to 25% of patients undergoing BMT, 1% to 13% of patients with granulocytopenia as a result of chemotherapy and hematologic malignancies, 1% to 2% in patients being treated for lymphoma, and 0.5% in patients undergoing treatment for solid tumors.¹⁶³ *Candida albicans* is most commonly isolated; however, many centers are experiencing a sharp rise in infections caused by non-*albicans* species, including *Candida glabrata*, *Candida tropicalis*, *Candida krusei*, and *Candida parapsilosis*.¹⁶⁴ The clinical relevance of this finding is that most non-*albicans* species are relatively resistant to azoles, including fluconazole and itraconazole, necessitating the use of alternative therapeutic agents, such as amphotericin and caspofungin.

There is a wide spectrum of diseases caused by *Candida* spp., including oropharyngeal mucosal infection, esophagitis, BSI, and hepatosplenic candidiasis. Pulmonary and neurologic involvement are rarely seen as isolated disease and most often occur in conjunction with disseminated infection.

Oropharyngeal candidiasis is characterized by the presence of typical adherent white plaques on the tongue, palate, or buccal mucosa. Staining or cultures of the adherent material usually is not necessary unless infection caused by non-*albicans* species is suspected. Treatment with clotrimazole troches is usually sufficient with limited oropharyngeal disease, although systemic therapy with fluconazole or itraconazole is mandatory in patients with severe disease or when concomitant esophagitis is suspected (Table 76.11).¹⁶⁵ Intravenous amphotericin or caspofungin may be necessary in patients with severe oropharyngeal disease caused by azole-resistant non-*albicans* species.

Candida esophagitis often presents with dysphagia, but retrosternal pain, nausea, vomiting, and gastrointestinal bleeding are other common complaints. Contrast radiographic studies are nonspecific and may be negative in up to 25% of cases; therefore, the diagnosis of candida esophagitis rests on detection of characteristic pseudomembranes and ulcerations by endoscopy. Examination of biopsy specimens, if obtained, confirms the diagnosis. Topical therapy with nonabsorbable antifungals is ineffective in patients with esophagitis, and systemic therapy with fluconazole, caspofungin, or IV amphotericin B is mandatory. The latter two agents are preferred in institutions with high rates of infections caused by non-*albicans* species or in patients with candida esophagitis who have received azoles in the past.

TABLE 76.11. Treatment of selected infections caused by *Candida* species.

Infection	Drug	Route	Dosage	Duration
Oropharyngeal	Clotrimazole	PO	10 mg troche 5 \times /day	7–14 days
	Fluconazole	PO	100 mg daily	7–14 days
	Itraconazole	PO	200 mg daily	7–14 days
	Amphotericin B	IV	0.3 mg/kg daily	7–14 days
	Caspofungin	IV	70 mg loading dose 50 mg daily thereafter	7–14 days
Esophagitis	Fluconazole	IV/PO	200–400 mg loading dose 100–200 mg daily	14–21 days
	Amphotericin B	IV	0.3–0.7 mg/kg daily	14–21 days
	Caspofungin	IV	70 mg loading dose 50 mg daily thereafter	14–21 days
Candidemia	Amphotericin	IV	0.3–0.5 mg/kg daily	14 days after last positive culture
	Fluconazole	IV	400 mg daily	14 days after last positive culture
	Caspofungin	IV	70 mg loading dose 50 mg daily thereafter	14 days after last positive culture
Visceral candidiasis	Amphotericin	IV	0.5–0.7 mg/kg daily	Until lesions have resolved or calcified
	Fluconazole	IV	400 mg daily	Until lesions have resolved or calcified
	Caspofungin	IV	70 mg loading dose 50 mg daily thereafter	Until lesions have resolved or calcified

Candida spp. are also an increasingly common cause of nosocomial BSI,¹⁶⁶ associated with case-fatality rates ranging from 30% to 60%.^{167,168} Disseminated infection usually occurs as a complication of candidemia and may be associated with cutaneous lesions, retinitis or endophthalmitis, osteomyelitis, and even endocarditis. Most episodes of candidemia in nongranulocytopenic patients originate from IVDs.¹⁶⁹ However, controversy exists over the relative role of IVDs versus intestinal translocation in patients with granulocytopenia or who have received intensive cytotoxic chemotherapy.¹⁷⁰

Studies performed two decades ago found that blood cultures are negative in more than 50% of patients with disseminated *Candida* infections confirmed at autopsy.¹⁷¹ In contrast, recent studies have found that automated blood culturing systems detect up to 93% of cases of active candidemia.¹⁷²

Recovery of *Candida* spp. from a blood culture should never be regarded as a contaminant in decisions regarding treatment. Controversies about the source of candidemia aside, a considerable body of literature suggests that retention of an IVD is associated with prolonged candidemia and excess mortality.^{102–104} As a result, we believe that IVDs should be removed from most patients with proven candidemia. Candidemia that responds rapidly to removal of the device and institution of IV amphotericin B can be reliably treated with a daily dose of 0.3 to 0.5 mg/kg and a total dose of 3 to 5 mg/kg.¹⁷³ If a lipid-associated formulation of amphotericin B is being used, a daily dose of 1 to 2 mg/kg and a total dose of 10 to 20 mg/kg should be sufficient in most cases.¹⁰⁴ If the patient has septic thrombosis of the central vein, associated with high-grade candidemia and florid sepsis, or infection caused by non-*albicans* species, a higher dose of IV amphotericin B is recommended, 0.7 mg/kg/day and 20 mg/kg or more total conventional amphotericin, 2 to 3 mg/kg/day and 20 to 30 mg/kg total, for a lipid-associated formulation.¹⁷³

Fluconazole (400 mg/day) has been shown to be as effective as IV amphotericin B in randomized trials in nongranulocytopenic patients,^{174,175} and has further been shown to be comparable to amphotericin B in observational studies of granulocytopenic patients with *Candida* IVDR BSIs,¹⁰⁴ but should not be used in IVDR BSIs associated with septic thrombosis and high-grade candidemia or in BSIs caused by azole-resistant species.
