an otherwise typical DLBCL that happened to involve the mediastinum, while others described this as a unique subtype of DLBCL derived from thymic B-cells in the mediastinum. Clinical and pathologic evidence to support the latter view included a propensity of occurrence in young women, a characteristic morphologic pattern including large lymphoid cells with polylobated nuclei and abundant clear cytoplasm in a background of sclerosis, and a unique immunophenotype including lack of surface immunoglobulin and expression of FIG1 (Copie-Bergman et al., 2003). Characteristic genomic changes included chromosomal gains at 9p and amplification at 2p13–15, which includes the *REL* and *BCL-11A* loci (Jaffe et al., 2001). However the relationship between DLBCL and PMBCL remained unclear.

Diagnosis and Lymphomagenesis

The LLMPP groups used GEP with the Lymphochip to establish a molecular signature of PMBCL. Using 35 PMBCL cases defined by a >6 cm mediastinal mass at clinical presentation, they found a GEP signature which was different from either the ABC or GCB subtypes of DLBCL. Characteristic genes that were over expressed included two genes previously described as over-expressed in PMBCL, MAL, and FIG1, as well as genes under-expressed as compared to DLBCL. 21/35 cases were true PMBCL while the others appeared to be ABC or GCB subtypes of DLBCL involving the mediastinum. Surprisingly, the GEP analysis also discovered similarities to Hodgkin lymphoma (HL) cell lines and microdissected malignant HL cells from patient lymph nodes. In particular, loss of expression of genes associated with the B-cell receptor signaling pathway were noticed in both lymphomas implying a similar lymphomagenic mechanism. HL is a different lymphoma in histologic appearance and classification, but some overlapping clinicopathologic features with PMBCL are apparent. After the GEP discovery, it was reinforced that both lymphomas often had involvement of the mediastinum, predominance in young women for cases with mediastinal involvement, frequent lack of surface immunoglobulin, genomic gains at 9p and 2p, and expression of CD30 (Rosenwald et al., 2003a). Simultaneously, the Shipp research group, using the Affymetrix U133A + B platform described similar findings: that PMBCL was a separate entity from DLBCL that had overlapping features with HL. These similarities included decreased expression of molecules involved in B-cell receptor signaling and activation of the NF-κB pathway (Savage et al., 2003). Excitingly, these landmark studies reached the same conclusions using different microarray platforms, samples, and analysis methods, indicating the strength of the conclusions. The discovery that PMBCL and HL may share a similar pathogenic mechanism shed light on the origins of the controversial cases of so-called "mediastinal gray zone" lymphomas. These rare lymphomas have features of both diseases and have been difficult to diagnose as either Hodgkin or non-Hodgkin lymphoma. Perhaps the "gray zone lymphomas" represent the missing link between PMBCL and HL (Calvo et al., 2004).

Therapeutic Targets

Further investigation of the NF-κB pathway as a potential therapeutic target in PMBCL was confirmed by demonstration of REL protein localization to the nucleus, high levels of NF-κB binding activity, and NF-κB inhibition (achieved by transduction with a super-repressor form of IκBα) of proliferation in a PMBCL cell line. The investigators further defined an "NF-κB activation" signature by re-analysis of the GEP data. This signature included increased expression of genes promoting cell survival and anti-apoptotic signaling via TNFα which was significantly different from the NF-κB signature exhibited by the ABC type DLBCL. They also noted partial overlap with the "host response" consensus cluster in DLBCL which may reflect the rich stromal background characteristic of PMBCL (Feuerhake et al., 2005). NF-κB activation is frequently but not invariably associated with gene amplification, suggesting the possibility of multiple pathogenic mechanisms. Taken together, these data clearly identify NF-κB as a potential therapeutic target in PMBCL. Therapies lowering NF-κB activity, such as the proteasome inhibitor, bortezomib, which decreases degradation of the NF-κB inhibitor IκBα, are under development for clinical use in lymphomas.

HODGKIN LYMPHOMA

HL has traditionally been kept separate from the non-Hodgkin lymphomas because of very characteristic clinical and pathologic features. HL always spreads in a contiguous fashion from one lymph node group to the adjacent lymph nodes on the same side of the diaphragm (above or below), next through the lymphatic system to lymph nodes on the opposite side of the diaphragm, then to the spleen, liver, and bone marrow. Involvement outside of the hematolymphoid system is therefore rare. Because of this predictable pattern of spread, radiotherapy can be curative in the early stage disease. The most common subtype of HL is the Nodular Sclerosis variant, which occurs classically in young women and involves lymph nodes above the diaphragm. This disease has a generally good prognosis. The Mixed Cellularity variant of HL is more often seen in male and HIV+ patients, has less mediastinal involvement, a higher stage at diagnosis, and a generally less favorable outcome (Jaffe et al., 2001). Histologically, HL is also very unusual in that the malignant cells, termed Reed-Sternberg cells, and their variants are uncommon in the tumor tissue. It is estimated that the malignant cells make up fewer than 1% of all cells present with the remaining cells being inflammatory cells: lymphocytes, eosinophils, plasma cells, and stromal elements. To further complicate the diagnosis, Reed-Sternberg cells generally do not express the characteristic immunophenotype of any normal hematopoietic cells. In fact, they lack CD45 (leukocyte common antigen), specific T-cell antigens, and have weak or no expression of specific B-cell antigens. For a long time, the lineage of Reed-Sternberg cells was therefore a matter for speculation. Investigators used laser microdissection to isolate primary Reed-Sternberg cells

directly from frozen tissue sections. PCR analysis of these cells demonstrated that they were B-cells with rearrangements of the immunoglobulin heavy and light chain genes (Kanzler et al., 1996; Marafioti et al., 2000). GEP studies of HL have often relied on HL cell lines derived from Reed-Sternberg cells since the process of microdissection to obtain enough mRNA for complete analysis is difficult and time consuming. However, some investigators have first used cell lines, which allows analysis of homogenous samples, then confirmed key findings using primary tissue samples (Kuppers et al., 2003). Cell sorting has also been used to isolate primary Reed-Sternberg cells from tissues (Cossman, 2001).

Lymphomagenesis

Building on the knowledge that immunoglobulin heavy and light chain genes could be successfully rearranged in HL but the proteins were not expressed, investigators used Affymetrix U95 microarrays on HL cell lines and discovered a loss of the B-lineage specific expression program which was confirmed by immunohistochemistry. These results agreed with those described by other research groups studying PMBCL previously described in this chapter. Interestingly, continued expression of the Pax-5 gene, a transcription factor essential for B-cell commitment in early development and maintenance of the mature B-cell phenotype, was noted, although many genes known to be transcriptionally activated by Pax-5 (CD19, CD21, CD22, CD79a, BLNK) were down-regulated. No mutations in the Pax-5 gene were found to account for this phenomenon, indicating that there must be another mechanism of loss of the B-cell phenotype (Schwering et al., 2003b). In the same year, the same group compared HL cell lines to GCB DLBCL cell lines using U95 Affymetrix microarrays and confirmed some of the findings with SAGE and RT-PCR on microdissected Reed-Sternberg cells from patient lymph nodes. They found that Reed-Sternberg cells had an altered expression of hundreds of genes including potential oncogenes (rhoC, L-myc, and PTP4A) and transcription factors (ATF-5, ATBF1 and p21SNFT) and most closely resembled the ABC type of DLBCL. (Schwering et al., 2003a). Comparison of HL to NHL (non-Hodgkin lymphoma) cell lines identified expression of the activating transcription factor, ATF3, exclusively in HL. RNA interference assays selectively diminished growth of the HL cell lines compared to the NHL lines indicating the importance of ATF3 in HL growth (Janz et al., 2005). GEP using chemokine, chemokine receptor, and cytokine DNA chips on whole lymph nodes of HL identified a mixed T helper1/T helper2 response by the background T-cells and found differing chemokine expression profiles mainly related to presence or absence of EBV infection rather than histologic subtype (Ohshima et al., 2003).

Prognosis and Subtypes

Another group analyzed whole lymph nodes with GEP using their own spotted microarrays and found 3 subtypes of HL; these corresponded to the known Mixed Cellularity and Nodular Sclerosis variants with the latter divided into good and poor outcome groups. The poor outcome genes related to angiogenesis, proliferation, cell adhesion, and growth factor receptors. Good outcome genes were involved with increased apoptosis, cell signaling, cytokines, cytokine receptors and transduction molecules (Devilard et al., 2002).

FOLLICULAR LYMPHOMA

FL is the most common of the low-grade lymphomas, accounting for nearly 40% of all NHL in the United States. This disease occurs mainly in adults and is thought to originate from GCB-cells. Patients present with one or multiple sites of lymph node involvement. The tumor cells express markers of germinal center differentiation and recapitulate normal germinal center architecture. The genetic hallmark of the disease is the t(14;18)(q32;q21) that brings the anti-apoptosis gene, *BCL-2*, to the vicinity of the immunoglobulin heavy chain gene enhancers resulting in the over expression of BCL-2 protein and prolonged cell survival. The disease follows a variable waxing and waning course over several years (Jaffe et al., 2001). Therapy has been generally reserved for those patients with discomfort or other symptoms related to the bulk or location of their disease. However, new monoclonal antibody therapies directed against tumor cell surface markers may be changing the treatment paradigm (Fisher et al., 2005). About 25–35% of patients' tumors will undergo "transformation" to DLBCL which will then require multi-agent chemotherapy (Jaffe et al., 2001). Efforts to predict the clinical course of individual patients have relied on clinical features similar to the IPI score developed for DLBCL (Solal-Celigny et al., 2004). Histologic grading based on counting the number of large "centroblastic" cells per high power microscopic field has also been used, but with variable reproducibility (Jaffe et al., 2001; The Non-Hodgkin's Lymphoma Classification Project, 1997). However, speculation has remained high regarding whether there are other features of FL useful in guiding clinical treatment decision making.

Diagnosis

One of the first papers on GEP in FL compared normal GCB-cells to malignant B-cells, both enriched from involved lymph nodes by negative selection. This procedure is different from most previously discussed procedures because it compared cell types rather than complete lymph nodes. Using the Atlas cDNA Expression array (Clontech, Mountain View, CA) containing 588 cDNAs and confirming their results with quantitative RT-PCR, it was reported that FL, compared to benign B-cells, upregulated genes related to cell cycle regulation, transcription factors including Pax-5, cell–cell interactions, tumor necrosis factor, interleukin-2 receptor, and interleukin-4 receptor while decreasing expression of genes related to adhesion including MRP8 and MRP14. BCL-2 expression was increased as expected from the characteristic chromosomal translocation in FL involving BCL-2. Some of these genes mapped to regions previously reported

to be altered in FL such as 6p21.1^{CIP1} and 6p21.3^{TNF} (Husson et al., 2002). Other investigators analyzed DLBCL cell lines with t(14;18)(q32;21) compared to mantle cell lymphoma (MCL) cell lines harboring the t(11;14)(q13;q32) involving the immunoglobulin heavy chain gene and CCND1 which encodes the cyclin D1 protein. Using a cDNA spotted microarray with 4364 genes printed at their own facility, they compared the t(14;18)-containing cell lines to purified B-cells from benign tonsils and described increased expression of genes related to cellular proliferation, survival, and metabolism in the cell lines. Numerous under-expressed genes identified in the t(14;18) containing cell lines included negative regulators of cell activation and growth. Not surprisingly, t(11;14) and t(14;18) containing cell lines had distinctly different GEP profiles, with t(11;14) cell lines expressing increased cyclin D1 and associated downstream genes as expected in MCL (Robetorye et al., 2002).

Transformation

In order to investigate the molecular basis for the transformation of low grade FL into DLBCL, investigators compared 7 paired tumor samples from the same patients taken pre- and post-transformation. They found increased expression of 36 genes related to proliferation and metabolism and decreased expression of 66 genes including T-cell genes, dendritic and stromal cell genes, and transcription factors previously known to be involved with transformation, along with 25 novel genes (de Vos et al., 2003a). Other researchers evaluated 12 matched pairs proven to be clonally related to each other using an in-house spotted microarray and identified increased expression of p38-mitogen-activated protein kinase (MAPK) and growth factor cytokine receptors in the transformed samples. Results were confirmed with quantitative RT-PCR and an independent, blinded set of FL and DLBCL cases yielded similar results supporting the validity of the observations. The same paper described that pharmacologic manipulation of phosphorylated MAPK in a t(14;18)/MAPK over-expressing FL cell line inhibited growth in vitro and *in vivo* in a NOD/SCID mouse model. These results suggested MAPK as a therapeutic target in FL. A third group of investigators studied transformed FL compared to untransformed cases using array CGH to assess genomic alterations and compared these results to their previously reported GEP results on the same cases. Interestingly, they described 2 different GEP signatures in transformed cases that were related to over- or under-expression of the oncogene, *c-myc*. Heterogeneous acquired chromosomal aberrations were also observed in the transformed FL. For example, gains at 18q21.3 were observed, but not related to BCL-2 levels, implicating other genes in that region as important in transformation. Gains or amplifications at the 2p16 locus implicated the REL and BCL11A genes. This work supported the idea that there may be more than one genetic mechanism for transformation to a higher grade neoplasm (Lossos et al., 2002; Martinez-Climent et al., 2003).

Prognosis

Due to the variable clinical outcome of patients with survival ranging from 1 to 20 years, there has always been a medical interest in identifying prognostic factors in FL. The LLMPP group analyzed a training set of 95 samples, using the Affymetrix whole genome oligonucleotide arrays (U133A + B) to define a prognostic GEP signature. Two different signatures related to patient outcome, independent of clinical risk factors, were described, termed immune response 1 (IR1) and immune response 2 (IR2). The IR1 gene signature is enriched in transcripts related to T-cell mediated immune responses including monocytes and cytotoxic T-cell genes while the IR2 signature is enriched in transcripts expressed by histiocytes and dendritic cells. Both signatures can be combined to create a survival predictor score. When patients were split into 4 quartiles based on this score, median survival varied from 3.9 to 13.6 years. Most interestingly, the tumor microenvironment, particularly the non-malignant immune cells, not the tumor cells, predicted patient survival. Differences in IR1 and IR2 between individual patients may reflect genetic variation in immune response and regulation between different individuals. Or, the differences in IR1 and IR2 between different tumors may reflect variation in the molecular biology of the malignant FL cells. There are 2 hypotheses about why IR1 and IR2 are associated with good and bad prognosis, respectively. In the "immune response" hypothesis, IR1 reflects an effective antitumor response by the adaptive immune system. In contrast, IR2 reflects genes expressed in the innate immune system implying that FL cases with increased IR2 signature have learned to evade the adaptive immune system. A second hypothesis termed "immune cell dependence" suggests that the tumor-associated immune cells supply trophic survival signals to the malignant cells. The malignant cells may therefore have difficulty leaving the lymph node. FL cases with increased IR2 signature may have lost dependence on the immune cells and be able to grow without such requirements, resulting in a more aggressive tumor and poorer prognosis. Further investigation will be necessary to dissect these interactions (Staudt and Dave, 2005). An independent study compared microdissected follicles from 10 FL and 10 lymph nodes with benign reactive follicular hyperplasia using a cytokine and chemokine cDNA microarray. They identified interleukin receptor 3-alpha as increased in FL follicles among several other increased and decreased genes. Since this receptor is derived from activated follicular dendritic cells, these findings also imply the importance of the tumor microenvironment in FL growth. Other investigators used paired samples from patients with low grade (Grade 1 or 2) FL compared to aggressive disease (Grade 3b or DLBCL) based on current histologic criteria (Jaffe et al., 2001). They constructed an 81-gene model to represent these categories. In aggressive disease, genes involved in cell cycle control, DNA synthesis, and metabolism are upregulated. Genes increased in indolent disease included T-cell and macrophage-derived genes, which could either implicate host immune and microenvironmental factors in good prognosis FL or just be a reflection of higher abundance of stromal elements in low grade versus high grade lymphomas. This model accurately classified 93% of the FL samples in an independent validation set of 58 cases. The authors noted that development of diagnostic assays to make the low versus high

grade distinction using custom-made mini-chips or multiplex RT-PCR may be clinically feasible (Glas et al., 2005).

MANTLE CELL LYMPHOMA

MCL is a NHL of B-lymphocytes thought to originate from the mantle zone surrounding the germinal center. Patients are middle aged to elderly, predominantly male, and have frequent involvement of the gastrointestinal tract. These lymphomas have very poor outcomes. Patient survival is variable ranging from less than 1 to over 10 years, with a median of approximately 3 years. Most patients cannot be cured (Jaffe et al., 2001). Therefore in MCL, similar to DLBCL and FL, there is a real clinical need to identify patients with a poor prognosis who might be candidates for alternate therapy as well as patients with a good prognosis who may require less aggressive treatment. MCL has a characteristic translocation t(11;14)(q12;q32), which brings the gene encoding the cell cycle protein, cyclin D1, to the vicinity of the immunoglobulin heavy chain enhancers leading to overexpression of cyclin D1 (Jaffe et al., 2001). This deregulation of cell cycle control presumably confers a proliferative advantage to these cells. Diagnostically, the presence of the t(11;14)(q13;q32) translocation, high expression levels of cyclin D1, and characteristic immunophenotype have made MCL a fairly uniform diagnostic category. Whether or not MCL can occur without the characteristic translocation and whether the sometimes variable nuclear cytologic appearance (blastoid variant (BV) represents transformation or different disease subtypes are other diagnostic questions.

Diagnosis

The initial two GEP papers on MCL focused on the differences between MCL and benign lymphoid populations. The first paper evaluated whole MCL lymph nodes versus whole benign hyperplastic nodes. Differential expression of apoptotic genes were identified and confirmed with quantitative RT-PCR in addition to the expected over-expression of cyclin D1 and associated genes (Hofmann et al., 2001). The second paper compared MCL to pre-germinal center (antigen-naïve) and post-germinal center (antigen-experienced) B-cells sorted from normal tonsils. They described normal levels of expression of the CCR7 receptor but decreased expression of other receptors that are expressed during transition of B-cells from primary follicles to GCB-cells. They challenged the previous belief that MCL originates from antigenically naïve, pre-GCB-cells suggesting a slightly later functional stage. MCL was characterized by decreased trafficking and differentiation genes, deregulated growth factors and growth factor receptors and oncogenes (*Cyclin D1*, *BCL-2*, and *MERTK*), increased metastasis and angiogenesis genes, defective apoptosis, and differential expression of neurotransmitter receptors. Two GEP patterns were identified indicating that there might be two different subtypes of MCL (Ek et al., 2002). Two other groups compared MCL to flow cytometry-sorted normal mantle zone lymphocytes. Altered apoptosis and signaling pathways were identified compared to normal populations. Gene expression signatures for pathologically defined subtypes included signatures for cases with somatic mutations of the immunoglobulin heavy chain gene, a proliferation signature, and a blastoid cytology signature (Martinez et al., 2003; Rizzatti et al., 2005). De Vos and colleagues investigated the BV of MCL and identified altered progress through the G1/S and G2/M checkpoints along with cyclin D1-associated genes indicating that the BV cases may represent MCL with additional alterations in the gene expression pattern related to cell cycle (de Vos et al., 2003b). A comparison of MCL with 2 other types of lymphoma, small lymphocytic lymphoma and marginal zone lymphoma, which sometimes have overlapping clinicopathologic variables, demonstrated that MCL had an upregulation of cell cycle control genes, as anticipated from the known association with t(11;14)(q13;q32), as well as multidrug resistance genes. This latter finding may have implications for treatment options (Thieblemont et al., 2004).

Prognosis

The LLMPP group analyzed 101 cases of MCL to identify a diagnostic and prognostic signature unique to this type of lymphoma. Genes associated with outcome were analyzed to develop a survival predictor model. A large proportion of the survival predictor genes (24/48, 58%) formed a signature related to proliferation. However, these proliferation genes were different than the proliferation signature genes that constitute an important survival predictor in DLBCL. In MCL, the proliferation genes were associated with cell cycle progression and DNA synthesis, but not with c-myc as seen in the DLBCL proliferation signature. Furthermore, the higher the expression of cyclin D1 transcripts, the worse the patient outcome. Independent of the elevated cyclin D1, deletion of the *INK4a/ARF* locus encoding the $p16^{INK4a}$ and $p14^{ARF}$ tumor suppressor genes related to cell cycle progression was more frequent in MCL with high expression of the proliferation signature. Thus, a quantitative model based on the proliferation signature was able to predict patient outcome (Rosenwald et al., 2003b). Interestingly, approximately 5% of cases submitted to the study but not included in the above analysis, had otherwise typical clinical pathologic features but did not overexpress the cyclin D1 mRNA or protein. However, they had other diagnostic, morphologic, and immunophenotype features of MCL as well as a characteristic MCL GEP. These cases expressed high levels of cyclin D2 or D3, perhaps as an alternative molecular mechanism of pathogenesis (Fu et al., 2005).

BURKITT LYMPHOMA

BL is a type of B-cell NHL which is thought to originate from germinal center centroblasts. Classically, the malignant cells are medium-sized, round, and uniform with frequent mitotic figures and frequent apoptosis. The apoptotic cells and necrotic debris are often engulfed by macrophages resulting in the characteristic "starry sky" effect. By immunophenotyping, the cells strongly

express B-cell antigens, show light chain restriction, and have markers of germinal center differentiation including CD10 and BCL-6 as well as high proliferation (Ki-67 antigen expression approaching 100%). BCL-2, found in many DLBCL, is typically negative. Genetically, BL is defined by a translocation between the *c-myc* oncogene and either the immunoglobulin heavy chain gene or one of the light chain genes. This translocation results in over expression of c-myc and dysregulated cell cycle. BL is a relatively common lymphoma in children, but much rarer in adults. BL is associated with EBV infection, particularly in the endemic form, which is found in children in Africa. Sporadic BL is less often associated with EBV and more common in adults. BL also occurs in immunocompromised patients (Jaffe et al., 2001). Because of the extremely high proliferation rate, BL is exquisitely sensitive to chemotherapy using cell-cycle specific drugs. Intensive chemotherapy regimens can be curative, but are also difficult to tolerate, particularly for adults. Thus, the clinical distinction between BL and DLBCL, which is more common and receives a less intensive chemotherapy regimen, is critical. Currently, diagnosis is based on a combination of morphologic and immunophenotypic features along with evidence of the characteristic c-myc translocation. Atypical Burkitt cases or "Burkitt-like" cases have also been recognized that have most features of BL but with cytologic features outside what is typically encountered (Jaffe et al., 2001). Cases with otherwise typical DLBCL morphology can also harbor the c-myc translocation. Cases with overlapping features are not infrequent, particularly in adult patients, a situation that can lead to a difficult diagnostic dilemma with significant clinical consequences.

Diagnosis

Because of the real-world difficulty in accurately diagnosing BL, two research groups independently pursued definition of a characteristic GEP pattern for classic BL as compared to DLBCL. Their results were published simultaneously in the same journal (Dave et al., 2006; Hummel et al., 2006). The first paper was published by the LLMPP group using Affymetrix's U133A + B chips. Their analysis of 303 cases of aggressive B-cell lymphomas clearly identified a characteristic gene expression signature associated with classic BL cases as diagnosed by a panel of expert hematopathologists with morphology, immunophenotyping, and FISH for the c-myc translocation. In addition, they found discrepant cases with either the clinicopathologic diagnosis of BL and GEP of DLBCL or the reverse, a clinicopathologic diagnosis of DLBCL or high grade DLBCL, but with the GEP signature of BL. Of interest, they found that cases with the BL GEP signature most likely benefited from more intensive chemotherapy regimens, regardless of the clinicopathologic classification. The genes that were highly expressed in BL included a subset of GCB-cell associated genes and targets of c-myc, while there was diminished expression of NF-kappa-B targets and MHC class I genes. The second study used Affymetrix U133A chips to study 220 aggressive B-cell lymphomas to develop a GEP signature for the disease. FISH and CGH studies were also performed. They defined a GEP signature for BL which was predominantly associated with Ig-c-myc rearrangement and low chromosomal complexity score. Other cases without the characteristic signature (mainly DLBCL) were usually without c-myc rearrangment. Intermediate cases with a mixture of features were also identified. Both of these papers examined large numbers of cases and arrived at very similar conclusions: BL is a molecularly definable group of lymphoma that can be characterized by GEP and translocation status, that the classic pathologic diagnostic approach can be enhanced with the addition of GEP information, and that intermediate cases with features of both DLBCL and BL do occur. This latter group of cases will require further study to define exact categories and implications for therapy. It was anticipated by both groups that the GEP definition of BL in some form will be taken forward and applied to clinical research and practice.

2009 UPDATE

Additional gene expression studies on peripheral T-cell lymphomas (PTCL) have been reported recently, aimed at defining the underlying mechanisms of disease (de Leval et al., 2007; Lamant et al., 2007; Piccaluga et al., 2007a, b). While the number of cases in these studies is still quite limited, there are some interesting findings, including the possible derivation of angioimmunoblastic T-cell lymphoma from T-follicular helper cells (de Leval et al., 2007; Piccaluga et al., 2007a).

There has been speculation that the originally described prognosticator for DLBCL may not hold with the addition of rituximab to the treatment regimen. A recent study provided evidence that the cell of origin classification is still predictive of survival and, in addition, the stromal signature is also highly significant (Lenz et al., 2008b). Other global investigations such as microRNA profiling (Lu et al., 2005; Zhang et al., 2006), CGH including high resolution array CGH (Bea et al., 2005; Kimm et al., 2007; Lenz et al., 2008; Salaverria et al., 2007), methylation studies (Pike et al., 2008), and mutation analysis (McLendon, 2008; Shendure and Ji, 2008; Wood et al., 2007) are being pursued, and all this information can be integrated to give a better understanding of the pathogenesis and evolution of hematologic malignancies. Interesting examples include the activation of the NF-kB pathway by recently discovered mutations affecting *CARD11* and *TNFAIP3* (Lenz et al., 2008a; Pasqualucci et al., 2008), which partially account for the frequent upregulation of the NF-kB pathway in the ABC-type of DLBCL.

It is uncertain how this information will be utilized in the clinical setting and with which platform. A diagnostic

array may be constructed for hematologic malignancies. Alternatively, useful information from GEP can be condensed and represented by a much smaller number of transcripts and adapted for quantitative RT-PCR (Malumbres et al., 2008) or immunohistochemistry (Hans et al., 2004) that can be applied to the study of paraffin embedded materials. It is also not clear if a single diagnostic platform can be designed that will incorporate important findings from multiple sources (e.g., GEP, aCGH, methylation, mutation) or whether several assays will have to be used to capture all relevant information. However, it is likely that some form of diagnostic assay for hematologic malignancies based on these global analyses will emerge in the next few years to provide additional relevant molecular information for clinical use.

CHAPTER

Genomics in Leukemias

Lars Bullinger, Hartmut Dohner and Jonathan R. Pollack

INTRODUCTION

Recently, our understanding of the hematopoietic system has expanded dramatically, revealing leukemias to exhibit an extraordinary biologic and clinical heterogeneity. While the broad classification of leukemias is still based on the cell of origin (e.g. myeloid or lymphoid) and the rapidity of the clinical course (e.g., acute or chronic), over the past several years efforts have been made to characterize additional biologically and clinically relevant leukemia entities. At the end of the 1990's, the World Health Organization (WHO) summarized consensus practices to formulate a revised classification of tumors of hematopoietic and lymphoid tissues (summarized in Table 33.1) (Harris et al., 1999). This classification, for example, divides acute myeloid leukemias (AML) into four large subclasses (AML with recurrent cytogenetic abnormalities, with multilineage dysplasia, therapy related, and not otherwise categorized), which are further subdivided into distinct AML subtypes. However, for many leukemia classes the genetic or pathogenic events are still unknown, and within well-defined leukemia subgroups, like AML cases with a t(8;21) or an inv(16), considerable clinical heterogeneity is observed (Schlenk et al., 2004). Thus, there is a need for a refined classification based on an improved understanding of the molecular mechanisms leading to leukemia.

Leukemia Cytogenetics and Molecular Genetics

Leukemias have a long tradition of being "first", with chronic myelogenous leukemia (CML) being the first malignancy in which a recurring chromosomal abnormality, the Philadelphia chromosome, was found to result from a translocation of genetic material from one chromosome to another (Rowley, 1973). The fusion gene resulting from this translocation t(9;22), *BCR-ABL*, was then shown to be responsible for the myeloproliferation observed in CML (Konopka et al., 1985; Shtivelman et al., 1985). Representing still the gold standard for the investigation of aberrations in leukemias, chromosome banding analyses have since led to the discovery of well over 100 chromosome translocations and the identification of a number of recurring chromosomal gains and losses in leukemic cells, thereby transforming our understanding of the genetic mechanisms involved in leukemogenesis.

At the molecular level, many of these chromosomal translocations result in the deregulated expression of oncogenes like e.g. *MYC* in acute lymphoblastic leukemia (ALL). Alternatively, translocations can result in the creation of chimeric fusion proteins, many of which alter transcriptional programs to block cell differentiation. For example, in AML, t(8;21) and inv(16) create the *AML1-ETO* and *CBFB-MYH11* fusions, respectively, both of which deregulate the activity of the transcription factor complex Core Binding Factor (CBF), altering the expression of genes and disrupting cell differentiation (Frohling et al., 2005; Licht and Sternberg, 2005).

Nevertheless, while many such aberrations like e.g. t(8;21) or inv(16) can block the differentiation of myeloid cells, they are not by themselves sufficient to cause a myeloid leukemia. On the other hand, it has been shown that constitutively activated signaling molecules, such as FLT3 or RAS family members, can induce the complementary myeloproliferative phenotype. Today,

Table 33.1 WHO Classification of Tumors of Hematopoietic and Lymphoid Tissues – Leukemias

	"Acute" clinical course	"Chronic" clinical course
Myeloid Origin	**AML with recurrent genetic abnormalities**	**Myeloproliferative diseases**
	AML with t(8;21)(q22;q22), (*AML1/ETO*)	Chronic myelomonocytic leukemia
	AML with inv(16)(p13q22), (*CBFβ/MYH11*)	Atypical chronic myeloid leukemia
	AML with t(15;17)(q22;q12), (*PML/RARα*)	Juvenile myelomonocytic leukemia etc.
	AML with 11q23 (*MLL*) abnormalities	
	AML with multilineage dysplasia	**Chronic myeloproliferative diseases**
	AML, therapy related	CML with t(9;22)(q34;q11), (*BCR/ABL*)
	AML not otherwise categorized	Chronic neutrophilic leukemia
		Chronic eosinophilic leukemia, etc.
Lymphoid Origin	**Precursor B-cell neoplasms**	**Mature B-cell neoplasms**
	Precursor B-ALL	CLL
	Burkitt leukemia	B-cell prolymphocytic leukemia
		Hairy cell leukemia etc.
	Precursor T-cell neoplasms	**Mature T-cell neoplasms**
	Precursor T-ALL	T-cell prolymphocytic leukemia
		T-cell granular lymphocytic leukemia, etc.

Table 33.2 Cytogenetic and Molecular Aberrations in AML

Risk category[a]	Cytogenetic findings [Genes involved]	Associated molecular abnormalities
Favorable	t(8;21)(q22;q23) [*ETO, AML1/RUNX1*]	*KIT* mutations (Exon 8 and 17, codon 816)
		CEBPA downregulation
	inv(16) (q13q22)/t(16;16) [*MYH11, CBFB*]	*KIT* mutations (Exon 8 and 17, codon 816)
		NRAS and *KRAS* mutations
		CEBPA downregulation
	del(9q)	*CEBPA* mutation
	t(15;17) (q22;q11∼q21) [*PML, RARA*][b]	*FLT3* ITD and *FLT3* activating loop mutation
Intermediate	Normal karyotype	*MLL* PTD
		FLT3 ITD and *FLT3* activating loop mutation
		CEBPA mutation
		NPM1 mutation
		BAALC over expression
	Trisomy 21	*RUNX1* mutation
	Trisomy 11	*MLL* PTD
Unfavorable	t(6;9)(p23;q34) [*DEK, CAN*]	*FLT3* ITD
	complex karyotype (3 or more aberrations)	*TP53* mutation

[a] Risk categories for overall survival according to the CALGB (Cancer and Leukemia Group B).

[b] Not included in the CALGB study, but favorable risk category in other studies.

there are further lines of evidence implicating a multistep leukemogenesis, and based on advances in molecular genetics many pathogenetically relevant mutations have been identified both in myeloid (Table 33.2) (Frohling et al., 2005; Licht and Sternberg, 2005) and lymphoid (Armstrong and Look, 2005; Pui and Evans, 2006) leukemias.

Leukemia Treatment

Regarding leukemias' tradition of being "first", acute promyelocytic leukemia (APL) was one of the first malignancies to be successfully treated with a molecularly targeted therapy, all-trans retinoic acid (ATRA). ATRA specifically targets the transforming potential of the fusion gene product, PML-RARA, that results from a t(15;17), which is commonly detected in APL. Likewise, CML was the first disorder in which a small molecule inhibitor had been designed to specifically target the disease-causing underlying molecular defect, the BCR-ABL fusion protein. Since then, additional novel drugs have been shown to be effective in leukemias, including numerous tyrosine kinase inhibitors (e.g. FLT3 inhibitors like PKC412), farnesyltransferase inhibitors (e.g. tipifarnib), demethylating agents (e.g. decitabine), histone deacetylase inhibitors (e.g. valproic acid), and monoclonal

antibodies (e.g. the anti-CD33 antibody gemtuzumab ozogamicin) (Tallman, 2005). While these agents are currently being investigated within clinical treatment trials, the combination therapies of cytotoxic drugs with or without stem-cell transplantation are still the gold standard and have increased the cure rate of leukemia, especially in childhood acute lymphoblastic leukemia (ALL) with an overall cure rate of over 80% (Pui and Evans, 2006). However, cure rates for adults remain much lower, thereby signaling the need for treatment approaches incorporating the above mentioned novel targeted therapies. This should be based on an improved risk stratification that reflects the biological and clinical heterogeneity of leukemias in order to guide efficient patient management.

Prognostic Factors in Leukemias

In AML, patients are assigned to risk-groups based on the underlying leukemia karyotype (Byrd et al., 2002; Grimwade et al., 1998; Slovak et al., 2000), which represents one of the most powerful prognostic factors in this disease (Table 33.3). However, the identification of novel molecular markers has recently permitted to further dissect existing prognostic leukemia subclasses, like for example the large group of AML patients presenting with normal karyotype disease (Frohling et al., 2005; Licht and Sternberg, 2005). Internal tandem duplications (ITD) of the *FLT3* gene, partial tandem duplications (PTD) of the *MLL* gene, as well as mutations of *CEBPA* and *NPM1* are of prognostic relevance in this AML subgroup, as is the expression level of *BAALC*. In chronic lymphoid leukemias (CLL), cytogenetic aberrations also provide prognostic information in addition to the immunoglobulin variable heavy chain gene (V_H) mutational status (Seiler et al., 2006). Nevertheless, despite this recent progress there is still no commonly accepted risk stratification for many leukemia subtypes as the mechanisms of leukemogenesis are not yet fully understood.

GENOMICS IN LEUKEMIAS: INSIGHTS INTO LEUKEMIA BIOLOGY

Genomics-Based Class Prediction in Leukemias

Over the past several years, genomics methods have offered a range of experimental approaches to capture the molecular variation underlying the biological and clinical heterogeneity of

leukemias. Since genome-wide gene expression profiling (GEP) based on DNA microarrays represents one of the most powerful genomics tools, we will mainly focus on the impact of this technology on leukemia management, especially as it was the leukemias in which the utility and promise of GEP was first demonstrated. By analyzing AML and ALL samples, Golub *et al.*, were able to distinguish AML and ALL without previous knowledge of these leukemia classes, and, by developing a supervised class predictor, new leukemia cases could be accurately assigned to one of these two leukemia classes (Golub et al., 1999).

Since then, DNA microarray technology has already contributed significantly to the field of leukemia research (Ebert and Golub, 2004; Staudt, 2003), including the identification of a general gene dosage effect for the expression of genes located in areas of chromosomal gains and losses (Haslinger et al., 2004; Rucker et al., 2006). Based on supervised analytical approaches, in childhood ALL distinct expression profiles were identified to correlate with prognostically important leukemia subtypes like e.g. T-ALL, *E2A-PBX1*, *BCR-ABL*, *TEL-AML1*, *MLL* rearrangement, and ALL with a hyperdiploid karyotype (>50 chromosomes) (Yeoh et al., 2002), and these findings have since been confirmed in other studies of both childhood and adult ALL (Armstrong et al., 2002; Ross et al., 2003). In AML, a gene expression-based discrimination of the cytogenetically defined subgroups inv(16), t(8;21), t(15;17) and t(11q23)/*MLL* could also be demonstrated (Bullinger et al., 2004; Ross et al., 2004; Valk et al., 2004) (Figure 33.1). Notably, in acute leukemia the same classifiers have been shown to apply to both pediatric and adult leukemia cases exhibiting identical genetic aberrations (Kohlmann et al., 2004; Ross et al., 2004), and it has been demonstrated that the respective signatures are quite robust (Kohlmann et al., 2005; Mitchell et al., 2004). Thus, gene expression profiling may provide a useful alternative approach to classify known leukemia subgroups with high accuracy (Haferlach et al., 2005).

Likewise, gene expression patterns associated with molecular genetic aberrations like the V_H mutational status in CLL have been demonstrated and led to the identification ZAP-70 (Rosenwald et al., 2001), which is now used as surrogate marker for the V_H mutational status. In AML gene expression patterns associated with e.g. *FLT3* ITD (Bullinger et al., 2004; Valk et al., 2004), *CEBPA* (Valk et al., 2004), and *NPM1* mutations (Alcalay et al., 2005) have been described. However, in contrast to translocations involving the *MLL* gene (Armstrong et al., 2002), no characteristic pattern has been identified for cases with *MLL* PTD (Bullinger et al., 2004; Ross et al., 2004), thereby suggesting that cases with *MLL* PTD might be more heterogeneous at a molecular level and that not all genetic alterations in leukemia result in definably altered gene expression patterns.

Genomics-Based Class Discovery in Leukemias

By analyzing 285 AML with unsupervised analytical approaches Valk et al., identified sixteen AML subgroups that included novel prognostically-relevant subtypes of leukemia (Valk et al., 2004). While cases with favorable cytogenetics generally exhibited "homogeneous clustering", novel clusters were often characterized by specific molecular alterations, like for example MLL abnormalities or increased *EVI1* expression. On the other hand, "homogenously grouped" classes, like cases with an inv(16) or a t(8;21), were also characterized by molecular variation depending on the probe sets included in the analysis (Valk et al., 2004). Using a different unsupervised clustering approach this molecular heterogeneity within t(8;21) and inv(16) cases was also observed in a separate study (Bullinger et al., 2004), thereby suggesting that distinct patterns of gene expression within the t(8;21) and inv(16) subgroups reflect alternative cooperating events leading to transformation.

Interestingly, in this study, cases with normal karyotype also segregated mainly into two distinct groups (Figure 33.2), each of which included a small number of cases from other cytogenetic classes (Bullinger et al., 2004). While *FLT3* aberrations were more highly represented in one subgroup, FAB (French American British) M4/M5 morphologic subtypes were more prevalent in the other subgroup, and Kaplan-Meier analysis identified a statistically significant difference in overall survival between the two subclasses (Bullinger et al., 2004). In agreement, Valk and colleagues also identified normal karyotype-predominated clusters associated with *FLT3* ITD, as well as a cluster including mainly specimens from AML patients whose blasts displayed FAB M4 or M5 morphology (Valk et al., 2004).

GENOMICS IN LEUKEMIAS: EVALUATION OF DRUG EFFECTS

Molecular Signatures of Anti-Leukemic Drugs

Leukemia was again one of the first diseases in which DNA microarray technology was applied for monitoring drug effects by analyzing the effect of all-trans retinoic acid (ATRA) treatment in APL-derived cell lines (Tamayo et al., 1999). These analyses showed that ATRA-regulated genes included members of the tumor necrosis factor (TNF) pathway, suggesting that this pathway might intersect with ATRA signaling and play a role in regulating cell survival in response to ATRA. GEP has also been successfully used to evaluate the sensitivity of CML to imatinib mesylate (Tipping et al., 2003), which targets the ABL kinase activity of the BCR-ABL fusion. Using a cell line model, differentially-expressed genes correlated with imatinib mesylate resistance could be identified, suggesting that alternative pathways maintain viability and promote growth independently of BCR-ABL.

Similarly, Rosenwald et al., have recently investigated the molecular consequences of fludarabine treatment of CLL patient samples using GEP (Rosenwald et al., 2004). Both *in vitro* and *in vivo* exposure to fludarabine, a purine analog currently used in standard CLL treatment regimens, resulted in a consistent "response signature" characterized by p53 target genes and genes involved in DNA repair, thus, providing a molecular explanation for the drug resistance and aggressive clinical course often seen in p53-mutated CLL patients. This analysis further suggested

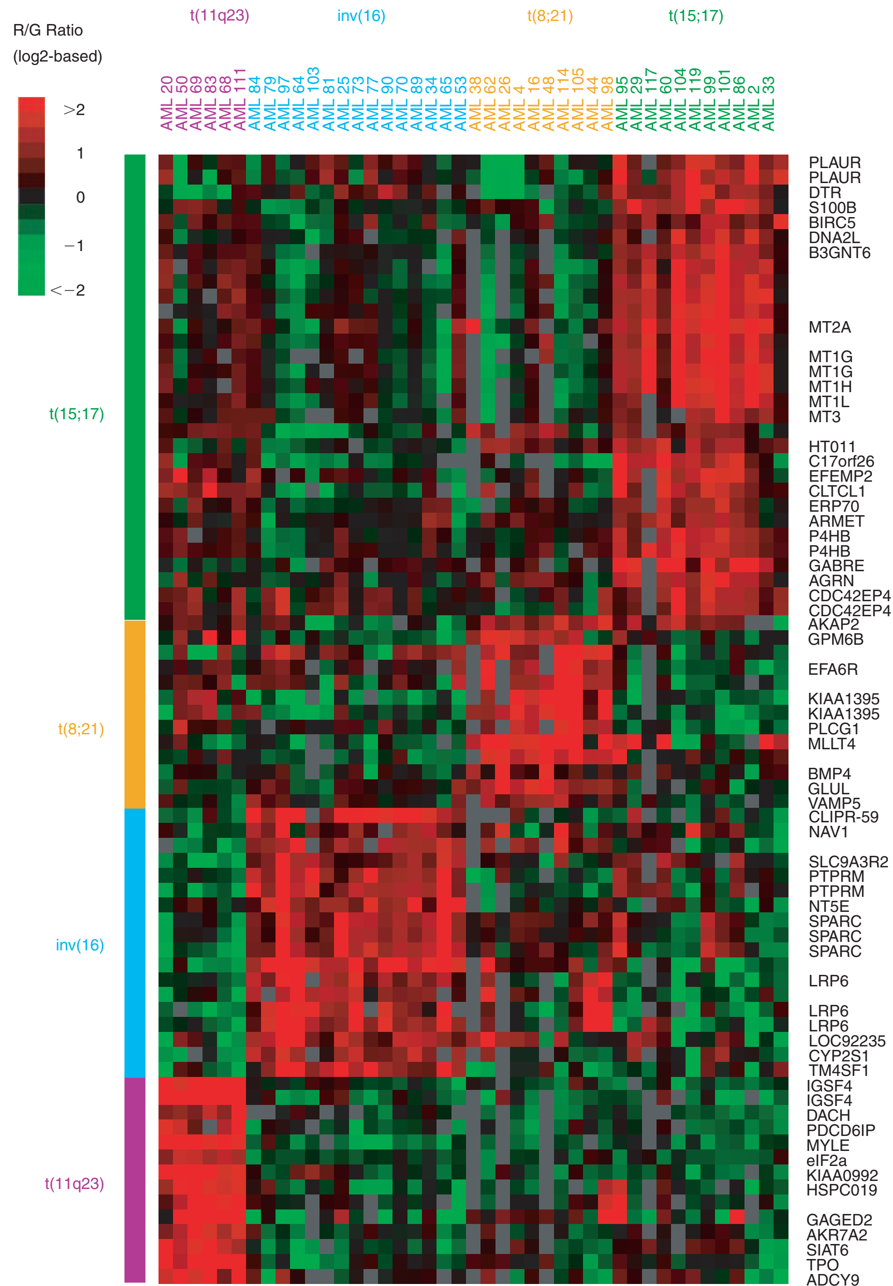

Figure 33.1 Gene expression signatures of leukemia cytogenetic classes. Shown is a “heat map” representation of selected genes identified by supervised analysis whose expression is significantly correlated with specific AML cytogenetic aberrations, like t(11q23), inv(16), t(8;21), and t(15;17). Gene-expression levels are depicted in a pseudo color scale as indicated (red indicates higher expression levels). The analysis shown was performed using publicly available microarray data that were based on a supervised analysis (Bullinger et al., 2004). Gene-expression signatures such as these can be used to classify the cytogenetic group of new specimens with high accuracy. AML 64 was initially characterized as “normal karyotype” by cytogenetic banding analysis, but for which RT-PCR subsequently identified the diagnostic *CBFB-MYH11* fusion transcript characteristic of inv(16) cases.

the importance of only treating patients that warrant therapy, as fludarabine treatment might select for p53 mutant CLL cells (Rosenwald et al., 2004). Another recent study sought to provide a better molecular understanding of resistance to L-asparaginase, an important component of most treatment regimens for ALL. *In vitro* exposure to L-asparaginase in cell lines and pediatric ALL samples followed by gene expression profiling revealed changes that reflect a consistent coordinated response to asparagine starvation, which is independent of asparagine synthetase base-line expression levels (Fine et al., 2005). Thus, targeting

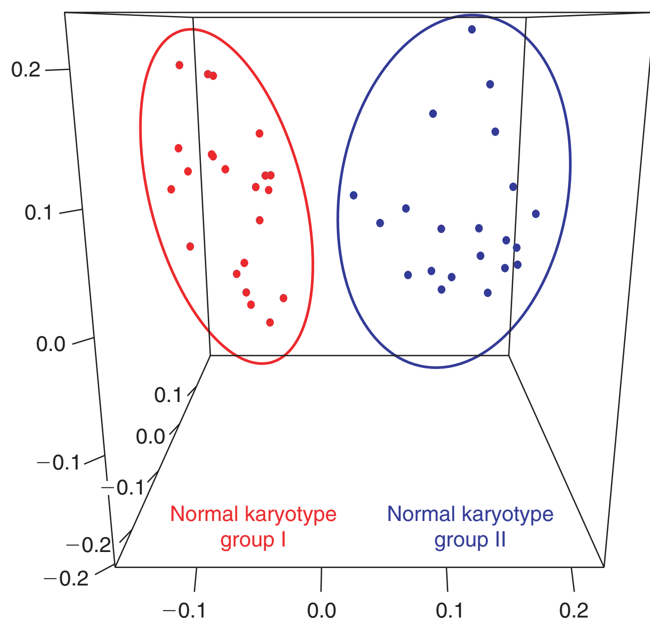

Figure 33.2 Discovery of new molecular subtypes of leukemia. Shown are the results of an unsupervised principal components analysis (PCA) displaying a projection of the first three principal components of variable gene expression for AML specimens with normal karyotype. Based on distinct patterns of genes expression, PCA identifies two novel subgroups of normal karyotype AML cases (indicated by red and blue dots, respectively). Group II cases exhibit more frequent myelomonocytic differentiation, while group I cases more often harbor *FLT3* mutations and are associated with shorter overall survival. Data are from Bullinger et al. (2004).

particular "amino acid starvation response" genes might provide a novel way to overcome L-asparaginase resistance of ALL cells.

Drug Response Prediction in Leukemia

To determine whether the cellular responses provoked by chemotherapeutic agents can be predicted, Cheok and colleagues profiled gene expression in childhood ALL cells before and after *in vivo* treatment with methotrexate and mercaptopurine, given either alone or in combination (Cheok et al., 2003). A gene expression pattern consisting of 124 genes, which included genes involved in apoptosis, mismatch repair, cell cycle control and stress response, accurately discriminated among the assigned treatments. Notably, this signature showed differences in cellular response to drug combinations versus single agents and indicated that common pathways of genomic response to the same treatment are shared by different ALL subtypes. Testing for *in vitro* sensitivity to prednisolone, vincristine, asparaginase, and daunorubicin, the identification of differentially expressed genes in drug-sensitive and drug-resistant ALL leukemia cells allowed the creation of a combined gene-expression score of resistance, which was shown to be of prognostic relevance in childhood ALL (Holleman et al., 2004).

Discovery of Novel Anti-Leukemic Drugs

Today, genomics approaches including DNA microarray technology play an important part in the drug target discovery process, not only by providing a valuable tool for the optimization and clinical validation of novel compounds. While at the beginning of the process GEP allows the identification and prioritization of potential therapeutic targets, subsequent expression profiling assists in drug discovery and toxicology. Then, various bioinformatics approaches are used to deduce from expression profiles the mechanism of action of new drugs as well as off-target effects. However, it is important to keep in mind the limitations of evaluating drug responses through measurements of mRNA abundance alone. Nevertheless, GEP provides a powerful tool in pharmacogenomics that promises an improved prediction of prognosis and drug response (Walgren et al., 2005).

In a recent example of the utility of GEP in drug discovery, a GEP-based high-throughput screening approach was applied to screen for chemical compounds with differentiation-inducing activity in leukemia (Stegmaier et al., 2004). Following definition and validation of a microarray-based differentiation signature, a high throughput screening method was designed to detect the respective gene pattern. Using this approach, treatment of a leukemia cell line with 1,739 different compounds revealed eight chemicals that reliably induced the differentiation signature (Stegmaier et al., 2004). Interestingly, one of these compounds inhibited epidermal growth factor receptor (EGFR) kinase activity, and the authors could show in a subsequent study that the Food and Drug Administration (FDA)–approved EGFR inhibitor gefitinib similarly promoted the differentiation of AML cell lines and primary patient–derived AML blasts *in vitro* (Stegmaier et al., 2005). Notably, the analyzed AML cells did not express EGFR, indicating an EGFR-independent mechanism of gefitinib induced differentiation in AML, thereby suggesting the presence of additional yet unknown key targets.

GENOMICS IN LEUKEMIAS: CLINICAL OUTCOME PREDICTION

Identification of Novel Surrogate Markers in Leukemia

Many groups have now demonstrated that GEP allows the identification of specific signatures correlated with and the subsequent prediction of known "favorable-risk" cytogenetic aberrations in both AML like e.g. cases with inv(16), t(8;21), or t(15;17) (Bullinger et al., 2004; Haferlach et al., 2005; Valk et al., 2004), and in ALL like e.g. cases with t(12;21) or hyperdiploidy (more than 50 chromosomes per leukemia cell) (Yeoh et al., 2002). Similarly, "unfavorable-risk" cytogenetics subgroups can be predicted, as well as prognostically relevant molecular genetic aberrations (Bullinger and Valk, 2005). Such analyses led to the identification of novel surrogate markers among which ZAP-70 represents the first to be clinically implemented. Coding for a

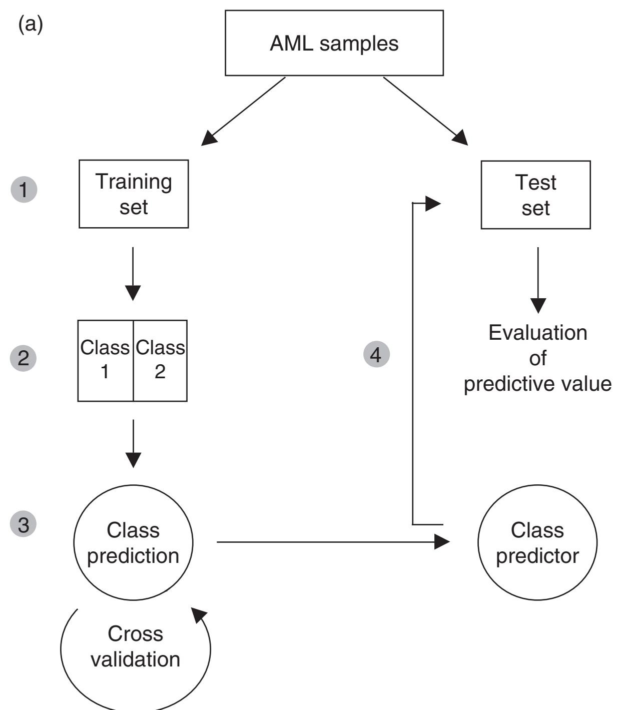
tyrosine kinase essential for T cell signaling, *ZAP-70* exhibited five-fold higher expression levels in patients with unmutated V_H genes compared to those in which the B cell clone had undergone the rearrangement of the immunoglobulin heavy-chain variable region (Rosenwald et al., 2001). The clinical usefulness of this novel marker, which can be readily measured at the protein level by flow cytometry, has recently been validated (Orchard et al., 2004).

Furthermore, GEP-based prediction of leukemias sensitive or resistant to chemotherapeutic agents can provide significant information regarding treatment outcome in leukemias. The fact that initial findings could be confirmed in independent sets of patients in ALL (Holleman et al., 2004; Lugthart et al., 2005) and AML (Heuser et al., 2005) suggests the feasibility of an improved treatment management in leukemias based on GEP. Furthermore, expression profiling might be used to predict leukemia cases with minimal residual disease (MRD) following treatment at high accuracy. Based on the hypothesis that this treatment resistance is reflected by an intrinsic feature of leukemia cells at the time of diagnosis, a prognostic signature predicting the MRD load following therapy could be defined (Cario et al., 2005).

Identification of Novel Prognostic Markers and Signatures in Leukemias

Using supervised approaches, many groups have tried to generate signatures correlated with good and poor outcome. However, in contrast to signatures correlated with resistance to chemotherapy, in our experience supervised signatures predictive of good and poor outcome have generally not been validated in independent data sets. This might be secondary to the limitation of strictly supervised approaches in outcome prediction as survival and survival time are impacted by many things other then the tumor cells themselves, and thus are likely to be very noisy surrogates for the underlying prognostically relevant tumor subclasses. In order to discover gene-expression signatures with prognostic value in addition to signatures correlated with cytogenetics, novel semi-supervised strategies combining the strengths of supervised and unsupervised approaches might be helpful in leukemia research (Bair and Tibshirani, 2004).

Semi-supervised approaches use the subset of genes correlating with survival time for supervised clustering (or supervised principal components analysis) of specimens to reveal the underlying prognostically relevant tumor subtypes, and then to build a predictor for these subtypes (Figure 33.3). Applying this approach to a cohort of AML patients, a 133 gene signature could be defined and validated as a significant independent outcome predictor, both across all cytogenetic classes and within the large subset of clinically-important AML cases with normal karyotype (Bullinger et al., 2004). Recently, this signature has been validated by applying it to an independent set of AML cases with normal karyotype (Marcucci et al., 2006). While these findings are definitely encouraging, further validation of results in larger cohorts and in independent studies are required before clinical implementation becomes feasible in leukemias.



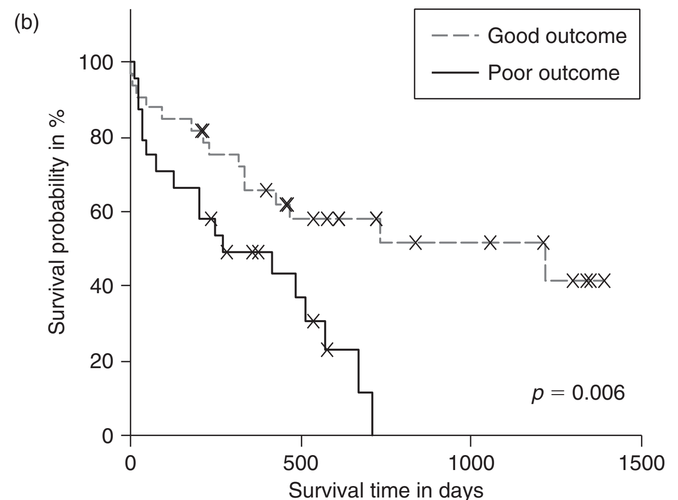


Figure 33.3 Semi-supervised approach for leukemia outcome prediction. (a) Schematic overview of a supervised clustering strategy. (1) AML specimens are randomized into separate training and test sets. (2) In the training set, genes whose expression correlates with survival are used to cluster samples into favorable and unfavorable outcome classes. (3) An optimal gene expression predictor is constructed for these outcome classes. (4) The outcome class predictor is then validated by predicting outcomes in the independent test set. (b) Evaluation of outcome predictor. Kaplan-Meier survival analysis of the independent test set validates the gene expression classifier (here comprising 133 genes) as a significant predictor of overall survival. Data are from Bullinger et al. (2004).

2009 UPDATE

During the last decade, microarray-based genomic approaches have contributed significantly to leukemia research, as demonstrated by microarray-based GEP findings in AML (Baldus and Bullinger, 2008; Wouters et al., 2009). Since its invention, GEP has contributed an important new facet to the exploration of hematologic malignancies; recent studies have confirmed its impact in leukemia classification (Verhaak et al., 2009) and have provided evidence that GEP might improve classification with regard to clinical importance (Bullinger et al., 2008). Furthermore, in AML, GEP-based class discovery approaches have identified novel core binding factor leukemia subgroups (Bullinger et al., 2007) and CEBPA mutated/silenced subgroups (Wouters et al., 2007). Finally, advances in prediction of treatment response to the farnesyltransferase inhibitor tipifarnib (Raponi et al., 2008) or the immunomodulatory drug lenalidomide (Ebert et al., 2008), as well as advances in outcome prediction (Metzeler et al., 2008), point to a potential usefulness of GEP-based molecular leukemia classification in the future. Increasingly, microarray assays will be applied to adequately diagnose leukemias, predict their course, and guide individualized treatment approaches.

Recently, novel molecular subgroups have been identified both in cytogenetically normal leukemia cases (Schlenk et al., 2008) and in leukemia subtypes characterized by distinct cytogenetic aberrations (Dohner and Dohner, 2008). However, first array CGH-based studies dissecting the genomic heterogeneity of leukemia by parallel analysis of global gene expression changes and copy number alterations (CNAs) provided not only useful information regarding novel leukemia relevant candidate (Rucker et al., 2006) but also suggested that genomic aberrations associated with leukemogenesis are likely to be far more complex than initially anticipated. Novel genome-wide single nucleotide polymorphism microarray-based analyses (SNP array) have not only revealed large-scale cryptic regions of acquired homozygosity in form of segmental uniparental disomy (Fitzgibbon et al., 2005; Gupta et al., 2008) but also submicroscopic CNAs and numerous germline copy number variations (CNVs) (Maciejewski and Mufti, 2008). For example, in ALL, a genome-wide analysis of leukemic cells using high-resolution SNP arrays and genomic DNA sequencing revealed deletion, amplification, point mutation and structural rearrangement in genes involved in B-cell development, and differentiation in B-progenitor ALL cases (Mullighan et al., 2007). Besides the *PAX5* gene, which was the most frequent target of somatic mutation being altered in almost one-third of cases (Mullighan et al., 2007), *IKZF1* (encoding the transcription factor Ikaros) was deleted in over 80% of *BCR/ABL1* positive ALL cases (Mullighan et al., 2008). *IKZF1* deletions resulted either in the expression of a dominant-negative Ikaros isoform or the complete loss of Ikaros expression, thereby suggesting that genetic lesions resulting in the loss of Ikaros function are an important event in the development of *BCR/ABL1* ALL (Mullighan et al., 2008). Thus, these data demonstrate the power of high-resolution, genome-wide SNP array approaches to identify new molecular lesions in leukemia.

In addition to genome-wide profiling for genomic aberrations, recent progress in profiling the expression of microRNAs (miRNAs), small nonprotein coding RNAs that play a crucial role in the transcriptional and posttranscriptional regulation of genes (Calin and Croce 2006), shed further light on the molecular heterogeneity of leukemias (Jongen-Lavrencic et al., 2008; Lu et al., 2005). Interestingly, distinct miRNA signatures might also be associated with outcome in both chronic (Calin et al., 2005) as well as acute leukemia (Marcucci et al., 2008). Next, microarrays also offer the possibility to screen for global epigenetic changes in leukemias (Esteller, 2007), and recent studies have already successfully demonstrated the power of this technology in investigating acute leukemia biology (Gebhard et al., 2006; Taylor et al., 2007). Furthermore, novel advances such as high-throughput sequencing technology that enable the timely sequence analysis of an entire genome might reveal novel leukemia-relevant gene aberrations, as suggested by the recent publication of an entire AML genome (Ley et al., 2008).

In the future, integrative analyses of high-dimensional genomics datasets, like SNP array and sequencing data, global transcriptome and epigenome information, as well as proteomics data (Kornblau et al., 2009), will allow the extraction of additional biological insights into leukemia pathogenesis. However, a prerequisite for a successful detection of leukemia relevant aberration will rely on additional functional analyses that possess the power to distinguish between driver and passenger aberrations in leukemia cells (Frohling et al., 2007).

CHAPTER

Genomics in the Diagnosis and Management of Lung Cancer

Hasmeena Kathuria, Avrum Spira and Jerome Brody

INTRODUCTION

In the early 1900s, lung cancer was a rare disease; today it is the most common cause of cancer death in the United States and in the world. Worldwide in 2006, there will be >1.2 million lung cancer deaths. In the United States alone, there will be 174,000 new cases of lung cancer in 2006, with 162,000 deaths, accounting for 31% of all cancer deaths in men and 26% of all cancer deaths in women. The incidence of lung cancer tracks, with a 30–40 year lag, the frequency of cigarette smoking in a population. Smoking incidence and lung cancer rates are similar to the United States in Western Europe, but are 30% higher in Eastern Europe and in China where 70% of men smoke, and an epidemic of lung cancer is predicted in the mid-21st century.

The fact that only 10–15% of smokers develop lung cancer suggests there are genetic factors that influence individual susceptibility to the carcinogenic effects of cigarette smoke. However, the late age at which lung cancer usually develops limits traditional genetic studies, since parents and siblings are not often available to study. Unfortunately, survival rates for newly diagnosed lung cancer remain at ~15%, virtually unchanged in the past 4–5 decades, largely because the disease is most often diagnosed at an advanced stage and there is presently no way to determine which of the 10–15% of current and former smokers are at highest risk for developing lung cancer.

This chapter summarizes the progress that has been made in understanding the molecular mechanisms and pathogenesis of lung cancer and attempts to describe how gene expression profiling on human lung cancer, airway, and peripheral blood specimens is leading to new approaches in lung cancer screening, classification, diagnosis, prognosis, and treatment. This review focuses mainly on the genomic studies of lung cancer, including a brief discussion on the findings of methylation and microRNA (miRNA) arrays in lung tumorigenesis. Studies using single nucleotide polymorphism (SNP) and protein arrays are beyond the scope of this review, as are studies of *in vitro* cell lines and mouse models. Although we have attempted to be as inclusive as possible, our list of studies reviewed is likely to be incomplete.

The section on "Early Diagnosis/Screening of Lung Cancer" provides a brief overview of the hereditary factors that may explain susceptibility to the carcinogenic effects of smoking and describes the polymorphisms in genes involved in the metabolism of the toxic components of cigarette smoke. This section also summarizes the current studies that use genomic profiling to identify the subset of smokers who are at high risk for developing lung cancer and highlights the importance of developing biomarkers and chemoprevention strategies aimed at high-risk current or former smokers. Although this section briefly discusses epigenetic changes that have been associated with smoking, discussions on other genetic changes, including cytogenetic changes and somatic mutations, are beyond the scope of this chapter.

Essentials of Genomic and Personalized Medicine

The section on "Classification and Prognosis" provides a brief overview of the different categories of genes known to be involved in tumorigenesis, including oncogenes, growth factors and their receptors, and tumor suppressor genes. Given the complexity of lung cancer, these tumors are likely dependent on more than one oncogenic signaling pathway. This section sites examples of how genomics has advanced our ability to predict the dysregulation of various oncogenic pathways in lung cancer (both the mutated gene product itself and its downstream targets), thus potentially offering an opportunity for developing new therapeutic drugs that are pathway-specific. This section focuses in some detail on recent advances in understanding epidermal growth factor receptor (EGFR)-mediated survival signals.

The section on "Pathogenesis and Treatment of Lung Cancer" begins by describing the tumor, node, metastases (TNM) tumor classification system. Although tumor staging is currently the most important prognostic variable for predicting survival, some of the limitations of the current system include the fact that patients diagnosed with similar stage and treated using similar protocols, often respond quite differently and have varying survival rates. This section describes how genomic expression profiling of lung cancer has identified prognostic genes and identified subtypes of adenocarcinomas, thus potentially guiding clinical decision-making in the future by identifying "high risk" lung cancer patients that would benefit from improved diagnostic and treatment options.

Gene expression profiling, combined with genetics, clinical information, proteomics, and imaging studies can be applied to developing tools for risk-assessment, early diagnosis, and new approaches for individualized treatment. With stronger working relationships and collaborations between bench scientists and their clinical counterparts and establishment of large databases with standardized methods for data collection and analyses, modern genomic technology promises continued improvement in diagnostic and therapeutic options for lung cancer patients.

EARLY DIAGNOSIS/SCREENING OF LUNG CANCER

Smoking, Lung Cancer, and Genetics

In the late 1920s, it was first suspected that cigarette smoking caused lung cancer, and in the 1950s and 1960s a variety of studies linking lung cancer to cigarette smoking were published. In the 1960s, over 40% of men in the United States smoked until the Surgeon General's report linked smoking to lung cancer. Since then, smoking rates in men have decreased to 20–25% with a subsequent leveling off and then fall in lung cancer incidence in the 1990s. Smoking rates in women, however, began to rise in the 1950s and lung cancer became the leading cause of death from cancer in women in the 1980s (reviewed by Spiro and Silvestri, 2005). By 2030, it is projected that smoking incidence will plateau at 20% of the adult US population in both men and women, ensuring a constant high rate of lung cancer throughout the first half of the 21st century.

There is controversy about whether lung cancer is now occurring more frequently in never-smokers. Environmental tobacco exposure or second-hand smoke may cause lung cancer in life-long non-smokers. There have been reports of lung cancer in large numbers of non-smoking Chinese women who have been exposed to fumes from cooking with charcoal in poorly ventilated dwellings (Luo et al., 1996; Zhou et al., 2000). These observations raise the question of whether lung cancer in other never-smokers might result from a variety of unrecognized toxic exposures especially in genetically susceptible individuals.

We now know that although 80–85% of patients with lung cancer have a history of smoking, only 10–15% of patients who smoke actually develop lung cancer suggesting that hereditary factors may explain susceptibility to the carcinogenic effects of smoking. It is well established that smokers who are first-degree relatives in families with a history of lung cancer have a two- to threefold increased risk of developing lung cancer (Thun et al., 2002). The risk is further increased with a family history of early onset lung cancer. Hereditary occurrence is also suggested since both smokers and non-smokers with a positive family history are at higher risk for developing lung cancer.

Epidemiological studies show that Native American and African American smokers are more susceptible to lung cancer than whites, while Latinos, and Japanese Americans are less susceptible (Haiman et al., 2006). These differences are accentuated in those who have smoked fewer than 10 cigarettes per day and tend to disappear in those who have smoked more than 30 cigarettes per day, suggesting genetically determined carcinogenic susceptibility that is masked at high levels of smoke exposure (Haiman et al., 2006). The reasons for the observed racial/ethnic differences in response to the carcinogenic effects of cigarette smoke are not yet known, but it is likely that both genetic and environmental differences are involved. African Americans, for example, tend to smoke menthol cigarettes or ones with higher levels of nicotine and tar (Okuyemi et al., 2004).

There have been a large number of studies that have attempted to define heritable causes of lung cancer susceptibility. Polymorphic variants in almost 50 genes have been claimed to be associated with either a reduced or elevated risk of lung cancer (reviewed by Cooper, 2005). Early studies focused on polymorphisms in genes involved in the metabolism of the toxic components of cigarette smoke. Most of the compounds in cigarettes are activated by phase I drug metabolizing enzymes (DME), such as cytochrome p450, to become active and carcinogenic. These phase I genes code for substances that convert smoke constituents to highly reactive intermediates that can bind to and mutate DNA. Phase II DMEs, such as *N*-acetyltransferases, sulfotransferases, and glutathianone *S*-transferases, detoxify carcinogenic products by conjugating these reactive species to less reactive, excretable products. While some studies support the importance of polymorphisms in both phase I and II genes, others have found no relation between polymorphisms in these genes and the incidence of lung cancer

(Perera et al., 2006; Raunio et al., 1999; Taioli et al., 2003; Wikman et al., 2001).

It is likely that there are a number of genes, some involved in interacting pathways that account for individual susceptibility to the carcinogenic effects of smoking. Recent studies have described polymorphisms in cell cycle checkpoint genes in African American smokers with lung cancer and in DNA repair genes in smokers both with and without lung cancer (David-Beabes and London, 2001; Wenzlaff et al., 2005). A promoter polymorphism that increases promoter activity in caspase-9, a cysteine protease involved in the caspase-mediated apoptotic pathway, was recently found to contribute to genetic susceptibility in lung cancer (Park et al., 2006). In addition, a number of studies have demonstrated linkage to lung cancer on chromosome 6q23 (Bailey-Wilson et al., 2004) and on chromosome 12q (Sy et al., 2004). Mouse modeling studies have identified similar linkage between lung cancer and chronic obstructive pulmonary disease (COPD), and many of the genes in the area of linkage are involved in inflammation, a process that is likely central in the pathogenesis of both diseases (Bauer et al., 2004).

Identifying Smokers at Risk

The risk for developing lung cancer increases with accumulated exposure to cigarette smoke, most often expressed as pack-years (calculated by multiplying the number of packs of cigarettes smoked per day by the number of years the person has smoked). As noted earlier, even in a high-risk population of smokers, however, the incidence of lung cancer is only ~15% over a lifetime. The incidence increases slightly in those over the age of 60 with greater than 30 pack-years, previous lung cancer, and/or atypia of bronchial epithelial cells in the sputum.

Because of the lack of effective diagnostic biomarkers that identify which of the current and former smokers are at the greatest risk for developing cancer, lung cancer is most often diagnosed at a late stage after it has spread. In contrast to most cancers, 5-year survival rates for lung cancer, ~15%, have not changed appreciably over the past 4–5 decades. Previous screening trials with frequent chest x-rays and sputum cytology have not demonstrated an effect on lung cancer mortality (reviewed by Jett and Midthun, 2004). Spiral computerized tomography (CT) scan screening can detect lung tumors at an early stage. The I-ELCAP study, a systematic case–control observational study that included more than 31,000 subjects who were at risk for lung cancer, found that screening by CT resulted in a diagnosis of lung cancer in 484 participants, of which 412 (85%) had clinical stage I lung cancer (Henschke et al., 2006). Spiral CTs, however, while highly sensitive, can be non-specific and many newly detected small lesions have proven on resection to be non-malignant scar tissue or old granulomas rather than early lung cancers (Jett, 2005). Thus, it is not yet known if this approach will alter lung cancer mortality or justify the relatively high cost of large-scale screening. Current trials, including the National Lung Cancer Screening Trial (NLST), will help answer these questions.

Developing biomarkers that are highly sensitive, specific, and target individuals with early stages of cancer is clearly necessary to improve lung cancer mortality. Several groups have used genomic profiling to identify the subset of smokers who are at higher risk for developing lung cancer. Powell et al. (2003) compared the gene expression profiles of tumor and matched normal tissues from smokers and non-smokers. Although hierarchical clustering did not separate tumors from smokers versus non-smokers, it did separate tumor and non-tumor tissue. Four times more genes were altered between tumor and lung in non-smokers as compared with smokers. Their findings demonstrate that underlying normal tissues from smokers and non-smokers differ, consistent with the concept of "field cancerization" in smokers where genes are altered in the entire respiratory epithelium.

To begin to understand the mechanisms by which some individuals protect themselves from the carcinogenic effects of smoking, Spira et al. (2004) used high-throughput genomic and bioinformatic tools to define the genome-wide impact of smoking and smoking cessation on bronchial airway epithelium. They demonstrated changes in both antioxidant and drug metabolizing genes in airway epithelial cells as well as increases in putative oncogenes and decreases in tumor suppressor genes. They also noted that the expression level of smoking-induced genes among former smokers began to resemble that of never smokers after 2 years of smoking cessation. Genes that reverted to normal within 2 years of cessation tended to serve metabolizing and antioxidant functions. In addition the authors found that several genes, including putative oncogenes and tumor suppressor genes, failed to revert to never-smoker levels years after smoking cessation, perhaps explaining the continued risk for developing lung cancer many years after individuals have stopped smoking (Spira et al., 2004). This same group has reported a lung cancer-specific diagnostic gene expression profile in histologically normal airway epithelial cells of patients being evaluated for the diagnosis of lung cancer (Spira et al., 2007). These genes also predicted lung cancer in previously published studies of normal and lung cancer tissue, raising the possibility that changes in airway gene expression of smokers might not only serve as biomarker for risk of developing lung cancer, but may reflect to some extend the genomic changes that occur in the actual lung cancers. These studies support the possibility that measuring gene expression in easily accessible airway epithelial cells may provide a biomarker that identifies smokers at high risk of developing lung cancer.

Detection of mutations or aberrant methylation in sputum or serum is a promising approach to the early diagnosis of lung cancer. Detection of promoter hypermethylation in the CDKN2A, DAPK1, RASSF1, CDH1, GSTP1, RAB, CDH13, APC, MLH1, MSH2, and MGMT genes have been demonstrated using sputum or bronchial lavage (reviewed by Cooper, 2005). Aberrant promoter hypermethylation has been shown to occur frequently in patients with resected lung cancers and concordance between methylation patterns in tumor specimens and bronchial epithelial cells has been demonstrated. In addition, recent studies demonstrated that gene promoter hypermethylation in sputum could identify people at high risk for lung cancer incidence. One study demonstrated FHIT methylation in preneoplastic lesions from smoking-damaged bronchial epithelium

(Zochbauer-Muller et al., 2001). Another study demonstrated hypermethylation of the CDKN2A gene promoter prior to clinical evidence of lung carcinoma (Kersting et al., 2000). Lastly, Palmisano et al. (2000) showed that p16 and/or MGMT could be detected in DNA from sputum up to 3 years before clinical diagnosis of squamous cell cancer.

Reports documenting the clinical potential of detecting tumor-related genes, mutations, loss of heterozygosity, polymorphisms, and promoter hypermethylation of circulating tumor DNA in serum are also surfacing. In addition high-throughput methods for analyzing the methylation status of hundreds of genes simultaneously are being applied to the discovery of methylation signatures that distinguish normal from cancer tissue samples (Bibikova et al., 2006; Wilson et al., 2006). However, none of these studies has tested the diagnostic potential in prospective multicenter trials.

Future Directions

Lung cancer is one of the few cancers for which screening is not recommended, even in high-risk individuals. Although spiral CT and autofluorescent bronchoscopy may increase the detection rate of early lesions, these procedures are costly and/or relatively invasive, have not been shown to be specific for the presence of lung cancer, and it is not yet known if screening will alter mortality. Since molecular, genetic, and epigenetic abnormalities precede morphological changes in bronchi and alveoli, biomarkers may help select a group of high-risk patients that would benefit from spiral CT and/or fluorescent bronchoscopy.

To develop screening profiles that could potentially predict those at risk for developing cancer and/or detect lung cancer at an earlier stage, profiles must be capable of identifying the few abnormal cells among many normal cells and samples ideally should be obtained in a relatively non-invasive fashion. The availability of a number of agents that might be effective in reversing the pre-malignant changes in airway epithelial cells (see below) has driven the search for biomarkers that identify individuals at highest risk for developing lung cancer. Genetic abnormalities can be detected from bronchial biopsies, respiratory cells from sputum, and circulating DNA, and gene expression profiles generated from these specimens offer a wide area of investigation for biomarker development. To be applied in a screening program, these biomarkers must be specific and cost effective with a high efficiency: the focus has been on intermediate markers that indicate risk but might be reversible with appropriate treatment.

A recent review has identified the benefits of and requirements for the ideal biomarker (Dalton and Friend, 2006). Benefits include (1) predict who will develop lung cancer and/or detect cancer at an early treatable stage, (2) serve as guides for treatment decisions (3) and serve to identify new targets for drug development. The authors in this review point out the need to develop biomarkers that deal with the molecular diversity of lung cancer that monitor disease progression and that predict and/or monitor response to preventative therapy. A biomarker that meets even the majority of these requirements remains to be discovered but will almost certainly evolve with modern genomic technology.

A relatively new field, "genetical genomics," which attempts to link gene expression in affected tissues with genetic polymorphisms promises to provide insights into heritable factors in lung cancer (Li and Burmeister, 2005). This field is derived from recent technological and computational advances that allow one to measure levels of gene expression in the affected tissue and relate them to high-density SNP discovery in genomic DNA (Pastinen et al., 2006). Patterns of gene expression in smoke-exposed tissue and linkage to SNPs in the affected genes are likely to lead to new insights into heritable cause of lung cancer.

Chemoprevention of high-risk current or former smokers represents one of the most important areas of current research in the prevention of lung cancer. It has been a topic of great interest for over 20 years. Despite numerous trials beginning with high doses of retinoids in the 1980s, there have been no studies to date that have demonstrated a positive outcome in terms of mortality from lung cancer and few studies that have demonstrated an effect of intermediate end points, such as sputum atypia or genomic markers of epithelial cell damage. Several recent publications review the results of previous randomized trials and the rationale for use of new chemopreventative agents (Hirsch and Lippman, 2005; Kelloff et al., 2006; Khuri and Cohen, 2004).

Chemoprevention (chemoprophylaxis) has assumed increasing importance as former smokers now account for 50% of new lung cancer cases in the United States. Since there are approximately 45 million former smokers in the United States, identifying which former smokers are at highest risk for developing lung cancer in the future is the most important first step in any chemoprevention program. Many new chemopreventative agents are being explored using agents that fall into several broad categories: (1) anti-inflammatory/antioxidants, (2) epigenetic modulators of methylation and/or acetylation, and (3) modulators of signal transduction, particularly those that affect the EGFR-signaling pathways. A recent clinical study conducted in 10 patients to assess the potential chemopreventive effect of myo-inositol in smokers with bronchial dysplasia showed a significant increase in the rate of regression of preexisting dysplastic lesions (Lam et al., 2006). The potential impact of chemoprevention is large, but the field awaits the emergence of intermediate markers of cancer risk that must be validated in prospective studies.

CLASSIFICATION AND PROGNOSIS

Histological Classification of Lung Tumors and TNM Staging

Lung cancers are classified as small-cell lung carcinomas (SCLC) or non–small-cell carcinomas (NSCLC). Small-cell lung cancers have neuroendocrine features that are identified by immunohistochemistry and histology. NSCLC are subcategorized as adenocarcinomas (most common), squamous cell carcinomas, and large-cell carcinomas, and are clinically distinct from SCLC. The pathological distinction between SCLC and NSCLC is very important since these tumor types are treated differently (reviewed by Spira and Ettinger, 2004).

Pre-malignant lesions termed low and high-grade dysplasia, carcinoma *in situ* (CIS), and atypical adenomatous hyperplasia (AAH) are associated with increased risk for developing lung cancer (reviewed by Kerr, 2001). When the airways are exposed to carcinogens, cellular and molecular changes occur over broad mucosal surfaces, a concept termed "field cancerization." Accumulation of mutations and epigenic alterations ensue, eventually leading to invasive lung cancer, a process called "multistep carcinogenesis" (reviewed by Cooper, 2005).

Histological analysis is currently used to identify and classify cancers, yet definitive diagnoses are often difficult to make. Furthermore, tumors with the same histological classification behave differently, and morphological classification has not been effective in predicting the aggressiveness of a cancer or how the cancer will respond to therapeutic agents.

In NSLC, tumor staging (*International System for Staging Lung Cancer*) is the most important prognostic variable for predicting survival. TNM staging takes into account the degree of spread of the primary tumor (T), the extent of regional lymph node involvement (N), and the presence or absence of metastases (M) (summarized by Hoffman et al., 2000). Recently adopted revisions to TNM staging include (1) the splitting of stage I into IA and IB; (2) the splitting of stage II into IIA and IIB; (3) reclassifying T3N0M0 from Stage IIIA to IIB; and (4) classifying multiple pulmonary tumor nodules as T4 if the satellite nodule(s) are in the same lobe, or M1 if the ipsilateral nodules(s) are in the non-primary lobe. Despite these changes and improvements in diagnosis including both non-invasive methods (CT/PET), and invasive methods (EUS, EBUS), patients diagnosed with similar stage and treated using similar protocols, often respond quite differently and have varying survival rates. Some tumors, though found at an early stage, will rapidly progress to metastatic disease. Furthermore, in patients who have undergone surgical resection, recurrence rates are high with 5-year survival rates only 40% for stage IIB NSCLC.

Although several combined clinical, histological, and laboratory variables such as age, stage or grade of tumor, and serum protein levels can be used to assess a patient's prognosis with variable accuracy, these criteria are not able to provide important information about the prognostic diversity within each stage such as how aggressive a particular subtype will be, or how a patient will respond to therapy. By combining clinical variables and histopathology with gene expression profiling, predicting a patient's prognosis could theoretically be improved.

Molecular Classification and Prognostic Value of Lung Cancer Genomics

Morphological tumor classification does not always accurately predict the patient's clinical behavior since lung cancer is genetically heterogeneous. For example, patients with stage IA lung cancer resected for cure still have 30% mortality from local recurrence, distant metastases, and/or new occurrence. Within each clinical stage, there is variability in the presence of specific mutations, deletions of tumor suppressor genes, amplifications of oncogenes, and chromosomal abnormalities. Genomics is a powerful tool for classifying tumor subtypes. Lung cancer patients with biomarkers that predict a poor outcome could be selected for adjuvant chemotherapy while those that predict a good prognosis may be able to avoid the toxicity and cost of unnecessary chemotherapy.

Recently, microarray studies have identified and validated specific genes whose expression differs between normal and tumor tissue. Using cDNA arrays, Wikman et al. (2002) compared gene expression profiles of 14 pulmonary adenocarcinoma patients with normal lung tissue. These authors demonstrated marked differences in gene expression level between normal lung and adenocarcinomas. Another study by Yamagata et al. (2003) showed that a profile based on gene expression could be used on blinded samples to differentiate primary NSCLC from normal lung and lung metastases. Furthermore, groups of genes were identified that were able to identify known histological subgroups of NSCLCs.

Genomic high-throughput technologies have been used in many studies to identify gene expression signatures that predict patient survival and/or relapse rates. A considerable number of expression profiling studies have been performed on clinical lung cancer specimens (summarized by Granville and Dennis, 2005; Kopper and Timar, 2005; and Cooper, 2005). Not only can gene expression profiles group tumor samples consistent with classical histology, but can also identify subgroups within histologic subclasses. In an attempt to discover previously unrecognized subtypes of lung cancer, two microarray studies aimed at class discovery by hierarchical clustering using primary lung cancer specimens were published in 2001 (see Figure 34.1). Garber et al. (2001) identified gene subsets that are characteristic of each of the known morphological subtype in NSCLSs. In addition, these authors found that these tumors could be further divided into subgroups with significant differences in patient survival. Another study by Bhattacharjee et al., (2001) showed by gene expression analysis of 186 lung carcinomas that biologically distinct subclasses of lung carcinomas exist. In their study, a subclass of adenocarcinomas defined by having neuroendocrine gene expression had a less favorable outcome, whereas a subset of patients with predominantly type II pneumocyte expression, had a more favorable outcome.

In a study designed to identify whether gene expression patterns could predict survival, Beer et al. (2002) demonstrated that expression profiles based on microarray analysis could be used to predict disease progression and clinical outcome in early-stage lung adenocarcinomas. Subdivision of the lung tumors based on gene expression patterns matched the morphological classification of tumors into squamous, large-cell, adenocarcinoma, and small-cell lung cancer. Furthermore, adenocarcinomas could be further subclassified based on their gene expression profiles that correlated with the degree of tumor differentiation and patient survival. They demonstrated by gene profiling that a list of 50 genes were most effective at dividing patients with stage I lung adenocarcinoma into high- and low-risk groups for mortality, thus potentially identifying a subset of stage I NSCLC cancer patients who would benefit from adjuvant therapy. This group has recently extended their observations to the squamous cell

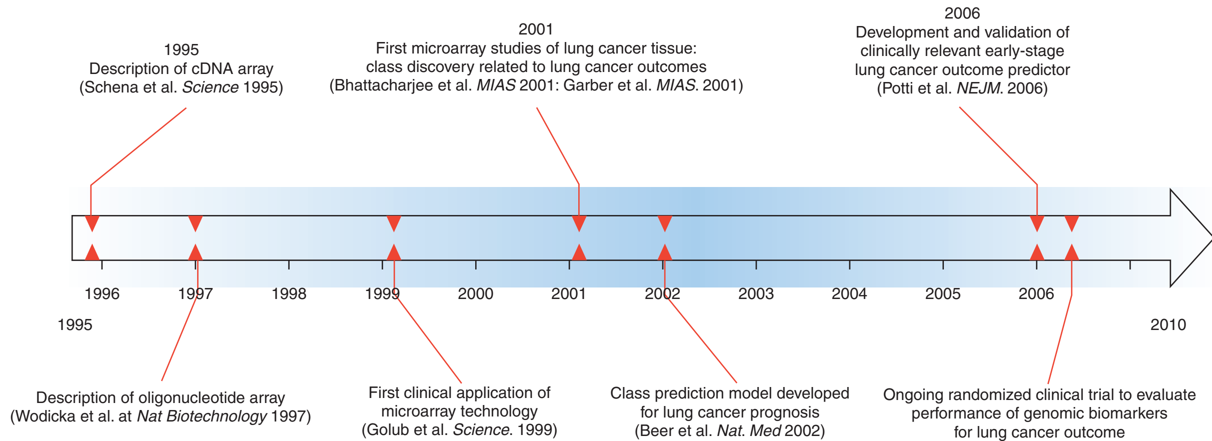

Figure 34.1 Timeline for the development of DNA microarray technology and its application to lung cancer. The key advances in the field of microarray technology and their clinical applications to lung cancer tissue for prognostic purposes are highlighted.

carcinoma subset of NSCLC and have generated a similar risk of progression stratifier which combined with the adenocarcinoma tool, will cover ~80% of all NSCLC (Raponi et al., 2006).

Recently, a clinically relevant prognostic tool that may alter clinical decision-making in early-stage lung cancer was developed using gene expression profiling (Potti et al., 2006a, b). Potti et al. (2006a, b) identified a gene expression profile that predicted the risk of recurrence in 89 patients with early-stage lung cancer (Figure 34.2). The authors then validated the model, termed the "lung metagene" model, in a group of 134 patients. The test predicted recurrence for individual patients significantly better than did clinical prognostic factors. This predictor also identified a subgroup of patients with stage IA lung cancer who were at high risk of recurrence and would potentially benefit from adjuvant therapy. Based on these findings, a multicenter clinical trial has been initiated. This upcoming clinical trial is the first to use a genomic test to select treatment options for individual lung cancer patients.

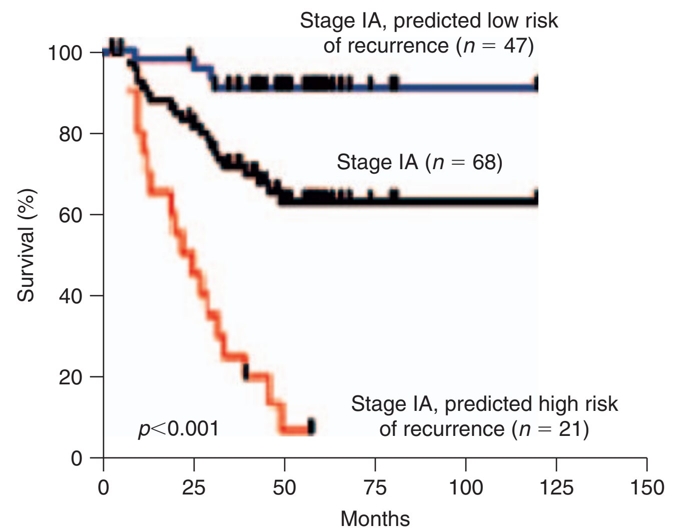

Figure 34.2 Application of the gene expression model to determine prognosis in stage IA NSCLC. Kaplan-Meier survival estimates from three cohorts of patients with stage IA disease. The middle black Kaplan-Meier curve represents the median survival estimate in all cohorts. The top and bottom Kaplan-Meier curves represent survival estimates for subjects predicted to have low and high risk of recurrence respectively by the gene expression model, demonstrating the ability of the genomic model to accurately predict survival in stage IA disease. Figure reproduced from Potti et al. *NEJM*, 2006.

Future Directions

Currently, lung cancer patients within a given clinical stage and tumor type receive the same treatment despite the genomic heterogeneity that exists between patients. Although expression profiling of lung cancer has identified prognostic genes and identified subtypes of adenocarcinomas, until recently, these profiles have not been ready to be incorporated into clinical practice. Comparison of array studies has been difficult because the array platforms, sample preparation, and technical factors have been different. In addition, many molecular classification studies do not match the classification based on tumor histology, perhaps because use of whole lungs for microarray studies may not accurately reflect gene expression in the cancer cells because of contamination and differences in abundance of stromal and surrounding normal cells. Although laser-captured microdissection (LCM) can be used to obtain a homogeneous population of epithelial cancer cells, excluding surrounding stroma may eliminate cells that contribute to the tumor environment.

Redefining tumor classification from strictly morphology-based schemes to molecular-based classifications using a variety of parameters including histological patterns, gene expression profiles including the presence or absence of oncogenes, tumor

suppressor genes, and miRNAs, and cell surface protein and receptor status, promises to provide clinically important information on tumor subsets within morphological classes. A recent expression profile analysis of lung adenocarcinomas, for example, classified tumors into two major subtypes, terminal respiratory unit (TRU) and non-TRU subtypes (Takeuchi et al., 2006). TRU type tumors retained features of normal peripheral lung features and had higher frequency of EGFR mutations. The presence of EGFR mutations in this adenocarcinoma subtype predicted a shorter post-operative survival.

A large study is underway in which participating centers are pooling and analyzing lung adenocarcinoma specimens, the results of which will hopefully lead to a gene expression signature that will differentiate the adenocarcinoma subtypes (Dobbin et al., 2005). Prognostic profiles and eventually, a prognostic-specific gene chip, may help guide clinical decision-making by identifying "high risk" lung cancer patients that would benefit from improved diagnostic and treatment options.

PATHOGENESIS AND TREATMENT OF LUNG CANCER

Molecular Alterations in Lung Cancer

Proto-oncogenes

Proto-oncogenes such as *Ras* and *Myc* were first discovered in the 1970s and 1980s, and it was only in the 1980s and 1990s that these genes were integrated into signaling pathways and that mutations in these genes were linked to human cancers. The *Ras* genes (*Hras*, *Kras*, and *Nras*) encode GTPase proteins that help transduce survival and growth-promoting signals. When oncogenic mutations occur, the normal abrogation of RAS signaling by hydrolysis of bound GTP to GDP is impaired, resulting in persistent signaling (reviewed by Singhal et al., 2005). Point mutations (found most frequently in codon 12, 13, and 61) are detected in 20–30% of lung adenocarcinomas (Slebos et al., 1990) and 90% of these mutations are found in Kras (see Table 34.1). Mutations in Kras are markers for poor prognosis in NSCLCs (Graziano et al., 1999) as mutations rarely occur in SCLC. *Myc* genes (*MYCL*, *MYCN*, and *CMYC*), which encode transcription factors that regulate genes involved in cell cycle regulation, DNA synthesis, and RNA metabolism, become activated by loss of transcriptional control or by gene amplification, resulting in MYC protein overexpression. C-Myc amplification occurs in 5–10% of NSCLCs (Richardson and Johnson, 1993).

Growth Factors and Their Receptors

Lung tumors often express growth factors and their receptors, and the resulting regulatory loops can stimulate tumor growth. EGFR, also known as ERBB-1, is highly expressed in many epithelial tumors, including a subset of lung adenocarcinomas (Reissman et al., 1999). When ligand (EGF or TGF-α) binds to EGFR, there is receptor tyrosine kinase activation and a series of downstream signaling events, including the mitogen-activated protein kinase (MAPK), PI3/Akt, and Jak/Stat pathways (see Figure 34.3) that can result in cellular proliferation, increased cell motility, tumor invasion, anti-apoptosis, and resistance to chemotherapy summarized by Baselga, 2006). EGFR tyrosine kinase, therefore, was proposed as a target for cancer therapy 20 years ago.

TABLE 34.1 Common molecular alterations in lung cancer

	Type of mutation	Frequency
Proto-oncogenes		
k-Ras	Point mutation	NSCLC: 20–30% (mostly adeno)
MYC	Translocation amplification	SCLC: 30–40% NSCLC: 5–10%
Bcl-2	Translocation	NSCLC: (30%) Squamous: 25%; Adeno: 10%
Growth factors		
EGFR (ERBB-1)	Deletion/Mutation amplification	SCLC: 0% NSCLC: 10% (BAC: 25%)
HER2 (erbB2)	Translocation amplification	NSCLC 30–40%
Tumor suppressors		
p53	Deletion/LOH	SCLC: 75% NSCLC: 50%
Rb gene	Point mutation	SCLC: 90% NSCLC: 15–30%
P16 (CDKN2)	Deletion/LOH	SCLC: >80% NSCLC: 30–50%
FHIT	Deletion/LOH	SCLC: 100% NSCLC: 60%

Anti-EGFR drugs approved for cancer treatment include the monoclonal antibodies directed against the extracellular domain of the receptor (anti-EGFR Mabs) and small-molecule inhibitors of EGFR's tyrosine kinase activity (TKIs). In NSCLCs, two trials have demonstrated that in unselected patient populations, anti-EGFR TKIs have modest levels of antitumor activity. In 10% of patients, however, tumor response is often dramatic, but responses tend to be transient. Responsive patients are most often non-smoking Asian woman with adenocarcinomas, often bronchioloalveolar carcinoma (BAC) (reviewed by Baselga, 2006; Dziadziuszko et al., 2006). Subsequent analyses demonstrated that lung cancers with somatic mutations in EGFR correlate with a positive clinical response to EGFR inhibitors (reviewed by Janne et al., 2005; Lynch et al., 2006; and Thomas et al., 2006). Unfortunately, these initial responders often develop resistance to these drugs. A second EGFR somatic mutation, T790M, occurs in some cases of NSCLC that recur after an initial response to TKIs (Kobayashi

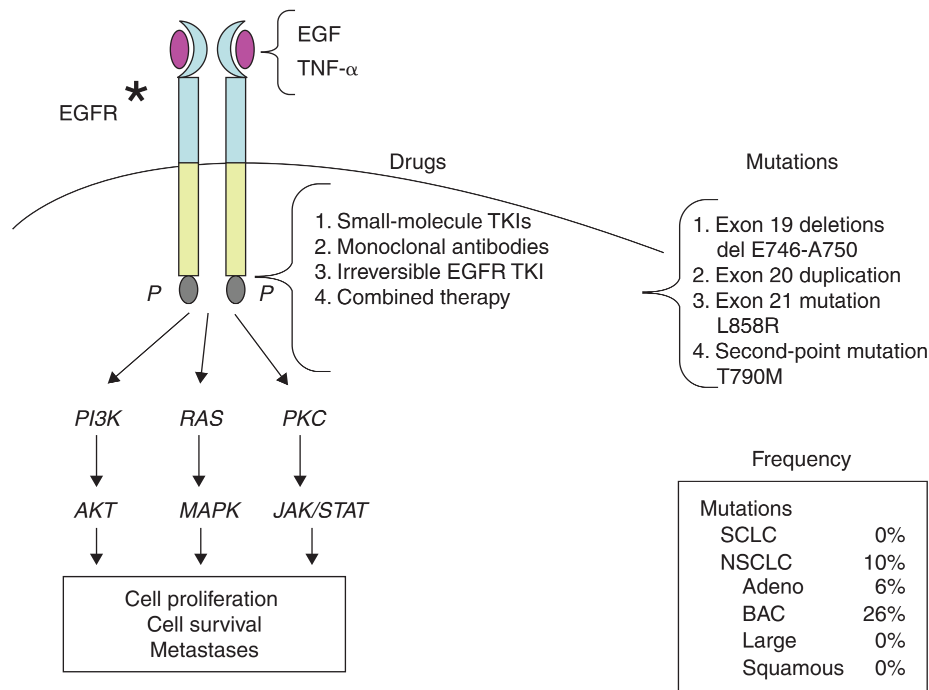

Figure 34.3 When ligand (EGF or TGF-α) binds to EGFR, there is receptor tyrosine kinase activation and a series of downstream signaling events, including the MAPK, PI3/Akt, and Jak/Stat pathways, that can result in cellular proliferation, increased cell motility, tumor invasion, anti-apoptosis, and resistance to chemotherapy. Receptor expression can be increased by gene duplication (*). Most of the tyrosine kinase domain and all activating EGFR mutations thus far are in exons 18–21. Deletions in exon 19 and substitution mutations in exon 21 account for the majority of mutations. Mutations occur most frequently in bronchoalveolar carcinoma (BAC), but not in squamous cell carcinoma or SCLC (Marchetti et al., 2005; Shigematsu et al., 2005). Anti-EGFR drugs approved for cancer treatment include the monoclonal antibodies directed against the extracellular domain of the receptor (anti-EGFR Mabs) and small-molecule inhibitors of EGFR's tyrosine kinase activity (TKIs). Examples of anti-EGFR Mabs include Cetuximab (Erbitux), Panitumumab, and Pertuzumab. Examples of TKIs include Gefitinib (Iressa) and Erlotinib (Tarceva).

et al., 2005). Germ line T790M mutations have been described in a family with multiple cases of lung cancer (Bell et al., 2005).

Clinical trials using alternate EGFR inhibitors, such as irreversible EGFR inhibitors, are underway in NSCLC patients. Some centers have begun to sequence EGFR in all resected tumors in order to tailor drug therapy to specific mutations, although further research is needed to more completely define the appropriate population for EGFR testing (reviewed by Sequist et al., 2006). The complexity of EGFR mutations is highlighted by a recent report identifying different EGFR mutations in the primary tumor versus lesions metastatic from the primary site (Italiano et al., 2006). Furthermore, Engelman et al. (2006) recently reported that allelic dilution of a biologically significant resistance mutation in EGFR-amplified lung cancer may be undetected by direct sequencing.

Tumor Suppressor Genes

The role of p53, a tumor suppressor gene, is to help maintain genomic integrity after DNA damage. When cells undergo stress, such as from carcinogen exposure, UV radiation, and/or hypoxia, p53 becomes upregulated and then acts as a transcription factor to increase genes such as p21 (which in turn controls G1/2 cell cycle transition) and induces apoptosis by activating genes such as BAX, PERP, and others (reviewed by Fong et al., 2003; Singhal et al., 2005). In lung cancer, missense mutations can occur and cause loss of p53 function in >75% of SCLCs and 50% of NSCLCs (Toyooka et al., 2003).

Decreased expression of p16 by promoter hypermethylation, mutations, or allelic loss occurs in 30–50% of NSCLCs. The *p16*^{INK4A}*-cyclin D1-CDK4-RB* pathway controls G1/S cell cycle transition, and loss of p16 releases the tumor cells from RB-mediated cell cycle arrest (reviewed by Fong et al., 2003). Alternatively, the Rb gene can be inactivated directly by deletions, point mutations, or alternative splicing, and are more commonly found in SCLCs (>90%), than NSCLCs (15–30%) (see Table 34.1).

Oncogenic Pathway Signatures

The malignant process is complex, involving multiple mutations leading to deregulation of signaling pathways (see above). In addition, the role of miRNA, very small non-coding RNA products that play a key role in regulatory networks by regulating the translation and regulation of mRNAs, are emerging

(reviewed by Calin and Croce, 2006). Recent studies have demonstrated altered miRNA gene expression in lung cancers. Dicer, a component of the miRNA machinery has been shown to be downregulated in NSCLCs (Karube et al., 2005). Reduced expression of *let*-7 miRNA family members have been found to correlate with shorter post-operative survival in potentially curative lung cancer resection (Takamizawa et al., 2004).

The feasibility and utility of monitoring miRNAs has been recently demonstrated in a study by Lu et al. (2005). These authors demonstrated, using a bead-based miRNA detection method, that a relatively small number of miRNA genes (~200 miRNAs) may be sufficient to classify human tumors. A study by Yanaihara et al. (2006) showed that lung cancer specimens have extensive alterations of miRNA expression that may dysregulate cancer-related genes. Furthermore, miRNA microarray analysis using a microchip for genome-wide miRNA profiling (developed by Liu et al., 2004) identified a signature that could discriminate lung cancer from non-cancer tissue, and could also correlate lung cancer specimens with patient survival. In their study, high *miR-155* and low *let-7a-2* correlated with poor survival in lung adenocarcinomas (Yanaihara et al., 2006).

let-7 miRNA family members have been shown to directly regulate Ras genes (Johnson et al., 2005). These combined studies suggest that *let*-7 may be a promising therapeutic agent to treat lung cancers caused by activating mutations in Ras genes (reviewed by Esquela-Kerscher and Slack, 2006).

DNA microarray–based gene expression signatures have been developed that have the ability to define oncogenic pathways. The ability to predict the deregulation of various oncogenic pathways (both the mutated gene product itself and its downstream targets) offers an opportunity for new therapeutic drugs that are pathway-specific. Sweet-Cordero et al. (2005) recently developed a KRAS-mutant signature from analysis of expression array data using the KRAS-mutant mouse model of lung adenocarcinoma, which was then transferred to a human KRAS-mutant signature. The signature accurately identified KRAS-mutant lung tumors. These results were confirmed using siRNA and real-time RT-PCR.

Another study by Bild et al. (2006a, b) demonstrated that DNA microarray–based gene expression signatures can not only predict cells expressing oncogenic activity from control cells, but can also predict deregulation of various oncogenic pathways in specific tumor types derived from mouse cancer models and human cancer specimens. These authors used multiple experimental models including functional cell-based assays, mouse lung cancer models, and human cancer specimens to demonstrate that the Ras pathway status clearly correlates with lung adenocarcinoma relative to squamous cell carcinomas subtypes. Furthermore, independent of tumor histology, patients displaying deregulation of multiple pathways (Ras with Src, Myc, β-catenin) had a poor survival.

Future Directions

Molecularly targeted therapy to reduce lung cancer mortality biomarkers provide an opportunity to identify subpopulations of patients who are most likely to respond to a given therapy and identify new targets for drug development. A study by Olaussen et al. (2006) for example, showed that in lung tumor specimens, the absence of ERCC1 (an enzyme that participates in the repair of DNA damage caused by cisplatin) was associated with a survival benefit from cisplatin-based adjuvant chemotherapy, whereas patients whose tumor expressed the enzyme failed to benefit from chemotherapy.

Several clinical studies have now shown the therapeutic efficacy and safety of tyrosine kinase inhibitors for specific tumor subtypes. Many of the 90 proteins with tyrosine kinase domains encoded by the human genome are aberrantly activated in human tumors. Intriguingly, after treatment with tyrosine kinase inhibitors in some tumor subtypes, there is marked reduction not only in tumor growth, but also in tumor viability. This concept of dependence of the tumor mutated oncogenes and/or on EGFR-mediated survival signals is referred to as "oncogene dependence or oncogene addiction" (Varmus, 2006; Weinstein, 2002). Oncogene dependence is also demonstrated in mouse models overexpressing constitutively active K-ras, where the mutant K-ras is then silenced. In this model, lung tumors rapidly regress as a result of apoptosis when K-ras is silenced even in the absence of important tumor suppressor genes (Fisher et al., 2001). An alternative hypothesis to explain oncogene addiction is through differential signal attenuation of multiple pro-apoptotic and pro-survival signals, a term coined "oncogenic shock" (Sharma et al., 2006).

The improved survival in NSCLC patients taking EGFR TKIs seems not to only be limited to patients with EGFR mutations. Markers such as EGFR gene amplification, ErbB3 levels, and Her2 mutations may also be predictors of responsiveness (reviewed by Engelman and Cantley, 2006). Ongoing studies to investigate EGFR TKIs as first line therapy in selected patients with mutations in exons 18–21, increased EGFR copy number or protein expression, and with clinical characteristics associated with response are needed (reviewed by Johnson, 2006). Although the majority of lung tumor cells acquire resistance mutations during therapy with EGFR TKIs, these cells seem to be to be sensitive to a new group of TKIs that covalently cross-link the receptor (Carter et al., 2005). In addition, a recent study showed that microarray gene expression profiling demonstrated a pattern of gene expression associated with sensitivity to EGFR (Coldren et al., 2006). Mouse lung models with inducible expression of mutations in EGFR have been generated and may help in further understanding the pathogenesis of human lung cancer and aid in the validation of cancer therapeutics (reviewed by Dutt and Wong, 2006).

Given the complexity of NSCLC, it is likely that these tumors are dependent on more than one oncogenic signaling pathway. Alterations in cancer-specific copy number and loss of heterozygosity (LOH) are important changes found in cancer cells and SNP array analyses may reveal pathways disrupted in tumorigenesis. SNP arrays have been used in genomic studies for detecting LOH in lung cancer and have both detected previously unknown regions of copy number change as well as

known regions of both amplification and homozygous deletion. It is likely therefore that combination targeted therapy directed at multiple oncogenic pathways may not only prove more effective than single agents alone, but may also prevent or delay secondary resistance.

Most tumors express multiple mutant genes, but the relative importance of mutated genes in maintaining the cancer phenotype is not yet known, nor is the role of growth-promoting signals by non-cancerous stromal cells. The success of anti-angiogenic strategies in NSCLC suggests that targeting specific proteases and growth signals supplied by the tissue environment may prove useful as therapeutics.

Establishing tumor banks to study the molecular phenotype of patients who are sensitive and resistant to therapy in order to identify the appropriate patients to treat is therefore crucial. Recently, gene expression signatures from tumor biopsy specimens have been developed that can predict sensitivity to individual chemotherapeutics. Furthermore, these chemotherapy response signatures are being integrated with signatures of oncogenic pathway deregulation to potentially identify new therapeutic strategies (Potti et al., 2006a, b). The considerable potential of using gene expression profiling of tumors to define causal molecular pathways and potential therapeutic targets for individuals is summarized in a recent review from Nevins' group (Bild et al., 2006a).

2009 UPDATE

Early Diagnosis/Screening of Lung Cancer

Developing biomarkers that identify smokers at high risk for developing lung cancer represents an important approach to improving lung cancer mortality. A study using DNA microarrays to profile the gene expression patterns of cytologically normal airway epithelial cells in current and former smokers undergoing bronchoscopy for the clinical suspicion of lung cancer found an 80-probeset lung cancer-specific biomarker that distinguishes smokers with and without lung cancer (Spira et al., 2007). The biomarker was sensitive and specific when tested on an independent test set and on an additional prospectively collected set of samples. In addition, this biomarker provides information about the likelihood of lung cancer that is independent of clinical risk factors for lung cancer among patients with non-diagnostic bronchoscopies (Beane et al., 2008). Since smoking-induced cancer-specific alterations in gene expression may precede the development of lung cancer, these biomarkers may prove useful in identifying high-risk lung cancer patients.

Classification and Prognosis

Accurate molecular classification of the subtypes of NSCLC, for tumor staging and prognosis, may provide a new approach to tumor-specific therapies. Chen et al. reported a 5-gene signature that predicts survival among patients with NSCLC (Chen et al., 2007). Sixteen genes were found to be associated with survival across training and test sets using DNA microarrays measuring 672 previously identified genes associated with invasive activity in invasive NSCLC cell lines (Chen et al., 2001).

A meta-analysis from seven different datasets to predict survival in patients with stage I NSCLC identified genes that were common to the microarray platforms used in all seven datasets (Lu et al., 2006). A total of 197 samples with stage I NSCLC from five of the seven datasets were used to identify a gene expression signature of 64 genes predictive of survival. The signature had higher classification power compared to stage and was accurately predicted survival in the two datasets not used to develop the signature.

Whole-genome gene expression microarrays on frozen tumor samples from 172 NSCLC patients (pT1-2, N0-1, M0) in five European institutions were used to develop a 72-gene expression prognostic NSCLC classifier (Roepman et al., 2009). Based on the classifier score, patients were classified as either high or low risk of disease recurrence. Patients classified as low risk showed a significantly better recurrence-free survival, both in the training set and in the independent validation set. Genes in the prognostic signature were strongly enriched for genes associated with immune response.

Recently in a large retrospective, multi-site, blinded study, Shedden et al. analyzed the performance of several prognostic models in 442 lung adenocarcinoma specimens collected from four different institutions (Shedden et al., 2008). Eight prognostic classifiers and classifiers based on the work of Potti et al. (2006) and Chen et al. (2007) were developed and evaluated on training and test subsets. The results varied, but the inclusion of clinical covariates improved the performance of most classifiers, and a small subset of the classifiers performed well across both tests sets when trained across all stages or stage I samples. The study presents a framework for conducting large studies to test gene expression signatures and illustrates the challenges associated with developing a prognostic gene expression signature for clinical application.

Pathogenesis and Treatment

Chemotherapy-resistance is common in cancer and biomarkers that identify chemotherapeutic-specific lung cancer subtypes may improve prognosis through use of individualized treatments. Hsu et al. (2007) developed predictors of cisplatin (a first line agent) and pemetrexed (a second line agent) sensitivity using the NCI-60 data and data from Gyorffy et al. (2006). The authors found an inverse correlation between *in vitro* cisplatin and pemetrexed sensitivity, and between the likelihood of cisplatin and pemetrexed response in patients.

In a recent study, gene set enrichment analysis was used to associate pathways with chemotherapy resistance in two data

sets: the NCI-60 cancer cell lines deemed sensitive and resistant to specific chemotherapeutic agents and a series of 40 lung cancer cell lines for which sensitivity to cisplatin and docetaxel was determined. Analysis of the lung cancer cell lines identified the bcl-2 pathway to be associated with cisplatin resistance and the AKT pathway enriched in cisplatin- and docetaxel-resistant cell lines. Results from Connectivity Map supported an association between phosphatidylinositol 3-kinase/AKT and docetaxel resistance and targeted inhibition of the phosphatidylinositol 3-kinase/AKT pathway, in combination with docetaxel, resulted in a synergistic effect in previously docetaxel-resistant cell lines. These results support the use of a genomic approach to identify drug-specific targets associated with the development of chemotherapy resistance (Riedel et al., 2008).

Conclusion

The contributions of modern genomic technologies, particularly those that provide measures of global gene expression, are depicted in Figure 34.4. Gene expression profiling provides a new approach to assessing risk of developing lung cancer, potential tools for early diagnosis, new approaches to determining prognosis and oncogenic pathways that will lead to individually targeted therapies. Combined with genome-wide SNP screens that hold the promise of determining heritable predispositions to developing lung cancer and defining pathway-based phamacogenomics, there is promise that lung cancer may no longer be the number one cause of cancer death in the world.

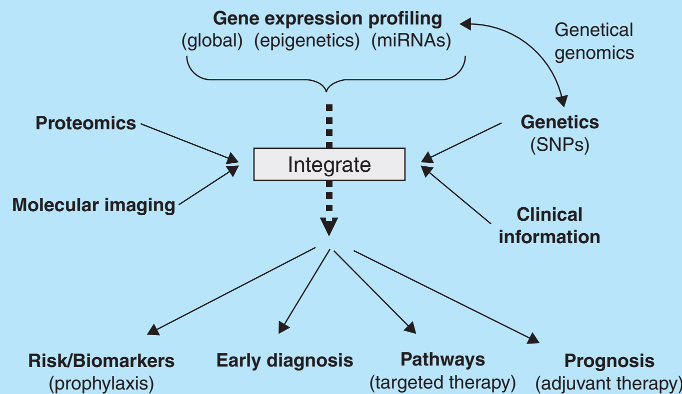

Figure 34.4 Diagram depicting contributions of gene expression profiling, combined with genetics, clinical information, proteomics, and imaging studies that can be applied to developing (a) risk-assessment tools that can be used to identify current and former smokers at highest risk for developing lung cancer and who might benefit from chemopreventative therapy; (b) tools for early diagnosis of current and former smokers with lung stage I-potentially resectable lung cancer; (c) tools that define molecular pathways that have lead to individual lung cancers and that predict what pharmacological approaches might be used to define best approaches to treatment of individual lung cancers; and (d) prognosis of resected cancers defining which patients have a high probability of recurrence or metastases and therefore should receive adjuvant therapy.

CHAPTER

Genomics in the Diagnosis and Management of Breast Cancer

Erich S. Huang and Andrew T. Huang

INTRODUCTION

Patient Presentation

Soon after her 55th birthday Joan Smith has her first screening mammogram. Her radiologist notes a small, 1 cm radiodensity associated with microcalcifications in the upper outer quadrant of her right breast. She cancels a planned vacation and spends her next week in and out of appointments with surgical, medical, and radiation oncologists. During the many hours she spends in clinic waiting rooms, she sees many women who share her fears and uncertainty. Some are younger, some older. Some are black, some white. The women she sees cover the range of size, shape, and race, but all share similar apprehensions about what is in store for them. Later, her core needle biopsy reveals an invasive carcinoma. From this point, Mrs. Smith is funnelled into a choreographed series of steps. Her surgeon performs a lumpectomy, the radiation oncologist begins planning her outpatient radiotherapy, and the medical oncologist initiates her chemotheraphy Herceptin treatments.

In spite of the variety of women Mrs. Smith sees in the clinic waiting rooms, the treatment they undergo are generally variations on a theme. For the most part, the diagnostic and therapeutic maneuvers they undergo are validated by large studies such as NSABP B-13, B-14, and B-21 or HERA (Table 35.1). All of these studies are established "dogma." They represent the best available evidence in treating women with breast cancer. The approach her doctors take is algorithmic; she is carried stepwise through a sequence of steps according to what is best supported in medical literature.

A patient support group becomes a source of great comfort for Mrs. Smith. There she learns of the revolutionary impact of estrogen blockade for hormone receptor-positive tumors, and Herceptin for HER2-positive tumors. Each member has a unique story to tell about her struggle with the disease; yet ironically, many of them have followed the same path in diagnosis and treatment. How is that, Mrs. Smith wonders? There is one woman in the group, Mrs. Brown, who was diagnosed with a small cancer 6 years ago, had a lumpectomy with clear margins and a negative axillary node dissection, yet she is now struggling with metastasis to her spine. She was initially told that her prognosis was quite good. Having been told the same thing, Mrs. Smith wonders what are the odds that she will find herself in the same situation at a time she will be looking forward to grandchildren and retirement? If Mrs. Brown's physicians could have foreseen her recurrence, how might they have used this information? Would they have treated her differently? In 8 cases out of 10, the standard treatment would have sufficed and cured her of disease, but this is little comfort to Mrs. Brown who proved to be among the 2 out of 10 exceptional cases.

THE PROMISE

Experiences like Mrs. Smith's are shared by more than 200,000 women in the United States yearly. And every year more than 40,000 of such women die from breast cancer – the second

TABLE 35.1 Large Clinical Trials for Management of Breast Cancer.

Trial	Treatment	Outcome
NSABP B-04	Total mastectomy versus total mastectomy with XRT versus radical mastectomy	No significant difference in disease-free or overall survival rates
NSABP B-06	Total mastectomy versus lumpectomy versus lumpectomy with XRT	No significant difference in disease-free or overall survival rates; addition of XRT to lumpectomy reduced local recurrence rate from 39% to 10%
NSABP B-13	Surgery alone versus surgery plus adjuvant chemotherapy in node-negative patients with estrogen receptor-negative tumors	Improved disease-free survival rate for adjuvant chemotherapy group
NSABP B-14	Surgery alone versus surgery plus adjuvant tamoxifen	Improved disease-free survival rate with adjuvant tamoxifen group
NSABP B-18	Neoadjuvant chemotherapy with doxorubicin, cyclophosphamide, or both for 4 cycles versus the same regimen given postoperatively	No significant difference in overall survival or disease-free survival rates (53% and 70% at 9 years in postoperative group and 69% and 55% in the preoperative group)
NSABP B-21	Lumpectomy plus tamoxifen versus lumpectomy plus tamoxifen plus XRT versus lumpectomy plus XRT for none-negative tumors <1 cm	Combination of XRT and tamoxifen was more effective than either alone in reducing ipsilateral breast tumor recurrence
NSABP B-27	Neoadjuvant chemotherapy comparing AC × 4 cycles then surgery versus AC × 4 cycles, docetaxel × 4 cycles then surgery versus surgery between 4 cycles of AC and 4 cycles of docetaxel	Groups I and III were combined and compared with group II; clinical and pathological complete response rates increased significantly among patients who received preoperative AC and docetaxel
NSABP B-32	SLN biopsy followed by axillary dissection versus SLN biopsy alone for clinical node-negative patients	SLN indentification rate was similar in both groups, accuracy was high for both, negative predictive value was high for both

SLN: sentinel lymph node; Reproduced from Anderson, *Surgical Oncology Handbook, 4th edition*, 39–40.

leading cause of death among females (Jemal et al., 2006). As the most common cancer diagnosis in women, one out of every six American women will confront breast cancer during her lifetime. The disease is more common in industrialized Northern America and Europe and is rising in developed Asia (Cheng et al., 2000).

In the past 30 years, mortality has decreased as screening mammography has become common practice. Screening mammography is a surveillance measure for clinically occult disease consisting of two views of each breast for asymptomatic women. Standardized criteria known as the BI-RADS (breast imaging reporting and data system) implemented by the American College of Radiology aid clinical decisions based on identified masses, their morphology and calcifications, their size, number, and morphology.

Not without some controversy, studies best support the notion that screening impacts mortality for women 50 years-old and greater, decreasing mortality by 20–30%, while strong evidence suggests similar mortality reduction in 40–49-year-old women. Current recommendations from the National Cancer Institute, American Cancer Society, and the US Preventative Services Task Force are that women between 40 and 50 years seek screening every 1–2 years with annual exams after 50.

Concomitantly, as more women have historically sought screening, incidence has increased due to broader detection, with the largest component of this increase being early Stage I cancers (Chu et al., 1996).

Risk factors include (1) Gender: 99% of breast cancers are found in women. (2) Age: incidence increases with age until menopause, when it plateaus (Peto et al., 2000). (3) Race: the diagnosis is more common among Caucasians, followed by African Americans, then Hispanic and Asian Americans (Jemal et al., 2006). (4) Family history, for which two factors dominate: number of first degree relatives and age. The presence of a first degree relative diagnosed at a younger age (<40 years) essentially doubles one's risk compared to having an elderly relative with breast cancer (Collaborative Group on Hormonal Factors on Breast Cancer, 2001). Familial breast cancers are estimated to comprise approximately 10% of breast cancers; hence, the large majority of breast cancers are sporadic events. (5) Hormonal status: a well-accepted risk modifier. Patients such as women with early menarche and late first full term pregnancy who have longer exposure to estrogen demonstrate higher risk, while those with shorter lifetime exposure are at reduced risk (Clemons et al., 2001).

GENETIC BASES

Genes implicated in familial breast cancers are classically the BRCA1 and 2 tumor suppressors, as well as the ubiquitously significant p53 proto-oncogene. Ashkenazi Jews, for example, are known to have specific BRCA1 mutations at a much higher frequency than other populations. This is attributed to a founder effect when the population of Ashekenazim was small. As groundbreaking their discovery has been, the BRCA genes account for a narrow segment of the disease.

BRCA1 and 2 gene products are involved in DNA repair of double-stranded breaks. This normally occurs via homologous recombination. In the absence of normal BRCA1 and 2 activity, cells demonstrate morphologically abnormal chromosomes attributed to impaired replication. Clinically, mutation of these genes is responsible for 5–6% of all breast cancers and a significant portion of inherited breast and ovarian cancers (Venkitaraman, 2002).

Unfortunately, multiple mutations of these loci are implicated in breast cancer, and widespread testing is controversial in its cost-effectiveness even for patients with suggestive family histories. With a cost of over $3000, most recommendations for primary care providers involve genetic counseling before ordering a test.

If testing is performed and a patient demonstrates a significant mutation, the options include: (1) prophylactic mastectomy, which is estimated to reduce risk of developing breast cancer between 90% and 95% (Hartmann et al., 1999; Rebbeck et al., 2004). Or (2) surveillance with yearly mammograms and MRI scanning. Clearly, when indicated and when providing useful results, BRCA testing provides information that may be acted upon and impacts developing breast cancer.

Other Mendelian disorders include mutation of the p53 tumor suppressor. Familial mutations are associated with Li-Fraumeni syndrome for which there is high penetrance for breast cancer. Epistatically related is mutatiom of an activator of p53, ATM, which results in Ataxia-Telangiectasia, a syndrome of cerebellar ataxia, immune deficiencies, and oculocutaneous telangiectasias associated with elevated propensity for malignancies, including breast cancer. Other germline mutations include those of the PTEN gene, a tumor suppressor whose mutation results in Cowden syndrome manifest in mucocutaneous hamartomas, dermatologic abnormalities and early onset thyroid and breast cancer. And Peutz-Jeghers syndrome, secondary to mutation of STK11, results in gastrointestinal hamartomatous polyps and mucocutaneous pigmentation and increased risk for malignancies, including breast.

The sporadic derangements that contribute to 90% of the remaining breast cancer cases are little understood.

MOLECULAR BASES

Molecular characteristics of breast tumors that have accepted predictive and prognostic impact in breast cancer include hormonal status and HER2.

Observations of the linkage between hormonal status and breast cancer date back to the late 19th century. This, in combination with the modern concept and discovery of the estrogen receptor has led to the paradigm of estrogen modulation in managing receptor-positive breast cancers. Hormonal status is predictive and arguably prognostic. Multiple studies indicate that the presence of estrogen receptors in breast tumors is strongly predictive of response to hormonal therapy, while an overwhelming minority of receptor-negative tumors demonstrate response (Bezwoda et al., 1991; Manni et al., 1980). Estrogen receptor-positive tumors tend to be more well-differentiated by histopathologic criteria and demonstrate lower rates of recurrence at 5 years. This paradigm demonstrates the profound clinical impact that a single clinical marker can have on managing a disease.

The importance of molecular markers is reinforced by the finding that amplification of HER2 in breast tumors has negative impact on survival and relapse (Slamon et al., 1987). Approximately one-fifth of tumors are found to overexpress this member of the epidermal growth factor receptor family. Studies also suggest that such overexpression predicts improved response to anthracycline-based chemotherapy (Thor et al., 1998; Pritchard et al., 2006). Though there is laboratory-based evidence that there are intersections between hormone-mediated pathways and HER2-based pathways, the clinical impact of overexpression in predicting response to hormone modulation is equivocal.

In any case, directed therapy against HER2 with Trastuzumab (Herceptin), a humanized monoclonal antibody to the receptor, represents a significant advance in identifying key molecular characteristics of a tumor and designing a therapy based on these data.

The apprehension that Mrs. Smith feels is reflective of the current state of breast cancer treatment. Accepted treatment modalities have gone a great distance to improve the care and outlook of breast cancer patients, but they do not take account of the heterogeneity of individual tumor biology. While AJCC cancer staging is undoubtedly useful for making treatment decisions, there are many cases where a presumably low-risk patient who receives definitive therapy develops recurrent disease, and cases where patients with presumably advanced tumors survive longer than expected. HER2 and estrogen and progesterone receptor status prove that understanding molecular aspects of someone's disease can dramatically impact their treatment; yet therapy tailored to the full spectrum of molecular biology in a patient's individual tumor is still a promise rather than a reality. The full complexity of biologic response to treatment does not stop with individual tumors, superimposed on these are the differences in how a patient responds to treatment. One to 4% of women who receive the Herceptin monoclonal antibody develop congestive heart failure, and 10% experience significant decrease in cardiac function (Chien, 2006).

The ultimate goal of all medical interventions, whether for cancer or essential hypertension, is to tailor therapy to the individual patient and her manifestation of disease. The current state

of the art is in designating a patient as being part of a population rather than as a unique individual. Our patient Mrs. Smith, by St Gallen's criteria, is a member of a low-risk population when using anatomic and pathologic parameters such as tumor size or axillary node status, but how she will fare based on the inherent properties of her particular manifestation of disease is unknown to us. As she enters a treatment system that is protocol-bound, Mrs. Smith wants desperately to feel as if she were being treated based on the behavior of her own cancer – that her treatment is calibrated according to her biology. Unfortunately, cancer care as it stands today is not amenable to fine gradations in biology because there are no technical means to identify such molecular particularities. In theory, the richness and diversity of information about a tumor that genome-scale technology provides is truly reflective of the biology of a particular tumor. This will provide an avenue, among others such as proteomics, to reaching the ultimate goal of individualized cancer treatment.

PROGNOSIS AND PREDICTION

Oncologic therapy is an exercise in minimizing morbidity and maximizing efficacy. In order to accomplish this, one needs to calibrate treatment, which is often morbid, with extent or aggressiveness of disease. Consequently, staging methods provide standardized criteria for measuring the anatomic extent of disease. National and international cancer organizations embrace these clinicopathologic yardsticks with the hope that clinicians can use them as universal standards for prognosis, treatment, and outcomes. Staging is anatomic and pathologic: tumor size, number of regional nodes, and the presence of metastasis are the sole components of the TNM system. This reflects a historical understanding of cancer beginning in one location, spreading locally, then accessing lymphatics or invading vascular structures. Implicit in this is that anatomic extent is a surrogate for a tumor's behavior. It is generally accepted as a first approximation that more aggressive tumors will manifest themselves at the time of diagnosis by the presence of lymph node metastasis, invasion into surrounding tissues or by distant metastases; while more indolent tumors are likely small and restricted to their site of origin.

Obviously, the weakness of TNM staging is this very assumption. While the TNM system serves admirably for allowing clinicians to gauge how aggressive treatment should be to how advanced or aggressive a particular patient's disease. Most clinicians acknowledge that it is a surrogate, an approximation of tumor behavior. For instance, modern practice has discarded removal of the pectoral muscle from Halsted's radical mastectomy as originally described, because this aggressive approach to local control ultimately does not save any more lives than the "modified" radical procedure that spares the muscle. The biology of breast cancer suggests that some point of its natural history involves leapfrogging past adjacent tissue – that it becomes a systemic disease. And at the time of surgery, clinicians simply concede their inability to gauge whether micrometastasis has already occurred when there is no gross evidence of invasion. Likely for this reason, while most women with curative resections of small tumors and negative axillary nodes are considered cured, a significant fraction returns years later with metastatic disease.

MOLECULAR MARKERS

Hormone receptor status and presence of HER2 represent molecular markers that undoubtedly impact breast cancer clinical management. The power of adjuvant and neo-adjuvant therapies directed against these entities suggests that therapies specifically directed against growth pathways, whether actuated by hormones or oncogenes (or both) can provide individualized therapy for the characteristics of a specific tumor. A natural outgrowth of this thinking is that identifying more molecular markers will highlight more pathways and more avenues for developing specific therapies. Until recently, there were no technically facile methods to survey and identify differentially expressed genes. Classical molecular biology required a hypothesis and painstaking analysis on a gene-by-gene basis. A graduate or post-doctoral fellow might spend a year assaying the acti-vity of a handful of genes by transferring them to nylon membranes and "blotting" them with radioisotopes to generate a hundred datapoints. With the draft completion of the Human Genome Project, microarrays represent a viable technology for analyzing the activity of several orders of magnitude more genes.

Microarrays are technological descendents of the Southern blot. Fixing a nucleic acid to a substrate provides a method for taking advantage of complimentary hybridization and various fluorescent or radioactive tagging schemes to establish the presence and abundance of a particular nucleic acid sequence from a sample. What a Southern or Northern blot can do for a handful of sequences, a microarray can do in multiplicity. The greater the number of distinct nucleic acids sequences represented on an array, the broader the survey of the genes being expressed in a tissue at the time it is harvested. Therefore tagged substrate derived from RNA harvested from a particular tumor when hybridized to an array can provide an estimate of how actively genes are being expressed at the time of harvesting. Technology has merely provided a complete genome sequence and the means to increase the physical density of sequences to a point where many thousands of sequences can be assayed in a timely manner.

Current generation arrays encompass most of the human genome. Therefore the scale of data provided by microarray experiments expands by orders of magnitude from the 100s available with traditional molecular biology, to the hundreds of thousands or even millions afforded by genome-scale assays. This explosion of data requires methods to analyze it. Researchers are embracing many methodologies for contending with data on such a large scale.

GENOMIC INSIGHTS

Individual Tumors are Identifiable in Principle

A variety of studies in the late 1990's and early 2000's demonstrated that microarray data from neoplastic tissues provided sufficient information to distinguish biological differences. Work from investigators such as Golub or Alizadeh respectively demonstrated not only that hematologic malignancies such as AML and ALL might be distinguished by "class prediction" tools, but that genome-scale microarray data could differentiate between chemotherapy-responsive and unresponsive large B cell lymphomas even if they were microscopically indistinguishable (Alizadeh et al., 2000; Golub et al., 1999).

Extending on this work, investigators soon realized that the richness and complexity of microarray data could provide "molecular portraits" of breast tumors. These portraits were so variegated and distinct that patterns of gene expression data from tumors after the presumed seismic changes of chemotherapy possessed enough of the characteristics of the tumors before therapy to be traced back to original patient. This finding held true when comparing a single individual's primary tumor and tissue from a lymph node metastasis. When using hierarchical clustering schemes, gene expression patterns from an individual, whether from tumor samples taken before chemotherapy or after, or from an individual's primary tumor and lymph node metastases, were more similar to one another than to samples between individuals, suggesting that genome-scale expression data possesses enough information to characterize an individual's particular tumor, even after the changes in that particular tissue's biology represented by exposure to doxorubicin or metastasis to a new microenvironment (Sorlie et al., 1999).

From a technical standpoint, this finding supports that varying expression levels of RNA even when derived from samples taken at different times from the same patient represent genuine biology about that patient. It is how to interpret these data and rigorously link biology with these "pervasive" gene expression patterns, as the authors put it, that continues to be the subject of active investigation.

Luminal and Basal Tumors

A follow-up study from the same investigators demonstrated the expression data derived from ER-positive tumors fell into two categories, Luminal A and B, while estrogen receptor-negative tumors also possessed distinct patterns and could be classified as Normal, Basal-like and Her2-related. More importantly, these classifications corresponded to clinical differences between patients.

The term "luminal" was applied to ER-positive tumors because ER-responsive genes such as trefoil factor 3, LIV-1, and GATA-binding protein thought to typify luminal epithelium were well represented. The distinction between Luminal A and B lay in lower expression of ER-responsive genes in the B subgroup. Particularly compelling were differences in survival between women whose breast cancers fell into either

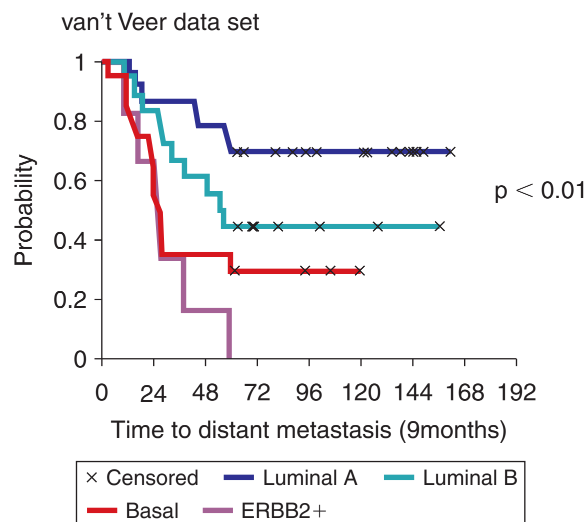

Figure 35.1 Kaplan–Meier analysis of disease outcome. Time to development of distant metastasis in the 97 sporadic cases from van't Veer et al. Patients were stratified according to the subtypes of Luminal A, Luminal B, Basal and ERBB2 (adapted from Sorlie et al., 2001).

of these taxonomies. Women classified as having Luminal A tumors tended to have better prognosis than those with Luminal B. Carrying the analysis further, patients with Basal-like and Her2-related tumors had poorer prognosis than either Luminal subtype with Her2-related tumors possessing the steepest Kaplan-Meier curves.

This type of study suggested that gene expression data could highlight subtle and clinically significant differences between breast tumors in a manner that can extend on conventional histopathologic diagnosis. It also demonstrated that a link might be drawn between the clinical behavior of a tumor and the patterns of gene expression within it (Sorlie et al., 2001) (Figure 35.1).

NETHERLANDS CANCER INSTITUTE STUDY

A prominent application of genome-scale expression studies to prognostication is a study of 78 tumors from lymph node-negative patients younger than 55 from the Netherlands Cancer Institute. A 70-gene classification signature was developed for distinguishing patients with poor prognosis defined as recurrence or metastasis within 5 years from patients with good prognosis (disease-free survival up to 5 years).

This study was promptly followed with a validation of this same signature in a more diverse group of tumor samples from a patient group with a mixture of lymph node positive and negative stage I and II disease. The classifier performed very well in patients with good prognosis; at 5 years it correctly identified 95% with distant metastasis-free disease. When taken out to 10

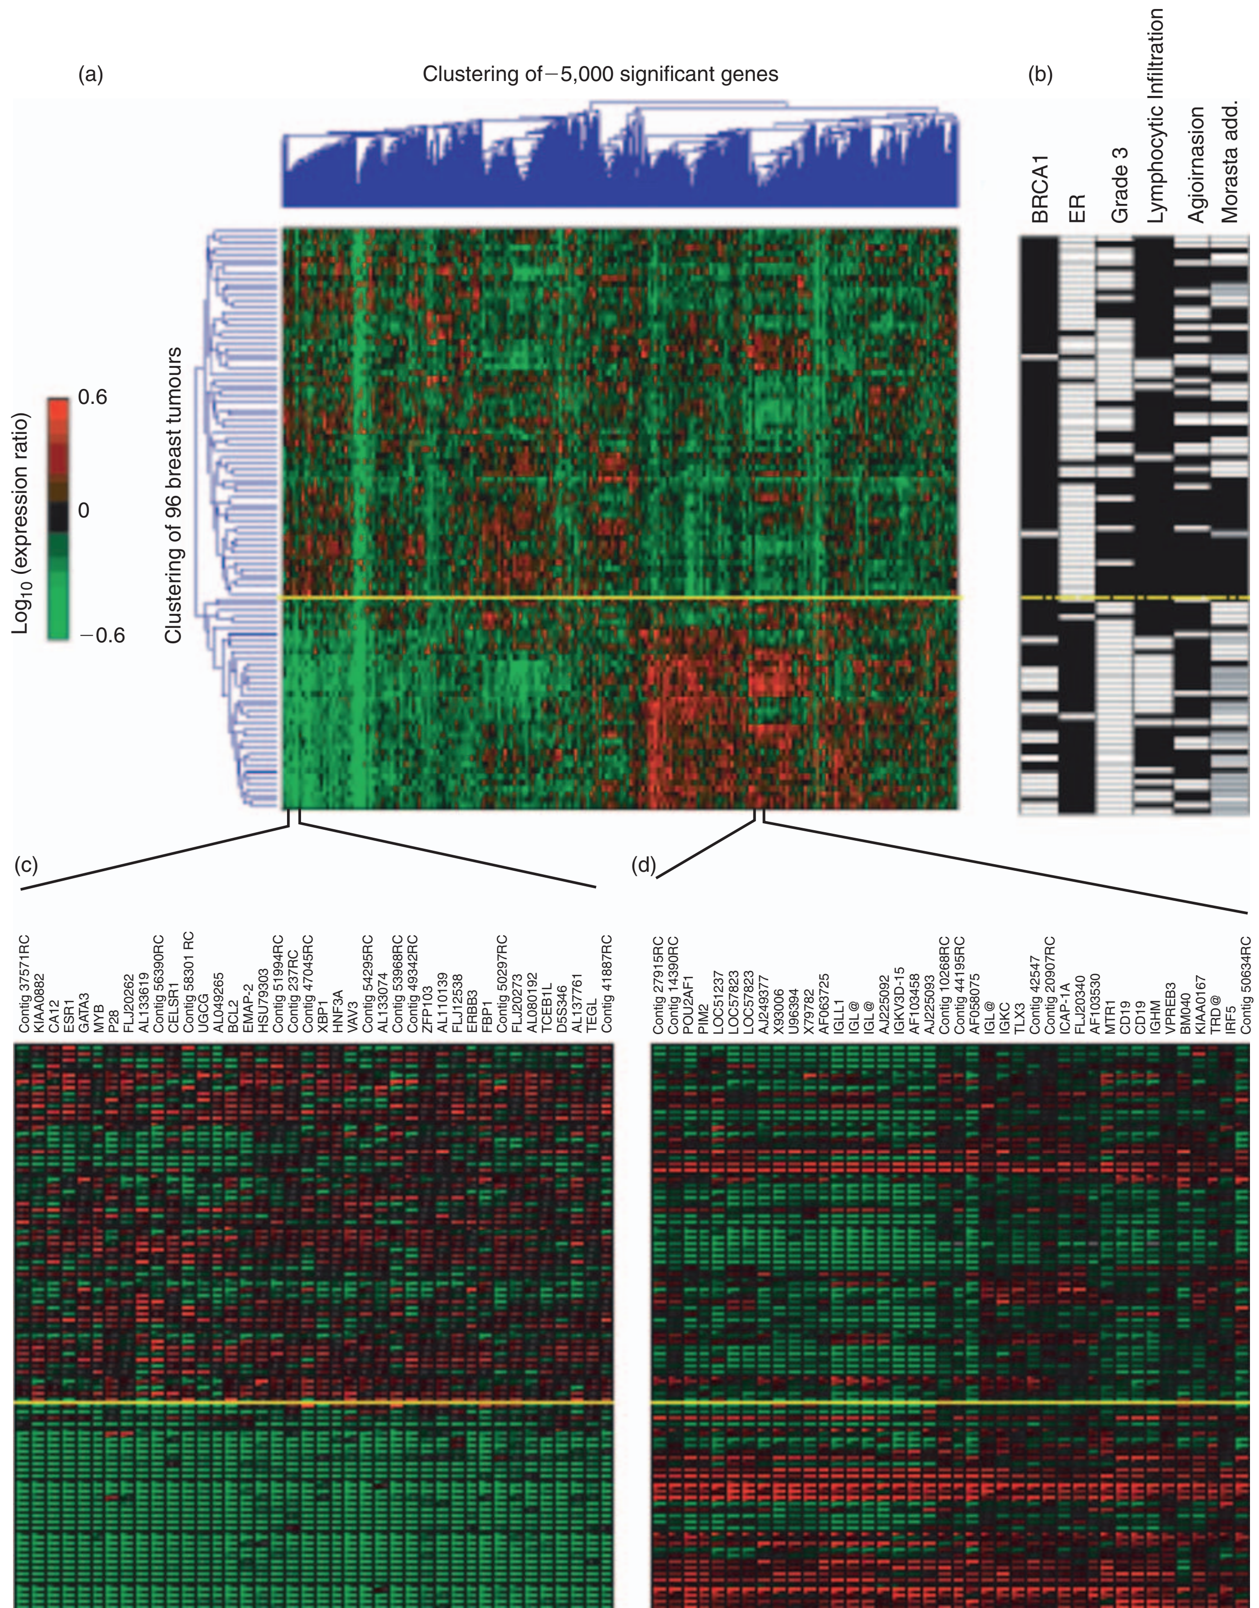

Figure 35.2 The Mammaprint 70 "prognosis classifier genes" across 295 consecutive patients.

years, 85% of patients were correctly classified. When applied to poor prognosis, however, its predictive capabilities were less satisfying. Five year accuracy was only 61%. By 10 years, this rate had declined to 51% (van de Vijver et al., 2002).

Accordingly, an EORTC-sponsored prospective randomized clinical trial based on this classifier, titled MINDACT (Microarray for Node Negative Disease May Avoid Chemotherapy), is in accrual in Europe. Its primary focus is assessing whether patients with clinically high-risk disease, whose 70-gene classifier suggests that they should actually be in a low-risk category can be "safely spared chemotherapy without affecting distant metastasis-free survival." Such a study represents the logical next step after numerous retrospective studies of relatively limited numbers of patients. It should be noted in this particular approach is that gene expression data and clinical parameters are placed in opposing camps.

In the United States, the 70-gene signature is now approved for marketing by the Food and Drug Administration as MammaPrint. It is not yet available for clinical use (Figure 35.2).

DUKE-TAIPEI STUDY

In a similar vein, a collaborative study involving investigators at Duke University and the Koo Foundation Sun Yat-Sen Cancer Center takes a different approach to using gene expression data to develop classifiers for understanding lymph node metastasis and 3-year recurrence in 89 cases. Lymph node status being the strongest clinical predictor of prognosis in breast cancer, it was used as a proof-of-principle for using gene expression data in breast cancer.

Rather than utilizing a single classifier, their analysis is based on multiple classifiers or "metagenes" that are used in aggregate via recursive partitions of the sample set. In other words, a single classifier metagene may correctly separate a large part, but not all of a dataset into lymph node positive or negative patients, and by successively "partitioning" the data with additional classifiers, the prediction of lymph node status is sharpened. A final predictive model is ultimately a composite of many different metagenes or classifiers. An additional advantage to such an approach is that metagenes provide a basis to understand the disparate biological processes in lymph node metastasis rather than attempting to compress a complex biological phenomenon into a single classifier.

Using this methodology, appropriately identifying whether a patient was likely to be lymph node positive or negative was achieved 90% of the time. Extending the analysis to recurrence at 3 years after diagnosis demonstrated similar accuracy (Huang et al., 2003a, b) (Figure 35.3).

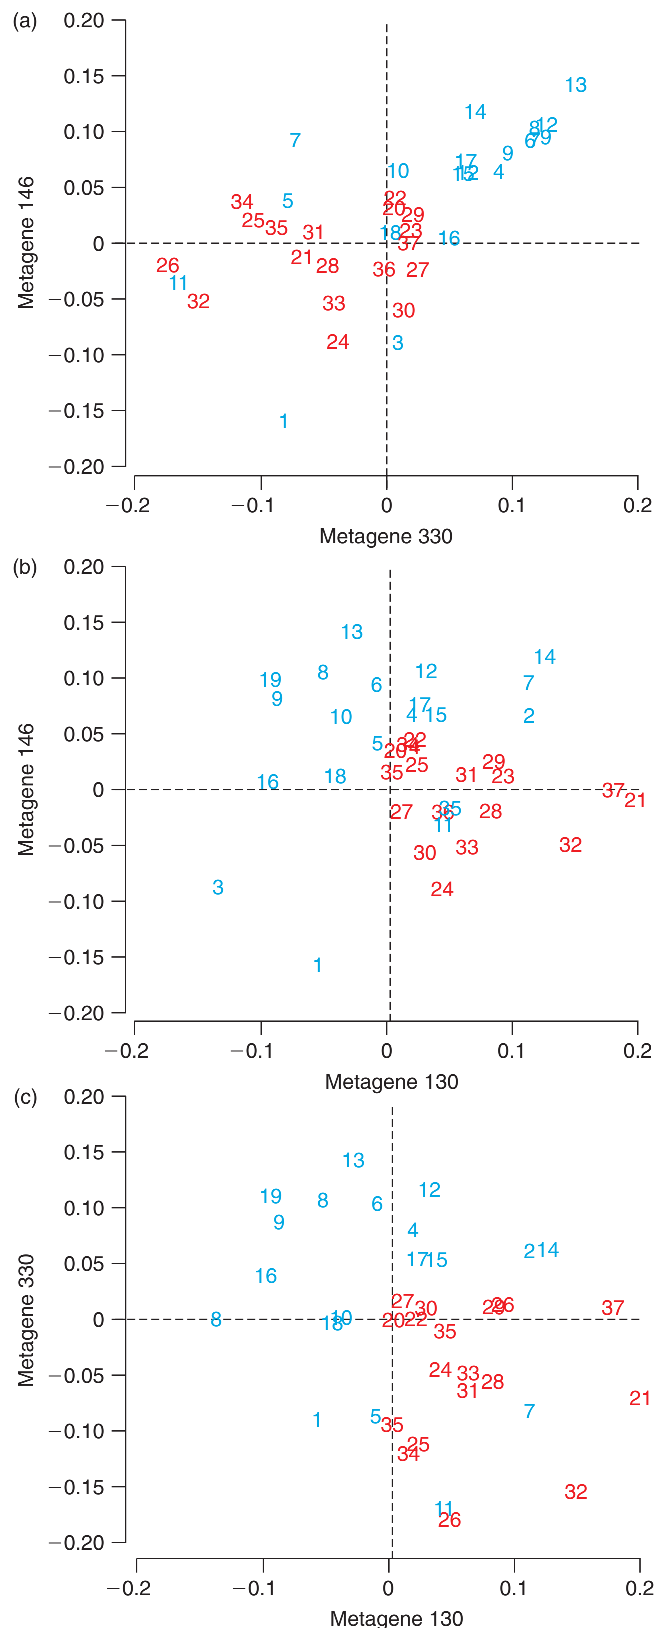

Figure 35.3 Differential contributions of separate metagenes in classifying high from low-risk patients. High risk are labeled in red, while low risk are in blue. Note how different metagenes segregate these patients in different manners.

NSABP STUDY

Members of the NSABP focused their attention on understanding distant recurrence in patients with node-negative,

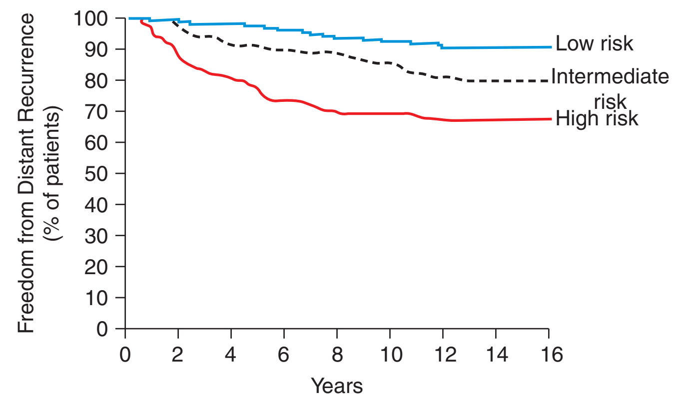
estrogen-receptor positive breast cancers. Successfully making this prediction could potentially obviate chemotherapy for the 85% of patients for whom tamoxifen after surgery is sufficient for preventing 10-year distant recurrence. In a departure from many such studies, the investigators use RT-PCR from paraffin-embedded samples up to 10 years old. Their assay consists of a set of 21 genes (including 5 reference genes) derived from an original set of 250 genes studied across three previous investigations. Their selection was based on their technical robustness in the process of RT-PCR and their performance as predictors. Genes within this set included known proliferation and cell cycle entities, as well as genes linked to tissue invasion and estrogen. An empirically derived "recurrence score" from these RT-PCR data determines whether a patient is low, intermediate, or high risk based on data from three training studies including samples from NSABP B-20 (Figure 35.4). Clinical data from this last study were used to establish the cutoff points for each of these recurrence categories. As applied to 668 samples in the NSABP collection, the investigators tested several hypotheses: first, whether the a low recurrence score accurately anticipated whether a patient would be free of distant recurrence more than 10 years after surgery, and whether there were a statistically significant relation between these two. By these criteria, in the setting of predicting 10-year recurrence in a population of node-negative, estrogen-receptor positive women, the recurrence score was accurate. In comparison to traditional clinical risk factors such as age and tumor size, the score demonstrated a higher degree of statistical significance (Paik et al., 2004). This predictor (commercialized as the Oncotype Dx assay by Genomic Health), is being validated in a Phase III trial (TAILORx Breast Cancer Trial) sponsored by the National Cancer Institute and guided by the Eastern Cooperative Oncology Group.

The trial will analyze whether patients within a low to intermediate risk range will benefit from addition of chemotherapy to hormonal therapy; and whether a particular threshold recurrence score can be used to anticipate whether chemotherapy would be beneficial or not. Patients below the risk range will receive hormonal therapy alone, while patients above this range will receive combined chemotherapy and hormonal therapy. Patients in the risk range will be randomized to hormonal therapy alone versus combined therapy.

As this trial accrues, Oncotype DX is finding use among medical oncologists on a day-to-day basis to inform the process of placing estrogen-receptor positive, node-negative patients on chemotherapy (Figure 35.4).

PATHWAY PREDICTION

Another promising application of genome-scale information is for pathway prediction. Early pilot studies indicated that overexpression of oncogenic activities in cell culture could evoke transcriptional profiles that both predicted and quantified oncogenic pathway activation in a fashion robust enough to be applied *in vivo* and appropriately identify the dysregulated activities evoking tumorigenesis in transgenic mouse models.



No. at Risk									
Low risk	338	328	313	298	276	258	231	170	38
Intermediate risk	149	139	128	116	104	96	80	66	16
High risk	181	154	137	119	105	91	63	13	

Figure 35.4 Likelihood of distant recurrence using the Oncotype DX assay to identify node-negative, estrogen-receptor positive patients to distinguish low versus high-risk patients.

This provides a facile approach to interrogating the potentially numerous growth activation, local invasion, metastatic, and oncogenic pathways that may be present in breast cancer. Analysis of the effects of chemotherapeutic drugs on lung cancer and breast cancer tissue culture lines suggest that this strategy identify metagenes that appropriately predict response to pharmacologic intervention (Huang et al., 2003a, b; Bild et al., 2006); Potti et al., 2006). This line of work will potentially provide clinicians tools based on tumor biology to decide whether patients for whom the decision to institute chemotherapy is equivocal by conventional clinico-pathologic criteria should undertake the toxicities of systemic therapy for maximal benefit.

THE REALITY OF CLINICAL GENOMICS

At this point in its development, the application of gene expression analysis to clinical decision-making in breast cancer is promising. The studies outlined above provide good evidence that genomics can potentially unmask the molecular particularities of a woman's breast cancer, but until the time-tested standard of a randomized, prospective trial actually validates this possibility, it remains only a promise.

There is little doubt that the massively multivariate data provided by genome-scale expression analysis of breast tumors potentially revolutionizes our understanding and our clinical approach to breast cancer. This depends on robust and reproducible measurement of the expression of thousands of genes. Yet at this point in time, it is arguable that microarray data alone are neither robust nor reproducible. The strong movement to using RT-PCR data on a handful of selected genes, as with the Oncotype DX product from Genomic Health, Inc. is a byproduct of skepticism about the consistency of genome-scale expression data derived

from microarrays. On the other hand, 5 years of experience with gene expression data demonstrate that their richness and complexity are concordant with the heterogeneity of cancer biology. Even early studies with a limited number of genes being studied–with first generation methodologies for interpreting expression data–show that there are pervasive expression patterns that unambiguously link a tumor to a single individual regardless of whether samples were taken before or after chemotherapy.

Many groups ultimately treat microarrays as a convenient screening tool for developing a restricted subset of genes that can be used as a predictor for a single outcome measure. Among the best known, the 70-gene predictor that is currently being tested in European clinical trials, and the 21-gene RT-PCR Oncotype DX assay that is currently commercially available to patients, divide patients into two to a few subgroups. Dividing patients into a "high risk" versus "low risk" groups, while representing a potential refinement in clinical decision-making, does not do justice to the potential of gene expression data.

The strongest challenge to such methodology is that further study of the dataset that produced the 70-gene predictor by an independent group reveals that there are many 70-gene predictors utilizing different genes that can predict risk with no less accuracy (Ein-Dor et al., 2005). If this is the case, why choose a particular group of 70 genes? It is tempting to take this analysis as evidence that the field need be reassessed and that predictors based on microarrays merely represent an arbitrary choice of what genes to include.

On the other hand, a new study in which data from 295 patients were analyzed utilizing previously published prognostic and predictive gene expression models showed that there was a remarkable degree of "concordance" – similar classification ability – between models even when the gene sets diverged significantly. The authors concluded that similar biological phenotypes were being tracked, even if constituent genes in a particular classification scheme might differ (Fan et al., 2006). Such a finding suggests a different interpretation: one may approach the data by extending the analysis beyond making prediction on a single outcome. Surely a group of patients can be divided into "high risk" versus "low risk", luminal versus basal, high probability for recurrence or low, and surely multiple gene expression-based models do equally well in making such divisions. So what does the presence of so many essentially "indistinguishable" predictors mean?

Where the answer lies is in the fact that the questions being asked may be extended further. If microarrays afford one a dataspace of thousands of patients and hundreds and thousands of genes, why stop at one division of the data? Does a single classification of "high risk" versus "low risk" do justice to the data? Why not apply every possible predictor to subdivide this complex dataspace as many ways as possible? In theory, by successively applying different predictors to a group of breast cancer patients, one can segregate the set down to small, homogeneous groups of patients with individualized prognosis. One might argue that "similar biological phenotypes" is an oversimplification. If one only wanted to divide a group of patients in two and stop, different gene expression models may perform similarly, but if one wanted to get at the biological particularities of particular patients, successive partitioning with different models (what our group would call metagenes) might carry us to that point.

Taking a step in this direction, one group found that a "core serum response" (CSR) profile derived from analysis of quiescent fibroblasts stimulated with serum appeared to be a useful way to study the behavior of tumors (Chang et al., 2004). By segregating a patient population into high risk and low risk first with the 70-gene predictor, and then applying the CSR. They found that patients who were high risk in addition to having an active CSR signature, were at much higher risk for metastatic disease than those with an inactive or "quiescent" profile. This method of successively partitioning genome-scale data maximizes one's opportunity for using all the useful data present in a dataset (Chang et al., 2005).

2009 UPDATE

At the time of this update, the two largest prospective, randomized trials for the application of gene expression signatures in breast cancer – the TAILORx (OncotypeDX), and MINDACT (Mammaprint) trials – continue to accrue patients. As noted in the main chapter, these trials seek to identify presumably low-risk patients with early stage, lymph node-negative disease who are at risk for recurrence. As such, the OncotypeDx and Mammaprint platforms, which both interrogate a small subset of genes, are prognostic tests. Their intent is to unveil the discordance between a clinically low-risk phenotype and a molecular phenotype indicative of aggressive biologic behavior and thereby optimize the risk-benefit equation for using cytotoxic chemotherapy. These trials represent a critically important first step in developing level I data for the day-to-day utility of gene expression indicators in clinical practice.

With the goal of tailoring a specific therapy to a specific breast cancer in mind, the decision point arrived at by the OncotypeDX or Mammaprint platforms does not specifically address how to tailor the treatment itself to the molecular characteristics of an individual's manifestation of breast cancer. This is particularly relevant with the growing armamentarium of pathway-directed therapies such as receptor-targeted biologics or Tyrosine Kinase Inhibitors.

One irony of breast cancer treatment is that, while modulation of the estrogen pathway and targeting of the ERBB2 (HER2) cell surface receptor represent landmark applications of growth pathway-directed therapies, large numbers of patients whose markers suggest that they should respond to these treatments possess disease that is unresponsive.

Evidence indicates that polymorphisms in loci related to the oxidative metabolism of Tamoxifen may explain why

estrogen receptor-positive breast cancers "escape" the inhibitory effects of Tamoxifen—a phenomenon long attributed to tumor resistance to estrogen pathway blockade. Patients with particular CYP2D6 polymorphisms demonstrate lower levels of Endoxifen, a potent metabolic product of Tamoxifen (Lim, et al., 2005; Tan, et al., 2008). As presented at the San Antonio Breast Cancer Symposium in 2008, retrospective subgroup analysis of the Austrian Breast and Colorectal Study Group-8 trial (a prospective trial evaluating treatment of post-menopausal women with estrogen receptor-positive breast cancers with 5 years of Tamoxifen, or 2 years of Tamoxifen followed by 3 years of Arimidex (Anastrozole), an aromatase inhibitor) showed that women treated with Tamoxifen alone, who were also identified to be "poor metabolizers" of Tamoxifen, had nearly four-fold increased risk for recurrence over "extensive metabolizers". Interestingly, poor metabolizers who were randomized to the switch to an aromatase inhibitor and who had not developed a recurrence while on Tamoxifen experienced a normalization of their relative risk for recurrence (Goetz, et al., 2008). This particular example is illustrative of metabolic polymorphisms rather than intrinsic characteristics of the tumor itself that can explain heterogeneity in response to treatment.

While the HER2-NEU marker is an important prognostic marker and identifies patients who potentially benefit from Herceptin (Trastuzumab), only a third of patients who demonstrate either ERBB2 amplification or high HER2-NEU expression at the cell surface respond to treatment. One explanation lies at the receptor level where there is evidence to suggest that some HER2-positive tumors may possess a truncation at the amino terminal that corresponds to impaired response to trastuzumab (Scaltriti et al., 2007). Another explanation lies in dysregulation of a downstream pathway. A functional genomic RNA interference (RNAi) screen for determinants of trastuzumab resistance has shown that PTEN is a dominant modifer of trastuzumab response. While PTEN mutations are only observed in a small minority of clinical samples, activating mutations of the upstream gene PIK3CA are more common and confer a similar resistance phenotype (Berns, et al. 2007).

Such data argue that tests that assess the functional status of cancer-related pathways may ultimately prove more useful in the clinical arena than individual mutations. In this vein, tests that only measure a restricted subset of genes cannot provide the depth of information needed to reconstruct the patterns of gene expression related to pathway activation. Genome-scale transcriptional profiling is one strategy to carry currently available transcriptome-based technologies from the realm of the prognostic to the predictive.

CHAPTER

Colorectal Cancer

G.L. Wiesner, T.P. Slavin and J.S. Barnholtz-Sloan

INTRODUCTION

Over the next year, approximately 112,340 new cases of colorectal cancer (CRC) will be diagnosed in the United States and over one million cases across the globe, making CRC one of the most common cancers worldwide (ACS, 2007; Curado et al., 2007). Accounting for 10% of cancer-related deaths, CRC is the third most common cause of cancer mortality in both men and women in the United States (ACS, 2007). CRC occurs in all races and all peoples, but the rates vary among people with different racial and ethnic backgrounds. African Americans have an increased incidence and mortality of CRC compared to European Americans in the United States, while Hispanic Americans and American Indian/Alaskan Natives have the lowest incidence rates (Ries et al., 2007). Survival rates also differ among racial/ethnic groups and are highly dependent on stage of disease at diagnosis; when the cancer is diagnosed at an early stage the 5-year relative survival can be as high as 90%. However, only about a third of all CRC cases are diagnosed in the early stages (Jemal et al., 2007). Despite this dismal statistic, both CRC incidence and mortality rates have steadily decreased over the last two decades (Ries et al., 2007). The simultaneous decline in these rates is most likely a reflection of an increase in screening practices that interrupt the development of invasive cancer by removing benign colon polyps or early stage disease in screened individuals (Burt, 2000; Vogelaar et al., 2006; Winawer et al., 2003). Screening may also decrease the incidence of CRC by reducing the time that the colon epithelium is exposed to potential environmental risk factors.

Many studies have shown that there are both genetic and environmental causes for CRC, as reviewed (Giovannucci and Wu, 2006; Potter and Hunter, 2002). Several inherited genetic syndromes that involve a high risk for CRC have been discovered such as hereditary nonpolyposis colorectal cancer (HNPCC), familial adenomatous polyposis (FAP), and other rare inherited polyposis syndromes (Rustgi, 2007). However, these syndromes taken together only account for 5% or less of all CRC diagnoses (Figure 36.1; Burt and Neklason, 2005). Important for public health is the approximately 15–20% of CRC cases with a family history of CRC and/or polyps (Burt, 1996a; Sandhu et al., 2001). The family members in this group have an elevated lifetime risk for CRC, implying additional, yet undiscovered, genetic and/or common environmental susceptibility factors underlying colon neoplasia.

The current theory of CRC causation states that multiple sequential mutations in cellular regulatory genes of the colon epithelium occur before an invasive cancer can develop (Figure 36.2; Fearon and Vogelstein, 1990; Vogelstein et al., 1988). This multi-step model of cancer development is also influenced by environmental factors, such as diet or smoking, and modifier genes, which are presumed to additionally alter key cellular functions. It is notable that much of the theoretical framework for understanding the root causes of carcinogenesis have stemmed from genetic and genomic research in CRC. A wider appreciation

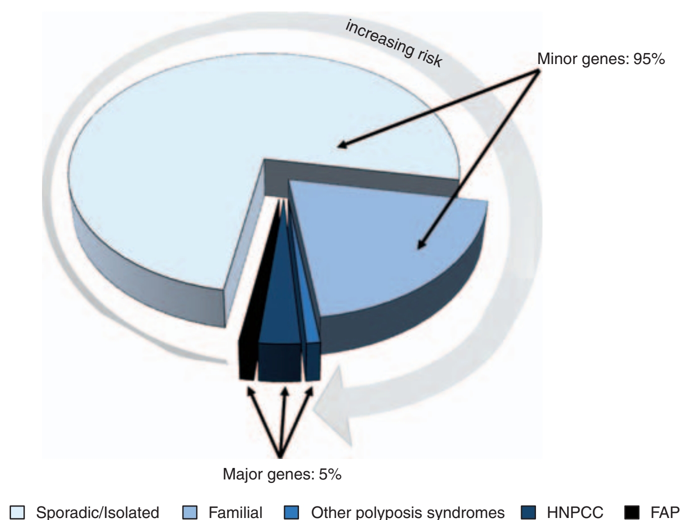

Figure 36.1 Genetic predisposition to CRC. The risk for CRC increases along a continuum; risk is lowest with a sporadic/isolated family history (~75% of cases), moderate with clear positive family history of disease (~20% of cases), and highest in known monogenic inherited CRC syndromes (~5% of cases).

of the multi-step phenomena, the pathways involved, and the global epigenetic alterations in cancer were gained using a genomic viewpoint of disease causation. The increasing availability and affordability of genetic/genomic tools will only improve the diagnosis, screening, treatment, and monitoring of patients in the future. With broader application of these technologies, genomics will be the mainstay of personalized medical care, rather than a private application for the unique patient or family.

This chapter will review the current understanding of genetic predisposition, somatic genomic alterations and environmental influences in the development of CRC. The application of genomic technologies for the patients with CRC or at risk for CRC will also be discussed. Lastly, the emerging genomic-based technologies that promise to personalize and improve healthcare will be reviewed.

GENOMIC MODEL OF CRC

Most malignant tumors of the colon arise from an adenomatous polyp, a benign growth of the colon that is easily identified and removed using colonoscopic screening and biopsy methods. Seminal studies of colonic karyotypes demonstrated the adenoma to carcinoma sequence, in which specific chromosomal and/or genetic alterations correlated with progressive growth of colon tumors from benign adenoma to overt cancer (Figure 36.2; Fearon and Vogelstein, 1990; Vogelstein et al., 1988). In fact, two separate progression pathways for CRC development have been discovered and validated: (1) the chromosomal instability (CIN) pathway and (2) the mismatch repair pathway (MMR) pathway. The multi-step process of carcinogenesis is complex, involving as many as six discrete molecular clonal alterations in the adenomatous tissue over a period of 20 or more years before transforming into an invasive carcinoma (Knudson, 2001). The earliest step in the CIN pathway is a mutation in the APC gene, a key factor in the WNT/β-catenin pathway, which is associated with the formation of small, microscopic clusters of proliferating cells called an aberrant crypt which then develops into a benign adenoma. About 15% of CRC have underlying errors in the mismatch repair (MMR) mechanism, identified by microsatellite instability (MSI), loss of MMR proteins and/or mutations in various DNA repair genes and growth factors (Figure 36.2; Ionov et al., 1993; Thibodeau et al., 1993). The newly described CpG island methylator phenotype (CIMP) may constitute an additional third CRC progression pathway in which epigenetic alterations in promoter regions of regulatory genes that cause the development of polyps and cancer (Toyota et al., 1999).

The key initiating event in the CIN pathway is a mutation in the adenomatous polyposis coli (APC; OMIM 611731) gene, which normally forms a stabilizing complex for β-catenin in the WNT signaling pathway (Albuquerque et al., 2002; Powell et al., 1992). Typically described as a tumor suppressor gene with a "gatekeeper" function, pathologic mutations in APC interrupt the normal APC–β-catenin interaction, which in turn, allows for unregulated nuclear signaling by β-catenin to downstream messengers (Chung, 2000; Kinzler and Vogelstein, 1996). Even though germline mutations in the APC gene cause a small fraction of CRC, approximately 85% of sporadic CRC harbor APC mutations, either by point mutations or overt 5q chromosome deletions (Powell et al., 1992; Rajagopalan et al., 2003; Vogelstein et al., 1988). Non-random gains or losses of chromosomal material is a consistent feature in the CIN pathway, with chromosome 18q and 17p frequently altered, presumably causing haploinsufficiency of gene targets like deleted in colorectal carcinoma (DCC; OMIM 120470) and TP53 (OMIM 191170), respectively, that then confers a selective advantage for specific clones (Rajagopalan et al., 2003).

The factors that initiate, promote, and favor metastasis are not completely understood, but most likely involve acquired mutations in specific gene targets, such as mutations in the K-ras oncogene and the TP53 tumor suppressor gene. Approximately 30–50% of large adenomas and CRC have an acquired mutation in the K-ras gene, a member of the tyrosine kinase super family that links extracellular signals to targeted genes in growth and differentiation pathways (Martinez et al., 1999; Vogelstein et al., 1988). Germline alterations in other Ras genes are often found in somatic tumors and are also associated with cancer development in rare inherited developmental disorders, indicating the pleiomorphic nature of this transcription factor (Schubbert et al., 2007). Similarly, germline mutations in the TP53 gene cause the inherited Li-Fraumeni syndrome (OMIM 151623), while acquired mutations occur in a wide variety of cancer types. For CRC, acquired TP53 mutations are found to be a late event in the adenoma to carcinoma sequence (Kinzler and Vogelstein,

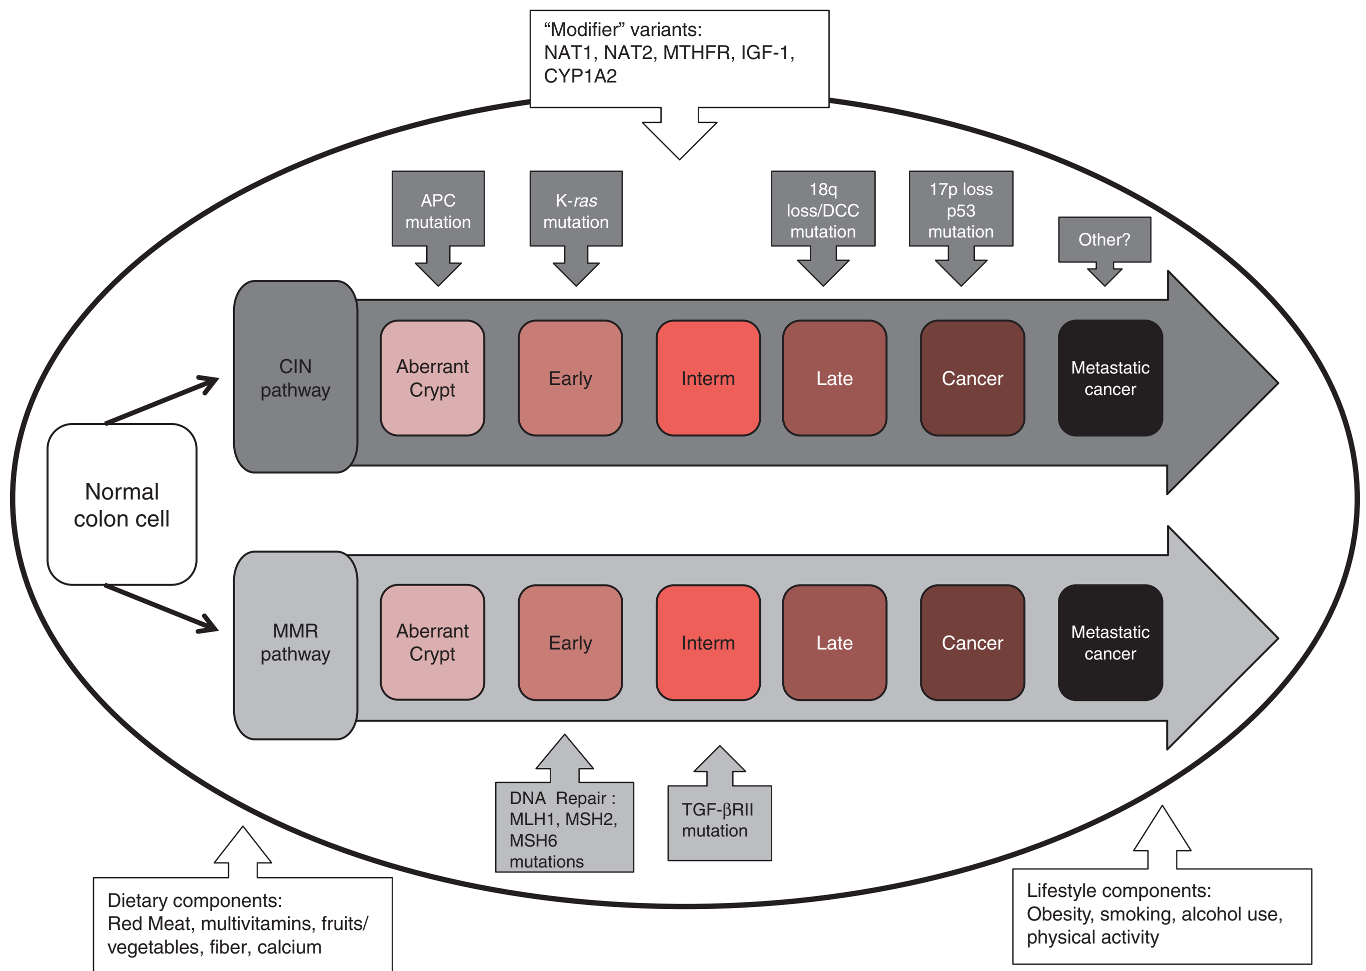

Figure 36.2 Multi-step progression of CRC development. There are many interacting factors, both genomic and environmental, that influence the transformation of a normal colonic epithelial cell into a metastatic cancer. The nuclear progression of the adenoma to carcinoma sequence is illustrated within the cell (i.e., depicted by the oval), denoting the multiple genetic alterations that occur in the CIN or MMR pathways. Outside the cell, are the many environmental dietary and lifestyle factors that promote the initiation and progression of the cancer. These factors may work through the constitutional genome of the individual that encode metabolizing proteins, such as NAT1/2 and MTHFR, that work to modify the course of cancer development. On the edge of the cell, are genes thought to be modifiers that could be involved with factors inside or outside the cell.

1996). As gene discovery in cancer advances, additional somatic mutations in other oncogenes, such as AKT1, will deepen the molecular understanding of CIN pathway progression in CRC (Carpten et al., 2007).

In contrast to CIN tumors, up to 15% of CRC has little, if any, evidence of aneuploidy. MMR-deficient tumors have a recognizable cellular phenotype with poorly differentiated mucinous histopathology with a peritumoral lymphocytic infiltration (Messerini et al., 1996). This type of CRC that evolves along the described MMR pathway (Figure 36.2) is thought to be caused by the loss of repair function of single basepair mismatches formed during S-phase in the epithelial colon cell, either through an inherited or acquired inactivation of one of the MMR genes. This inactivation renders the cell susceptible to further somatic mutations throughout the genome, increasing the cellular mutation rate from 100 to 1000 fold in mono- and di-nucleotide sequences (de la Chapelle, 2004; Gryfe, 2006). Molecular analysis of these sequences can reveal a unique profile known as MSI that correlates with cellular loss of specific proteins encoded by the MMR genes, hMSH2, hMLH1, hMSH6, hPMS1, and hPMS2 (OMIM 609309, 120436, 600678, 600258, and 600259, respectively) (Ionov et al., 1993; Thibodeau et al., 1993). The increased mutation rate in mono- or di-nucleotide tracts could explain the high frequency of acquired mutations in TGFβRII (OMIM 190182) and other genes that appear to be targeted in MSI tumors, as well as the more rapid rate of adenoma

to carcinoma progression compared to the CIN pathway CRC (Boland et al., 2007). TGFβRII (OMIM 190182) is an extracellular receptor and a member of the serine/threonine protein family containing a mono-tract of A_{10} that is somatically mutated in MMR deficient tumors, causing a loss of the natural inhibitory signal to the TGFβ/SMAD pathway and proliferation of the aberrant clone (Boland et al., 2007; Ionov et al., 1993; Markowitz et al., 1995; Samowitz et al., 2005).

The CIN and MMR pathways appear to have little overlap, with the CIN tumors exhibiting distal location in the bowel, non-random chromosomal aneuploidy, and mutations in APC, K-ras and TP53 genes and the MSI tumors primarily exhibiting a proximal location, mucinous histopathology, MSI, loss of MMR proteins, and acquired mutations in TGFβRII. While the initial observation of tumor instability was in tumors from patients with germline mutations in the MMR genes, it is now clear that the majority of MSI tumors are sporadic and may be due to widespread epigenetic inactivation of CpG islands in the promoter regions of specific genes, such as hMLH1 and others. Researchers have proposed that the CIMP is an additional third CRC pathway, with older age of onset and tumors that exhibit a serrated histopathology, MSI, and increased mutations in specific oncogenes, K-ras and BRAF (OMIM 164757) (Deng et al., 2004; Minoo et al., 2007; Samowitz et al., 2005). Serrated adenomas are a newly recognized type of polyp with cancerous potential and hyperplastic and adenomatous features. When advanced, these lesions can develop areas of dysplasia with somatic CpG island methylation and mutations in the BRAF oncogene (OMIM 164757). BRAF mutations can be used to differentiate a tumor into CIMP or CIN, as a correlative study of 126 colon tumors using six CIMP-related markers, six tumor suppressor genes, MSI, and loss of heterozygosity (LOH), demonstrated that the BRAF V600E mutation is highly predictive of the CIMP phenotype (Minoo et al., 2007). Promoter methylation of MLH1 and other genes, such as $p16^{INK4\alpha}$, $p14^{ARF}$ (OMIM 600160) is also now recognized as an important mechanism of colon carcinogenesis and may cause wider dysregulation in the cancer development process, providing further molecular evidence of heterogeneity in CRC carcinogenic pathways (Goel et al., 2007; Minoo et al., 2007). Nonetheless, it is not clear if the CIMP phenotype is a discrete and separate pathway from the MMR deficiency pathway and further work will need to clarify whether specific genes underlie these genomic mechanisms (O'Brien et al., 2006; Ogino et al., 2007; Xu et al., 2004).

The search for the genes in the CIN, MMR and CIMP pathways is ongoing using the current genomic tools of comparative genomic hybridization (CGH) and gene expression microarrays on cancer tissues (Vendrell et al., 2005). Ried and colleagues examined tissue from 14 normal colons, 12 adenomas, 14 high grade adenomas, and 16 CRCs using florescent microarray probes and found increases of chromosome 20q, 13q, 8q, 7p, 1q, and 5p and losses on chromosomes 4, 8p, 18q, and 17p (Ried et al., 1996). Advances in technology have improved the resolution of CGH studies for copy number variations. One recent study examined 42 primary CRC and 37 tumor cell lines, using an oligonucleotide array of 22,500 elements mapping to 16,097 loci. Fifty minimal common regions or MCRs, defined by the occurrence of overlapping events in two or more samples, were identified. Of the 28 amplified and the 22 deleted copy number MCRs, 5 regions held previously known genes, 15 recurring MCR regions were more focal and contained less than 12 genes, and 10 regions contained a total of 65 identifiable genes linked to cancer. Importantly, this method identified 21 new candidate genes that had not previously been linked to CRC (Martin et al., 2007). Correlating gains and losses of chromosomal material with cancer transformation is important, but whether these copy number variants alter the expression pattern and activity of known cancer susceptibility genes is not known. For CRC, this issue has begun to be explored by analyzing colon biospecimens with expression arrays. For example, Nosho and colleagues examined 550 known susceptibility genes for at least a threefold elevation or threefold diminution of activity in 36 adenomas and 14 early invasive cancers and found 13 upregulated and 19 downregulated genes (Nosho et al., 2005). This study confirms the progression of colon adenomas to carcinomas in CRC, but also suggests that the expression of a relatively small number of genes is altered in colon neoplasias.

In order to identify a set of susceptibility genes associated with acquired cancer development, an alternative approach of high-throughput sequencing of over 13,000 candidate genes was used to systematically categorize the genetic alterations in 11 breast and 11 colon tumors. Individual tumors had on average a large number (~90) of different mutated genes even though a small subset of 189 genes was consistently mutated in all of the tumors (Sjoblom et al., 2006). Using a pathway analysis of the global sequencing data, the team developed a "landscape" of breast and colon tumor non-random mutational events and showed that, while some genes were consistently mutated in all tumors examined, the majority of genetic defects in cancer were not frequently mutated. Nonetheless, taken together, these mutations caused defects in specific pathways that provided an overall fitness advantage to that specific clone (Wood et al., 2007). In the future, there will be more reliance on genomic tools in the discovery and delineation of cancer pathways in CRC, with future directions focused on developing and improving personalized tests and treatments.

PREDISPOSITION FOR CRC

Predisposition for CRC is a continuum of increasing risk and is dependent on several risk factors, including age, gender, nationality, existing medical conditions (i.e., previous polyps or inflammatory bowel disease) and family history. From a healthcare perspective, CRC is one of the most common tumors of adulthood, and categorizing the cancer into inherited monogenic, familial and sporadic/isolated forms is useful to determine the level of risk for disease (Figure 36.1). Sporadic CRC is a disease of aging, as the risk is low in younger individuals and increases later in life. The lifetime risk for CRC development in

the United States is ~6% compared to 80–100% in individuals who harbor mutations in monogenic familial syndromes (Burt, 1996b; Doxey et al., 2005; Lynch and de la Chapelle, 1999; Ries et al., 2007). Up to 20% of CRC cases will have a family history of the disease, which confers a moderate two- to three-fold elevation in risk compared to the general population. Although the risk increases for these individuals with earlier onset of disease and with more than one family member affected, there is less precision in determining the level of risk (Fletcher et al., 2007; Sandhu et al., 2001; St John et al., 1993; Winawer et al., 1996). Genetic researchers use these categories to identify mid- to high-risk kindreds for gene discovery and other genomic studies (Wiesner et al., 2000, 2003). Further, these major categories also form the basis for clinical care for individuals at risk for CRC, determining the level of screening, and identification of those patients and specific family members who should consider genetic testing (Lynch et al., 2007).

Inherited Monogenic Syndromes

The characterization of the monogenic CRC syndromes (Table 36.1) has provided an essential understanding of the genomic natural history of cancer. Altogether, these syndromes have been recognized for over 100 years, even though they account for only 5% of all CRC cases (see Figure 36.1; Burt and Neklason, 2005). Primarily divided into polyposis and nonpolyposis syndromes, most monogenic forms are caused by highly penetrant germline alleles in genes that encode proteins in the CIN or MSI pathways (Figure 36.2). Following the multi-hit cancer paradigm, cancer development arises in individuals harboring a germline mutation after acquired alterations of specific regulatory genes occur in the colon epithelium. Clinically, most of these syndromes are inherited as autosomal dominant traits with variable expressivity and incomplete penetrance, with an extremely high risk for individuals and families who carry the mutated allele(s). However, because of the rarity of pathologic alleles in the general population, these mutations do not confer a high attributable risk for CRC in the general population. Thus, recognition of these monogenic syndromes is essential for proper risk management, which begins with genetic evaluation and testing (Doxey et al., 2005; Lagerstedt et al., 2007; Rustgi, 2007).

Familial Adenomatous Polyposis

Familial adenomatous polyposis (FAP; OMIM 175100) was the first recognized form of monogenic inherited CRC accounting for about 1% of all CRC (Rustgi, 2007). Inherited as an autosomal dominant condition, individuals typically develop multiple adenomatous polyps in adolescence, which, if left untreated, will ultimately progress to invasive CRC (Jo and Chung, 2005; Kwak and Chung, 2007). Gastrointestinal manifestations include the development of hundreds to thousands of adenomatous polyps, invasive CRC, gastric cancer, and peri-ampullary duodenal cancer. If prophylactic surgery is not performed, CRC occurs in nearly 100% of mutation carriers, with the average age at onset of initial CRC by 40 years or less (Jo and Chung, 2005; Kwak and Chung, 2007). There are several extra-gastrointestinal manifestations of FAP, some that are useful in diagnosis of the condition, like congenital hyperplasia of the pigment epithelium (CHRPE), and some, such as osteomas and desmoid tumors, that also contribute to the morbidity and mortality of the disorder.

FAP is caused by germline mutations in the APC gene, which has been shown to be a key mutational target in sporadic CIN CRC (Figure 36.2). Karyotypic analysis of two patients with polyposis and developmental delay allowed researchers to identify the location of the gene on the long arm of chromosome 5, illustrating the historical impact of early genomic technology in delineating the causes of CRC (Bodmer et al., 1987; Herrera et al., 1986). After the APC gene was identified using positional cloning, mutational analyses of families with FAP have shown that germline mutations occur throughout the gene, with most mutations causing premature stop codons and more severe disease (Groden et al., 1991). Further genetic analysis of families has also demonstrated several allelic variants of FAP, such as Gardner syndrome, Turcot syndrome, and the attenuated form of FAP (AFAP; OMIM 175100). AFAP is characterized by later onset of CRC, a lesser number of polyps termed oligopolyposis, and a lack of extra-gastrointestinal manifestations. Patients with AFAP have mutations clustering in the 5′ or 3′ segment of the APC gene, while patients with Gardner syndrome have mutations primarily between codons 767 and 1513 (Bisgaard and Bulow, 2006). Patients with profuse and extensive polyposis have been identified with APC mutations near the β-catenin binding site (Nieuwenhuis and Vasen, 2007). Further, some APC alleles, such as the I1307K allele found in up to 28% of patients with Ashkenazi Jewish descent and a family history of disease, do not manifest a high rate of polyp formation, again emphasizing the need to fully explore the genomic mechanism(s) of polyp and cancer formation (Laken et al., 1997, 1999).

Genotype–phenotype correlation studies have also shown that up to 30% of patients with polyposis have no identifiable mutations in the APC gene (Moisio et al., 2002). Using a pathway analysis approach, a possible autosomal recessive form of oligopolyposis called Mut Y Homologue gene (MYH)-associated polyposis (MAP; OMIM 604933) was recognized in 2002, with the description of a sibship with multiple adenomatous polyps and CRC but without detectable mutations in the APC gene. Candidate gene analysis of the excision repairs genes in this kindred identified mutations in the MYH gene located on chromosome 1p (Al-Tassan et al., 2002). Defects in the MYH gene leads to the accumulation of G:C to T:A transversions in genes with susceptible GAA sequences. In fact, APC is an example of a gene that is highly predisposed to these type of transversions (Al-Tassan et al., 2002; Cheadle and Sampson, 2003; Lipton and Tomlinson, 2004). MAP has been identified in 7–8% of APC negative polyposis families and is associated with early-onset colon neoplasia, with the average polyp onset of 46 years and CRC of 49.7 years (Doxey et al., 2005; Jo and Chung, 2005). Interestingly, a recent population-based case control study suggests that the risk for polyps and cancer may not be strictly recessive, as both monoallelic and biallelic mutation carriers

TABLE 36.1 Monogenic colorectal cancer syndromes

Syndrome	Gene	OMIM	Gene map	Major syndrome features[a]
Polyposis				
Adenomatous polyposis				
FAP	APC	175100	5q21–22	>100 Colorectal adenomatous polyps or < 100 polyps with family history
Attenuated FAP	APC	175100	5q21–22	<100 Colorectal adenomatous polyps; oligopolyposis
Gardner	APC	175100	5q21–22	Polyposis, osteoma, desmoid, CHRPE
Turcot	APC	175100	5q21–22	Polyposis, glioblastoma, meduloblastoma
MYH-associated	MYH	604933	1p32–34	Autosomal recessive adenomatous oligopolyposis and pilomatricomas
Hamartomatous polyposis				
Juvenile polyposis	SMAD4	174900	18q21.1	Juvenile polyps, pulmonary arterio-venous malformations, digital clubbing
	BMPR1A	174900	10q22.3	
Cowden	PTEN	158350	10q23.31	Papillomatous papules, acral keratoses, facial trichemommas, mucosal lesions breast/uterine/thyroid/brain/renal cell cancers, fibroids
Bannayan-Ruvalcaba Riley	PTEN	153480	10q23.31	Lipomas, glans penis macules, macrocephaly, pectus excavatum, scoliosis, hyperextensibility, mental retardation
Peutz-Jeghers	STK11 / LKB	175200	19p13.3	Mucosal hyperpigmentation, thyroid cancer, sex cord/gynecomastic tumors, ovarian cysts/cancer, breast/bladder/lung cancers
Basal cell nevus	PTCH	109400	9q22.3	Coarse facies, basal cell cancer, jaw keratocysts, macrocephaly, forehead bossing, facial milia, medulloblastoma, cardiac and ovarian fibromas
Multiple endocrine neoplasia 2B	RET	162300	10q11.2	Mucosal neuromas, enlarged lips, medullary thyroid cancer, pheochromocytoma, "marfanoid" body habitus
Mixed polyposis				
Hereditary mixed polyposis[b]	HMPS1	610069	15q15	Typical juvenile polyps, colonic adenomas, and colorectal carcinomas
Non-polyposis				
HNPCC (Lynch)	MSH2	120435/ 609309	2p21–22	Early-onset MSI CRC diagnosed younger than 50 years; presence of synchronous, metachronous CRC, gastrointestinal cancer, uterine, ovarian cancer. Refer to Bethesda Criteria[c]
	MLH1	120436	3p21.3	As above
	MSH6	600678	2p16	As above, with a higher rate of uterine cancer
	MLH3	604395	14q24.3	No kindreds have been identified with germline mutations to date
	PMS1/2	600258/ 600259	2q31/ 7p22	
Turcot	MLH1 or PMS2	276300		Early-onset CRC and brain cancers, primarily glioblastoma
Muir-Torre	MSH2 or MLH1	609309		Early-onset CRC and sebaceous skin tumor
Familial CRC[b]	CRCS1	608812	9q22–23	Early-onset MSS CRC
	CRCS2	611469	8q24	

[a] Clinical manifestations from Online Mendelian Inheritance in Man (OMIM) (http://www.ncbi.nlm.nih.gov/sites/entrez?db=OMIM; Accessed December 2007).

[b] Linkage analysis identified chromosomal location; specific gene(s) not identified.

[c] Bethesda criteria for HNPCC include CRC in an individual at 50 years or less without a family history or kindreds meeting Amsterdam I or II guidelines (see Box 36.1, Umar et al., 2004 and Lindor et al., 2006).

of the most common MYH Y165C or G382D variants had a twofold increased risk compared to controls (Croitoru et al., 2004). A later population-based study found a similar result for the MYH Y165C variant, but not for other identified variants, suggesting that MYH variants are low-penetrant alleles (Balaguer et al., 2007).

Hereditary Nonpolyposis Colorectal Cancer

Hereditary nonpolyposis colorectal cancer (HNPCC) or Lynch syndrome comprises 1–3% of CRC and is characterized by early-onset proximal CRC exhibiting MSI (de la Chapelle, 2005; Kwak and Chung, 2007). Inherited as an autosomal dominant trait, HNPCC individuals face a 50–70% lifetime risk of developing CRC, in addition to other malignancies (Hampel et al., 2005). Other HNPCC-associated cancers include tumors of the gastrointestinal tract, hepatobiliary system, urinary collecting system, and female reproductive system. Women with HNPCC have a lifetime risk for endometrial cancer as high as 40–60% and up to a ~12% lifetime risk of developing ovarian cancer (Hampel et al., 2006; Kwak and Chung, 2007). Clinical variants of HNPCC also exist (Table 36.1), including Muir-Torre syndrome with skin keratoacanthomas and sebaceous neoplasms, and the Turcot syndrome with brain glioblastomas (Kwak and Chung, 2007; Rowley, 2005; Rustgi, 2007). That these syndromes overlap with similar phenotypes caused by APC/CIN pathway mutations reinforces the concept of genetic and genomic heterogeneity in CRC.

HNPCC is caused by germline mutations in one of five MMR genes, hMSH2, hMLH1, hMSH6, hPMS1, or hPMS2 (Table 36.1). Several guidelines have been developed, including the Amsterdam I, Amsterdam II, and the Bethesda criteria, to assist in the recognition of kindreds with HNPCC (see Box 36.1; Rodriguez-Bigas et al., 1997; Vasen, 2000; Vasen et al., 1991). Initially proposed as eligibility criteria for gene discovery studies, the Amsterdam I guidelines are the most stringent and have been described simply as the 3-2-1 rules, requiring the occurrence of three individuals with CRC in two generations, one of whom developed CRC less than 50 years and is an immediate relative of the other two (Vasen et al., 1991). Amsterdam II family phenotype allows the substitution of other extracolonic tumors, such as endometrial cancer, renal cancer or small bowel cancer in assessing families (Vasen et al., 1999). Because families have been identified with MMR gene mutations who do not meet these criteria, the less stringent Bethesda criteria were developed to clinically identify individuals and families who should consider germline testing (Umar et al., 2004).

Other Major CRC-Associated Genetic Syndromes

The inherited hamartomatous syndromes comprise an additional set of CRC polyposis syndromes distinct from the adenomatous polyposis or nonpolyposis syndromes. The hamartomatous syndromes are characterized by a malformed overgrowth of mesodermal, endodermal, or ectodermal cellular colonic elements (Schreibman, 2005). These rare syndromes carry a large risk of

BOX 36.1 Criteria used for HNPCC testing

Amsterdam criteria I:

1. One member diagnosed with CRC before age 50 years.
2. Two affected generations.
3. Three affected relatives, one of them a first-degree relative of the other two.
4. FAP should be excluded.
5. Tumors should be verified by pathological examination.

Amsterdam criteria II:

1. There should be at least three relatives with a Lynch syndrome-associated cancer (CRC or cancer of the endometrium, small bowel, ureter, or renal pelvis).
2. One should be a first-degree relative of the other two.
3. At least two successive generations should be affected.
4. At least one should be diagnosed before age 50 years.
5. FAP should be excluded in the CRC cases.
6. Tumors should be verified by pathological examination.

Revised Bethesda Guidelines for Colorectal Tumor MSI Testing:

1. CRC diagnosed in an individual younger than 50 years.
2. Presence of synchronous, metachronous colorectal, or other Lynch syndrome-associated tumors (i.e., endometrial, stomach, ovarian, pancreas, ureter and renal pelvis, biliary tract, and brain tumors; sebaceous gland adenomas and keratoacanthomas; and carcinoma of the small bowel), in an individual regardless of age.
3. CRC with MSI-high pathologic associated features diagnosed in an individual younger than 60 years.
4. CRC or Lynch syndrome-associated tumor diagnosed in at least one first-degree relative younger than 50 years.
5. CRC or Lynch syndrome-associated tumor diagnosed at any age in two first- or second-degree relatives.

Genetics of Colorectal Cancer (PDQ®) (http://www.cancer.gov/cancertopics/pdq/genetics/colorectal/healthprofessional)

developing CRC as well as other types of cancer (Table 36.1). Together, they occur at approximately 1/10th the frequency of the adenomatous syndromes and therefore account for less than 1% of CRC (Schreibman, 2005). The approximate incidence of each syndrome listed is 1 in 200,000 births, with the exception of juvenile polyposis syndrome, which is seen 1 in 100,000 births (Schreibman, 2005). While a comprehensive review is beyond the scope of this chapter, each of these syndromes have been associated with mutations in specific pathways, such as the PTEN pathway (OMIM 601728) in Cowden and Bannayan-Ruvalcabe-Riley syndromes and the LKB1 pathway (OMIM 602216) in Peutz-Jeghers syndrome, which again highlights the importance of a genomic approach in delineating the mechanisms of CRC development (Rustgi, 2007).

Familial CRC

Familial CRC accounts for about 20% of all CRC cases and is loosely defined as a positive history of at least one family member with CRC but not meeting the criteria of any of the cancer syndromes discussed previously (Figure 36.1 and Table 36.1). However, this group is heterogeneous and includes families with multiple affected members as well as families with a single affected individual. For example, the label syndrome X has been used to describe kindreds with early-onset CRC and microsatellite stable (MSS) tumors, suggesting that there are as yet unidentified single gene defects that account for familial clustering of CRC (Lindor et al., 2005; Lipkin and Afrasiabi, 2007). Genome linkage studies scans support this notion and have identified multiple regions of interest, including chromosome 9q21.3 (CRCS1, OMIM 608812), chromosome 8q24 (CRCS2, OMIM 611469), chromosome 15 (HCRA/CRAC1, OMIM 610069), and a variety of other loci (Daley et al., 2008; Jaeger et al., 2003; Haiman et al., 2007a; Tomlinson et al., 2007; Wiesner et al., 2003). The analysis of the HCRA/CRAC1 region is instructive of the improvements in genomic technology in gene discovery, as kindreds with oligopolyposis were first linked and verified to this region using microsatellite markers (Daley et al., 2008; Jaeger et al., 2003). The region was next examined with single nucleotide polymorphism (SNP) variant analysis in CRC cases and controls and found statistical evidence for variants near GREM1 and SCG5 with a P value of 4.44×10^{-14} (Jaeger et al., 2008).

Rather than a discrete autosomal dominant or recessive condition, most familial forms of CRC are complex genetic traits involving the interaction of many variables. Risk assessment is based on epidemiologic studies that show a two- to four-fold increase in risk for family members, depending on the number of close relatives affected with CRC and the age at onset of disease. Thus, for a person who has a single parent with CRC, the lifetime risk doubles that of the general population (Sandhu et al., 2001). However, the risk is fourfold the general population risk for individuals with three close relatives with CRC or if the family member developed cancer at an early age (Boardman et al., 2007; St John et al., 1993). Importantly, the National Polyp Study demonstrated that the risk for CRC also increases with a family history of adenomatous polyps, indicating that there are familial risk factors in the initiation of colon neoplasias (Winawer et al., 1996). Causes are likely to include undiscovered low penetrance or recessive alleles as well as undefined gene–gene interactions and gene–environmental interactions, among others. Future genome-wide association studies may identify links that can be then further studied.

Sporadic or Isolated CRC

Approximately 75% of all CRC occurs in individuals with no known genetic predisposing factors for disease and about 80% are caused by somatic defects in the CIN pathway as shown in Figure 36.2 (Gryfe, 2006). This set is often designated as the "general population" and includes a wide spectrum of individuals who may or may not have a combination of modifiable environmental factors and/or somatic genetic changes that have been shown to modify one's risk for CRC or affect prognosis and response to treatment. Epidemiologists have also studied many environmental risk factors to better understand risk of CRC, beyond reporting of a family history of CRC. The factors that have been shown to be associated with an increased risk of CRC include obesity (insulin resistance), limited physical inactivity, smoking, heavy alcohol use, a diet high in red or processed meat and low in fruits and vegetables (folate), fiber, and calcium/dairy foods, non-multivitamin use, non-steroidal anti-inflammatory drug use (NSAIDs), and non-post-menopausal hormone replacement therapy (Giovannucci and Wu, 2006; Potter and Hunter, 2002). In addition, other underlying colon inflammatory diseases, such as Crohns disease and ulcerative colitis, have been shown to have a significant increased risk of CRC development, although the lifetime estimates vary widely from 7% to 30% (Eaden et al., 2001; Ekbom et al., 1990). The overall risk of CRC development is similar for each of these inflammatory diseases (Gillen et al., 1994; Greenstein et al., 1981). After excluding inherited monogenic and familial forms of CRC, much of the remaining variation in genetic risk for CRC is most likely explained by combinations of common low-risk variants. This "common disease – common variant" hypothesis is believed to hold true for most human complex diseases, including cancer. Several researchers have suggested that studying SNPs for association with CRC risk should be a powerful research strategy and several candidate gene and whole genome linkage scans have been performed seeking to identify these putative common variants (Botstein and Risch, 2003).

Historically, genetic risk factor studies have focused on single variants in single genes involved in metabolism of heterocyclic amines from dietary factors and folate metabolism pathways (Potter and Hunter, 2002). These candidate genes have been shown to be associated with risk of CRC when considered together with certain environmental exposures (Potter, 1999). Polymorphisms in three relevant enzymes for metabolism of heterocyclic amines and polycyclic aromatic hydrocarbons, *N*-acetyltransferases (NAT1; OMIM 108345 and NAT2: OMIM

243400) and cytochrome-P1A2 (CYP1A2; OMIM 124606), have been studied extensively for their role in risk of CRC associated with meat consumption, cigarette smoking and alcohol use with inconsistent results (Brockton et al., 2000; Chen et al., 1998; de Jong et al., 2002; Potter et al., 1999; Vineis and McMichael, 1996; Ye and Parry, 2002).

One of the possible nutrients responsible for the association between vegetables and multivitamin intake and reduced CRC risk is folic acid (Giovannucci, 2002a). Therefore, the association between CRC risk, folate intake and variants in key folate metabolism genes, such as methylenetetrahydrofolate reduc-tase (MTHFR; OMIM 607093) and thymidylate synthase (TS; OMIM 188350), has been studied repeatedly (Chen et al., 1998; Curtin et al., 2004; Hubner et al., 2007; Slattery et al., 1999; Ulrich et al., 2002). The data from the studies of MTHFR polymorphisms show that individuals with the TT genotype for the polymorphism 677C → T are "hyper-responders" to folate and to alcohol. If the diet was high in folate and low in alcohol, then the patients were at a significantly lower risk of CRC compared to those individuals with the CC or CT genotype. Additionally, a growing body of evidence suggests that individuals with higher circulating levels of IGF-1 have an increased risk of CRC; the association between another IGF candidate, IGF-binding protein 3 (IGFBP3), and CRC risk is less consistent (Giovannucci, 2001; Giovannucci et al., 2000; Kaaks et al., 2000; Ma et al., 1999). These data suggest that common variants exist in these genes, altering predisposition to CRC in the general population. However, genomic technology does not yet have the capacity to test for all such variants simultaneously and to determine the exact level of statistical risk for an individual. Thus translating these variants into clinical risk algorithms must wait for the complete identification of variants and improved study designs to determine the attributable risk for each predisposing or protective factor.

With the invention of genotype microarrays and other high-throughput genotyping techniques, the capacity to genotype more than 500,000 SNPs on a single individual at one time is now available. Hence, many genome-wide association (GWA) studies of various complex diseases are utilizing this technology to assess genetic risk on a genome-wide global scale. CRC is no exception, where several case-control studies have now identified a region on the long arm of chromosome 8 (8q24) that may confer increased genetic risk for CRC (Broderick et al., 2007; Poynter et al., 2007; Tomlinson et al., 2007; Zanke et al., 2007). This region has also been implicated in prostate cancer susceptibility, supporting the notion that there is variability in the disease phenotype from defects in cancer pathways that overlap in tumor development (Gudmundsson et al., 2007; Haiman et al., 2007b; Yeager et al., 2007). There are multiple different interesting CRC candidate genes in this region that warrant further study. In addition, GWA studies have demonstrated that SNPs in the SMAD7 gene located on chromosome 18, which is part of the TGFβ/WNT signaling pathway, is associated with CRC (Broderick et al., 2007). Key to understanding common variants and risk for CRC will be the correlation of copy number variants and gene expression variants on sporadic CRC within the context of specific cellular pathways. As whole-genome approaches become more accessible and more affordable and bioinformatics techniques advance, large-scale, genome-wide studies of gene–gene and gene–environment interactions will be able to better delineate factors associated with CRC risk.

RISK ASSESSMENT, EVALUATION, AND GENETIC TESTING

Personalized medicine will rely on improved genomic and proteomic tests for diagnosis treatment, including new drugs and therapies. The practical application of genomic information in healthcare today is primarily in risk assessment and direct genetic testing. As knowledge of genetic susceptibility to cancers increases, researchers, healthcare providers, and the public are finding it increasingly difficult to incorporate recommendations for healthcare based on genomic discoveries (Acheson et al., 2000; Burke, 2005). Several studies have shown that physician knowledge about genetic and genomic concepts is limited, even though a family history of cancer is among the most commonly encountered genetic issue encountered in primary care (Acheson et al., 2000; Carroll et al., 2003; Giardiello et al., 1997). New tools are needed to assist clinicians to recognize at-risk individuals and families with hereditary cancer susceptibility, to tailor cancer screening and prevention and to screen for eligibility to participate in cancer genetic research (Acheson and Wiesner, 2004; Acheson et al., 2006). One such tool under development will categorize families by level of risk for cancer, including CRC, and will generate a report for patients and physicians with screening and genetic testing recommendations (Acheson et al., 2006). Computerized programs have been developed for breast cancer and are used to assist the clinician in evaluating the individual's risk and in considering genetic testing (Berry et al., 2002; Evans et al., 2004; Kelly and Sweet, 2007; Lindor et al., 2007). Risk algorithms similar to BRCAPRO called MMRPRO are based on known risk factors for colon cancer of family history and other risk factors (Chen et al., 2006).

Genetic testing for FAP and HNPCC are conditions in which genomic technology has been successfully translated into clinical care. Various guidelines for genetic testing for colon cancer susceptibility have been suggested by professional organizations and experts in the field, with the consistent recommendation that genetic counseling and evaluation should be provided to patients considering genetic testing (ASCO, 2003; Levin et al., 2006; Lynch et al., 2007; NCCN, 2007). Genetic evaluation includes a detailed medical history including the cancer and pre-neoplastic diagnoses, the construction of a three to four generation family tree, physical examination, risk assessment, and consideration of genetic testing, including a full discussion of possible genetic discrimination. Genetic testing is generally warranted if the personal or family history is suggestive of an inherited monogenic syndrome, the testing can be adequately interpreted and/or the results can be used to guide medical and

surgical management for the patient and other family members (ASCO, 2003). One of the most difficult issues in genetic testing for cancer is in the interpretation of results, as adequate studies to determine the clinical utility of the test are often not available, due to the rarity of the individual disorders and the lack of power in the statistical analyses needed to determine sensitivity and specificity of the tests (Burke et al., 2002). Further, most tests based on medical sequencing can also identify variants with indeterminate clinical significance and, thus, may not provide a diagnosis or further clarification of risk for the individual or family. Clinicians must also recognize that locus and allelic genetic heterogeneity will alter the final interpretation, as a negative result may be a reflection of incomplete testing.

Risk assessment of the family medical tree is the first step in deciding what test to offer a patient of family who may be at risk for colorectal neoplasia (Figure 36.3). The family tree should be examined for evidence of autosomal dominant inheritance and any occurrences of early-onset CRC or polyposis to determine whether the family member represents a polyposis syndrome or nonpolyposis syndrome. Verifying the pathology of the reported CRC and colon polyps and other cancers in the family is often recommended (Box 36.1 and Table 36.1). If the individual has multiple adenomatous polyps and a suggestive family history, genetic testing for APC mutations is warranted, However, the clinician should recall that up to 20–30% of FAP patients are affected due to spontaneous *de novo* APC mutations in the germline, without a family history of the disorder in either parent (Burt and Neklason, 2005). Thus, genetic testing of the APC gene is important for any patient with multiple adenomatous polyps at an early age regardless of family history (NCCN, 2007). Additionally, FAP is one disorder in which the testing of children may be warranted because screening would commence by age 10, if a pathologic mutation is identified (ASCO, 2003).

The evaluation of HNPCC begins with analysis of the family tree using the Amsterdam I, Amsterdam II, and Bethesda criteria (see Box 36.1). HNPCC testing is first done with tumor tissue screening for loss of immunohistochemical (IHC) staining

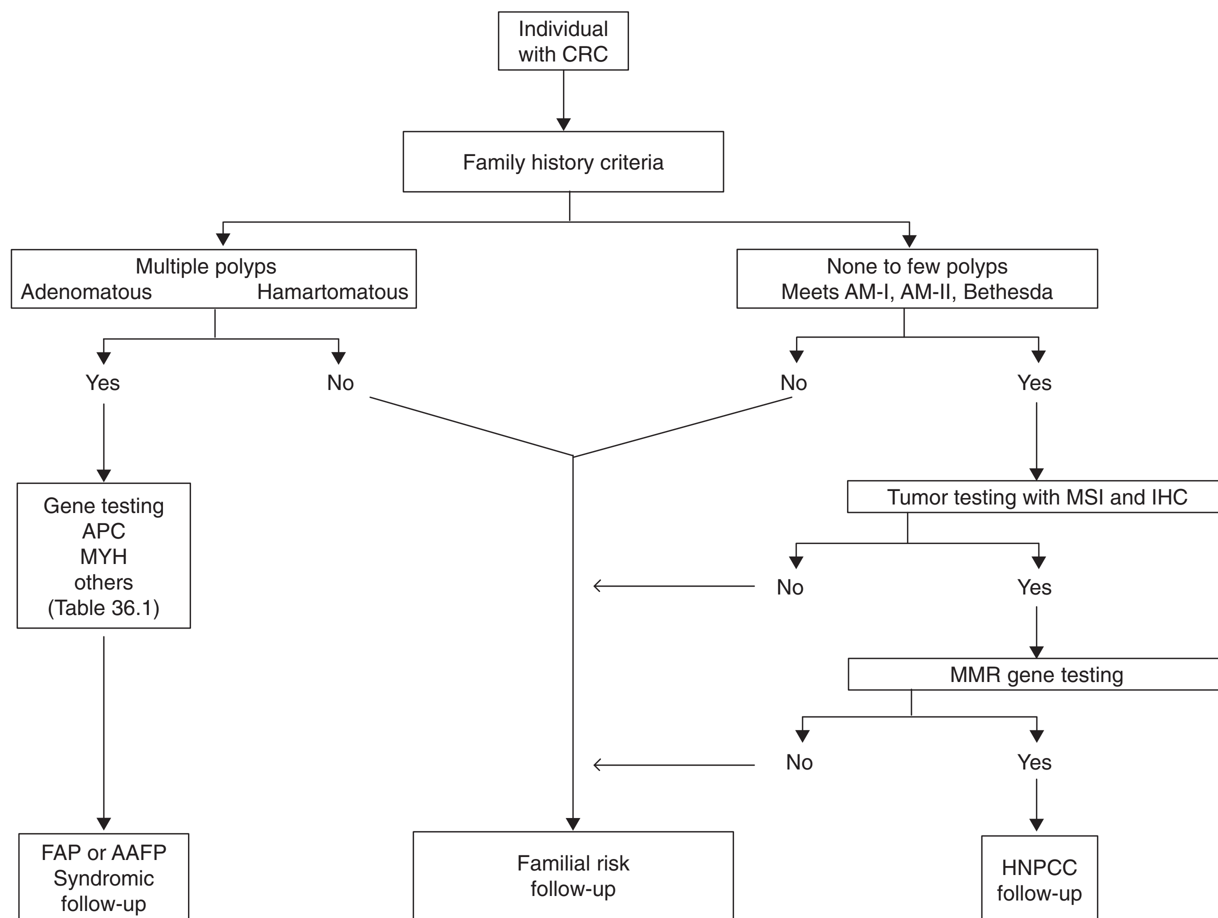

Figure 36.3 Clinical decision tree for the systematic evaluation of suspected inherited CRC syndromes. Evaluation begins with a detailed family history of CRC and/or polyps for each patient and the progresses to either the appropriate long term follow-up and observation or genetic testing depending on the family history and polyp status of the patient.

for proteins encoded by hMSH2, hMLH1, hMSH6, hPMS1, or hPMS2, and DNA polymerase chain reaction assay for MSI (NCCN, 2007). This strategy is based on the observation that a high level of MSI (MSI-H) in HNPCC tumors are also accompanied by loss of the MMR protein that corresponds to the gene mutation. The Bethesda guidelines recommend a standard set of mono- and di-nucleotide tracks that are particularly sensitive to MMR deficiency, with MSI-H defined as instability in 30% or more markers (Rodriguez-Bigas et al., 1997; Umar et al., 2004). As acquired BRAF mutations are highly associated with sporadic MSI-H tumors, testing tumor DNA for BRAF V600E mutation will help to categorize the patient (Minoo et al., 2007). If the screening tests are indicative of an inherited MMR deficiency, direct sequencing of MMR genes is next performed looking for germline mutational error in the family (Hendriks et al., 2006; Kwak and Chung, 2007).

SCREENING AND SURVEILLANCE

Many studies have proven that screening for CRC with fecal occult stool testing and colonoscopy methods has reduced the incidence, morbidity, and mortality of the disease (Burt, 1996b; USPSTF, 2002; Winawer et al., 2003). Despite this, less than 35% of adults follow screening guidelines, and there is great interest in genomic screening tools that may improve compliance and or clinical utility for identifying CRC in average risk and high-risk populations (CDC, 1996). Standard recommendations for average risk individuals have been published by the American Cancer Society (ACS), and other professional organizations, such as the National Comprehensive Cancer Network (NCCN) (ACS, 1999; NCCN, 2007; Winawer et al., 2006). In general these recommendations suggest colonoscopic screening starting at age 50, and that occult blood testing of the stool with left sided endoscopic screening or double contrast barium enema be performed if colonoscopy is not available (Davila et al., 2005; Smith et al., 2001). However, if the individual has a modest family history and no other risk factors, colonoscopy screening should commence at least a decade earlier at age 40 (Fletcher et al., 2007).

Specific guidelines have been developed for FAP and HNPCC with screening and surveillance recommendations starting at a younger age for specific tumor manifestations of the condition (Lindor et al., 2006; NCCN, 2007). In general, at risk family members for FAP and HNPCC begin a screening and surveillance program at 10 and 20 years, respectively (Lindor et al., 2006; Rustgi, 2007). While a review of these guidelines is beyond the scope of this chapter, the importance of identification and screening cannot be overstated. One study demonstrated a 70% reduction in the standardized mortality rate in 140 HNPCC families enrolled in a large scale surveillance program in the Netherlands (de Jong et al., 2006).

Newer non-invasive genetic technologies, such as stool and serum testing, have been developed to reduce the need for invasive colonoscopic screening and/or increase the sensitivity of the examination (Hundt et al., 2007; Levin, 2006). Several studies have shown that fecal material retains the cellular remnants of the colonic epithelium and that the nuclear DNA from these cells remains intact. Molecular analysis of genes known to be altered in CRC progression were first examined in patients with CRC finding that three genes, TP53, BAT26, and K-Ras, accurately identified such patients (Dong et al., 2001). Multiplex tests for specific genes and methylation signatures are now available commercially; one early study examined 21 gene mutations in 80 cases compared to 212 controls and identified 63% of CRC cases and 57% of advanced adenomas, with a calculated specificity of 94% in individuals without colon neoplasia or with small adenomas (Tagore et al., 2003). Aberrant methylation of three genes in stool DNA found nearly 94% sensitivity but only 77% specificity in a small sample of 52 patients with CRC, 35 patients with benign colon disease (21 with adenomas), and 24 patients with negative colonoscopies (Huang et al., 2007).

The identification of potential serum biomarkers for CRC diagnosis has also received some attention, given the ease of collecting serum as compared to other invasive diagnostic techniques for CRC. Newer approaches, mostly mass spectrometry (MS) based surface-enhanced laser desorption/ionizing time-of flight (SELDI-TOF) or matrix-assisted laser desorption/ionizing time-of flight (MALDI-TOF) methodologies, can produce high-throughput proteomic "signatures" from a variety of biospecimens. The ability of the measured protein intensities to distinguish cancer from non-cancerous biospecimens is assessed with multivariate statistical analyses. A recent proteomic study of CRC by Ward and colleagues (2006) identified a combination of four proteins that were significantly different between CRC cases and controls and then used this signature to classify serum samples from 62 CRC cases and 31 controls with a 95% sensitivity and 91% specificity. However, further validation of these proteomic techniques in sera of CRC cases compared to controls is necessary in order to advance CRC personalized medicine.

PROGNOSIS AND TREATMENT

Prognosis and treatment preferences after CRC diagnosis are highly dependent on stage of disease. The early stages of CRC (stage II or less) are treated primarily with surgery with or without chemotherapy and can have a 5-year survival >90% (Ries et al., 2007). However, the 5-year survival for late-stage disease is <10% and treatment can include a combination of surgery, chemotherapy, and/or radiotherapy. Additional significant independent predictors of survival are age at diagnosis, race/ethnicity, and family history of CRC. Whether a colon tumor develops along the CIN or MSI pathway may also have therapeutic implications. Sporadic MSI tumors have a significantly improved prognosis compared to MSS tumors (Bettstetter et al., 2007; Lim et al., 2004; Popat et al., 2005; Samowitz et al., 2001). Although the results are inconsistent, patients with stage II or III

MSI tumors may not benefit from 5-Flouorouracil (5-FU) adjuvant chemotherapy, a standard agent used in CRC (Barratt et al., 2002; Jover et al., 2006; Ribic et al., 2003). In contrast, CIN CRCs have been observed to be associated with poor prognosis, but not as consistently as the improved prognosis finding for MSI tumors (Bardi et al., 2004; Risques et al., 2003; Vendrell et al., 2005). Resolution of these inconsistencies in clinical outcome may need to wait until genomic methodologies mature more fully.

As most sporadic colorectal tumors are MSS, progression is linked to abnormalities of chromosome number, allelic imbalance or LOH, which are independently associated with poor survival (Bardi et al., 2004; Lanza et al., 1998; Risques et al., 2003; Vendrell et al., 2005). Chromosomes 5q, 17p, and 18q show the most frequent LOH in sporadic CRC, therefore, studies of alterations in specific genes in these chromosomal locations have been studied for an association with prognosis with conflicting results (Munro et al., 2005; Popat and Houlston, 2005). A systematic review of TP53 abnormalities and CRC outcome from 241 studies involving ~19,000 individuals showed that the presence of a TP53 mutation conferred a 30% decrease in survival compared to those with no mutation (Munro et al., 2005). Another review of genetic changes and outcome focused on another common genetic event in CRC, 18q loss and/or loss of DCC expression, showing that individuals with loss of DCC expression have twice the risk of dying compared to individuals without these genetic changes (Popat and Houlston, 2005). MSI status, p53 mutation and DCC expression are commonly identified in CRC; however it is still not well understood whether the association seen with clinical outcome is indicative of an underlying biological pathway or a specific defective gene (Gryfe, 2006).

Promising research in breast cancer has recently shown the utility of gene-specific expression profiling and clinical outcome, and this technology has been rapidly accepted by clinicians to guide chemotherapy (Morris and Carey, 2007). Similar utility of whole-genome gene expression profiling in predicting prognosis after CRC diagnosis has also been sought (Barrier et al., 2007; Eschrich et al., 2005; Wang et al., 2004). Two studies, both using the Affymetrix Human U133A gene expression chips, have identified a discrete set of expressed genes that predicted survival with 78% accuracy (Barrier et al., 2007; Wang et al., 2004). However, there was little overlap in the genes included in these two predictive gene sets, and only Wang and colleagues validated their findings for prediction of recurrence. A third study, using gene expression information from spotted cDNA arrays, found an optimal gene set of 43 genes with 93% sensitivity and 84% specificity in predicting CRC outcome (Eschrich et al., 2005). Gene expression profiling has also been shown to be able to discriminate different histological types of CRC, different stages of CRC and CRC from control colon tissue (Joyce and Pintzas, 2007). Again, there was little to no overlap in expressed genes with the previously described gene sets, highlighting the significant challenges faced in developing this technology. Differences in microarray platforms, data analysis techniques and, in particular, the inclusion/exclusion criteria for study subjects could have contributed the observed differences.

Although gene expression profiling has yielded some interesting prognostic candidates, many other types of genetic changes could also be significantly associated with prognosis. Genome-wide analyses of copy number changes and methylation status have been used in other cancers to predict clinical outcomes and could also prove useful in CRC outcomes analysis. Additionally, the role of environmental risk factors in prognosis is poorly understood and needs further study particularly studying gene–environment interactions and how these might affect prognosis.

PHARMACOGENETICS/GENOMICS OF CHEMOPREVENTION AND CHEMOTHERAPY

Pharmacogenetics/genomics seeks to discover the genotype or genotypes that predict overall drug response in terms of clinical outcomes and toxicity and to tailor this information for patients who have been categorized to have good drug response and low toxicity to a particular treatment (Marsh, 2007). These discoveries would also help in identifying patients at risk for adverse clinical outcomes or toxicities and as a result treat them with a different agent. Agents have been developed as chemopreventative agents for individuals at risk for CRC as well as treatment therapies for patients diagnosed with CRC. The multiple mutational events in both sporadic and inherited forms of CRC (Table 36.1 and Figure 36.2) have been explored for predictive and prognostic potential with a few showing promising results (Allen and Johnston, 2005).

Some of the factors that are associated with CRC, such as diet, are modifiable and have therefore been targets for prevention and intervention studies or have been used as potential chemopreventative agents (Boursi and Arber, 2007; Giovannucci, 2002b). The most well-established agent in CRC chemoprevention is NSAID use, in the form of regular over-the-counter aspirin (Markowitz, 2007; Raju and Cruz-Correa, 2006). The molecular basis of NSAID chemoprevention is mostly due to the inhibition of cyclooxygenase (COX) enzymes, which have two isoforms COX-1 and COX-2, but NSAIDs may also inhibit CRC through non-COX mediated pathways (Brown and DuBois, 2005; Hawk and Levin, 2005). The strongest evidence for a protective effect of NSAID use on risk of CRC comes from two double-blind randomized trials, showing a 20–45% reduced risk of CRC depending on aspirin dose (Baron et al., 2003; Sandler et al., 2003). Sulindac, a non-steroidal agent, has also been used in chemoprevention trials for high-risk patients with FAP, with modest success (Keller et al., 1999). Other chemopreventative agents that show promise are calcium carbonate, selenium and hormone replacement therapy; however, the molecular mechanisms of these agents are not well understood and evidence from randomized trials of these agents is inconsistent (Gryfe, 2006).

Systemic combination chemotherapy is now the mainstay of treatment for patients with advanced CRC, and includes the combination of 5-FU with other agents, such as irinotecan or oxaliplatin (Kelly and Goldberg, 2005). From a genomic standpoint, several genes have been identified that play a role in either predicting response or side effects to specific drugs used for individuals with CRC. Many of these genes are specific drug targets with known variants or genes and/or enzymes involved in drug metabolism pathways. Table 36.2 lists the drugs commonly used to treat CRC and their associated genetic target(s) (Kruzelock and Short, 2007; O'Dwyer et al., 2007).

The most well understood of these chemotherapy agents and its biological markers for drug response are 5-FU or capecitabine, which is metabolized to become 5-FU (Parker and Cheng, 1990). 5-FU is given intravenously, while capecitabine is dosed orally (Diasio, 2001). The four key enzymes that can influence the toxicity and/or efficacy of 5-FU (and capecitabine) are: thymidylate synthetase (TS), dihydropyrimidine dehydrogenase (DPD), thymidine phosphorylase (TP), and methylenetetrahydrofolate reductase (MTHFR). In general, low levels of TS, DPD, or TP have been shown to confer better drug response and hence better survival (Kruzelock and Short, 2007). Interestingly, when intratumoral gene expression levels of the combination of TS, DPD, and TP were analyzed, 92% of responders to 5-FU had very low levels of all three enzymes compared to non-responders, who had at least one enzyme expressed at above normal threshold levels (Salonga et al., 2000). Two specific SNP variants in MTHFR (677C → T and 1298A → C) are functionally linked to reduced activity of this enzyme; harboring the T allele of the 677 variant may be associated with increased response rates to 5-FU (Cohen et al., 2003; Etienne et al., 2004; Weisberg et al., 1998).

Newer chemotherapeutic medications for advanced CRC, such as the topoisomerase inhibitor, irinotecan, also appear to have functional variants that are associated with the development of serious side effects (Table 36.2). The UGT1A1*28 7/7 variant was significantly associated with the development of grade III/IV neutropenia in a study of 141 patients with advanced CRC treated with the combination chemotherapy FOLFIRI. In addition, patients who harbored both the TS 3′-UTR 6 + /6 and XRCC3-241 C/C genotypes had an increased risk of disease progression compared to similar staged non-carrier patients (Ruzzo et al., 2007).

Most of the current knowledge in CRC predicting response to treatment is based on gene expression transcriptional analysis (i.e., at the mRNA level only). However, it is the protein that plays the crucial active role in all cells in the body. Quantification of gene expression from mRNA analysis is not always directly correlated with measured protein level as there can be translational and post-translational modifications that determine the amount of cellular protein. Therefore, proteomic profiling has great potential to better understanding the relationship between protein levels and response to treatment (Nishizuka et al., 2003). Ma and colleagues used a well-described panel of 60 human cancer cell lines (NCI-60), which includes 7 CRC cell lines, to predict response to a wide array of anticancer drugs using reverse-phase protein lysate microarrays (Ma et al., 2006; Paweletz et al., 2001). They were able to

TABLE 36.2 Drugs commonly used to treat CRC and their associated genetic target(s)

Drug	Genetic targets			
5-FU and Capecitabine	Thymidylate synthetase (TS)	Dihydropyrimidine dehydrogenase (DPD)	Thymidine phosphorylase (TP)	Methylenetetrahydrofolate reductase (MTHFR)
Irinotecan	Uridine diphosphateglucuronosyltranferase 1A (UGT1A)	Cytochrome P450s (specifically the CYP3A family)	Carboxylesterases (CES)	Adenosine-triphosphate binding cassettes (ABC transporters)
Oxaliplatin	Excision repair cross-complementing 1 and 2 (ERCC1 and ERCC2)	Glutathione-S-transferase-P1 (GSTP1)		
Bevacizumab	Vascular endothelial growth factor (VEGF)			
Cetuximab	Epidermal growth factor receptor (EGFR)			
Panitumumab	Epidermal growth factor receptor (EGFR)	Transforming Growth Factor alpha (TGFα)		

identify eight protein markers that predicted response to 5-FU (CDH1, CDH2, KRT8, ERBB2, MSN, MVP, MAP2K1, and MGMT), where all but one of these was known to be involved in colon cancer development. Additionally the CRC cell lines clustered into two separate groups, which also differed from the other cell lines using these eight protein markers, showing the utility of this set to not only predict chemosensitivity to 5-FU, but to distinguish the CRC cell lines from other cancer types. Proteomic analysis shows tremendous promise not only as a diagnostic tool but also as a clinical outcome prediction tool.

While these studies hold the promise of profiling patients to tailor the selection of drug treatment, there is a lack of consensus among cancer specialists as to the use of pharmacogenomic profiling for patients with CRC. The American Society of Clinical Oncology guidelines currently support genetic testing for variants in TS, DPD, and TP genes for prognostic information, but not for selection of chemotherapeutic agents, such as 5-FU (Locker et al., 2006). Validation of additional predictive markers of response will require randomized clinical trials by tumor markers status, which would require large sample sizes since the prevalence of some of these markers is low in the population and the individual markers may have small effects individually but larger overall effects in combination with other markers (Sargent et al., 2005).

2009 UPDATE

Several studies have examined the clinical utility of whole-genome technologies for the early detection of colon cancer. Assays have been developed to detect somatic gene mutations, epigenetic modifications of specific genes, and gene-specific expression in fecal cells and serum; however, it is not clear which method, if any, will ultimately improve standard clinical screening. Echoing an earlier prospective study (Imperiale et al., 2004), a large multisite study of 4482 average risk patients demonstrated that fecal DNA analysis is superior to standard fecal occult blood testing in identifying clinically relevant advanced adenomas or colon cancers (Ahlquist et al., 2008). This study also compared the first generation 23 marker DNA assay to a smaller 3 marker DNA assay, which includes hypermethylation of the vimentin gene and showed that the smaller test had a twofold increased in sensitivity (40% versus 20%) (Ahlquist et al., 2008). Hypermethylation of the vimentin gene with rigorous assessment of DNA integrity in the stool sample may be important elements of the fecal assay, as a study of 82 colon cancer cases and 363 controls demonstrated a sensitivity and specificity of 83% and 82%, respectively, for colon cancer when only these two markers were used (Chen et al., 2005; Itzkowitz et al., 2008). The search for noninvasive, early detection methods will continue, as more sensitive and specific methods for analyzing DNA from fecal and other tissues are currently under development (Diehl et al., 2008; Koga et al., 2008).

Analysis of microRNAs (miRNA), a family of short non-coding small RNAs, has also emerged as an area that may hold significant diagnostic biomarker and therapeutic target potential in cancer research (Zhang et al., 2007). miRNA microarray expression profiling of paired CRC tissue and normal colon tissue from 84 CRC patients was recently tested for an association with survival (Schetter et al., 2008). This study found that 37 miRNAs were differentially expressed in the CRC tissue and that one of these, miRNA-21, was associated with a 2.5-fold increased risk of death in both the initial set of 84 CRC tissue/normal pairs and a validation set of 113 separate individuals with CRC, independent of other covariates, such as stage of disease, age at diagnosis, gender, race, and tumor location. Interestingly, miRNA-21 is expressed at high levels in most cancerous solid tumors and has been shown to act an as antiapoptotic factor (Volinia et al., 2006). Profiling of miRNAs in colon cancer tissue may also provide prognostic information for patients. Seventeen of 315 miRNAs profiled in a set of 49 stage II colon cancers and 10 normal mucosal tissues were found to correlate with metastasis in microsatellite stable cancers with a sensitivity of 77% and specificity of 83% (Schepeler et al., 2008). Differences between primary tumor and metastatic colon cancers may exist, as differential expression of 80 genes were identified using oligonucleotide arrays of 12 sets of normal, colon cancer, and metastasis from a single individual (Koh et al., 2008). Importantly, these types of studies may pave the way for chemotherapy decision strategies much like current breast cancer care based on individual tumor expression profiles (Munoz et al., 2008).

The search for genetic factors that increase colon neoplasia continues with whole-genome SNP association studies (Broderick et al., 2007; Joyce and Pintzas, 2007; Tomlinson et al., 2007; Zanke et al., 2007). Tenesa and colleagues identified a cancer susceptibility locus at 11q24 and confirmed two previously identified loci, 8q24 and 18q21, with a genome-wide SNP analysis, first analyzing 1012 early-onset colon cancer cases and controls and then testing the strongest associations in nearly 14,000 cases and controls (Tenesa et al., 2008). This population was then combined with other collections in a metaanalysis based on over 20,000 cases and 20,000 controls, which identified four previously unreported loci at 14q22.2 near the BMP4 gene, at 16q22.1 near the CDH1 gene, at 19q13.1 near the RHPN2 gene, and at 20p12.3 (Houlston et al., 2008). Further study will be required to verify these putative susceptibility loci, as linkage has not consistently been verified in different study populations, such as the previous linkage to 3q22 and chromosome 9q (Kemp et al., 2006; Papaemmanuil et al., 2008; Wiesner et al., 2003). Comparison

between genome-wide association studies can be difficult due to a variety of differences between studies, such as eligibility criteria, sample collection and storage, incomplete correlative demographic and clinical information, nucleic acid extraction methods and quantification, diversity of microarrays tools used and hybridization techniques, and small sample sizes. Future studies will most likely focus on larger populations with standardized phenotypic criteria.

CHAPTER

Genomic Evaluation and Management of Prostate Cancer

Phillip G. Febbo and Philip W. Kantoff

INTRODUCTION

Prostate cancer is the second leading cause of cancer death in men living in Western countries. The management of men diagnosed with prostate cancer remains predicated on a combination of clinical and pathological characteristics of the individual and the cancer. Molecular features of prostate cancer remain largely of academic interest and are not used in the delivery of care. However, the dramatic response of metastatic prostate cancer to castration demonstrates the profound impact of successful molecularly targeted therapy, and increasing insight into the molecular pathogenesis of prostate cancer undoubtedly holds further therapeutic promise (Balakumaran and Febbo, 2006; Nelson et al., 2003).

The genetic and epigenetic events that result in the transformation of prostate epithelial cells are becoming better understood, and genomic tools have fueled many of the recent discoveries. The synchronous development of multiple, high-quality models of prostate cancer, together with sophisticated genomic technologies, have accelerated our molecular understanding of prostate cancer over the past decade and have been instrumental in the identification of key molecular events driving prostate cancer initiation, progression, and metastasis.

The molecular story of prostate cancer, however, remains far from complete. A comprehensive molecular characterization of the approximately 220,000 men diagnosed each year in the United States of America remains untenable. As the sequence of the human genome and technologies for global assessment of DNA, RNA, and protein patterns are now available, it is hoped that the many molecular insights established over the past decade will be effectively woven together into a molecular map of prostate cancer to characterize and define therapy for each individual diagnosed.

This chapter will highlight recent prostate cancer discoveries empowered by our nascent ability to perform global analysis on DNA variation, RNA expression, and protein expression.

GENETIC PREDISPOSITION AND ALTERATIONS IN PROSTATE CANCER

Highly Penetrant Prostate Cancer Genes

Despite significant efforts, there have been limited gains in the identification of germline mutations accounting for families with a significantly increased risk of prostate cancer. Likely due to a combination of disease heterogeneity and high disease prevalence, few highly penetrant prostate cancer-causing genes have been identified to date. Genes located in regions in linkage disequilibrium with prostate cancer that have confirmed mutations in at least some families at increased risk include ELAC2, MSR1, and RNAseL (reviewed in [Schaid, 2004]), but there are no genes that are the equivalent to those such as BRCA1 and breast cancer (see Chapter 35).

Essentials of Genomic and Personalized Medicine

In 2002, germline mutations within the ribonuclease L gene (RNAseL) gene were found to account for some families with a high risk of prostate cancer (Carpten et al., 2002). Subsequent work has found that a variant of RNAseL, the non-synonymous change Arg462Gln, confers decreased enzymatic activity and is associated with an increased risk of prostate cancer (Casey et al., 2002). While the mechanism(s) behind the association between prostate cancer risk and RNAseL remains unclear, a screen for viral DNA in prostate cancers identified a novel gamma-retrovirus in prostate cancers occurring primarily in individuals with a variant of RNAseL associated with decreased activity (Urisman et al., 2006). The virus, now referred to as xenotropic murine leukemia virus-related virus (XMRV), has been isolated and shown to infect human cells (Dong et al., 2007). Further studies are currently underway to determine if infection with the virus is associated with an increased risk for prostate cancer. This intriguing finding suggests a provocative mechanism connecting the RNaseL variant with an increased risk of prostate cancer through compromised immunity and resulting viral infection.

Germline Variation and Prostate Cancer Risk

Variation of many germline polymorphisms have been associated with an individual's risk of developing prostate cancer (Pomerantz et al., 2007). Most early studies focused on genetic polymorphisms, oligonucleotide repeat (di-, tri- etc.), or single nucleotide repeat polymorphisms, with potential functional impact on proteins within the androgen metabolism pathways (reviewed in [Singh et al., 2005]). However, as the paradigm of genomic assessment has shifted from single polymorphism to allele structure (haplotypes), more comprehensive analyses are now possible.

In 2006, analysis of germline polymorphisms and their association with prostate cancer identified a region on chromosome 8 in significant linkage disequilibrium with the disease (Amundadottir et al., 2006). Although the association was identified initially in an Icelandic population, two variants were found to have a strong association with prostate cancer risk across multiple populations, with the largest population attributable risk observed in African-American men (Amundadottir et al., 2006). Using an alternative approach of admixture mapping in order to identify prostate cancer risk alleles in African-American men, an independent group also identified this locus (Freedman et al., 2006). Subsequently, multiple studies have confirmed the association of this region with risk of prostate cancer and have determined that there are two independent loci that impact risk of prostate cancer located within 8q24 (Gudmundsson et al., 2007; Haiman et al., 2007a, b; Schumacher et al., 2007; Wang et al., 2007; Yeager et al., 2007). While the proximity of these polymorphisms to the MYC oncogene (~150 KB) suggests that they may act through modulation of MYC expression, the specific markers are within non-transcribed regions of the genome and the mechanism underlying the association of these loci with prostate cancer risk remains unknown.

With the advent of technologies to rapidly assay hundreds of thousands of SNPs (see Chapter 4), genome-wide association studies are becoming more prevalent and are likely to result in additional insights. For example, using a 100K SNP array from Affymetrix, investigators looked for loci with strong association with prostate cancer for incident cases within men participating in the Framingham heart study (Murabito et al., 2007). While no loci met statistical criteria for genome-wide significance, association with prostate cancer was found for two SNPs within the MSR1 gene (discussed above as being associated with a familial risk of prostate cancer). Thus, in time, more granular technologies and assessment of large cohorts with different racial and ethnic constitution will likely result in additional insights as to the genetic influence on the development of prostate cancer.

Mitochondrial DNA

Another compelling finding is the association of mutations within mitochondrial genes and prostate cancer risk (Petros et al., 2005). When the cytochrome oxidase subunit I gene (COI) was sequenced in patients with prostate cancer, 11–12% were found to have mutations that altered conserved amino acids compared to <2% individuals without cancer (Petros et al., 2005). Both germline and somatic mitochondrial mutations have been found to contribute to the risk of prostate cancer, underscoring their potential importance (Gomez-Zaera et al., 2006; Petros et al., 2005). A plausible mechanistic explanation involves the role these mutations may play to increase reactive oxygen species and oxidative stress. Increased oxidative stress is a commonly associated mechanism with prostate cancer development and may explain the observed associations between prostate cancer onset and NKX3.1 loss (Ouyang et al., 2005), as well as GST-Pi methylation (Parsons et al., 2001) in prostate cancer. Thus, changes in the mitochondrial genome may further highlight the importance of oxidative stress on the development and progression of prostate cancer.

Epigenetic Changes in Prostate Cancer

Along with genetic changes in the DNA sequence, epigenetic modifications (see Chapters 6) have been associated with the development and progression of prostate cancer. Methylation of GST-Pi is one of the earliest and most consistent findings in prostate cancer (Lee et al., 1994). Subsequently, many additional genes with CpG-rich promoters have been found to be preferentially methylated with the development of prostate cancer. A few relatively recent examples include 14-3-3sigma (Pulukuri and Rao, 2006), P4501A1 (Okino et al., 2006), TIMP-2 (Pulukuri et al., 2007), and RASFF1A (Kawamoto et al., 2007). Clearly, epigenetic regulation plays a role in the development and progression of prostate cancer, but the relative importance of the individual genes thus far identified remains largely unknown.

Investigations using technology platforms with greater coverage of the human genome are currently ongoing and are likely to continue to identify specific genomic regions altered with

prostate cancer progression (reviewed in [Nelson et al., 2007]). Already patterns of post-translational acetylation and dimethylation of histones H3 and H4 have been shown to identify two groups of low-grade prostate cancers with different risks of recurrence independent of tumor stage, preoperative prostate-specific antigen levels, and capsular invasion (Seligson et al., 2005). Importantly, the availability of high-throughput methods such as DNAse hypersensitivity that assess high-order chromatin structure (Crawford et al., 2006) represents yet another outstanding opportunity for discovery.

Somatic DNA Alterations

Genomic screens for DNA-based changes have recapitulated previous findings from targeted analyses. In one study, a microarray genotyping single nucleotide polymorphisms (SNPs) identified loss of heterozygosity in regions on chromosomes 8p (22%), 8q (24%), 16q (20%), 13q (18%), 10q (12%), and 4q (12%) (Lieberfarb et al., 2003). With the exceptions of 8q and 4q, each of these regions had been previously implicated in prostate cancer (Nelson et al., 2003). Similarly, in a recent study using array comparative genomic hybridization (aCGH), gains were seen at 1q, 7, 8q, 16p and 17q and losses at 2q, 4p/q, 6q, 8p, 13q, 16q, 17p, and 18q (Saramaki et al., 2006). With the increased resolution offered by the 16,000-feature microarray used for this study, smaller regions of gains or loss could be discerned.

Genomic analyses of somatic changes in prostate cancer have highlighted the role of specific oncogenes and pathways in prostate cancer (Table 37.1). A few are consistently associated with prostate cancer development and progression and deserve specific mention. Importantly, the detailed knowledge of these pathways in prostate cancer and specific details with respect to their role in prostate cancer provide important molecular paradigms with which to consider the role of novel molecular alterations in prostate cancer as they are identified.

PTEN/PI3K/mTOR

PTEN antagonizes the growth-promoting effects of the family of proteins constituting the dimeric complex with PI3K activity by removing the phosphate moiety from the 3′position of phosphotidylinositol 3,4,5-triphosphate (PIP3) (Li et al., 1997).

TABLE 37.1 Common chromosomal alterations in prostate cancer

Gene	Chromosomal location	Change observed	Function	Reference
ETS family members	21,7,others	Translocation downstream of AR regulated genes (primarily TMPRSS2)	Transcription factors	(Tomlins, 2006)
GSTPi	11	Methylation of promoter	Responds to oxidative stress	(Nelson, 1994)
PTEN	10q23	Loss	Tumor suppressor gene involved in regulation of the phosphatidylinositol 3-kinase pathway. Loss of the PTEN enzyme can lead to rapid cell growth and proliferation.	Hughes (2005)
NKX3.1	8p21	Loss/Inactivation	Tumor suppressor gene that is prostate specific and regulates epithelial growth and differentiation.	Hughes (2005); Shand (2006)
c-myc	8q	Gene amplification	Encodes a transcription factor that regulates the expression of multiple genes leading to increased cell proliferation.	Hughes (2005); Jenkins (1997)
Rb	13q	Loss (LOH, mutation)	Tumor suppressor gene that prevents replication of damage DNA through the cell cycle.	Hughes (2005); Phillips (1994)
p53	17p	Loss (LOH, mutation)	Tumor suppressor gene that prevents entry of damaged DNA into the cell cycle and promotes apoptosis.	Grignon (1997); Hughes (2005)
AR	X	Amplification, mutation in hormone refractory disease	Transcription factor	Koivisto (1995)

Homozygous loss of PTEN is common in advanced prostate cancer (Sansal and Sellers, 2004), and loss of one allele is likely to be an early event (Bello-DeOcampo and Tindall, 2003). Inhibition of PI3K by targeted molecules devastates prostate cancer cells with PTEN loss largely through pro-apoptotic effects (Lin et al., 1999).

It is now clear that PTEN has gene dosage effects in prostate cancer that are profound. The two transgenic mice thus far developed with prostate-specific Pten knockout (Trotman et al., 2003; Wang et al., 2003) have provided remarkable insight into PTEN biology. Although complete inactivation of PTEN is observed in a significant number of cases of advanced prostate cancer, only one allele is lost in many patients at presentation. Trotman and coworkers created a Pten hypomorphic allele to generate a series of Pten transgenic mice that had progressively decreasing levels of the PTEN protein expressed in the prostate. The incidence of prostate cancer, latency and progression correlated with Pten dose in the prostate, thus providing definitive evidence that PTEN copy number is important in prostate cancer and that the hemizygous state of PTEN may play a key role in the initiation of prostate cancer (Trotman et al., 2003).

The impact of this work has been extended with the recent demonstration of cooperativity between PTEN and p53 (Chen et al., 2005c). PTEN protects p53 protein from Mdm2-mediated degradation (Mayo et al., 2002), and p53 enhances PTEN transcription (Stambolic et al., 2001). In transgenic mice, conditional inactivation of p53 fails to produce a prostate tumor phenotype in mice, and in the same strain complete PTEN inactivation in the prostate triggers tumor formation with a long latent period. However, combined inactivation of Pten and p53 leads to formation of invasive prostate cancer as early as 2 weeks after puberty and is often lethal by 7 months of age (Chen et al., 2005c). This work demonstrated that acute PTEN inactivation induces growth arrest through the p53-dependent cellular senescence pathways both *in vitro* and *in vivo*, which can be fully rescued by combined loss of p53. This could potentially explain observations in human prostate cancer where evidence of cellular senescence is seen in early stages (by strong beta-gal staining in regions of prostatic intraepithelial neoplasia (PIN) but not in frank tumor) where cells presumably have lost p53. p53 appears to be an important checkpoint that restricts Pten-deficient tumors, and lysates from pten-null mice prostates showed a 10-fold induction of p53 (Chen et al., 2005c).

Along with major genetic modifiers such as p53, germline genetic variation is also likely to impact the phenotype of PTEN loss in prostate epithelium. This possibility is suggested by the somewhat disparate phenotypes of two prostate-specific, complete Pten knockout mice. The Pten-null C57Bl/6 × 129/Balb/c F2 mice developed by Wang and coworkers using a cre-lox knockout approach (Wang et al., 2003) exhibit a latent period for PIN formation of 8–10 months for heterozygotes mice and as short as 1.5 months for the homozygous mutant mice, which further supports the dose-dependent effects of PTEN. In addition, homozygous mutants develop invasive adenocarcinoma that progresses to metastasis and does not respond to castration. However, in a pure C57Bl/6 background, PTEN loss results in invasive cancer but not metastasis (Trotman et al., 2003).

MYC

c-Myc is a transcriptional factor that is required for expressing many genes involved in cell-cycle transition events and proliferation (Adhikary and Eilers, 2005). Overexpression of MYC will result in increased apoptosis unless there are mutations in MYC itself (Hemann et al., 2005) and/or deficits in homeostatic mechanisms that facilitate escape from p53 and p19ARF mediated apoptosis (Dang et al., 2005). Frequent amplification of chromosome 8q24 and/or the MYC oncogene has been demonstrated in androgen-independent prostate cancer with greater frequency of amplification noted as prostate cancer progresses (Edwards et al., 2003).

p53 and Rb

While distinct in their biology, p53 and Rb have both been implicated in late-stage prostate cancer and have a demonstrated causative role in transgenic mouse models. Loss of heterozygosity at the Rb loci is frequent in early prostate cancer (60% in [Phillips et al., 1994]). Rb loss results in dysregulation of the E2F transcription factors which activate genes critical for cell-cycle progression and proliferation. p53 is best characterized as causing cell-cycle arrest and apoptosis in the setting of DNA damage. p53 mutations have been associated with prostate cancer. In addition, both p53 and Rb immunohistochemistry have prognostic importance in prostate cancer (Theodorescu et al., 1997).

Fascinating recent work has further demonstrated significant interaction between Rb loss and p53 signaling (Hill et al., 2005). While the supportive role of the prostatic stroma in cancer development and progression has been recognized for some time (Cunha et al., 2002), somatic genetic changes have inconsistently been found and there was little direct support for processes whereby genetic or epigenetic events preferentially occur in stromal adjacent to malignant epithelial cells. In transgenic mice with Rb loss, there is paracrine selective pressure on the stromal fibroblasts to escape from p53 growth arrest. As a result, investigators found p53 mutations occurring within the stromal cells (Hill et al., 2005). While this specific model provides only a single example of somatic genetic changes in the stroma driven by epithelial malignancy, it likely represents a common phenomenon that helps explain the stable phenotypic differences observed between stromal cells adjacent to either benign epithelial glands or malignant epithelial glands (Cunha et al., 2003).

PROSTATE CANCER DETECTION

The discovery of circulating prostate-specific antigen (PSA) and its subsequent use as a screening test has resulted in earlier detection, but PSA screening has yet to demonstrate a survival benefit. Importantly, while PSA can diagnose prostate cancer earlier than symptoms, physical exam, or other blood chemistries, it

remains limited as a predictive marker and provides little insight as to the specific biology of an individual's prostate cancer. The goal of many genomic projects in prostate cancer is to improve upon the specificity of serum PSA and to discover and develop biomarkers that provide additional predictive or biological insight (Figure 37.1).

Urine Biomarkers

Prostate cancer cells slough into the prostatic glands and ducts and can be found in the urine. As high-grade prostate intraepithelial neoplasia often is associated with prostate cancer, the identification and characterization of prostate cells within the urine may provide an opportunity. In addition, degraded proteins derived from the serum and passing into the urine may also provide diagnostic, prognostic, or predictive information (M'Koma et al., 2007). Single molecular markers demonstrate correlation between biopsy results and urine protein levels. For example, there is good correlation between the presence of α-methylmalonyl co-A racemase (AMACR) detected in the urine and biopsy results in men undergoing diagnostic evaluation for prostate cancer (Rogers et al., 2004). When PCR-based promoter methylation assays were used to compare cells collected in the urine to prostate biopsies, correlation was very high for three genes (94% for GST-pi and APC, 82% for EDNRB) (Rogers et al., 2006). Additional urine biomarkers of potential clinical utility currently under study include PCA3 (de Kok et al., 2002; Tinzl et al., 2004) and the TMPRSS2/ERG translocations (Hessels et al., 2007). Thus, molecular events detected in cells or prostate-specific proteins present in the urine seem to reflect changes within the prostate and may serve as biomarkers to provide a means for earlier diagnosis.

Broader proteomic approaches have demonstrated some early success in correlating protein patterns with prostate pathology. Using a mass spectrometry approach (MALDI-TOF-MS), investigators have identified calgranulin B in the urine of men with prostate cancer following prostatic massage (Rehman et al., 2004). Alternatively, by adsorbing urine proteins onto a reverse-phase resin and subsequently directly spotting them onto a specific matrix (α-cyano-4-hydroxycinnamic acid), another group demonstrated peaks that could be used to distinguish between individuals with benign prostatic hypertrophy (BPH), PIN, and prostate cancer with approximately 75% specificity and 70% sensitivity (M'Koma et al., 2007). These early analyses require validation, but suggest that urine holds some promise as a source for informative biomarkers. The relative utility of urine-based analysis compared to serum-based analysis remains to be fully explored.

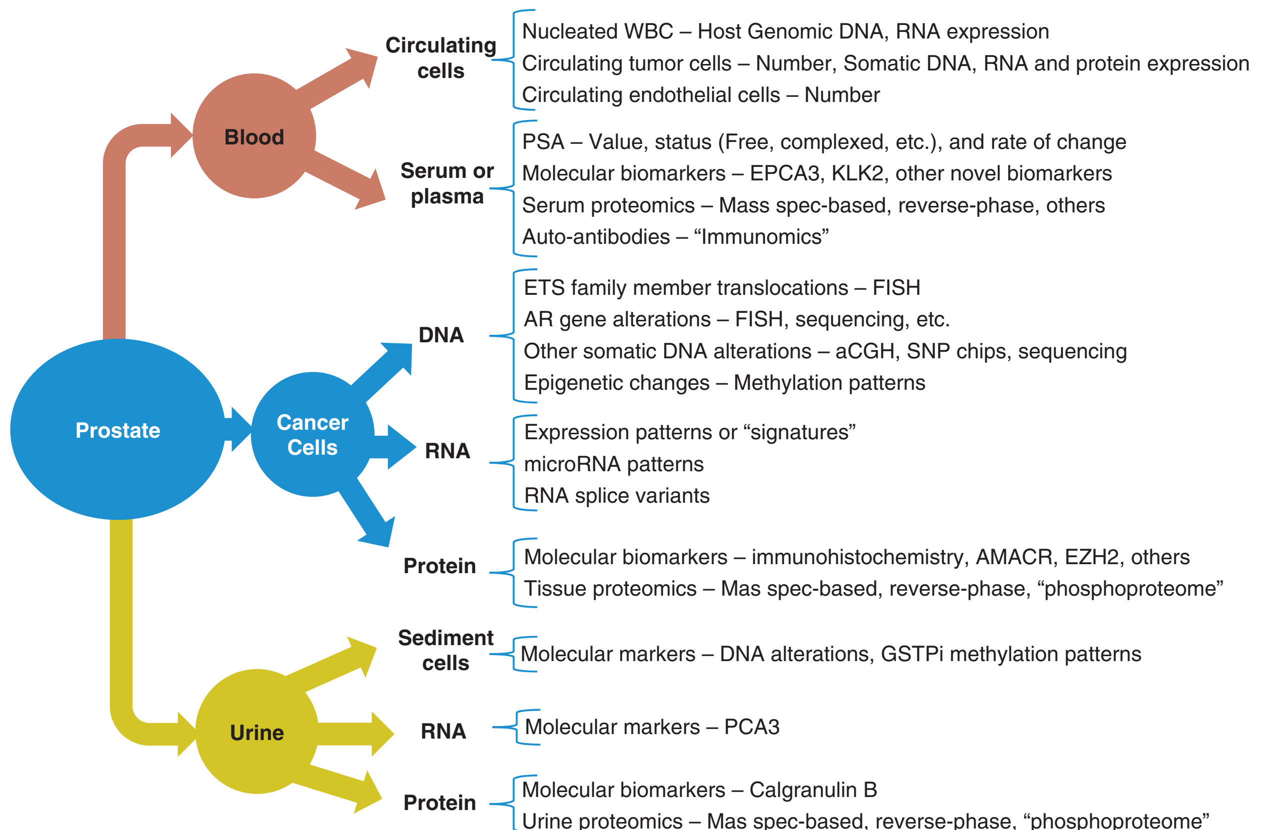

Figure 37.1 Biomarkers in prostate cancer.

Serum Biomarkers

There has been great interest in improving our ability to detect and anticipate the behavior of prostate cancer beyond that currently enabled by serum PSA. PSA kinetics (e.g., PSA velocity or PSA doubling time) has been recently broadly recognized to improve the prognostic accuracy of PSA (D'Amico et al., 2005; Freedland et al., 2005; Partin et al., 1994), but still provide relatively limited insight into the molecular biology of an individual's cancer. To this end, multiple groups have performed proteomic analysis of serum samples in an attempt to identify more sensitive and/or specific markers. Comprehensive analysis of circulating serum proteins in patients at risk or diagnosed with prostate cancer have used two-dimensional polyacrylamide gel electrophoresis (2D-PAGE), MS-based technologies (e.g., matrix assisted laser desorption ionization time-of-flight (MALDI-TOF) or surface enhanced laser desorption ionization time-of-flight (SELDI-TOF)), and reverse-phase protein arrays (Ornstein and Tyson, 2006).

There have been early suggestions that proteomics can distinguish patients with prostate cancer from patients with a normal PSA (Petricoin et al., 2002) and can distinguish patients with advanced prostate cancer from patients with advanced breast or bladder cancer (Villanueva et al., 2006). Significant effort is now focused on determining the best technological platforms and clinical applications for use in the care of men diagnosed with prostate cancer. However, blood collection and processing remains a significant challenge to open-ended proteomic technologies such as MALDI-TOF or SELDI-TOF, as small changes in storage or protein isolation can significantly impact proteomic profiles (Gelmann and Semmes, 2004). When sample processing is standardized, differential patterns have been identified that correlate with the presence of prostate cancer (Villanueva et al., 2006) and the presence of bone metastasis (Li et al., 2005), but these findings require more extensive testing before their true prognostic or predictive value is known.

An alternative approach, referred to as reverse-phase proteomics, has also demonstrated promise (Wang et al., 2005). In a specific example, prostate cancer cDNA library is used to create a bacteriophage library and single clones expressing prostate cancer antigens are spotted onto glass microarrays. Patient's serum is labeled and hybridized to the arrays in the presence of an alternatively labeled "normal" serum. This technique determines differential presence of auto-antibodies directed against prostate cancer antigens. Investigators found that this approach had greater sensitivity and specificity than PSA in men with serum PSA measured between 4 and 10 ng/dl (Wang et al., 2005). These reverse-phase proteomic approaches may be less impacted by sample processing and be deployable clinically.

Currently, many associations between proteomic analysis and prostate cancer remain limited to single investigator teams, and no single marker or proteomic-based model has been incorporated into clinical practice. However, with improved standardization of processing and platforms, serum proteomics have great promise to improve prostate cancer care. Early studies have already provided proof of concept by identifying serum proteins that may improve upon PSA for prostate cancer diagnosis and treatment and prospective evaluation and clinical implementation of the best markers is likely to occur over the next few years.

Circulating Tumor Cells

As tumors progress, malignant cells can be found within the circulation. Surrogate measures of circulating tumor cells (CTC), such as RT-PCR for PSA from whole blood (Seiden et al., 1994), have been associated with prostate cancer risk (Ghossein et al., 1999). The development of methods to isolate CTC from blood has created further opportunity to determine if the CTC number and nature provides an emerging opportunity for biomarker development. Patients with prostate cancer seem to have a relatively heavy burden of CTC, and increased numbers of CTC are associated with more advanced disease (Moreno et al., 2001) and survival (Moreno et al., 2005). Decreases in CTC numbers in response to therapy have recently been found to be associated with survival in men treated with castration-refractory prostate cancer (Moreno et al., 2007). However, it remains to be seen if the biology of an individual's CTC significantly reflects that of their metastatic disease.

Given the relatively small numbers (a median of 5 CTC/7.5 ml of blood in patients with advanced prostate cancer [Moreno et al., 2005]), the isolation and analysis of CTC has proved to be a significant challenge. Thus far, analysis has been largely restricted to specific proteins or genes (PSA, PSMA, etc.) (Chen et al., 2005a). However, investigators have demonstrated the ability to detect molecular markers such as EGFR expression, DNA ploidy, and/or androgen receptor (AR) amplification in samples with >5 CTC/7.5 ml of blood (Shaffer et al., 2007). As cells are more efficiently isolated and methods of DNA or RNA amplification improved, it is possible that genomic analysis of this compartment may provide surrogate prognostic or predictive biomarkers.

Imaging Prostate Cancer

Imaging of the prostate is performed routinely, but thus far has demonstrated limited utility in defining intraprostatic disease burden, and no imaging modality has provided strong predictive correlates with prostate cancer behavior. Imaging modalities that have been in routine use and tested for their ability to define either intraprostatic tumor burden or histopathological correlates include transrectal ultrasound, pelvic CT, pelvic MR, pelvic MR with endorectal coils, Prostascint scans, and positron-emission tomography scans. A few imaging modalities are successful in suggesting extraprostatic disease (CT, pelvic MR +/− endorectal coils) or enlarged regional lymph nodes (MR +/− endorectal coil). In a recent study, MR evidence of non-organ confined disease (either extracapsular, seminal vesicle, or lymph node involvement) contributed to the prognostic nomograms (Kattan nomogram) that are frequently used in clinical practice (Wang et al., 2006). However, no modality has been proven to provide sufficient clinically useful information about intraprostatic

tumor burden, pathology, or biology so as to warrant widespread adoption.

MR spectroscopy is an emerging technology that has yet to be fully evaluated for its potential to provide prognostic and/or predictive information about cancer (Sorensen, 2006). Preliminary studies focused on prostate cancer have shown considerable promise (Hricak, 2005). MR spectroscopy of prostates after removal have demonstrated spectroscopic correlates with pathology (Cheng et al., 2005) and *in vivo* studies are underway. MR spectroscopy was found to contribute to the anatomical information provided by MR in the study by Wang and coworkers although the contribution was not found to be statistically significant (Wang et al., 2006). While widespread use of MR spectroscopy has been somewhat limited because of concerns regarding technical reproducibility, emerging work has started to identify spectroscopic approaches that are more readily performed across institutions. In addition, while there has been relatively poor correlation between MR imaging and intraprostatic tumor volume or pathology, few studies have addressed the correlation of MR spectroscopy and intratumor volume and/or pathology. Finally, there have been no studies bringing together MR spectroscopy and genomic analyses of prostate cancer to determine if there are spectroscopic findings that identify prostate cancer tumors with poor prognostic or specific predictive genomic signatures.

GENOMIC CHANGES ASSOCIATED WITH PROSTATE CANCER BEHAVIOR

The progression of the prostate epithelial cells from benign to malignant and from local to metastatic is associated with genetic, epigenetic, RNA, and protein alterations. Significant effort has lead to our understanding how specific molecular events impact the development and progression of prostate cancer. More recently, global approaches of genomic interrogation have been applied to discover and define the most important molecular events in prostate cancer.

Prostate Cancer Initiation

Early expression analyses of prostate cancer focused on global differences between benign tissue (either "normal" prostate glands or BPH) and "cancer." Multiple groups have demonstrated significant differential gene expression between benign and malignant localized prostate cancer specimens using microarrays (Dhanasekaran et al., 2001; Lapointe et al., 2004; Luo et al., 2001; Singh et al., 2002; Welsh et al., 2001). The difference in global gene expression between tissue samples comprised of benign epithelium and those containing malignant prostate cells were profound and several genes (e.g., AMACR and hepsin) were common to multiple groups. Importantly, microarray analysis demonstrated that AMACR had consistently increased expression in prostate cancer (Luo et al., 2001). AMACR expression was subsequently validated by immunohistochemistry (Luo et al., 2002; Rubin et al., 2002) and is currently used clinically in some situations when the diagnosis of malignancy is unclear.

Perhaps one of the most significant findings resulting from microarray analysis is the identification of recurrent chromosomal rearrangements associated with prostate cancer (Tomlins et al., 2005). By looking at data from gene expression microarrays, this group identified outlier genes whose expression was uncharacteristically high in individual cases of prostate cancer compared to other cancers. This approach identified the frequent aberrant expression of two transcription factors belonging to the ETS family, *ERG* and *ETV1*. When the genomic location and organization of these genes were further interrogated, they were found to be fused to the 5′ end of the prostate-specific, androgen-regulated gene *TMPRSS2,* with one or the other fusion present in a very high proportion of localized prostate cancer specimens (23/29) (Tomlins et al., 2005), suggesting that fusion of an ETS family member with TMPRSS2 may be a common initiating event in prostate cancer. Multiple groups have likewise identified these translocations in a high percentage of prostate cancer patients (Hermans et al., 2006; Iljin et al., 2006; Tu et al., 2007). In addition, there have been early reports that the presence of ETS translocations are associated with more aggressive pathology (Mosquera et al., 2007) and higher prostate cancer specific mortality (Demichelis et al., 2007). The translocation between *TMPRSS2* and an ETS family member appears to be an important early event in prostate cancer and, while it may have less impact on late-stage disease (Hermans et al., 2006), targeting these translocations is likely to be a clinically important approach.

Biochemical Relapse Following Surgery

As an imperfect but feasible measure of progression, many groups have analyzed the difference in RNA expression patterns between prostate cancers from men who were cured (or remained biochemically free of disease for at least 4 years) versus men who had biochemical recurrence (Glinsky et al., 2004; Henshall et al., 2003; Lapointe et al., 2004; Singh et al., 2002). Interestingly, while each independent group could consistently find expression patterns anticipating biochemical recurrence using multi-gene predictive models, there was little overlap in the genes used in each group's specific model. This can be interpreted in many ways, but is likely due to the consistent presence of expression structure associated with biochemical relapse that is subtle (i.e., low signal to noise ratio) yet deep (many genes). The consistency of such an outcome signature suggests that genetic events in the primary tumors do determine a propensity to spread; however, the biology driving such expression patterns remains far from clear, and recurrence signatures may not be unique to prostate cancer.

The pre-existence of genetic or epigenetic events that determine aggressive behavior is also supported by DNA-based analysis. Using aCGH, investigators have found a higher frequency of DNA copy number changes associated with recurrent disease and specifically identified loss of 8p being associated with advanced stage and gain of 11q13 with biochemical recurrence

(Paris et al., 2004). The specific regions found to be amplified contained the *MEN1* gene, and subsequent analysis confirmed a difference in RNA expression.

Integrative Analysis

While preliminary genomic analysis of prostate cancer was largely restricted to single molecular compartments (i.e., DNA, RNA, etc.), there is an increasing utilization of integrative analysis that uses more than one molecular compartment to investigate tumor biology. An integrative approach using extensive genomic and proteomic analysis of prostate cancer found that, compared to benign prostate, 64 proteins were altered in localized prostate cancers, and an additional 156 proteins were detected in metastatic cancer. Only 48–64% concordance was observed between the RNA and proteomic analyses but the genes that were correlated with outcome by either both methods served as good predictors of clinical outcome in prostate cancer as well as other tumors (Varambally et al., 2005). Such integrative analyses are likely typical of future genomic studies and will help to determine molecular sub-types of prostate cancer in order to provide a more comprehensive understanding of prostate cancer biology and improve prostate cancer treatment.

Another approach, while not involving more than one molecular compartment, is to use differential gene expression as a phenotype and to assess the similarity between gene expression as prostate cancer progresses with a broad range of expression phenotypes derived experimentally. In a recent paper, gene expression was assessed in prostate samples ranging from benign to malignant disease including a number of metastatic samples (Tomlins et al., 2007). Differential gene expression between stages of progression was used to assess similarity with gene expression changes associated with other expression-based phenotypes. For example, this process – termed the molecular concept map (MCM) – found that genes associated with proliferation in cell lines had a coordinated increase in expression as prostate cancer transitioned from local to metastatic cancer. While somewhat limited due to their analysis of only 44 individuals were, this analytic method has started to identify the biology underlying prostate cancer progression and metastasis and suggests further analysis of larger datasets will be fruitful.

Correlates with Pathology

There are also gene expression signatures associated with prostate cancer pathology (Singh et al., 2002). Genes found to have increased expression in tumors of increasing pathological grade (as measured using the Gleason grading system) were found to be consistent across independent sets of prostate cancer specimens (Singh et al., 2002). Interestingly, a large number of these genes were downstream targets of TGF-beta signaling and were among the top genes correlated with Gleason score (Febbo and Sellers, 2003). Subsequent work has further supported strong gene expression associations with Gleason grade (Halvorsen et al., 2005) and found that gene expression patterns can be used to distinguish Gleason grade 3 from Gleason grade 4/5 with 76% accuracy (True et al., 2006).

These analyses suggest that a biology associated with aggressive behavior can be found in the localized tumors and likely predates the spread of cancer. While genes such as *MUC1* (Lapointe et al., 2004), monoamine oxidase A (True et al., 2006) and many others have been associated with Gleason score, the specific biology driving prostate cancer aggressive disease is not fully understood.

Changes Associated with Progression to Metastatic Prostate Cancer

An alternative approach to identifying molecular changes associated with aggressive prostate cancer is to compare local to metastatic disease. By measuring gene expression in hormone-refractory prostate cancer and comparing it to local disease, RNA and protein expression of *enhance of zeste homologue 2* (EZH2) was found to be elevated (Varambally et al., 2002). Increased expression of EZH2 in localized tumors was subsequently associated with recurrence.

Interestingly, the prognostic importance of genes differentially expressed between local and metastatic tumors may be independent of tumor type. When local tumors from a variety of solid cancers were compared to a variety of metastatic samples, a 17-gene signature of metastasis was derived. When this signature was applied to prostate, breast, and meduloblastoma, the signature could anticipate disease recurrence greater than expected by chance alone (Ramaswamy et al., 2003). However, when the prognostic importance of single genes such as *EZH2* are assessed in independent datasets and in the context of multivariable models, they seldom hold greater prognostic value than established clinical and pathological features (Rhodes et al., 2003).

Literature Mining

In another example of integrative analysis, the interpretation of differential gene expression between different stages of prostate cancer can be aided by high-throughput annotation programs, such as those that perform text-based literature mining. In a recent example, genes found to have differential expression between local and metastatic prostate cancer were used as a set to find pathways that cooccurred in the corpus of medical literature more frequently than expected by chance alone. This approach identified FOSB as being associated with the genes differentially expressed in metastatic prostate cancer, and subsequent immunohistochemistry found increased nuclear FOSB staining in metastatic prostate cancer compared to local prostate cancer (Febbo et al., 2007). Additional annotation approaches using Gene Ontology or Pathway membership are being used with increasing frequency to help interpret genomic findings.

Prostate Cancer Response to Treatment

Genomics to Inform Clinical Trials

Genomics have already been incorporated into clinical trials so as to investigate the biological response to novel treatments in prostate cancer and identify potential mechanisms of resistance. In the setting of a phase II neoadjuvant Docetaxel (Taxotere)

trial for high-risk localized prostate cancer, microarray-based gene expression was measured in tumors following docetaxel (Taxotere) therapy and compared to untreated prostate tumors matched for Gleason grade (Febbo et al., 2005). While there were no genes with large differences in expression (>5 fold between treated and untreated tumors), gene set enrichment analysis (GSEA) (Subramanian et al., 2005) identified altered expression of genes involved in androgen metabolism. This finding further underscores the potential importance of androgen signaling in prostate cancer and has helped to inform the development a large multi-center phase III trial (CALBG [cancer and leukemia group B] 90203) that compares neoadjuvant docetaxel (Taxotere) and androgen ablation followed by surgery to surgery alone for men with similar high-risk prostate cancer (Eastham et al., 2003).

In another example, patterns of gene expression were determined in localized prostate cancer before and after neoadjuvant Imatinib Mesylate (Gleevec) given to men with intermediate to high-risk prostate cancer prior to prostatectomy (Febbo et al., 2006). Microarray analysis following laser capture microdissection and RNA amplification was used to determine gene expression changes associated with therapy from nine patients. The study revealed large gene expression differences, and the gene most differentially expressed, *MPK1*, was validated by immunohistochemistry. GSEA comparing Imatinib Mesylate (Gleevec)-treated prostate cancer with untreated or pre-treatment biopsies highlighted a potential impact of treatment on apoptosis of cells associated with tumor microvasculature. Additional studies are now underway that look to improve the impact of targeted therapy on microvasculature by either using agents that target multiple receptor tyrosine kinases on the tumor vasculature (Neoadjuvant Sunitinib [Sutent], Duke University Medical Center, Daniel George, P.I., and Neoadjuvant Sorafenib (Nexavar), Fred Hutchinson Cancer Research Center, Evan Yu, P.I., which targets both PDGFR and VEGF) or combining targeted therapy with chemotherapy (Neoadjuvant Bevacizumab [Avastin] and Docetaxel [Taxotere], Dana Farber Cancer Institute, William Oh, P.I.). Further studies using laser capture microdissection and RNA amplification with targeted agents have the potential to lead to the discovery of potential mechanisms of targeted therapy in cancer.

Guiding Cytotoxic or Targeted Therapy

In 2004, two pivotal trials, TAX 327 and SWOG 99-16, demonstrated a survival benefit for docetaxel in metastatic prostate cancer (Petrylak et al., 2004; Tannock et al., 2004). While this represents a significant advance, fully 40% of patients treated with docetaxel progress by the sixth cycle of docetaxel, and improved therapeutic options are required. Multiple phase III trials testing docetaxel-doublets are underway aimed at improving the outcome for men treated with docetaxel, but an alternative approach remains improved selection of patients who receive the greatest benefit from docetaxel. As men who normalize their PSA in response to docetaxel have median life expectancies that reach almost 3 years, additional therapies may only add toxicity. Recently, *in vitro* data from the NCI-60 panel of cell lines with Affymetrix microarray data and chemotherapy sensitivity data have found that chemotherapy sensitivity signatures can be developed that predict clinical response in patients with breast, lung, and ovarian cancer (Potti et al., 2006). Studies are now underway to determine if these genomic signatures can predict response to docetaxel in prostate cancer.

Along with chemotherapy sensitivity genomic signatures, pathway activity signatures have been published that may help identify patients most likely to respond to targeted therapy (Bild et al., 2006). Important questions remain regarding the most effective means of developing predictive pathway signatures to help guide therapy, but multiple studies are currently underway that use genomics to enrich for responsive patients. At Duke University, a single arm Phase II study of RAD001 (Everolimus – Novartis) in men with HRPC is underway in which CT-guided biopsies are performed prior to and following treatment with RAD001 (Everolimus) to evaluate the molecular, genetic, and genomic effects of RAD001 in these tumor specimens and to determine if response to RAD001 can be predicted based upon the molecular state an individual's tumor.

GENOMIC CHANGES ASSOCIATED WITH HORMONE-REFRACTORY PROSTATE CANCER

AR Activity

Prostate cancer's dependence on androgens has been known for over a half a century since Huggins and Hodges demonstrated the dramatic palliative effects of orchiectomy for patients with metastatic prostate cancer (Huggins and Hodges, 1941). Classically, androgens act by binding to the intracellular AR, a ~110kD nuclear transcription factor with a central DNA binding domain, a ligand binding domain, and both ligand-dependent and ligand-independent transcriptional activation domains (reviewed in [Febbo and Brown, 2002]). The regulation of AR activity involves a complex dance of protein–protein and protein–ligand binding eventually resulting in transcription of a subset of genes containing androgen response elements (AREs). While this classic mechanism of action remains valid, complexities including non-transcriptional effects of androgens, AR co-regulators and transcriptional specificity, and non-autonomous AR effects have built upon the "classic" understanding of AR actions (Taplin and Balk, 2004).

AR Transcriptional Targets

It is clear that identification of critical downstream targets of the AR likely holds significant biological and therapeutic importance in prostate cancer. The precise identification of AR targets is complicated by the ubiquitous presence of the degenerate AR response element in the genome and the complex interaction of AR with regulatory proteins. Of the known AR chaperones, Hsp90, has, perhaps, the most significant impact on AR activity. Inhibition of Hsp90 function results in proteosomal degradation

of proteins that require this chaperone for stability, including AR (Solit et al., 2002). In prostate cancer models, inhibition of hsp90 has been shown to modify the effect of dihydrotestosterone and inhibit the growth of hormone-sensitive and resistant tumors (Harashima et al., 2005; Solit et al., 2003). Interestingly, when the gene expression patterns following androgen exposure in LNCaP cells, an androgen sensitive prostate cancer cell line, was used as a "signature" with which to identify small molecules with expression antagonistic expression profiles, inhibitors of hsp90 were among the top chemicals on the list (Hieronymus et al., 2006).

Recent studies have looked at the global expression changes induced by castration in men with prostate cancer so as to glean biological insight. Interestingly, many of the genes identified in cancer cell lines were found to decrease following chemical castration when intraprostatic androgen levels were sufficiently reduced (Mostaghel et al., 2007). However, often some AR signaling was maintained as determined by the continued expression of putative AR target-genes and serum androgen levels did not correlate strongly with intraprostatic hormone levels. Thus, proactive assessment of continued AR activity and more aggressive AR inhibition is likely to be a fruitful area of future clinical research.

AR Addiction

Androgen ablation is the first line of therapy in prostate cancer. The significant biochemical and/or symptomatic response by most patients to castration demonstrates oncogenic addiction to AR signaling. However, most patients develop resistance to the treatment and prostate cancer progresses to the "hormone-refractory" stage. Importantly, it is now clear that while prostate cancer is progressing in the setting of low circulating levels of testosterone, most cancers are still dependent on AR signaling (reviewed in [Scher and Sawyers, 2005]). In approximately one-third of patients with hormone-refractory prostate cancer, the *AR* gene is amplified (Bubendorf et al., 1999; Koivisto et al., 1995; Visakorpi et al., 1995). For patients treated with specific AR-inhibitors, a subset will develop mutations in the AR gene that enable the mutant AR to be activated by additional androgens as well as progesterone and estrogen (Taplin et al., 1995, 1999). Similarly, a prostate cancer cell line, MDA PCa, established from a patient who had undergone castration, had two mutations in the AR receptor that made it more responsive to a sub-family of circulating steroids not effected by castration (Krishnan et al., 2002; Zhao et al., 1999).

Recently, in hormone-resistant prostate cancer xenografts, increased *AR* RNA expression was the most consistent RNA change associated with hormone-refractory growth (Chen et al., 2004). Subsequently, the authors demonstrated that increased AR expression was both sufficient and necessary for "hormone-refractory" growth of the xenografts (Chen et al., 2004). This work is supported by analysis of metastatic, androgen-independent human tumors that have very high expression of the AR and upregulation of metabolic enzymes that increase bioactive androgens when compared to local, untreated tumors using microarrays (Stanbrough et al., 2006). Thus, it has become very clear that continued AR signaling is a critical mechanism of hormone-refractory prostate cancer. Ongoing investigations are focused on the mechanisms by which prostate epithelial cells can maintain AR signaling in the setting of low circulating androgens.

2009 UPDATE

Important progress continues to be made in the biological understanding of the development and progression of prostate cancer. The desire to leverage biological insight for therapeutic gain continues to be fueled by disappointing negative results from multiple promising approaches for the prevention (Vitamin E and Selenium) and treatment (DN-101, GVAX, satraplatin) of prostate cancer (Jakobsdottir et al., 2009; Lippman et al., 2009). In 2008–2009, the field continued to be focused on studies aimed at the identification of additional prognostic and predictive genomic biomarkers, the clinical and biological implications of chromosomal translocations involving ETS family members, the persistent role of the AR in castration-resistant prostate cancer (CRPC), and overcoming therapeutic resistance to docetaxel.

Genome-wide association studies continue to identify novel regions associated with prostate cancer risk including loci on chromosomes 3, 6, 7, 9, 10, 11, 19, 22, and X (Duggan et al., 2007; Eeles et al., 2008; Hsu et al., 2009; Sun et al., 2009; Thomas et al., 2008). Individually, the identified regions had relatively minor absolute impact on risk, and the ideal means to aggregate alleles and produce a composite score remain unclear. Indeed, even when additive models of aggregate risk are shown to have promising results using logistic regression and receiver operator characteristic (ROC) curves, these may not translate into a clinically useful test (Jakobsdottir et al., 2009).

Expression-based prognostic and predictive models have also continued to be developed in order to improve upon risk stratification and to identify men at high risk for recurrence following definitive local therapy. Over the past 2 years, this work has transitioned from analysis of frozen prostate tissue to paraffin-embedded prostate tissue. Incorporating genes differentially expressed between prostate cancers with a high (4 or 5) or low (3) Gleason grade, investigators developed a model with an area under the curve of 0.81 in ROC analysis (Cheville et al., 2008). In the largest study of its kind, investigators at the Mayo Clinic were able to distinguish patients

who only had biochemical recurrence following prostatectomy ($n \sim 200$) from those who progressed to clinically metastatic disease ($n \sim 200$) (Nakagawa et al., 2008). While these models still seldom outperform multivariate predictive nomograms that use only clinical and pathological features (i.e., the Kattan nomograms and/or Partin tables), they offer the promise of molecular insight so as to guide the most appropriate treatment to those in greatest need.

Finally, new molecular compartments have been shown to be prognostically important in prostate cancer. First, the metabolic profiling has associated sarcosine levels with aggressive prostate cancer (Sreekumar et al., 2009). Using mass spectrometry, investigators from Michigan investigated the association between approximately 1100 metabolites in over 200 samples representing a range of prostate cancer progression. They found that, similar to RNA-based analysis, the different stages of prostate cancer could be differentiated based upon metabolic profile and that sarcosine was markedly elevated in advanced prostate cancer. Inhibition of the metabolic pathway generating sarcosine reduced invasive behavior of prostate cancer. In addition, micro-RNA 101 has been found to be a target of chromosomal loss resulting in increased expression of EZH2 and increased invasive behavior of prostate cancer (Varambally et al., 2008). While the particular implications of these findings for the diagnosis and treatment of prostate cancer remain unclear, additional work in blood, urine, and semen is likely to provide additional prognostic information.

The identification of translocations in prostate cancer has been expanded beyond the originally described ones (TMPRSS2:ERG1 and TMPRSS2:ETV1) (Tomlins et al., 2005). Indeed, additional translocations resulting in the juxtaposition of ETS family members with constitutively active regions have been identified (Tomlins et al., 2007). Most recently, a transcriptome resequencing effort has identified additional translocations (Maher et al., 2009). While general statements regarding the prognostic impact of these translocations have not held up, their frequency in prostate cancer continues to suggest their fundamental role and high potential as therapeutic targets.

Finally, there continues to be great enthusiasm for targeting AR in what was previously called androgen-independent or hormone-refractory prostate cancer. This stage is now commonly referred to as CRPC due to a number of independent groups finding persistent dependence on AR activity despite castrate levels of circulating testosterone. *De novo*, local synthesis of androgens has been identified as a common mechanism (Mostaghel et al., 2007; Stanbrough et al., 2006). The selective pressure of a low androgen state also results in a variety of AR mutations including those previously described in the ligand-binding domain (Taplin et al., 1999) as well as novel mutations impacting protein–protein interactions (AR and E3 ubiquitin ligase) and protein–DNA interactions (Steinkamp et al., 2009). These and many other findings continue to underscore the AR as a critical therapeutic target and are generating great enthusiasm for the novel AR-targeting agents, aberaterone (Haidar et al., 2003) and MDV3100 (Tran et al., 2009). These agents are in mid- to late-stage clinical trials and are likely to represent future therapies for men with CRPC.

It has also become clear that while most prostate cancers continue to have an active AR, the extent of AR activity is heterogeneous within and between individuals. Using a gene expression-based signature for AR, investigators have demonstrated that while activity of the AR decreases with progression to CRPC, some individuals maintain levels as high as those in patients with treatment naïve prostate cancer (Mendiratta et al., 2009). While the novel AR-targeting therapies are likely to represent a significant advance for patients with persistent AR activity, there are few promising treatment approaches for individuals who are found to have tumors with little to no AR production (i.e., AR-null tumors). It is likely that these AR-null tumors will become more important as more effective AR-targeting therapies select for cells that have become truly androgen independent. Using tissue-based, serum-based, or circulating tumor cell-based assays to distinguish between patients afflicted with tumors with high or low AR activity is likely to impact care by providing the most appropriate therapy for each man with CRPC.

CHAPTER

Genomic Assessment of Ovarian Cancer

Tanja Pejovic, Matthew L. Anderson and Kunle Odunsi

INTRODUCTION

The normal human ovary is lined by a cuboidal epithelium. These cells remain quiescent for most of their lifespan, proliferating only to repair the ovarian surface after ovulation. Epidemiologic evidence demonstrates a clear correlation between the frequency of ovulation and the incidence of epithelial ovarian cancer. As a result, particular attention in the search for precursors to ovarian cancer has focused on small inclusion clefts that persist after repair of the ovarian surface. The molecular environment influencing these clefts is unique, the epithelia lining these clefts express specific cell adhesion molecules, including cadherins, not normally observed in other areas of the ovarian surface epithelium.

While in other organs, such as colon, distinct pre-malignant lesions have been identified and found to accumulate, genetic defects that ultimately result in the pre-malignant ovarian change has not yet been clearly identified. Histologic findings consistent with a pre-invasive lesion for ovarian cancer have been described by a number of investigators in ovaries from high-risk women undergoing prophylactic oophorectomy and in areas of ovarian epithelium adjacent to early stage ovarian cancers that demonstrate a transition from normal to malignant cells (Schlosshauer et al., 2003). The hypothesis that these lesions are pre-malignant is strengthened by observations that regions of epithelial irregularity express levels of p53 and Ki-67 intermediate between those found in normal ovary epithelium and ovarian cancers. Each of these observations is consistent with the hypothesis that, similar to cancers originating in other organs, ovarian cancer evolves from an intraepithelial precursor. If so, improved means to detect and/or eradicate these lesions may prove fruitful for preventing ovarian cancer. Research efforts, designed to improve the early detection of ovarian cancer or optimize its clinical management at later stages, are likely to be more successful based on the understanding of molecular events responsible for this disease.

INHERITED OVARIAN CANCER SYNDROMES

Linkage analysis of familial breast and ovarian cancers provided some of the first insights into the molecular basis of ovarian cancer. These efforts ultimately identified two genes, *BRCA1* and *BRCA2*, each clearly associated with an increased incidence of ovarian cancer (Miki et al., 1994; Wooster et al., 1994). Although only a minority (8–10%) of diagnosed ovarian cancers are familial, about 60% of familial ovarian cancers are associated with mutations at the *BRCA1* locus, located on 17q21 (Easton et al., 1995). Hundreds of mutations in *BRCA1* have been identified, most commonly loss of function nonsense or frameshift mutations. Two of the three specific founder mutations, 185delAG and 5382insC, are found in 1% and 0.1% of Ashkenazi Jewish women. The population-based studies have suggested that the lifetime risk of ovarian cancer in *BRCA1* mutation carriers is about 20–30%, but this increased risk is not manifest until the age of 40.

The functional consequences of loss of function mutations in *BRCA1* are potentially profound. *BRCA1* regulates p53, an

Copyright © 2010, Elsevier Inc.
All rights reserved.

oncogene frequently implicated in ovarian cancer. Thus, loss of BRCA1 function allows DNA damage to accumulate via a loss of its activation of p53 check point. Other mechanisms of BRCA1-associated ovarian carcinogenesis such as site-specific dysregulation of X-linked gene expression in BRCA1-associated epithelial ovarian malignancies have been described.

BRCA2 gene plays a role in DNA repair by homologous recombination. About 35% of hereditary ovarian cancers may be attributed to *BRCA2* mutations and both female and male carriers of the mutation are at risk for breast cancer. The third founder mutation 6174delT occurs in *BRCA2*. Mutations in *BRCA1* and *BRCA2* are only rarely observed in sporadic, non-familial ovarian cancers. Characterization of genome-wide patterns of gene expression in sporadic breast cancers has allowed investigators to classify these tumors as either *BRCA1*-like or *BRCA2* like in the patterns of their gene expression. These observations implicate alterations in other components of the BRCA1/2-regulated pathways that contribute to sporadic ovarian cancer.

OPTIONS FOR SCREENING AND PREVENTION

The standard recommendations for women at increased risk for ovarian cancer include pelvic examination, serum tumor markers, and pelvic ultrasound. Unfortunately, none of these strategies have proven effective as a screening modality. Most cancers detected in high-risk populations are detected at an advanced stage. The high risk combined with the ineffectiveness of current screening methods has led to the recommendation that women with high risk undergo risk-reducing salpingo-oophorectomy (RRSO) after completion of child-bearing.

To be considered at high-risk for ovarian cancer, subjects must satisfy one of the following criteria (Table 38.1) (US Preventive Services Task Force recommendations, 2005).

Unfortunately risk-reducing surgery is not fail-safe. Cases of peritoneal surface serous carcinoma have been described in 2% of cases occurring from 1 to 27 years after risk reducing oophorectomy (Offit, 1998).

TABLE 38.1 Criteria for high-risk for ovarian cancer population

1.	The family of the subject has a documented deleterious *BRCA1* or *BRCA2* mutation – in either the subject herself, or a first- or second-degree relative.
OR	
2.	For non-Ashkenazi Jewish women: The family of the subject contains at least two ovarian and/or breast cancers among the first- or second-degree relatives within the same lineage. This condition can be satisfied by multiple primary cancers in the same person. Where breast cancer is required to meet this criterion, at least one breast cancer must have been diagnosed at the age of 50 years or younger.
OR	
3.	For non-Ashkenazi Jewish women: A combination of three or more first- or second-degree relatives with breast cancer regardless of age at diagnosis.
OR	
4.	For non-Ashkenazi Jewish women: A first-degree relative with bilateral breast cancer.
OR	
5.	For non-Ashkenazi Jewish women: A history of breast cancer in a male relative.
OR	
6.	For women of Ashkenazi Jewish heritage: Any first-degree relative or two second-degree relatives within the same lineage with breast or ovarian cancer.
OR	
7.	The subject is of Ashkenazi Jewish heritage and has had breast cancer herself. To meet this criterion, her breast cancer must have been diagnosed at the age of 50 years or younger.

GENOMIC INSTABILITY AND OVARIAN CANCER

Genomic instability is a hallmark of all cancer, including epithelial ovarian cancers. In order to become genetically unstable the cell has to become intolerant to DNA damage. The cell can achieve this by inactivating in any of the six major DNA repair pathways: base excision repair (BER), mismatch repair (MRM), nucleotide excision repair (NER), homologous recombination (HR), non-homologous recombination (NHR), and translesion DNA synthesis (TLS). The specific DNA pathway affected often predicts the specific type of mutations observed in particular cancers, its sensitivity to drugs, as well as clinical outcome of affected patients.

SOMATIC MUTATIONS IN OVARIAN CANCER

Ovarian carcinoma is a monoclonal disease that progresses through a series of genetic alterations that successively accumulate and transform a normal to a neoplastic cell. The molecular complexity of ovarian cancer has become apparent through the use of novel technologies that explore the genome, transcriptome, and proteome. These novel high throughput technologies are expected to provide information that allows for earlier diagnosis and individualized treatment of ovarian cancer. Biomarkers could be also used to stratify ovarian cancer into disease groups of varying aggressiveness. Stage III and IV ovarian cancer has a consistently high mortality rate, while Stage I and II ovarian cancer has a widely variable rate of mortality. It may be possible to

stratify ovarian cancer in its earliest stages into groups of cancer with varying degrees of aggressiveness and subsequent mortality.

Gene Expression Profiling of Ovarian Cancer

Ovarian cancers have been subjected to transcriptional profiling using *complementary DNA* (*cDNA*) or *oligonucleotide* array types. Alterations in gene expression have been suggested as useful markers of histologic differentiation in ovarian cancer. Marquez and coworkers (2005) showed distinct expression profiles of different ovarian cancer histologic subtypes and identified several markers of mucinous tumors, including *TFF1*, *AGR2*, *LGALS4*, *CEACAM6*, and *CTSE*. Several of these genes are also upregulated in normal colon and are important for protection and healing of the human gastrointestinal tract (Devine et al., 2000). In addition, Wamunyokoli et al. (2006) identified upregulation of *NET1* and *ERBB3* in low-malignant potential mucinous ovarian tumors and invasive mucinous carcinoma of the ovary leading to the hypothesis that these two genes may participate in the initiation of the transformation process in mucinous ovarian cancer. *ERB-B2/HER-2/NEU* was also found to be differentially upregulated in clear cell ovarian cancer. This gene encodes the target for the humanized anti-HER2/neu antibody, trastuzumab (Herceptin), that is showing promise for treatment of patients with ovarian cancers showing overexpression of Her-2/neu protein (Wang et al., 2006).

Recently, gene expressing profiling has successfully been used to predict response to platinum-based chemotherapy (Dressman et al., 2007). The accuracy of detecting platinum resistant disease based on expression profiling was 89%. Within this group expression signatures consistent with SRC and Rb/E2F pathways were identified and successfully targeted *in vitro*.

Proteomics

Proteomics is the study of the proteome of a population of cells. The proteome is a result of many factors including DNA alterations, mRNA splicing, post-translational modifications, and functional regulation of gene expression (An et al., 2006; Banderal et al., 2003). Technology platforms incorporating mass spectrometry (MS) for proteomic biomarker discovery include both pattern-based methods that produce MS-derived protein pattern via SELDI (surface-enhanced laser desorption and ionization), MALDI, or electrospray and identity-based methods that yield lists of sequence-identified peptides from LC-MS/MS analysis of proteolytically digested proteins (Zhang et al., 2006). Pattern and identity combine in MS/MS analysis of selected spots from differential protein displays such as two-dimensional polyacrylamide gel electrophoresis (2D-PAGE). Each method has strengths and limitations. The SELDI technique was used by Petricoin et al. (2002) for the search for ovarian cancer detection markers. This group studied serum samples of 50 ovarian cancer patients and 50 unaffected women. A protein pattern specific to ovarian cancer was identified and applied to a set of 116 serum samples from 50 women with cancer and 66 unaffected women. The proteomic pattern correctly identified all patients including 18 Stage I cancers. Only 3 of the 66 unaffected women were wrongly diagnosed as having ovarian cancer. This study awaits further validation.

ONCOGENES AND GROWTH FACTORS

Increased mutagenic signaling by receptor tyrosine kinases play a major role in ovarian carcinogenesis. Overexpression of *ERBB1*, *ERBB2/HER2/neu*, and *c-FMS* has been reported repeatedly in ovarian cancer. One of the major downstream mediators of signaling initiated by these receptors is the phosphatidylinositiol 3-kinase (PIK3K)-AKT/mammalian target of rapamycin (mTOR) pathway. This pathway is activated by multiple genomic aberrations in up to 70% of ovarian carcinomas. For example, with the *PIK3CA* gene at chromosome 3q26 being amplified in 25–40% of the cases. This proto-oncogene encodes the p110α catalytic subunit of PI3K and, when amplified or mutated, activates signaling through the PI3K/AKT/mTOR pathway. This pathway is thought to be a critical target for therapy of ovarian cancer. Indeed PI3K inhibitor molecules decrease ovarian cancer proliferation and ascites formation and increase chemotherapy induced apoptosis (Table 38.2).

It has been reported that >75% of ovarian carcinomas are resistant to transforming growth factor-β (TGF-β) (Hu et al., 2000), and the loss of TGF-β responsiveness may play an important role in the pathogenesis and/or progression of ovarian cancer. In addition, it has been shown that TGF-β_1, the TGF-β receptors (TβR-II and TβR-I), and the TGF-β-signaling component Smad2 are altered in ovarian cancer (Wang et al., 2006).

TABLE 38.2 Genetic alterations in sporadic ovarian carcinoma

Gene	Function	Mechanism	Frequency (%)
HER2/neu	Tyrosine kinase	Amplification/ overexpression	20–30
EGFR	Tyrosine kinase	Amplification/ overexpression	12–17
KRAS	G-protein	Mutation	15–60
CMYC	Transcription factor	Overexpression	30
PIK3CA	Kinase	Amplification	25–40
AKT2	Kinase	Amplification	10
p53	Tumor suppressor	Mutation/ deletion Overexpression	30–60
p16	Tumor suppressor	Homozygous deletion	15

Alterations in TβR-II have been identified in 25% of ovarian carcinomas (Lynch et al., 1998) whereas mutations in TβR-I were reported in 33% of such cancers (Chen et al., 2001). Loss of function mutations of TGF-β1, TβR-I, and TβR-II can lead to disruption of TGF-β-signaling pathways and subsequent loss of cell cycle control novel TGF-β-signaling component, termed km23. Sequence alterations in human km23 in epithelial ovarian cancer were found in 42% of ovarian carcinomas (Ding et al., 2005). The expression of IGF-II and IGFBP-3 also vary substantially by clinical and pathologic features of ovarian cancer. High levels of IGF-II expression are associated with unfavorable prognostic indicators of the disease, whereas high expression of IGFBP-3 is related to favorable prognostic variables. Patients with high IGF-II expression tend to have higher risk of disease progression and death regardless of the level of IGFBP-3 expression (Lu et al., 2006). However, the IGF-II does not seem to be an independent marker for ovarian cancer prognosis.

Ras pathway also appears to be activated in ovarian cancers. The KRAS is mutated in 15% of borderline serous ovarian tumors and 47% of mucinous neoplasm. While the mutation rate is higher in borderline mucinous (30–60%) than in invasive mucinous cancers (19%), it appears that these mutations play a role in the progression of the mucinous adenoma to borderline tumor to invasive mucinous carcinoma (Ren et al., 2006).

KRAS activates PKCi on 3q26.2, a key regulator of a complex required for localization of E-cadherin to cell junctions, for maintenance of tight junctions and for cell polarity, loss of which would allow aberrant interactions of cell signaling molecules and autocrine cell activation (Macara, 2004). In ovarian cancer PKCi is associated with cyclin E induction. Amplification of the CMYC oncogene also occurs in about 30% of ovarian cancers, however the functional significance of this amplification is unclear if overexpression of the corresponding protein occurs at the same time.

TUMOR SUPPRESSOR GENES

Loss of tumor suppressor gene function plays a major role in the development of most cancers. This involves a two-step process in which both copies of tumor suppressor gene allele are inactivated. In most cases there is mutation of one allele of the gene and loss of the other allele due to deletion of the large region of the chromosome where the gene localizes. Some tumor suppressor genes are inactivated via epigenetic changes, such as hypermethylation of GpC islands in the promoter area, while the gene structure remains intact.

Aberrations of p53 tumor suppressor gene are the most frequent genetic event in ovarian carcinoma (Berchuck et al., 1994). The frequency of p53 mutations is higher in advanced versus early ovarian carcinomas (50–60% versus 10–20%) and is uncommon in borderline ovarian tumors.

While in most cases of ovarian cancer, single amino acid change in the DNA binding domain of p53 (missense mutation) result in overexpression of non-functional protein, 20% of advanced stage ovarian carcinoma contain mutations that result in a truncated protein that is not over-expressed.

Other tumor suppressor genes known to be inactivated in ovarian cancer include *PTEN* and p16 (Table 38.2). *PTEN* is inactivated in some endometrioid ovarian carcinomas (Obata et al., 1998). In addition p16, an inhibitor of cyclin-dependent kinases, may be inactivated via homozygous deletion or promoter methylation in a small fraction of ovarian cancer (Havrilesky et al., 2001).

EPIGENETICS IN OVARIAN CARCINOGENESIS

It has become increasingly apparent that epigenetic events can lead to cancer as frequently as loss of gene function due to mutations or loss of heterozygosity. The overall level of genomic methylation is reduced in cancer (global hypomethylation), but hypermethylation of promoter regions of specific genes is a common event (Jones and Baylin, 2002) that is often associated with transcriptional inactivation of specific genes (Costello et al., 2000). This is critical because the silenced genes are often tumor suppressor genes and their loss of function can be evident in early stages of cancer, and can also drive neoplastic progression and metastasis. Epigenetic gene silencing is a complex series of events that includes DNA hypermethylation of CpG-islands within gene promoter regions, histone deacetylation, methylation or phosphorylation, recruitment of methyl-binding domain proteins and other chromatin remodeling factors to suppress gene transcription. Global hypermethylation of CpG islands appears to be prevalent but highly variable in ovarian cancer tissue (Ahluwalia et al., 2001). Specific aberrant methylation of cancer-associated genes such as *p16INK4A*, *RASSF1A*, *BRCA1*, and *hMLH1* have been reported for ovarian tumors or cell lines, albeit in various degrees and in a non-tumor type-dependent fashion (Esteller et al., 2000; Rathi et al., 2002). While a higher degree of DNA methylation is associated with drug resistance and believed to be the reason for treatment failure and death of 90% of patients with metastatic disease, the demethylation activity of chemotherapeutic drugs can elevate the expression of proteins such as MDR1 (Bell et al., 1985) that lead to a more frequent disease recurrence after chemotherapy (Wei et al., 2002). Thus, the specificity of demethylation of select genes is important to ensure the success of treatment and prevent disease recurrence.

OVARIAN CANCER METASTASES

Metastasis is the functional hallmark of all cancer. In contrast to cancers where metastasis clearly depends on the ability of cells to invade blood or lymphatic vessels, direct dissemination within the peritoneal cavity plays a critical role in the progression of ovarian cancer. A wide variety of gene products have been implicated in the metastasis of ovarian cancer. These include growth factor receptors such as epidermal growth factor receptor (EGFR), insulin-like growth factor receptors (IGFRs) and kinases, such as

jak/stat, focal adhesion kinase, PI-3 kinase and c-met. Comparisons of primary and metastatic ovarian cancers by transcriptional profiling have failed to reveal significant differences in the expression of gene products likely related to the metastatic process.

Particular attention has recently focused on the role of lysophospatidic acid (LPA) in promoting the metastasis of ovarian cancers. LPA is constitutively produced by mesothelial cells lining the peritoneal cavity; its levels are increased in the ascites of women with both early and late stage ovarian cancers (Ren et al., 2006). At a molecular level, exogenous LPA enhances ovarian cancer invasiveness both by activating matrix metalloproteinase-2 via membrane-type-1-matrix metalloproteinase (MT1-MMP) and downregulating the expression of specific tissue inhibitors of metalloproteinases (TIMP-2 and -3) (Sengupta et al., 2006). LPA also promotes dissemination of ovarian cancer by loss of cell adhesion (Do et al., 2007). However, LPA has also been shown to promote the invasiveness of ovarian cancers by additional mechanisms dependent on interleukin-8 (IL-8) (So et al., 2004). The G12/13-RhoA and cyclooxygenase pathways have also been implicated in the LPA – induced migration of ovarian cancers. These mechanisms appear to be independent of the ability of LPA to induce changes in MMP2 expression.

Until recently, the metastasis of ovarian cancer has been almost exclusively studied as a process involving individual cells. However, multicellular clusters of self-adherent cells, known as spheroids, can be isolated from the ascitic fluid of women with ovarian cancer. Spheroids readily adhere to both extracellular matrix proteins, such as collagen IV, and mesothelial cells in monolayer culture using beta1 integrins. Once adherent, the cells contained in spheroids disaggregate, allowing them to invade underlying mesothelial cells and create invasive foci. These observations are consistent with the hypothesis that ovarian cancer spheroids play an important role in the metastasis of ovarian cancer. Recent evidence has shown that a loss of circulating gonadotropins result in a dose-dependent decrease in the expression of VEGF in their outer proliferating cells of ovarian cancer spheroids, that these cell cluster remain responsive to signals in their microenvironment that may further promote metastasis (Schiffenbauer et al., 1997).

The presence of spheroids in ascites may also help to explain the frequent persistence and frequent recurrence of ovarian cancer after treatment. Spheroids express high levels of p27 and P-glycoprotein which contribute, at least in part, to their relative resistance to the cytotoxic effects of paclitaxel when compared to ovarian cancer cells in monolayer culture (Xing et al., 2007). However, the mechanisms by which the aggregation of malignant cells promote or enhance cell survival remain unclear. However, these observations are consistent with *in vitro* studies that demonstrate that the signals generated by adhesion to specific components of the extracellular matrix, such as collagen IV, can modify the sensitivity of ovarian cancers to chemotherapy.

It is also unclear, at present, how the aggregation of these malignant cells might promote or enhance the migration, attachment or invasion of ovarian cancer cells. However, insight into these questions is likely to come from genetic models, such as the migration of the border cell cluster in *Drosophila*. Analyses of border cell migration indicate specific shifts in epithelial polarity and changes in the patterns of signals arising at junctional proteins are necessary for the invasion and migration of epithelial clusters. Signals arising from these junctional proteins appear to be integrated by specific steroid receptor coactivators, known as AIB1 (SRC3). Overexpression of AIB1 is a frequent feature of ovarian cancers suggesting that the pathways regulated by this transcriptional coactivators may indeed play a critical role in promoting ovarian cancer metastasis.

2009 UPDATE

MicroRNAs (miRNAs) and short interfering RNAs (siRNAs) are classes of regulatory small RNA molecules, ranging from 18 to 24 nucleotides in length, whose roles in cancer are becoming increasingly recognized. They function by altering the stability or translational efficiency of messenger RNAs (mRNAs) with which they share sequence complementarities and are predicted to affect about one-third of all human genes.

MicroRNAs

miRNAs represent a class of small, 22 nucleotide long, noncoding RNAs that control gene expression by targeting mRNAs and triggering either translation repression or RNA degradation in the cell (Lagos-Qintana et al., 2001). They differ from siRNA in that they are processed from single-stranded RNA precursors and show only partial complementarities to mRNA targets. The human genome contains about 1000 miRNAs (Zamore and Haley, 2005). Each miRNA may target several different genes simultaneously or in sequence (Pillai et al., 2007; Wang et al., 2006). Recent evidence clearly suggests that miRNAs may participate in key cellular processes such as proliferation, apoptosis, and stem cell division (Brennecke et al., 2003; Hatfield et al., 2005; Xu et al., 2003). Therefore, any aberration in miRNAs may contribute to carcinogenesis by changing the final protein profile of cells.

Comparison between ovarian cancers and its normal counterparts have revealed distinct miRNA expression profiles (Iorio et al., 2007). Most prominently overexpressed miRNAs were miR-200a, miR-141, miR-200c, and miR-200b, whereas miR-199a, miR-140, miR-145, and miR-125b1 were underexpressed. In ovarian cancer, miRNA is deregulated by both genetic and epigenetic mechanisms. In 2006, Zhang et al., showed a high frequency of DNA copy number aberrations in regions containing miRNA in 109 ovarian cancer cases. In addition, they showed that miRNA copy number

changes directly correlated with the levels of miRNA expression (Zhang et al., 2006). Using miRNA microarrays, Dahyia et al. identified several miRNAs aberrantly expressed in human ovarian cancer tissues and cell lines. For example, miR-221 was found to be highly elevated in ovarian cancer, whereas miR-21 and several members of the let-7 family were downregulated (Dahiya et al., 2008).

The expression of miRNAs may be altered by mechanisms such as imprinting or via different epigenetic processes including methylation. Experimental and computer-assisted approaches have led to the identification of hundreds of imprinted small RNA genes, mainly clustered in two chromosomal domains (human 15q11→q13 and 14q32 loci) (Royo et al., 2006). Also, many miRNA genes, including let-7a-3, are located in CpG islands, suggesting possible epigenetic regulation of their expression.

Investigations into the miRNA expression profiles and interaction of miRNA and their targets may provide novel therapeutic options where miRNA are therapeutic targets.

Short interfering RNAs

Small interfering RNA (siRNA) has a well-defined structure: a short (usually 21-nt) double strand of RNA (dsRNA) with 2-nucleotide 3' overhangs on both the ends (Elbashir et al., 2001; Fire et al., 1998). The siRNA are produced in vivo by the action of the enzyme Dicer and can complex with complementary sequences on an mRNA activating a post-transcriptional destruction cascade spearheaded by RNA-induced silencing complex (RISC), hence rendering it non-viable (McManus and Sharp, 2002). Inducing destruction of specific mRNA using siRNA is a powerful tool in analysis of protein function, but until recently its use as a therapeutic modality has been limited. Landen et al. have used efficient siRNA incorporated into the neutral liposome 1, 2-dioleoyl-sn-glycero-3-phosphatidylcholine (DOPC) for efficient *in vivo siRNA* delivery. DOPC-encapsulated siRNA targeting the oncoprotein EphA2 was highly effective in reducing *in vivo* EphA2 expression in Nu/nu mice. Therapy experiments in an orthotopic mouse model of ovarian cancer with EphA2-targeting siRNA-DOPC reduced tumor growth when compared with a nonsilencing siRNA. When EphA2-targeting siRNA-DOPC was combined with paclitaxel, tumor growth was dramatically reduced compared with treatment with paclitaxel and a nonsilencing siRNA (Landen et al., 2005).

Most recently, Merritt et al. examined the effect of IL-8 gene silencing with siRNAs incorporated into neutral liposomes alone and in combination with docetaxel, on *in vivo* tumor growth, angiogenesis (microvessel density), and tumor cell proliferation and found that in this mouse model, siRNA-mediated IL-8 gene silencing decreased tumor growth through antiangiogenic mechanisms (Merritt et al., 2008).

The emerging therapies of ovarian cancer hint at exploiting these mechanisms to target signaling proteins, their ligands, and their pathways. Used alone or in combination with existing chemotherapy, these biologics have potential for more robust tumor response and less toxicity.

CHAPTER

Genomic Evaluation of Pancreatic Neoplasms

Asif Khalid and Kevin McGrath

INTRODUCTION

Pancreatic cancer is a lethal disease, where yearly prevalence equals mortality. It currently is the fourth leading cause of cancer-related death in the United States (Jemal et al., 2006). Unfortunately, despite medical and surgical advances, overall survival has not changed over the last several decades. Owing to the insidious onset of non-specific symptoms, pancreatic cancer generally presents in an advanced state, where the overall 5-year survival rate remains at 5% (Jemal et al., 2006).

Since detection at the earliest stage provides the best chance for cure, recent research efforts have focused on the improved diagnosis, early detection and screening for pancreatic cancer. There is abundant literature supporting the development of pancreatic cancer in parallel with accumulation of genetic alterations. As such, molecular analysis has emerged as an area of intense interest in this regard. Pancreatic intraductal precursor lesions have been re-classified as pancreatic intraepithelial neoplasia (PanIN) based on degree of cellular atypia (Hruban et al., 2001). The prevalence of genetic mutations appears to increase with increasing atypia of these precursor lesions, temporally correlating to PanIN grade progression (Figure 39.1) (Hruban et al., 2000). Understanding the genetic basis of the pancreatic cancer progression model will hopefully provide targets for innovative molecular-based screening and diagnostic testing.

Oncogene activation (e.g., K-ras), tumor-suppressor gene losses (e.g., p53, p16, DPC4, HER-2/neu) and genome-maintenance gene mutations (e.g., BRCA2, microsatellite instability, telomerase) appear to parallel the cellular evolution of pancreatic cancer. Histologically, these changes progress through the PanIN classification, where PanIN-1A is characterized by flat mucinous epithelium, PanIN-1B by papillary change, PanIN-2 by atypical papillary change, and PanIN-3 by carcinoma-*in-situ*. K-ras oncogene point mutations and over-expression of the HER-2/neu gene product appear to be early events in pancreatic carcinogenesis, as these are prevalent in lower grade PanIN lesions (Day et al., 1996; Hruban et al., 1993). p16/INK4a tumor-suppressor gene inactivation is found more frequently in higher grade PanIN lesions, suggesting it is an intermediate event (Wilentz et al., 1998). Inactivation of p53, DPC4/SMAD4 and BRCA2 is prevalent in PanIN-3 lesions and rarely found in low-grade lesions, representing late molecular events (Goggins et al., 2000; Luttges et al., 1999; Wilentz et al., 2000;). Thus, this temporal model of molecular carcinogenesis can serve as a template to allow integration of histologic or cytologic information with that derived from mutational analysis of DNA present in cellular samples, cyst fluid and pancreatic juice with the ultimate goal of increasing early detection rates and diagnostic accuracy.

There is a wealth of information rapidly accumulating regarding the role of molecular analysis in the early detection and diagnosis of pancreatic cancer. This chapter will discuss current molecular capabilities for screening, early detection and improved diagnosis of pancreatic cancer. The focus will be on direct clinical applicability in this rapidly evolving field, amounting

to translational research in motion. Diagnosis and evaluation of mucinous cystic neoplasms (MCN), which are premalignant pancreatic cysts, will also be discussed, along with new insights into molecular prognostication and tumor-directed gene therapy.

PREDISPOSITION (GENETIC AND NON-GENETIC)

It is estimated that up to 10% of pancreatic cancers may be linked to an inherited component (Lynch et al., 1996). Two distinct groups of patients are considered to be at risk for pancreatic cancer: (1) familial pancreatic cancer, requiring at least two first-degree relatives to be afflicted with the disease in the absence of other familial cancers, and (2) hereditary tumor syndromes carrying an increased incidence of pancreatic cancer. Unfortunately, there has been no definitively identified gene responsible for familial pancreatic cancer, and there is likely phenotypic influence in addition to genetic predisposition. Additionally, the absolute risk is unknown. In the latter group of hereditary tumor syndromes, genetic alterations have been discovered, therefore at-risk patients can be readily identified based on genetic testing. Hereditary syndromes with an increased incidence of pancreatic cancer include familial atypical multiple mole melanoma (FAMMM), Peutz-Jeghers syndrome (PJS), hereditary non-polyposis colorectal carcinoma (HNPCC), familial breast and ovarian cancer (FOBC), cystic fibrosis (CF), ataxia-telangiectasia (AT) and familial adenomatous polyposis (FAP) (Hahn and Bartsch, 2004).

The vast majority of pancreatic cancers are sporadic, without an apparent genetic linkage. Risk factors for sporadic pancreatic cancer include increasing age, tobacco use, chronic pancreatitis and long-standing diabetes mellitus. Additionally, dietary factors such as high intake of meat and fats appear to increase the risk.

SCREENING

Pancreatic Cancer

The ability to reliably screen patients for pancreatic cancer would be a major clinical advance. As with other clinical screening tests, the goal is early detection of disease, ideally in the premalignant stage, as only early detection offers any chance of curative treatment with this deadly disease. Given the relatively low prevalence of pancreatic cancer (33,700 cases estimated for 2006) (Jemal et al., 2006), screening of the general population is not practical. However, secondary screening of high-risk patients, such as those with hereditary pancreatic carcinoma syndromes (up to 10% of cases) may prove feasible. Current screening strategies employ various imaging modalities (computed tomography [CT], endoscopic retrograde cholangiopancreatography [ERCP], endoscopic ultrasound [EUS]) in high-risk patients, such as those with hereditary pancreatic carcinoma syndromes.

An early experience using EUS in high-risk families histologically correlated subtle EUS and ERCP findings suggestive of chronic pancreatitis with dysplasia, or PanIN lesions. Twelve patients from high-risk families were referred for pancreatic resection based on EUS and ERCP findings. Ten had total pancreatectomy and two had distal pancreatectomy; all had widespread dysplasia by surgical pathology, mostly involving small- and medium-sized ducts. CT and serum markers (CEA, CA19-9) had low sensitivity for pancreatic dysplasia (Brentnall et al., 1999; Kimmey et al., 2002). The Seattle group's current screening protocol employs EUS beginning 10 years before the earliest age of cancer development in the affected relative. Normal EUS findings are followed up every 2–3 years; an abnormal EUS is evaluated with ERCP. As the age of the surveyed patient approaches that of the affected relative, the surveillance interval increases to yearly. It is acknowledged that the ideal surveillance interval remains unknown. Given the high prevalence of PanIN lesions in pancreata (Stelow et al., 2006), this aggressive surgical strategy should only be reserved for those high-risk individuals with hereditary pancreatic carcinoma syndromes.

In a larger prospective controlled series, 78 asymptomatic high-risk patients were evaluated with both CT and EUS at baseline and 12 months (Canto et al., 2006). ERCP was performed if EUS detected an abnormality. To date, eight patients have undergone surgery with a confirmed diagnosis of pancreatic neoplasia: six benign Intraductal papillary mucinous neoplasm (IPMN), one malignant IPMN and one focal PanIN. Thus, there was a 10% yield in screening this high-risk population. EUS findings of chronic pancreatitis were more commonly seen in the study group as compared to matched controls. EUS detected more pancreatic lesions than multidetector CT; however, CT scan discovered extra-pancreatic neoplasms not evident on EUS. Hence, the Johns Hopkins group currently recommends both CT and EUS for screening these high-risk patients, as the tests appear to be complementary. Surveillance intervals for lesions detected but not resected are not currently defined, however three patients in this study had IPMN enlargement over the course of 1 year (Canto et al., 2006).

Screening programs for pancreatic cancer, such as the above mentioned, currently depend on imaging modalities to detect radiographic abnormalities. Ideally, molecular analysis of pancreatic juice to detect key mutations involved in pancreatic carcinogenesis could serve as a stand-alone screening test or an adjunct to EUS examination. To this end, the oncogene K-ras has been the most thoroughly studied in pancreatic juice. Studies to date report a widely variable sensitivity and specificity for detection in juice of pancreatic cancer patients, ranging from 30% to 100% (Furuya et al., 1997; Kondo et al., 1994; Kondoh et al., 1998; Matsubayashi et al., 2006; Tada et al., 1993; Trumper et al., 2002; Watanabe et al., 1998; Yamashita et al., 1999). Further troubling has been the detection of K-ras in pancreatic juice of control patients and those with chronic pancreatitis (Furuya et al., 1997; Trumper et al., 2002), where it may reflect the existence of PanIN lesions. Mutational and methylation status analysis of p16 and p53 have also been performed; however, in isolation, these have a low sensitivity for detecting pancreatic cancer (≤42%) (Fukushima et al., 2003; Klump et al., 2003; Matsubayashi et al., 2003; Yamaguchi et al.,1999). It therefore seems unlikely that any one marker will have a future role as a stand-alone screening or diagnostic test.

A recent study evaluated a combination of K-ras, p16 and p53 mutations for predicting the presence of pancreatic cancer (Yan et al., 2005). Pancreatic juice was aspirated at the time of ERCP in 48 patients with pancreatic cancer, 49 patients with chronic pancreatitis and 49 patients with biliary stone disease. p53 mutations were detected in 42% of cancer cases, 4% of patients with chronic pancreatitis, and 0% of controls. K-ras mutations were detected in 54%, 34% and 21% of these cohorts, respectively. Sixty-two percent of cancer patients had p16 promoter methylation levels >12%, compared to 8% of those with chronic pancreatitis and 13% of controls. Although individual mutational analysis lacked sensitivity and specificity, combination analysis increased the discrimination between benign and malignant disease. The authors concluded that the level of discrimination would allow high-risk patients to be stratified from a negligible risk to over a 50% probability of harboring malignancy (Yan et al., 2005). Although case-controlled, the above study was conducted in symptomatic pancreatic cancer patients. The level of discrimination was modeled for screening high-risk patients; however, it remains unproven in asymptomatic patients at risk.

The Johns Hopkins group analyzed pancreatic juice to detect aberrantly methylated DNA for use as a marker of pancreatic neoplasia, as promoter methylation is a common mechanism for gene silencing during carcinogenesis (Matsubayashi et al., 2006). Patients with known pancreatic cancer, IPMN, chronic pancreatitis and controls were evaluated, where juice was obtained via pre-operative ERCP or at surgical resection. Pancreatic juice DNA was analyzed for promoter methylation using methylation-specific PCR assays for 17 genes. There was a significantly higher percentage of genes methylated in the juice of pancreatic cancer patients as compared to the controls and those with chronic pancreatitis. Additionally, a higher percentage of genes were methylated in pancreatic juice obtained at ERCP as compared to surgically obtained juice. Reasoning for this is unclear, but may reflect the use of secretin to stimulate juice production during ERCP (Matsubayashi et al., 2006). Deserving of further study, this analysis may serve as an adjunct to aid in the diagnosis of pancreatic cancer, and may also have screening applications.

Molecular analysis of pancreatic juice for pancreatic cancer screening is currently an intense area of translational research. It is likely that broad-based molecular panels targeting multiple mutations commonly involved in pancreatic carcinogenesis will have the highest yield, and results of ongoing studies are anxiously awaited. It is presumed that these analyses will be performed on pancreatic juice collected at the time of screening EUS examinations.

DIAGNOSIS

Pancreatic Cancer

Short of surgery, pancreatic cancer can prove difficult to diagnose in a subset of patients. Current modalities for diagnosing pancreatic cancer include ERCP with bile duct or pancreatic duct brush cytology, percutaneous ultrasound- (US) or CT-guided fine needle aspiration (FNA) and endoscopic ultrasound-guided FNA (EUS-FNA). Definitive pre-operative diagnosis of pancreatic malignancy is thus dependent on morphologic cellular criteria of cytologic specimens. Cytology-based diagnosis of pancreatic cancer from bile duct brushings has a diagnostic sensitivity of <60% (Farrell et al., 2001; Glasbrenner et al., 1999; Macken et al., 2000; Pugliese et al., 2001; Stewart et al., 2001), where EUS-FNA has a diagnostic sensitivity of 60–95% based on precise targeting of the tumor (Brandwein et al., 2001; Eloubeidi et al., 2003; Shin et al., 2002; Wiersema et al., 1997). In a percentage of cases, sampling error, paucicellular samples, confounding inflammation and desmoplasia and cell drying artifact can result in an indeterminate diagnosis, necessitating repeat invasive procedures which may result in the delay of a definitive diagnosis and ultimately treatment for several months. Molecular

applications applied to indeterminate cytology have potential to increase the diagnostic accuracy for pancreatic cancer.

Microdissection-Based Genotyping

Khalid and colleagues developed an innovative method to evaluate indeterminate cytologic specimens to increase diagnostic yield (Khalid et al., 2004, 2006). Microdissection-based genotyping (MBG) coupled with loss of heterozygosity (LOH) analysis was used to evaluate for a broad panel of tumor-suppressor gene-linked microsatellite markers and k-ras point mutations. This application involves dissecting individual cell aggregates from existing slides and subjecting them to polymerase chain reaction (PCR) to generate DNA for broad panel genotyping of microsatellite allele loss markers. Tumor-suppressor gene loss is based on determination of LOH for informative loci situated within or adjacent to specific genes of interest using fluorescent capillary electrophoresis. Fractional allelic loss (FAL) or fractional mutational rate (FMR), defined as the number of mutations (k-ras-2 point mutation +/− significant allelic imbalance) divided by the total number of informative microsatellite markers plus 1 for k-ras status, is used to measure overall mutation accumulation. As each individual possesses a unique panel of informative polymorphic microsatellite markers, the FAL or FMR allows comparison across cohorts with respect to cumulative acquired LOH.

This technique was first applied to biliary stricture brush cytology obtained at ERCP, which has an overall sensitivity <60% for diagnosing pancreatic cancer. LOH and k-ras codon 12 mutational analysis of PCR amplified DNA from brush cytology specimens discriminated reactive from malignant cells with 100% sensitivity, specificity and accuracy (Khalid et al., 2004).

MBG has since been applied to EUS-FNA cytology samples from pancreatic mass lesions. Benign inflammatory pseudotumors, due to focal chronic pancreatitis or autoimmune pancreatitis, can be impossible to differentiate from malignancy based on imaging alone. All too frequently, EUS-FNA cytology samples are indeterminate due to cellular atypia, and patients are subjected to surgical resection for a definitive diagnosis. Indeed, approximately 10% of pancreaticoduodenectomies performed for presumed malignancy reveal benign disease on pathological evaluation (Abraham et al., 2003; Weber et al., 2003). If surgical pathology proves a benign entity, resection in retrospect is considered unnecessary. LOH analysis of FNA samples shows promise in accurately differentiating benign from malignant pancreatic masses and increasing the diagnostic sensitivity of inconclusive cytologic samples (Khalid et al., 2006). Based on comparison to final surgical pathology, LOH analysis of indeterminate cytology specimens, as compared to positive controls, accurately differentiated benign pseudotumors from pancreatic cancer with high-statistical significance. It additionally improved diagnostic accuracy (100%) for suspicious but inconclusive samples. The FMR for cases ultimately proven malignant was significantly higher than benign cases. Five of six benign cases carried no mutations, where one case of autoimmune pancreatitis harbored a k-ras mutation in the setting of coexisting PanIN lesions (Khalid et al., 2006). Although a currently small experience in this regard, the adjunct genomic analysis will prove to be a powerful tool in the clinical evaluation and management of these difficult cases.

Proteomics

Proteomics is an emerging field incorporating large-scale analysis of proteins in biologic fluids or cells by biochemical techniques. This is an attractive arena for pancreatic cancer research, specifically early detection and diagnosis. Candidate biomarkers have been discovered by analyzing resected pancreatic cancer, pancreatic juice and serum. Analysis of pancreatic juice seems the appropriate strategy when screening high-risk patient groups, whereas serum analysis would be most appropriate for wide-based screening. Although still in its early stage, the use of proteomic profiling for pancreatic cancer biomarker discovery is encouraging.

Two-dimensional electrophoresis for protein separation followed by mass spectrometric identification of proteins has been utilized in analysis of pancreatic cancer and pancreatic juice. However, this method is limited to a relatively low-throughput scale of research (Chen et al., 2005). A more appealing approach for disease biomarker development uses proteomic pattern analysis. This approach uses the pattern of signals within a mass spectrum to identify differentially abundant peaks within normal and disease samples for distinguishing the two groups. Surface-enhanced laser desorption/ionization time-of-flight (SELDI-TOF) mass spectrometry (MS) has been employed in this regard, whereby MS is used to generate proteomic patterns in biological fluids and then pattern recognition algorithms are applied to distinguish cancer patients from normal controls. This technique is suited for high-throughput research and can be applied to body fluids such as pancreatic juice or serum using biochip technology and antibody microarrays to enable multiplexed and rapid protein measurements (Chen et al., 2005).

SELDI-TOF has also been applied to pancreatic tissue to identify protein peaks to differentiate benign from malignant states. In one study, a training model was developed that could accurately distinguish pancreatic cancer from benign pancreatic tissue based on the protein peak pattern (Scarlett et al., 2006). A similar study found a large number of proteins differentially expressed in chronic pancreatitis and pancreatic cancer as compared to normal pancreatic tissue (Crnogorac-Jurcevic et al., 2005). It is unclear whether this technology will enhance preoperative diagnostic accuracy in this regard, as these methodologies have yet to be applied to EUS-FNA cytology samples. More importantly, these protein profiles may potentially be applied to pancreatic juice or serum to screen high-risk patients.

As such, the first comprehensive study of the pancreatic juice proteome revealed numerous proteins associated with pancreatic cancer (Chen et al., 2006). This study identified candidate biomarkers differentially expressed in cancer patients as compared to normal controls. This group has since evaluated pancreatic juice proteins in the setting of pancreatitis, in hopes of eliminating false-positive results for cancer given the potential for overlapping biomarkers (Chen et al., 2007). Similar preliminary work has also been applied to serum via plasma protein

profiling. Honda and colleagues compared plasma proteomes between pancreatic cancer patients and matched controls using SELDI-TOF MS. A learning algorithm was applied to discriminate proteomic patterns, identifying a set of four mass peaks that differentiated sera from pancreatic cancer patients with high accuracy rates (Honda et al., 2005). Although exciting, this work will need to be confirmed in a large-scale multi-center trial to truly determine clinical utility. There is also a potential role for proteomics to monitor for disease recurrence in patients who have undergone pancreatic cancer resection. An innovative study using two-dimensional electrophoresis identified a group of plasma proteins that consistently change following resection. Furthermore, this group identified proteins that correlated with recurrence of disease (Lin et al., 2006). Although a small study, the clinical applications of this type of technology could revolutionize post-operative monitoring and surveillance.

Pancreatic Cystic Neoplasms

Incidental pancreatic cystic lesions are being detected with increasing frequency due to the widespread use of high-quality abdominal imaging. Contrary to previous belief, the majority of cysts detected today are MCN (Fernandez-del Castillo et al., 2003). MCN are considered premalignant and encompass IPMN and MCN. Surgical resection of mucinous pancreatic cysts is generally recommended given the concern for malignant degeneration. However, the natural history regarding the frequency and timing of malignant change of MCN remains unknown.

Evaluation of pancreatic cysts involve cross-sectional imaging (CT or MRI) and EUS-FNA with cyst aspirate analysis. Unfortunately, in the absence of an associated solid mass, imaging modalities cannot reliably differentiate benign from malignant cysts (Ahmad et al., 2001, 2003; Brugge et al., 2004). Given the paucicellular nature of the cyst aspirate, the sensitivity of cytologic analysis has proven suboptimal. Currently, an elevated cyst fluid CEA level is considered the most reliable indicator of a mucinous cyst; however it does not distinguish premalignant from malignant state (Brugge et al., 2004). Given the unknown natural history of MCN and associated morbidity of pancreatic resection, better tools to assess presence of malignancy are desirable. This is especially important in marginal surgical candidates with small incidental cystic neoplasms.

As the cellular content of pancreatic cyst aspirates is frequently suboptimal, molecular analysis of the cyst fluid itself is attractive in hopes of detecting mutations that correlate with malignant degeneration. It is hypothesized that cyst epithelial cells undergoing malignant change would have a higher turnover rate, thereby releasing more DNA into the fluid that bathes the cells. PCR amplification of DNA from these whole or lysed cells shed into the fluid from the cyst lining may therefore be predictive of the cyst pathology, where a high level of accumulated mutational damage would reflect an underlying malignancy, and similar alterations would not be seen in benign cysts.

To investigate this hypothesis, a single center study was conducted, applying LOH and K-ras mutational analysis to pancreatic cyst aspirates targeting markers for pancreatic carcinogenesis (Khalid et al., 2005). Based on comparison to surgical pathology of the resected cyst, LOH analysis of the cyst fluid aspirate accurately predicted the existence of malignancy. Thirty-six cysts with confirmed histology were analyzed: 11 malignant, 15 premalignant and 10 benign cysts. The malignant cysts could be differentiated from premalignant cysts based on the number of mutations and the temporal sequence in which the mutations were acquired ($p < 0.001$). Early K-ras mutation followed by allelic loss was the most predictive of a malignant cyst (sensitivity 91%, specificity 93%) (Khalid et al., 2005). Thus, it appears that pancreatic cyst fluid contains adequate DNA to allow mutational analysis that can serve as an ancillary tool to the conventional workup of pancreatic cysts. A multi-center trial to further evaluate this technology has been completed, with the interim analysis showing that the quantity of DNA and temporal sequence of mutations continue to predict cyst pathology (Khalid et al., 2006a, b).

Several studies have also investigated whether telomerase activity can serve as a marker for malignancy in cystic neoplasms. In one small study evaluating IPMN, pancreatic juice aspirated at the time of ERCP was analyzed. Cytology alone diagnosed malignancy in 4/13 patients, but when combined with analysis for telomerase activity, the yield increased to 11 of 13 patients being correctly diagnosed with malignant IPMN. As telomerase activity was not detected in benign tumors, the authors suggest telomerase may be a useful adjunct to standard cytologic analysis (Inoue et al., 2001).

In another study analyzing a spectrum of cystic lesions, Yeh and colleagues found expression of telomerase activity in malignant and borderline malignant cysts, but not in benign cysts (mucinous or serous) or pseudocysts. The sensitivity of telomerase for predicting at least borderline malignant change was 67% with a specificity of 100% (Yeh et al., 1999). Thus, it appears that telomerase activity takes part in malignant transformation and may be a useful marker to distinguish malignant from benign cystic neoplasms.

The Johns Hopkins group has evaluated gene expression profiles to help differentiate invasive from non-invasive IPMNs. Employing RT-PCR and oligonucleotide microarrays, they were able to identify genes that were overexpressed in IPMNs associated with invasive carcinoma. Immunohistochemical validation revealed that claudin 4, CXCR4, S100A4 and mesothelin were associated with the invasive phenotype. This analysis was performed on resected specimens; thus further work is required to see if these results can be reproduced pre-operatively on aspirated cyst fluid, as they could be used to guide management regarding surgery or observation (Sato et al., 2004).

PROGNOSIS

Pancreatic Cancer

Pre-operative prognostication for malignant disease is currently based on the cancer stage and grade. Prognostic markers are desired to stratify treatment protocols, to enable individualized

therapy, and to develop new treatment strategies. For pancreatic adenocarcinoma, in which the majority of cases present with locally advanced and unresectable disease, prognostication unfortunately has not been of significant clinical importance to date given the high-mortality rate with only few long-term survivors (Jemal et al., 2006). However, gene expression profiling of the tumor may predict clinical course and outcome in select patients with potentially resectable disease.

In a recent study from MD Anderson Cancer Center, single nucleotide polymorphisms (SNPs) in DNA repair genes were evaluated to see if they affected clinical prognosis. Previous studies have shown that individual variation in DNA repair capacity can affect response to therapy and overall survival. All patients underwent neoadjuvant therapy with gemcitabine and radiotherapy after gene expression was determined from whole blood. Genotypes *RecQ1* A159C, *RAD54L* C157T, *XRCC1* R194W and *ATM* T77C had a significant effect on overall survival. The overall mean survival of the group was 20.2 months. However, patients with none of the adverse genotypes had a mean survival of 62.1 months. Those with one, two or three or more at risk alleles had median survival times of 27.5, 14.4 and 9.9 months, respectively (Li et al., 2006). Thus, for these earlier stage tumors, it appears that polymorphic variants of DNA repair genes affect the clinical course of disease, which hopefully will translate to novel targeted therapy in the future.

Other studies have been performed *ex vivo*, where resected pancreatic cancer has been profiled and compared to the outcome of the patient. Cytokeratins (CK) 7 and 20 were found to be overexpressed in pancreatic cancer, where CK 20 expression defined a subset of tumors with a worse prognosis (Matros et al., 2006). Peroxisome proliferator-activated receptor gamma (PPARgamma) is a ligand-activated transcription factor shown to be overexpressed and associated with a higher tumor stage and grade, thus correlating to a worse prognosis (Kristiansen et al., 2006). Secreted protein acidic and rich in cysteine (SPARC), a protein involved in cell migration and cell matrix interactions, is frequently silenced in pancreatic cancer but expressed in stromal fibroblasts. Peritumoral SPARC expression has also been associated with a poor clinical prognosis (Infante et al., 2007).

Thus, many genes have been identified that are differentially expressed in pancreatic cancer, some of which are predictive of clinical outcome. If this could be determined routinely in a pre-operative fashion, a patient could be counseled as to the true benefit of major pancreatic surgery. A study evaluating EUS-FNA cytology samples revealed that RT-PCR detected increased expression of lipocalin 2 (LCN 2) and tissue-type plasminogen activator (PLAT) in pancreatic cancer (Laurell et al., 2006). Not only could this technology increase diagnostic accuracy, but more importantly, could provide pre-operative prognostic information. The field of gene expression profiling is expanding quickly in the pancreatic cancer arena and will continue to evolve rapidly. Not only is it anticipated to provide reliable prognostic information, it may also give insight into the pancreatic carcinogenesis pathway and provide novel targets for therapy.

Pancreatic Endocrine Tumors

In less aggressive pancreatic tumors, the ability to pre-operatively prognosticate may be very significant, especially for marginal surgical candidates given the morbidity associated with pancreatic surgery. Pancreatic endocrine tumors (PET) have been reported to occur with an incidence of 1 per 100,000 persons per year (Barakat et al., 2004); however, it is expected that incidental PETs will be discovered with increasing frequency given widespread use of cross-sectional imaging, much like the phenomenon occurring with incidental pancreatic cystic lesions (Warner, 2005). The biological behavior of PETs can vary widely from clinically indolent to highly aggressive. Elevated Ki-67 proliferative index >2%, mitotic rate ≥2, size ≥4 cm, nuclear atypia, capsular penetration with local invasion, and/or metastatic disease define a malignant PET. The Ki-67 index and mitotic rate also correlate with survival (La Rosa et al., 1996; Panzuto et al., 2005). Unfortunately, these indices and histologic assessment come from surgical resection specimens.

Similar to pancreatic adenocarcinoma, the developmental progression and malignant transformation of PET also appear to correlate with accumulation of genetic alterations. Recent studies indicate that chromosomal losses occur more commonly than gains or amplifications, and the LOH profile correlates with tumor size, extent and malignant phenotype (Barghorn et al., 2001a, b; Guo et al., 2002a, b; Hessman et al., 1999, 2001; Speel et al., 1999, 2001; Stumpf et al., 2000; Zhao et al., 2001). Furthermore, molecular markers such as telomerase activity, Her-2/neu overexpression, hMLH1 methylation and microsatelliteinstability may predict PET behavior independent of the tumor's functional status or histopathologic features (Furlan et al., 2004; Goebel et al., 2002; House et al., 2003; Lam et al., 2000). These data suggest that molecular analysis of PET may provide relevant information of clinical and prognostic utility. To date, however, these analyses have only been performed on surgically resected specimens. The molecular investigation of pre-operative EUS-FNA samples from PET are very appealing for predicting the clinical course specifically in an era where more incidental lesions are being detected.

To that effect, the Pittsburgh group performed broad panel microsatellite loss analysis on pre-operative cytologic samples obtained via EUS-FNA. Twenty-five patients were studied; 13 with "benign" or indolent and 12 with malignant disease, respectively, based on pathologic assessment and clinical course. As previously reported, tumor size greater than 3 cm and high Ki-67 index and mitotic rate correlated well with disease progression. However, FAL appeared to be the strongest factor associated with disease progression. Four of 13 "benign" PETs contained a single microsatellite loss; the other nine were without mutation (mean FAL 0.028). All 12 malignant PETs harbored multiple allelic losses (mean FAL 0.37). The LOH profile not only differentiated benign from malignant PET (FAL 0.2, sensitivity 83%, specificity 100%), but also correlated best with disease progression and survival. Thus, for the first time, this molecular information can be used for clinical decision-making and prognostication *pre-operatively*, especially in those patients who are marginal surgical candidates (Nodit et al., 2006).

2009 UPDATE

Pancreatic Cancer Development

The role of microRNA (miRNA) in various aspects of cancer pathogenesis, including cell growth and apoptosis, has become an area of intense interest. A recent study analyzing the differential expression of 95 miRNA by real time RT-PCR found that the expression of most miRNA was substantially changed in pancreatic cancer specimens and pancreatic cancer cell lines compared to normal pancreatic tissue. Additionally each pancreatic cancer specimen or cell line had a substantially different profiling pattern. A detailed analysis on 10 pancreatic cancer cell lines and 17 pairs of pancreatic cancer and normal tissues revealed eight miRNAs (miR-196a, miR-190, miR-186, miR-221, miR-222, miR-200b, miR-15b, and miR-95) that were significantly up regulated (70-100%) in most pancreatic cancer specimens and cell lines (Zhang et al., 2008).

Pancreatic Cancer Diagnosis

In a study from Johns Hopkins Hospital, ERCP brush DNA concentrations of methylated Cyclin D2, NPTX2, and TFPI2 promoter DNA were measured in 130 individuals with biliary tract strictures (64 malignant; 41 pancreatic cancer and 10 bile duct cancer, 66 benign) by real time quantitative PCR. A significantly higher number of pancreatic cancer (73.2%) and bile duct cancer (80%) samples had at least 1 gene positive for methylation compared with 13.6% of patients with a benign stricture (Parsi et al., 2008). This study adds to the existing literature on the incremental yield of molecular techniques on routine cytology.

There have been two studies that provide promising data that, although in its infancy, may serve as a platform for the development of a "screening test" for pancreatic cancer. In the first study, serum-based LOH analysis of 12 microsatellites on chromosomal arms 2p, 5q, 9p, 13q, 17p and 17q was performed in 35 pancreatic cancer patients, 22 patients with chronic pancreatitis and 20 healthy individuals. Thirty-two patients manifested LOH with the majority (30) with two or more regions of LOH. Single LOH was observed in 7/22 patients with chronic pancreatitis and none in the healthy individuals (Wachowiak et al., 2007). In the second study, differential methylation profiles of plasma DNA utilizing multiplexed array-mediated analysis in 30 pancreatic cancer patients and an equal number of matched controls could identify cancer, albeit with a sensitivity of 76% and specificity of only 59% (Melnikov et al., 2008).

Pancreatic Cancer Prognosis

In a study correlating the presence of k-ras mutation and LOH affecting 5q, 6q, 9p, 10q, 12q, 17p and 18q in resected pancreatic cancer with postoperative survival, once again the importance of genetic events on tumor biology is illustrated. In this study with a median f/u of 18 months, tumor stage, nodal and margin status were not predictive of survival. However, the presence of LOH and k-ras and the combination of both were significantly associated with shorter median survival (Franko et al., 2008).

Pancreatic Endocrine Tumors

The clinical course of endocrine pancreatic tumors (PET) is often difficult to predict as previously alluded to. As further evidence for the key role specific DNA alterations play in this context, a study of 47 insulinomas and 24 non-insulinoma PET revealed that chromosomal alterations affecting 3p, 6q and 12q were most significantly associated with a poor outcome in insulinomas, and 7q gain in non-insulinoma PET. CK19 expression was the most optimal predictor of tumor-specific death (Jonkers et al., 2007).

CHAPTER

Genomic Evaluation of Head and Neck Cancer

Giovana R. Thomas and Yelizaveta Shnayder

INTRODUCTION

Head and neck squamous cell carcinoma (HNSCC) of the upper aerodigestive tract (UADT) represent approximately 4% of all cancers, with an estimated 40,500 new cases of oral cavity, pharynx and larynx cancer and 12,000 expected deaths in the United States in 2006 (Ries et al., 2006). Approximately half of all patients with HNSCC have advanced stage disease at the time of diagnosis, with an expected 5-year survival rate between 10% and 40%. Despite treatments that may consist of mutilating surgery, radiotherapy, and/or chemotherapy, overall long-term survival remains low due to uncontrollable persistent or recurrent HNSCC. The low rate of survival of patients with locoregional and distant recurrences has highlighted the need for new approaches for diagnosis and treatment.

As a result of exposure to carcinogens, molecular analyses of normal, precancerous, and head and neck cancers have revealed over-time accumulation of specific genetic alterations in proto-oncogenes and tumor suppressor genes (TSG) that are associated with potential for locoregional spread, time to recurrence, and overall survival.

Several experimental models of molecular epithelial carcinogenesis have been proposed. However, there are certain genetic alterations common to these models.

Epithelial carcinogenesis and progression has been characterized by promoter hypermethylation or loss of heterozygosity (LOH) at 9p21 leading to loss of TSG *p16*, mutation at 17p13 leading to loss of *TP53* TSG function, and gene amplification at 11q13 leading to overexpression of cyclin-D1. Importantly, changes in expression levels of EGFR and VEGF have also been associated with malignant progression. DNA microarray technology has been useful in identifying a specific pattern of deregulated network of genes and proteins that may provide a means for early detection, a unique target therapeutic intervention or used to monitor HNSCC disease progression.

In this chapter, we summarize and discuss recent advances in our knowledge concerning the pathogenesis, diagnosis, monitoring, prognosis, and treatment of head and neck cancer obtained by using modern molecular biological tools to study gene expression and chromosomal aberrations. In addition, we discuss novel molecular targeting strategies in the treatment of HNSCC and suggest where future progress may occur.

HEAD AND NECK SQUAMOUS CELL CARCINOMA

Predisposition

The predominant environmental risk factors for developing HNSCC identified to date are the use of alcohol and tobacco, immunosuppression, chewing betel quid nuts, and exposure to high-risk human papilloma virus (HPV). However, not all smokers and drinkers develop cancers; therefore, genetic predisposition and other host factors may play an equally important role in tumorigenesis.

Benzo(a)pyrene diol epoxide (BPDE) is a toxic metabolite of benzo(a)pyrene, the main carcinogenic component of tobacco smoke. BPDE has been shown to exert its mutagenic effect mostly by irreversibly binding to DNA, forming BPDE-DNA adducts, or by DNA oxidation. Other components of tobacco smoke such as catechols and nitrosamines produce free radical compounds known to cause DNA fragmentation. The individual capacity for nucleotide excision and repair of normal DNA after BPDE-induced damage has been shown to correlate with HNSCC development independent of age, sex, ethnicity, smoking status, or alcohol use in a case-control study (Cheng et al., 1998).

Mutagen hypersensitivity or individual's capacity of DNA repair against free radical damage and its relevance to the development of HNSCC was examined by Schantz et al. (1997). The relationship between the risk of HNSCC, nutrition, and mutagen hypersensitivity as determined by the quantity of bleomycin-induced chromosomal breaks within peripheral blood lymphocytes was examined in HNSCC patients and controls. Dietary intake of some antioxidants such as vitamins C, E, and carotenoids; cigarette smoking; alcohol drinking; and body mass index (BMI) were also examined. The study found that mutagen hypersensitivity was strongly associated with increased risk of HNSCC. Also, high intakes of vitamins C and E and some carotenoids were independently related to a decreased risk of HNSCC.

The role of genomic instability on the development of HNSCC was further elucidated in a study of patients with Fanconi anemia, a rare autosomal recessive disorder characterized by a high degree of spontaneous chromosomal aberrations (Kutler et al., 2003). The overall incidence of HNSCC in Fanconi anemia patients was 3% as compared to the incidence of 0.038% in general population, and median age of these patients with HNSCC was 31. The cumulative rate of disease recurrence after treatment by the age of 40 was 50% in this patient population.

In recent years, there has been mounting epidemiologic and experimental evidence of a role for HPV as the etiologic agent in a small proportion of HNSCC, mostly in non-drinkers and non-smokers. A recent study identified high-risk HPV16 DNA inside the nuclei of cancer cells of 90% of HPV-positive oropharyngeal HNSCC specimens by *in situ* hybridization (Gillison et al., 2000). These cancers, as compared to non-HPV-associated oropharyngeal HNSCC, tended to be in non-drinkers, non-smokers, have basaloid features on histology, not associated with p53 mutation, and have a 59% reduction in risk of dying from cancer, after adjustment for stage of disease, morbidity, and other confounding factors. In addition, the association between HPV16 infection and HNSCC in specific sites suggests the strongest and most consistent association is with tonsil cancer, and the magnitude of this association is consistent with an infectious etiology (Hobbs et al., 2006).

Screening

The multistep carcinogenesis process results in epigenetic and metabolic changes that give rise to histologically distinct precursor phenotypes that harbor specific genetic alterations. Pre-malignant lesions of the UADT can present as leukoplakia (white patch) or erythroplakia (red patch). Histologically, leukoplakia may demonstrate benign hyperkeratosis of the surface epithelium, epithelial hyperplasia, dysplasia, or invasive carcinoma. Up to 8% of leukoplastic lesions may demonstrate invasive squamous cell carcinoma (SCC), whereas erythroplakia has a much greater potential for malignancy. Approximately 90% of erythroplastic lesions may demonstrate severe dysplasia, carcinoma *in situ* or invasive SCC. The transformation rate of dysplasia to cancer has been reported as high as 36.4%.

Improvements in overall survival in patients with HNSCC rests on early identification of pre-malignant lesions and intervention in patients at risk prior to development of advanced stage disease. Since epithelial carcinogenesis is a multistep process directed by complex molecular events that involve specific genetic defects in proto-oncogenes and TSG, early identification of genetic alterations that may represent early transition into malignant phenotype may be possible through various measures recently described.

Early detection of oral and oropharyngeal SCC using brush biopsies to detect exfoliated cytology and DNA cytometry have been investigated. Cytologic diagnosis combined with DNA-image cytometry to measure DNA aneuploidy has proven to have high specificity and sensitivity for malignancy in studies of patients evaluated with pre-malignant lesions in the oral cavity (Maraki et al., 2004; Remmerbach et al., 2001). In fact, these investigators have shown that cytology combined with DNA-image cytometry may predict malignant transformation up to 15 months before its histologic confirmation.

The measurement of DNA ploidy in epithelial cells of oral leukoplakia has been studied by Sudbo and colleagues (reviewed in Sudbo and Reith, 2005). These investigators have shown that patients with aneuploid dysplastic oral lesions had a 96% rate of oral cancer with 70% rate within 3 years, an 81% rate of subsequent cancer, and 74% rate of death from cancer. Moreover, newer molecular methods such as microsatellite analysis to detect genetic alterations in exfoliated oral mucosal cells (Spafford et al., 2001) or in serum (Nawroz-Danish et al., 2004) also suggest that this approach is feasible to detect occult carcinoma in patients at risks for developing HNSCC. These studies suggest that biomarkers of genomic instability, such as aneuploidy and allelic imbalance, can accurately measure the cancer risk of oral pre-malignant lesions.

The use of molecular imaging studies for detection of HNSCC is still in the very early pre-clinical stages. Less than a handful of studies have addressed this potential method for detection of HNSCC. Hsu et al. (2005) using a simple fluorescence spectroscopy system developed a molecular-specific contrast agent targeted against EGFR as a screening technique for oral cancer. The system was tested in four *in vitro* models including fresh tissue slices from normal and abnormal oral cavity biopsies and whole normal and abnormal oral cavity biopsies. These investigators proved that an inexpensive and simple spectroscopy system can be used in biological models of living

systems to detect the optical signal from a contrast agent targeted toward a cancer-related biomarker with good signal-to-noise ratios. This system has the potential to improve the early detection of oral neoplasia by providing a low-cost screening tool. Scher (2007) analyzed whether *in vivo* videomicroscopy (IVVM) is useful for the study of distant metastasis and studied the possible role of nitric oxide in the development of metastasis from HNSCC. Videomicroscopic images of a human squamous cell carcinoma cell line (FaDu) labeled with an intracytoplasmic fluorescent marker were analyzed in the microcirculation for cell adhesion, morphology, deformation, circulation, location of adhesion within the microcirculation, and alteration of microvascular circulation. He concluded that IVVM allows direct assessment of circulating HNSCC with the microcirculation and is a powerful model for the study of distant metastasis. In addition, he found that nitric oxide and IL-1 play a role in increasing the arrest of HNSCC in the liver and are important in the generation of distant metastasis in patients with HNSCC.

In a study by El-Sayed et al. (2005), nanoparticle technology was used as potential biosensors in malignant oral epithelial cells. These investigators used a simple and inexpensive technique to record surface plasmon resonance (SPR) scattering images and SPR absorption spectra from both colloidal gold nanoparticles and from gold nanoparticles conjugated to monoclonal anti-epidermal growth factor receptor (anti-EGFR) antibodies after incubation in cell cultures with a nonmalignant epithelial cell line (HaCaT) and two malignant oral epithelial cell lines (HOC 313 clone 8 and HSC 3). They showed that the anti-EGFR antibody conjugated nanoparticles specifically and homogeneously bind to the surface of the cancer type cells with 600% greater affinity than to the noncancerous cells and suggested that SPR scattering imaging or SPR absorption spectroscopy generated from antibody conjugated gold nanoparticles can be useful in molecular biosensor techniques for the diagnosis and investigation of oral epithelial living cancer cells *in vivo* and *in vitro*.

Diagnosis

Because the probability of curing patients with HNSCC is related to the stage of disease, the importance of diagnosing HNSCC at an early stage cannot be overemphasized. Visual inspection is the most common method of detecting oral and oropharyngeal squamous carcinoma. The diagnosis of HNSCC, however, is frequently delayed because symptoms for which patients will seek medical attention such as pain, dysphagia, and shortness of breath occur late in the stage of disease. Laryngeal squamous cell carcinoma remains one of a few subsite that is likely to be detected at earlier stages due to the presenting symptom of persistent hoarseness, which can occur with mild alterations of the vibratory surfaces of the true vocal cords.

Radiologic imaging modalities such as computed tomography (CT), magnetic resonance imaging, positron-emission tomography (PET), combined PET/CT, ultrasound, and lymphoscintigraphy are critical tools that provide information on extent of tissue invasion, involvement of regional lymph nodes, and presence of distant metastatic disease. The information provided by imaging modalities is critical for staging and subsequent treatment planning. However, there remains significant variability in outcomes for patients within the same tumor-node-metastasis (TNM) stage. Therefore, many attempts have been made to identify high-risk patients through molecular markers.

Exposure to carcinogens such as tobacco and alcohol may result in pre-malignant epithelial changes over a wide field of epithelial surface within the aerodigestive tract. This clinical phenomenon has been called "field cancerization" and may lead to frequent occurrence of multiple primary tumors in epithelial areas affected by widespread pre-malignant disease and possibility of distant-related primary tumors in UADT. For this reason, it is imperative to evaluate mucosa of the UADT including the esophagus and trachea with directed biopsies of suspicious areas during endoscopic examination.

By identifying patients at risk for cervical lymph node metastasis and extracapsular spread without the need for surgical node dissection, tissue or serum biomarkers can play a vital role in clinical decision-making. The molecular profiling of primary tumors from HNSCC has been investigated for the potential of predicting the presence of lymph node metastasis at the time of diagnosis. DNA microarray gene expression of primary tumors of the oral cavity and oropharynx found that signature or predictor gene sets can detect local lymph node metastases using material from primary HNSCC with better performance than current clinical diagnosis (O'Donnell et al., 2005; Roepman et al., 2005). Additionally, the gene expression profile of 53 genes with roles in cell differentiation, adhesion, signal transduction, and transcription regulation have been associated with depth of invasion in patients with oral SCC (Toruner et al., 2004).

A large number of genes that are abnormally expressed compared to control have been found in tumors from patients with oral SCC. A large percentage of these were upregulated proteins including metalloproteinases (MMPs), proteins involved in regulation of cell adhesion and cell-cycle-related proteins; and downregulation of potential tumor suppressors, suggesting that oral SCC show aberrant expression of genes involved in proliferation, apoptosis, extracellular matrix degradation, and other cellular pathways (Kornberg et al., 2005).

Although expression signatures may potentially be able to accurately identify subjects harboring HNSCC and may represent an advance in the classification of these tumors, application of this methodology to the clinical setting has not yet been successfully put to practice.

Prognosis

The most important factor correlating with prognosis of HNSCC currently remains TNM staging. Large primary tumor size, presence of lymph node metastasis, positive margins after surgical excision, and perineural invasion have been reliable indicators of poor clinical outcome in patients with HNSCC. However, the single most important factor that determines survival is the metastatic status of the cervical lymph nodes at the time of diagnosis. Particularly, the presence of extracapsular spread in cervical lymph node metastasis remains the most

Table 40.1 Prognostic markers in HNSCC

Marker	Chromosome	Function	Mutation in HNSCC	Result of mutation	Method of study in HNSCC tumors	Correlation with:	Possible clinical applications	References
p53	17p13	Tumor suppressor	50–69%	Overexpression	IHC	Decreased disease-free survival, overall survival in larynx SCC	Cisplatin resistance: consider other agents Increased radiosensitivity	Cabelquenne et al. (2000); Ogawa et al. (1998)
EGFR		Transmembrane tyrosine kinase	34–80%	Overexpression	IHC	Short disease free survival and overall survival	New chemotherapy agents: 1. Inhibitors of tyrosine kinase (Gefitinib, Erlotinib), 2. Antibodies against EGFR (Cetuximab)	Grandis and Tweardy (1993); Bonner et al. (2006)
VEGF		Angiogenic factor		Overexpression	IHC	Poor overall survival	Antibodies against VEGF-A (Bevacizumab)	Teknos et al. (2002); Caponigro et al. (2005)
Cyclin D1	11q13	Proto-oncogene	17–79%	Gene amplification Overexpression	IHC FISH RT-PCR	Tumor extension, regional lymph node metastases, advanced clinical stage		Capaccio et al. (2000); Bova et al. (1999)
P16	9p21	Tumor suppressor	52–82%	Loss of expression	IHC RT-PCR	Disease relapse		Bazan et al. (2002); Yuen et al. (2002)

significant clinical prognostic indicator of survival, local–regional recurrence and distant metastasis in patients with HNSCC. Although these clinical prognostic parameters provide the best possible criteria for deciding treatment modalities, they are limited in discerning future behavior of aggressive HNSCC.

The search for novel molecular prognostic markers with potentially significant predictive value for biological aggressiveness of HNSCC has exploded in the recent years. Better prediction of the risk of developing distant metastases would help introduce a more selective treatment approach according to the biological aggressiveness of the tumor. Several molecular mediators of tumor progression, invasion, and metastasis, which function in growth factor signaling, metastasis, and suppressor genes have been well investigated in HNSCC (Table 40.1) and will be described below.

TP53 is a tumor suppressor gene located on 17p13 and consists of 11 exons that encode a protein, p53, and function in carcinogenesis by initiating G1 arrest in response to certain DNA damage and apoptosis. The prevalence of *TP53* mutations is 50–69% in HNSCC. A number of studies have shown that *TP53* gene mutations are associated with increased risk for locoregional recurrence and poor outcome (Erber et al., 1998; Mineta et al., 1998). Mutated p53 protein overexpression has also been associated with tumor recurrence, poor disease-free survival rate, poor overall survival rate, increased rates of local control, and decreased disease-free survival in HNSCC. A significant correlation between p53 expression and clinical outcome appears to be the strongest in the subsite of patients with laryngeal SCC. In these patients, overexpression of mutated p53 predicts poor disease-free and poor overall survival rates.

Epidermal growth factor receptor (EGFR) is a transmembrane tyrosine kinase capable of promoting neoplastic transformation. The downstream signaling events upon ligand binding include activation of tyrosine kinase and activation of intracellular Ras, Raf, and mitogen-activated protein kinase (MAPK) cascades. EGFR expression has been extensively studied in HNSCC and its overexpression reported in 34–80% of HNSCC using IHC (Beckhardt et al., 1995; Grandis and Tweardy, 1993). This marker has been significantly associated with short disease-free survival, overall survival, and poor prognosis in patients with HNSCC. The EGFR family includes EGFR (*c-erbB1 or Her1*), *c-erbB2* (Her2-*neu*), *c-erbB3* (Her3), and *c-erbB4* (Her4), which have the ability to form receptor heterodimers and crosstalk between them. Both EGF and transforming-growth factor-alpha (TGF-α) are ligands that bind to EGFR. Co-expression of Her2 and Her3, which do not have intrinsic tyrosine kinase activity, is reported to increase transforming activity and their expression has been strongly associated with shortened patient survival. In addition, the co-expression of Her2 and Her3 significantly improved the predictive power in patients with oral SCC and suggest a common regulatory mechanism.

Vascular endothelial growth factor (VEGF) induces proliferation, migration, and survival of endothelial cells during tumor growth by binding to specific tyrosine receptor kinases. Thus far, six members of the VEGF family have been identified; VEGF-A/vascular permeability factor (four isoforms), VEGF-B/VEGF-related factor (VRF), VEGF-C/VEGF-related protein (VRP), VEGF-D/c-fos-induced growth factor (FIGF), VEGF-E and placenta growth factor (PlGF) and abnormal regulation of angiogenic factors have been implicated in the pathogenesis of cancer. Overexpression of VEGF-A and VEGF-C has been correlated to poor overall survival in patients with advanced stage HNSCC (Teknos et al., 2002). Furthermore, pre-treatment levels of VEGF-A and/or VEGF-C in early stage disease appear to be independent predictors of presence of cervical lymph node metastasis (O-Charoenrat et al., 2001).

Cyclin D1 (*CCND1*) is a proto-oncogene located on chromosome 11q13 that modulates a critical step in cell cycle control progression. Amplification and/or overexpression of *CCND1* have been demonstrated in 17–79% of tumor specimens from patients with HNSCC with immunohistochemistry, FISH, or RT-PCR. *CCND1* amplification and/or overexpression of the structurally normal protein has been shown to correlate significantly with tumor extension, regional lymph node metastases and advanced clinical stage of HNSCC (Capaccio et al., 2000). In addition, many recent studies show convincing data of *CCND1* aberration as a prognostic marker for disease-free survival and overall survival in patients with this disease (Bova et al., 1999; Michalides et al., 1995).

The role of *P16* in HNSCC carcinogenesis and progression has not been clearly established. The p16 protein, which is encoded by the *CDKN2A* (*MTS1*, *INK4A*) tumor suppressor gene on chromosome 9p21, inactivates the function of cdk4-cdk6-cyclin D complexes. Using fluorescence *in situ* hybridization (FISH) or PCR-based techniques, *P16* deletion or mutation was detected in 48–52% of tumor specimens from patients with HNSCC and has been significantly associated with decreased survival, development of distant metastases, and as an independent predictive factor for disease relapse and death (Bazan et al., 2002). However, downregulation of p16, although found in 48% of tumors and associated with a more locally advanced tumor, had no prognostic significance for nodal metastasis and survival in studies examining p16 expression by immunohistochemical techniques or *P16* gene alterations by RT-PCR in specimens of patients with HNSCC (Danahey et al., 1999; Yuen et al., 2002). The contrast in these study outcomes may not only reflect differences in the type of tissue and methods used for examination, but also depend on differences in treatment protocols.

In larger studies of patients with HNSCC, DNA microarray analysis has been used to identify distinct gene expression signatures associated with clinical outcome in HNSCC. Distinct subtypes of HNSCC with different clinical outcomes based on gene expression patterns obtained from tumor samples from patients with HNSCC were recently described. These subtypes had significant differences in clinical outcomes including recurrence-free survival and overall survival, and were able to identify patterns of expression that could predict the presence of lymph node metastases in HNSCC tumors (Chung et al., 2004).

Pharmacogenomics

The response to chemotherapy, radiation and their side effects in patients with head and neck cancer is dependent on several factors including pharmacogenetics (see Chapter 15).

Organ preservation therapy using chemotherapy with cisplatin-based chemotherapy and 5-fluorouracil combined with radiotherapy have been used effectively in patients with advanced HNSCC. In addition, studies have shown that patients that achieve a complete response to chemotherapy have a better prognosis than those that do not. Ideally, molecular markers could be used to determine individual pharmacogenetic profiles to identify patients most likely to have chemotherapeutic benefit and patients with the highest risk of suffering genotoxic side effects. These profiles will ideally lead to individualized therapies, improved treatment outcomes, and a movement toward clinically applied pharmacogenetics.

Cisplatin (*cis*-diamminedichloroplatinum [CDDP])-based chemotherapy as part of multimodality treatment has shown significant activity against HNSCC, as a DNA-damaging agent. However, its effectiveness in the treatment of recurrent HNSCC has been limited due to acquired or intrinsic resistance. The mechanisms of resistance to cisplatin-based chemotherapy are not well understood. Molecular markers involved in cisplatin resistance phenotype has been investigated by various groups in cisplatin resistant and sensitive HNSCC cell lines using cDNA microarray analysis. Upregulation of the gene expression of glycoprotein hormone alpha subunit and downregulation of human folate receptor and tumor-associated antigen L6 were described (Higuchi et al., 2003). Decreased expression of caveolin-1, a novel TSG correlated with cisplatin resistance in patients with oral SCC (Nakatani et al., 2005).

Resistance to cisplatin chemotherapy has also been shown to be significantly correlated to expression of mutant p53 (Bradford et al., 2003), which is frequently present in head and neck cancer. Tumor cell lines from patients with HNSCC with mutant p53 have shown significantly more sensitivity to cisplatin than those that do not contain these mutations. The authors of these studies state that tumors that are resistant to cisplatin also overexpress anti-apoptotic proteins Bcl-2 and Bcl-$x_{L.}$ Other studies have shown that p53 mutated tumors was higher in the group of patients with nonresponse to cisplatin-fluorouracil neoadjuvant chemotherapy than in the group of responders (Cabelquenne et al., 2000). Overexpression of mutant-type p53 expression in HNSCC was also shown to be associated with increased sensitivity to ionizing radiation (Ogawa et al., 1998; Servomaa et al., 1996).

Recently, low expression of the apoptosis-blocking protein family members has been shown to be a good predictor of chemotherapy response in patients with head and neck cancer. Low expression of Bcl-x_L in tumor specimens from patients with HNSCC enrolled in the Department of Veterans Affairs Laryngeal Cancer Group Study correlated with response to induction chemotherapy (Bradford et al., 2003). In addition, it was shown that induction of mutant p53 in HNSCC lines resulted in decreased expression of Bcl-2 and increased susceptibility to cisplatin-induced apoptosis and implicates Bcl-2 in the deregulation of p53-induced apoptosis (Andrews et al., 2004).

Increased tumor resistance to cytotoxic agents, including radiotherapy (Milas et al., 2003, 2004; Baumann and Krause, 2004) has been associated with EGFR overexpression in HNSCC in addition to its association with more aggressive tumor behavior. This suggest that evaluation of EGFR status at the time of diagnosis may help identify subset of patient who are at increased risk of neck node metastasis, may have an unfavorable treatment outcome with radiotherapy and may, therefore, benefit from more aggressive treatments.

Monitoring

Patients treated for HNSCC are followed clinically for evidence of recurrent disease, development of second primary lesions or distant metastasis. The chance of developing a second primary tumor has been estimated at 2–3% per year in patients with HNSCC. In addition, 20–30% of patients treated for HNSCC will develop recurrent disease at primary site and is the most common cause of treatment failure. Because prognosis of late stage recurrent disease is dismal, early detection is imperative. Distant metastatic disease occurs in 11–15% of patients treated for HNSCC and, at this stage, treatment is palliative. Identifying molecular markers in primary tumors that are associated with locoregional relapse may allow for early identification of patients needing additional surveillance and treatment and may have the potential of decreasing probability of distant disease. For example, EGFR overexpression has been shown to be an independent prognostic factor for neck node relapse in primary specimens of patients with laryngeal SCC undergoing primary resection (Almadori et al., 1999). In addition, when surgical margins of primary HNSCC are examined for mutational changes, there is an increased risk of local recurrence when positive margins demonstrating clonal alterations in *TP53* are observed (van Houten et al., 2004).

Promoter hypermethylation is an important mechanism to silence TSG in cancer. Aberrant DNA methylation of *P16*, O6-methylguanine-DNA-methyltransferase, glutathione S-transferase P1, and death-associated protein kinase (DAP-kinase), key genes involved in critical pathways in head and neck tumor progression, have been detected in the serum and in the saliva of patients with HNSCC (Sanchez-Cespedes et al., 2000; Rosas et al., 2001). Thus, promoter hypermethylation of key genes may be promising serum and saliva markers for monitoring affected patients with HNSCC.

Gene expression signatures using DNA microarray technology have potential utility as biomarkers to predict patients at risk for locoregional recurrence. Several gene expression signatures from HNSCC tumors from various anatomical sites in the head and neck have been identified. In one study, deregulated gene expression of the met-proto-oncogene and its ligand hepatocyte growth factor/scatter factor; snail homologue 2 (SNA12/SLUG), a transcriptional repressor involved in epithelial/mesenchymal transitions; and genes important for tumor cell/extracellular matrix interactions such as laminins and integrins were associated with risk of local treatment failure (Ginos et al.,

2004). In addition, six novel poorly characterized differentially genes potentially involved in acquisition of metastatic potential were identified when tumors from patients with SCC of the hypopharynx were studied for identification of biomarkers of aggressive clinical behavior (Cromer et al., 2004). These studies show the feasibility of monitoring HNSCC patients at risk for developing locoregional recurrence by molecular characterization of genes in primary tumors or in serum and saliva of patients with HNSCC.

Because surgical salvage rates are greatly diminished when occult nodal disease becomes clinically manifest, planned post-treatment neck dissection is advocated but may not be necessary in all patients. The role of PET-CT in this scenario remains unproven but holds promise in being able to identify which patients with advanced nodal disease prior to treatment may be harboring residual disease in the neck after chemoradiotherapy. These patients may then go on to planned post-treatment neck dissection. The implementation of as yet unidentified molecular tumor markers in combination with PET-CT may ultimately prove to be effective in identifying patients who will best benefit from post-therapy neck dissection.

Proteomics and Metabolomics of Head and Neck Cancer

Whereas genomics offers the opportunity to examine gene expression or variation in gene sequence, proteomics encompasses evaluation of protein expression, activation, modification, and degradation and targets protein function. Likely both proteomics and genomics will provide clinically useful and complementary information that will speed scientific understanding of HNSCC. Proteomic profiling of serum using surface-enhanced laser desorption/ionization time-of-flight mass spectrometry (SELDI-TOF-MS) is an emerging technique to identify new biomarkers in biological fluids and to establish clinically useful diagnostic computational models.

Proteomics of HNSCC have revealed significant findings. Baker et al. (2005) combined laser-capture microdissection (LCM) with liquid chromatography-tandem mass spectrometry (LC-MS/MS) to identify proteins expressed in histologically normal squamous epithelium and matching SCC. Immunohistochemical analysis of HNSCC tissues revealed lack of keratin 13 in tumor tissues and strong staining in normal epithelia, and high expression of Hsp90 in tumors. Likewise, cellular proteomes of 30 matched normal squamous epithelial cells and carcinoma specimens were analyzed after tissue microdissection using microarray composed of 83 different antibodies by Weber et al. (2007). Of the 83 proteins examined, 14 showed differential expression between HNSCCs and normal epithelium. The protein microarray approach revealed an upregulation of eight proteins and a downregulation of six proteins. Bag-1, Cox-2, Hsp-70, Stat3, pescadillo, MMP-7 (matrilysin), IGF-2, and cyclin D1 were identified to be significantly upregulated, whereas suppressor of cytokine signaling 1, thrombospondin, TGF-beta1, Jun, Fos, and Fra-2 were downregulated. Upon correlation of differentially regulated proteins with the clinicopathologic data of their patients, MMP-7 (matrilysin) was found to be associated with survival in univariate, but not multivariate, analysis.

Protein expression profiles from two laryngeal carcinoma specimens and corresponding adjacent normal tissue were recently investigated as potential biomarkers which may contribute to the pathogenesis of laryngeal carcinoma using two-dimensional differential in-gel electrophoresis and mass spectroscopy. Differentially expressed proteins were identified, and they included stratifin, S100 calcium-binding protein A9, p21-ARC, stathmin, and enolase (Sewell et al., 2007). Protein expression profiles were also analyzed by Roesch-Ely et al. (2007) in 113 HNSCCs and 73 healthy, 99 tumor-distant, and 18 tumor-adjacent squamous mucosa by SELDI-TOF-MS on IMAC30 ProteinChip Arrays. Calgizarrin (S100A11), the Cystein proteinase inhibitor Cystatin A, Acyl-CoA-binding protein, Stratifin (14-3-3 sigma), Histone H4, alpha- and beta-Hemoglobin, a C-terminal fragment of beta-hemoglobin and the alpha-defensins 1-3 were identified by mass spectrometry. Comparison of the protein profiles in the tumor-distant-samples with clinical outcome of 32 patients revealed a significant association between aberrant profiles with tumor relapse events.

Zhou et al. (2006) studied 100 serum samples including 48 from HSCC patients and 52 from normal controls by SELDI-TOF-MS. They found that 45 potential biomarkers could differentiate HSCC patients from normal controls.

Metabolomics, the study of metabolite changes in a biological system, is believed to be a good reflection of the phenotype of any cell or tissue, and studies have reported that tumoral tissue differ in metabolic content from their benign counterpart. Proton nuclear magnetic resonance (HNMR) spectroscopy is emerging as a rapid and noninvasive method in identifying new markers potentially useful for clinical diagnosis in biofluids, such as urine and plasma. However, this new -omic science has not yet been significantly evaluated in clinical studies in HNSCC. Although, metabolomics may be a complimentary tool to genomics and proteonomics in diagnosing cancer, refining the process of targeted drug discovery, defining surrogate markers that may predict response, toxicity, and prognosis, several years of study will be necessary before the impact of this new technology in HNSCC can be truly assessed.

GENOMICS OF HNSCC: CLINICAL APPLICATIONS

Genomic technologies have the potential to change the basis of clinical oncologic practice in various ways. Information on the disease pathology of HNSCC generated from genomic technologies could be translated into: (1) diagnostic tests of biomarkers of cellular proliferation, cell damage or death, and cellular metabolism, and (2) therapeutic products, as is seen with the development of EGFR antagonists, which are presently in clinical practice for treatment of HNSCC.

Genomic approaches are also changing the conduct of clinical trials. Many clinical trials of HNSCC are now being designed

with genomic testing in mind. Importantly, biomarkers in tissue or body fluids identified by genomics offer a means for detecting early or recurrent disease in patients that are at risk for HNSCC. This technology has the added potential to characterize individuals that are likely to have a response to chemotherapy and/or radiotherapy, so that treatment can be tailored to the individual patient. As a preventive approach, genome-based information of the potential risk for HNSCC may allow early intervention with preventive measures, which may ultimately reduce healthcare costs.

The economic value of using genomic technology in clinical setting and in clinical trials have not been fully addressed. However, because of the potential advantages in targeted drug development and drug-safety concerns, significant growth of molecular approaches to clinical medicine will continue. Therefore, the combination of genomic, proteomic, and metabolomic technologies may allow us to monitor a large number of key cellular pathways simultaneously and may provide a better understanding of HNSCC.

2009 UPDATE

Recent data continue to support a strong etiologic role for HPV in the pathogenesis of HNSCC (D'Souza et al., 2007; Ernster et al., 2007). Studies have further defined distinct clinical behavior between HPV-positive and HPV-negative cancers. HPV-positive cancers arise mainly from the lingual and palatine tonsils (oropharynx), are associated with distinct risk factor profile of sexual behavior and marijuana use, typically occur in patients younger than 60 years of age, and are associated with an improved prognosis when compared to HPV-negative patients (Charfi et al., 2008; Chaturvedi et al., 2008; Dahlstrand et al., 2008; Fakhry et al., 2008; Gillison et al., 2008; Hafkamp et al., 2008). Presence of antibodies to HPV-16 E6 and E7 oncogenes in serum has also been associated with better clinical outcomes (Smith et al., 2008), suggesting their role as potential biomarkers for diagnosis and response to treatment for HPV-associated tumors. The p73 variant and p53 codon 72 variant genotypes show promise as potential markers of genetic susceptibility to HPV-16-associated HNSCC of the oropharynx, particularly in never smokers and never drinkers (Chen et al., 2008; Ji et al., 2008), suggesting that p73 and p53 polymorphism may modulate the risk of HPV-16-associated HNSCC of the oropharynx.

To summarize, recent molecular studies suggest that two distinct pathways may be involved in the pathogenesis of HNSCC of the oropharynx: one driven by alcohol and tobacco and associated with cytogenetic changes, such as p53 mutations, loss of p16, cyclin D1 overexpression, and increased numbers of EGFR; and the other driven by HPV-induced genomic instability with minimal molecular alterations.

CHAPTER

Genomic Evaluation of Brain Tumors and Gliomas

Sean E. Lawler and E. Antonio Chiocca

INTRODUCTION

Approximately 20,000 new patients with primary brain tumors are diagnosed in the United States each year (De Angelis, 2001). These constitute the most common solid tumors in children, and rank first among all cancer types in average years lost. They rarely metastasize outside the central nervous system; however, more than 100,000 patients per year die with symptomatic intracranial metastases due to systemic primary cancer.

Tumor type is currently determined by histopathologic analysis of biopsy samples and graded on a scale of I (benign) to IV (highly malignant) based on a range of histological tumor features (frequency of mitotic figures, necrosis, nuclear atypia and vascularity) according to the WHO classification of nervous system tumors (Kleihues and Cavenee, 2000; Louis et al., 2007). The various brain tumor types show similarities in clinical presentation, diagnosis and treatment. Most are treated by aggressive surgical resection when possible, followed by chemo and/or radiotherapy. Brain tumors are especially challenging, because they are often resistant to therapies, progress rapidly, and infiltrate normal brain tissue. Even a benign brain tumor may seriously compromise normal brain function, and surgical tumor excision must be carried out without damaging vital brain structures. Delivery of drugs to the central nervous system, and therapy induced neurotoxicity present further obstacles to effective treatment.

This article will focus on gliomas, the best studied and most common primary brain tumor type, accounting for approximately half of all cases. Gliomas are usually classified as either astrocytic or oligodendroglial (summarized in Table 41.1). Low-grade gliomas such as pilocytic astrocytomas are benign and have a good prognosis. Survival range for Grade II and III astrocytomas is broad, and these usually progress to higher-grade tumors. The most common and most aggressive astrocytic tumor is the Grade IV glioblastoma multiforme, among the deadliest of human cancers with a median survival of around 12 months, even with aggressive treatment. Oligodendrogliomas and the mixed oligoastrocytomas are less common than pure astrocytomas, and typically have longer survival times. Most low-grade oligodendrogliomas progress to a higher-grade tumor. With early diagnosis by MRI and chemotherapy, the mean survival is 16 years.

There are several well established molecular alterations commonly seen in gliomas, which are also observed in many other cancer types (reviewed in Louis, 2006; Schwartzbaum et al., 2006). Gliomas are typically characterized by increased tyrosine kinase receptor activation through activation of platelet-derived growth factor receptor (PDGFR) or epidermal growth factor receptor (EGFR) signaling. This is reflected in amplified levels of receptors and/or their ligands, or the presence of mutated constitutively active receptors such as EGFRVIII. This leads to activation of downstream intracellular signaling pathways, the

TABLE 41.1 Common subtypes of glioma and their basic characteristics

Tumor type	Characteristics	Peak incidence	Survival
Astrocytic			
Pilocytic Astrocyoma (I)	Slow growing, often cystic	Children	Infrequently fatal
Diffuse Astrocytoma (II)	Slow growing, invasive tendency to progress	Young adults	Mean 6–8 years highly variable
Anaplastic Astrocytoma (III)	tendency to progress	40–60 years	Mean TTP 2 years
Glioblastoma (IV)	*De novo*, or secondary mitotic figures, anaplasia, necrosis, vascularity	45–70 years	12 months
Oligodendroglial			
Oligodendroglioma (II) and Anaplastic oligodendroglioma (III)	Grow diffusely in cortex and white matter	50–60 years	3–15 years
Mixed			
Oligoastrocytoma (II) and anaplastic oligoastrocytoma (III)	Oligodendrocytic and astrocytic characteristics	35–50 years	4–7 years

PI3K/Akt pathway being considered as extremely important by promoting cell survival. High-grade gliomas are also associated with loss of the tumor suppressor phosphatase and tensin homolog (PTEN), which acts by further activating PI3K signaling. The cell cycle is deregulated through disruption of p53 (alterations in p53, HDM2, and $p14^{ARF}$) and RB (through alterations in p16 and RB) pathways. Based on age of onset and pathology, two different kinds of glioblastoma exist, with characteristic genetic alterations, although they are clinically similar (Kleihues and Cavenee, 2000). Glioblastoma in older patients shows no sign of previous low-grade tumors, and is known as either *de novo* or primary glioblastoma (95%). Typically these tumors show EGFR amplification, p16 deletions and PTEN deletions. Secondary glioblastoma occurs in younger patients (5%) and is due to progression from lower-grade astrocytoma. These are characterized by p53 mutation and amplification of PDGF signaling. In contrast to astrocytomas, oligodendrogliomas are characterized by allelic loss of 1p and 19q. However, tumor progression is associated with changes similar to those seen in astrocytomas (see Figure 41.1). Emerging data from the use of high-throughput, chip-based global molecular profiling techniques such as array-CGH and gene expression profiling suggest that these changes represent only a fraction of the alterations in gliomas, as described in the following sections.

PREDISPOSITION

Relatively few genetic and environmental factors that influence brain tumor development have been clearly identified (reviewed in Schwartzbaum et al., 2006), and only a small minority of tumors can be attributed to inherited predisposition. For example, a shared susceptibility to breast cancer, brain tumors, and Fanconi anemia was reported in four families with germline BRCA2 mutations (Offit et al., 2003). In addition, genetic predisposition is associated with various familial cancer syndromes (Turcot's, NF1, NF2, and Li-Fraumeni), accounting for 1–2% of all brain tumors. Inherited polymorphisms that may influence brain tumor formation involve oxidation, DNA repair, and immune function. For example, the DNA repair gene XRCC7 G7621T variant, leads to a 1.8-fold increased risk of glioblastoma (Wang et al., 2004) and the hTERT MNS16A allele results in a twofold increase in survival, due to higher expression levels of this allele (Wang et al., 2006). A consistent inverse association between self-reported allergic conditions and glioma has been observed. Asthma-associated polymorphisms in IL-4RA and IL-13 were inversely associated with glioblastoma incidence. This is a provocative observation because these factors have also been shown to inhibit glioma growth, and suggests a link between glioblastoma and immune function (Schwartzbaum et al., 2005).

Epidemiological studies have shown that glioblastoma has higher incidence in the white population and is more common in men than women (ratio 3:2), for unknown reasons. Many environmental risk factors have been investigated, including the use of cell phones, electromagnetic fields, viral infection, diet, tobacco, and previous head trauma/injury (Schwartzbaum et al., 2006). Gamma-radiation is the most widely accepted risk factor for gliomas. Indeed, genetic sensitivity to radiation or environmental carcinogens may play a role in brain tumor pathogenesis (Bondy et al., 2001). The limited findings on genetic and environmental factors involved in brain tumor development may reflect the complexity of genetic interactions with environmental factors. In addition, there is a need for studies to be carried out

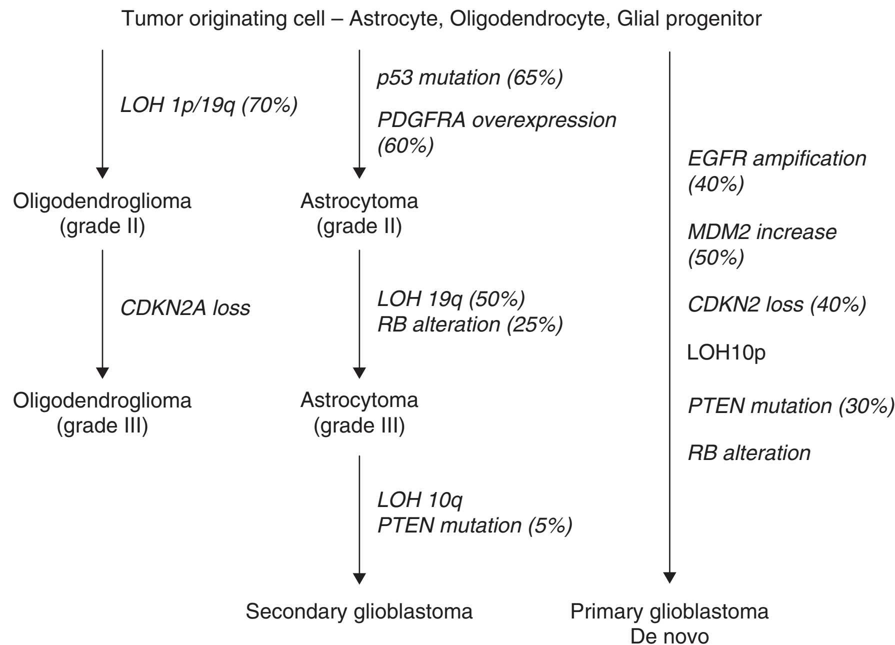

Figure 41.1 Pathways to glioma formation. Three pathways of genetic alteration are currently known that define Oligodendroglioma, primary glioblastoma and secondary glioblastoma. The major genetic alterations associated with tumor progression are shown, with their approximate frequency.

in large sample groups to confirm many preliminary findings, that have been reported in small studies. A brain tumor epidemiology consortium has recently been established in order to further understanding in this area (Schwartzbaum et al., 2006).

DIAGNOSIS AND PROGNOSIS

Brain tumor diagnosis is currently based largely on histologic analysis of tumor biopsies, according to WHO guidelines. Major prognostic factors in gliomas are tumor type and grade, patient age, symptom duration, degree of surgery and neurological deficit. The few long-term survivors of glioblastoma are young, in otherwise good health, and able to undergo gross total resection followed by chemo and radiotherapy. The current WHO tumor classification system suffers from well recognized problems due to interobserver variability, tumor heterogeneity and ambiguous tumor types (Louis et al., 2001). Very few further molecular markers are in common use at present, although codeletion of 1p and 19q is useful in predicting clinical responsiveness in oligodendroglioma, as described below. The incorporation of molecular information would allow less subjective diagnosis, and more precise prognostic information.

Chromosomal Alterations in Brain Tumors

A range of characteristic genetic changes have been observed, which in high-grade gliomas are variable and complex (reviewed by Bayani et al., 2005). Benign tumor types are characterized by fewer changes, the most prominent being alteration of chromosome 22. Cytogenetic analysis often reveals a normal karyotype for grade I astrocytomas, whereas grade II gliomas often have mutations in the *TP53* gene and overexpression of *PDGFRA*. The most commonly observed genetic alteration in glioblastoma is loss of chromosome 10 (60–80%), resulting in reduced *PTEN* expression, although it is possible that other genes on chromosome 10 are important. Gain of chromosome 7 (EGFR), and loss of 9p (p16 and $P14^{ARF}$), are also consistently observed (shown in Figure 41.1). Other consistently observed chromosomal alterations are shown in Table 41.2.

Recent, detailed microarray-based high-resolution genomic mapping studies have confirmed the presence of the commonly observed genetic changes in brain tumors and are revealing many more alterations whose significance is not yet understood, which may also eventually become useful diagnostic tools. Kotliarov et al. (2006) reported the use of Affymetrix high density 100 K SNP arrays to analyze genomic alterations in 178 glioma samples at an unprecedented resolution of 25 Kb. Array-CGH analysis of glioblastoma has uncovered numerous novel changes and can easily distinguish primary from secondary glioblastoma, and also showed that secondary glioblastoma falls into two distinct groups (Maher et al., 2006). Each tumor group had many more unique events than shared and therefore may benefit from quite different therapeutic approaches. cDNA microarray-based CGH was able to predict tumor type successfully based on common genetic alterations (Bredel et al., 2005). All these studies revealed large numbers of previously unidentified alterations. Other studies have reported deletions in chromosomes 6, 21, and 22 (Lassman et al., 2005). Two regions in 6q26 were found to be commonly

Table 41.2 Common genetic alterations seen in glial tumors

Region	Alterations	Candidate glioma genes
1p (34-pter) (various)	Gains and deletions	Unknown
1q32	Gains	*RIPK5, MDM4, PIK3C2B*
4q	Deletions	*NEK1, NIMA*
7p11.2 – p12	Amplification/gain	*EGFR*
9p21 – p24	Deletions	*CDKN2*
10q23	Deletions	*PTEN*
10q25 – q26	Deletions	*MGMT*
12q13.3 – q15	Amplification	*MDM2, CDK4*
13p11 – p13	Loss	*RB*
19q13	Loss	*GLTSCR1, GLTSCR2, LIG1, PSCD2*
22q11.2 – q12.2	Loss	28 genes including *INI1*
22q13.1 – 13.3	Loss	Not known

deleted, containing three novel genes, which may have tumor suppressor functions (Ichimura et al., 2006). Furthermore, the NIH Cancer Genome Atlas Project (CGA) promises to carry out large-scale genomic sequencing to fully understand genetic alterations in cancer. Glioblastoma is one of the initial three cancer types that will be analyzed in this project (http://cancergenome.nih.gov). This analysis promises to revolutionize the level of understanding of this cancer.

The most commonly used molecular diagnostic tool based on chromosomal alterations at present is in oligodendroglioma. Oligodendrogliomas frequently show a remarkable sensitivity to PCV chemotherapy, (procarbazine, CCNU, and vincristine), with a response rate of approximately 75%. Thus, within a histologically indistinguishable entity, there exist subgroups which show different biological behavior. Molecular genetic studies revealed that LOH of chromosome 1p which is found in 60–80% of oligodendrogliomas, and often accompanied by LOH of 19q (Cairncross et al., 1998), was the underlying reason for the increase in sensitivity. This occurs in both high and low-grade oligodendrogliomas and also applies to radiotherapy and temozolomide (Hoang-Xuan et al., 2004), the current chemotherapeutic drug of choice in glioma. Combined loss of 1p and 19q are strong correlates of longer survival in oligodendroglioma (Cairncross et al., 1998) and has been associated with increased survival in glioblastoma patients (Ino et al., 2000). Therefore genetic analysis for 1p and 19q is now commonly performed for oligodendroglioma and can be used to determine the most suitable therapeutic strategy. The prognostic significance of 1p/19q was confirmed in large recent trials (Van den Bent et al., 2006).

Identification of the key genes involved at 1p and 19q may lead to novel treatment strategies broadly applicable to gliomas in general. It has recently been shown that 1p/19q co-deletion is a result of an imbalanced translocation. This finding may lead to a better understanding of the functional importance of 1p/19q co-deletion (Jenkins et al., 2006). Studies also show that oligodendrogliomas and oligoastrocytomas may be further subgrouped on the basis of distinct genetic changes in addition to 1p and 19q alterations. CGH revealed a hemizygous deletion in 500 kb region in 11q13 and 300 kb region in 13q12 in virtually all low-grade oligodendrogliomas, regardless of 1p/19q status (Rossi et al., 2005), suggesting that further markers exist.

Other molecular diagnostic tools include analysis of EGFR amplification, seen commonly in gliomas. Glioblastomas with amplified EGFR often occur in older patients and can be difficult to distinguish from anaplastic oligodendroglioma due to their small cell appearance. Assessment of EGFR along with 1p and 19q can therefore be helpful in this situation (Burger et al., 2001). In summary, at present, to distinguish between different glioma groups, the following changes are the most typical and some are used diagnostically. Loss of chromosomes 1p/19q is typical of oligodendrogliomas, whereas gains of chromosome 7 in the setting of intact 1p/19q are more typical of astrocytomas. The detection of amplified EGFR favors the diagnosis of high-grade astrocytomas over anaplastic oligodendroglioma, which is especially relevant for small cell astrocytomas.

Transcriptional Alterations in Brain Tumors

Global transcriptional profiling using microarrays has revealed many novel changes in brain tumors (reviewed by Mischel et al., 2004). This initial burst of studies has revealed many alterations of potential utility. However, the vast majority of this data has not been replicated in independent patient cohorts. Expression profiles can readily distinguish different histologically classified tumor types. For example, microarray data could separate glioblastoma from oligodendroglioma on the basis of a 170 (Shai et al., 2003) or a 70 gene signature (Nutt et al., 2003). EGFR amplified glioblastoma was distinguished from non-amplified EGFR tumors using a 90 gene signature (Mischel et al., 2003), grade II and grade III oligodendrogliomas by a 200 gene subset (Watson et al., 2001) and also oligodendrogliomas with and without 1p loss (Mukasa et al., 2002). Gene expression analysis has also identified tumor subgroups that are indistinguishable histologically. For example, clustering analysis separated oligodendrogliomas into two survival groups based on gene expression (Huang et al., 2004). Two microarray studies of glioblastoma identified gene signatures corresponding to different survival groups, and suggest that increased expression of genes that promote infiltration can lead to a poor prognosis (Liang et al., 2005, Rich et al., 2005). Furthermore, microarrays were better

predictors of survival than histological grading for oligodendrogliomas (Nutt et al., 2003). Gene expression profiling therefore may provide useful diagnostic and prognostic information.

In a comprehensive study, gene expression profiles were obtained from 76 resected astrocytomas with known survival data (Phillips et al., 2006). Tumors were separated into either short or relatively long survival groups, and cluster analysis then segregated tumors into 3 distinct discrete sample sets based on 35 signature genes. These were defined by the predominant class of gene expressed, as either proneural (*PN*), proliferative (*Prolif*), or mesenchymal (*Mes*). The *PN* subset was associated with substantially longer survival, was more prominent in younger patients, and showed activated Notch signaling as seen by elevated delta-like protein 3 (DLL3) expression. Poor prognosis was associated with upregulation of proliferative markers such as proliferating cell nuclear antigen (PCNA), topoisomerase 2a (TOP2A), and angiogenesis markers such as vascular endothelial growth factor (VEGF) and its receptors, and platelet endothelial cell adhesion molecule 1 (PECAM1). Markers of neural stem cells were also associated with poor prognosis. All WHO classified grade II tumors were *PN*, whereas for grade IV tumors 31% were *PN*, 20% were *Prolif* and 49% were *Mes*, with expression profiles shifting toward the *Mes* class after recurrence. This suggests that the identified subtypes represent stages of tumorigenesis rather than different tumors. This study also correlated gene expression profiles with genetic abnormalities demonstrating that losses of chromosome 10 and gains on chromosome 7 are associated with *Prolif* and *Mes* phenotypes (around 80%), compared with 20% for the *PN* class. The authors therefore propose a model in which *PN* phenotype progresses to a *Prolif* phenotype, and ultimately the *Mes* phenotype, with the poorest prognosis. This kind of study demonstrates that useful information could be obtained from a small subset of signature genes. A similar study identified a 44 gene expression signature to classify gliomas into previously unrecognized biological and prognostic groups which outperformed histology-based classification in survival prediction (Freije et al., 2004). In agreement with Phillips et al. key genes identified include DLL3 (good prognosis), TOP2A (poor) leukemia inhibitory factor (LIF) (poor), S100A4 (poor), and VEGF (poor).

The most common alterations seen in gene expression profiling studies of gliomas are in genes involved in immune system regulation, hypoxia, cell proliferation, angiogenesis, neurogenesis, and cell motility. Ten of the most commonly reported upregulated genes in glioblastoma are summarized in Table 41.3. Many of these changes were not predicted by analysis of chromosomal alterations. Of these highly upregulated genes, the transmembrane glycoprotein GPNMB (Kuan et al., 2006) and YKL40 (also known as chitinase 3 like-1 (CHI3L1)) (Hormigo et al., 2006), have been proposed as prognostic markers. YKL-40 has emerged from gene screening studies as one of the most robust and consistently observed markers in glioblastoma (Freije et al., 2004; Phillips et al., 2006). YKL-40 mRNA was on average 82-fold higher in glioblastoma than anaplastic oligodendrogliomas (Nutt et al., 2003). A further study showed that that YKL-40 may be a better marker than glial fibrillary acidic protein (GFAP) which is currently the standard in distinguishing diagnostically challenging gliomas, and suggests that combining YKL-40 and GFAP staining is the best approach at present (Nutt et al., 2005). YKL-40 expression is also associated with radioresistance (Pelloski et al., 2005). Serial analysis of gene expression (SAGE) analysis of glioma samples revealed that it is the most upregulated gene compared with normal brain (Boon et al., 2004). Taken together the data described shows that gene expression profiling may predict tumor type, patient outcome, and is providing the data to identify new therapeutic targets (Horvath et al., 2006). However, there are a large number of potential markers, and it is not yet clear which of these will finally be used clinically.

A potential drawback of transcriptional profiling is that mRNA levels in a given sample may not be representative of the whole tumor, and also that they do not provide an accurate indication of the translation into protein. mRNA must be bound to polysomes in order to be translated, and a study of polysomal RNA in glioma cell lines revealed marked differences to global RNA in the same sample (Rajasekhar et al., 2003). In addition, the recently discovered non-protein coding RNA

TABLE 41.3 The "top ten" overexpressed genes in glioma as judged by their reported appearance in microarray studies cited in this chapter

Gene	Symbol(s)	Function
Fibronectin 1	*FN1*	ECM – angiogenesis, invasion
Insulin like growth factor binding protein 2	*IGFBP2*	Promotes invasion
Collagens (IV and VI)	*COL6A/ COL4A*	ECM, promotes invasion
Topoisomerase 2A	*TOP2A*	DNA replication and transcription
Biglycan	*BGN*	ECM proteoglycan. Role in glioma unknown
Chitinase 3-like-1	*CHI3LI*	ECM, invasion, angiogenesis, survival
Vascular endothelial growth factor	*VEGF*	Angiogenesis, invasion
Vimentin	*VIM*	Intermediate filament, invasion
Epidermal growth factor receptor	*EGFR*	Survival, growth, invasion
TGF-β1	*TGFB1*	Proliferation, differentiation, invasion

molecules such as microRNAs can have a profound impact on gene expression by either causing degradation of specific transcripts, or by preventing translation of the mRNA. MicroRNA expression is altered in many cancers (Volinia et al., 2006), including brain tumors, with mir-21 being particularly over-represented in glioblastoma (Chan et al., 2005; Ciafre et al., 2005). This also has functional importance because knockdown of mir-21 leads to apoptosis in glioma cells (Chan et al., 2005).

Proteomic Studies in Brain Tumors

Proteomic studies on brain tumors typically have used the 2-dimensional gel electrophoresis and mass spectrometry approach. Comparison of glioblastoma with non-tumor tissue identified 11 upregulated and 4 down-regulated proteins including the fatty acid binding protein FABP7 – also identified as a prognostic marker in microarrays (Hiratsuka et al., 2003, Liang et al., 2005). The study closely examined SIRT2, a tubulin deacetylase, downregulated in 12 out of 17 gliomas, and suggested it may act as a tumor suppressor. Another study used 2d-gel-based proteomics to molecularly classify and predict survival in 85 samples including various tumors and normal brain. Expression patterns were identified that could distinguish tumor types and predict survival (Iwadate et al., 2004). Proteomics may find utility in the identification of serum biomarkers that could lead to much simpler diagnosis and monitoring. Few studies have yet been performed in this area, although cathepsin D was found to be elevated in the serum of glioblastoma patients, and associated with poor prognosis (Fukuda et al., 2005). Matrix metalloprotease-9 (MMP-9) and YKL-40 have also been detected in the serum of glioblastoma patients (Hormigo et al., 2006). However, like other studies in this area, independent analysis on further patient groups is not yet available.

Direct mass spectrometry of tissue samples is emerging as a powerful tool and may become increasingly influential in the diagnostic arena (Caprioli, 2005). Analysis of 162 patient biopsies from glioma patients using this approach, known as direct tissue matrix-assisted laser desorption ionization mass spectroscopy (MALDI-MS), was used to generate a novel classification scheme based on protein expression profiles, which segregated long-term and short-term survivors (Schwartz et al., 2005). The authors were able to distinguish normal brain from glioma biopsies and also to distinguish various grades of tumor by protein expression in these samples. MALDI-MS technology is also amenable to high-throughput tissue screening in a clinical setting. Significant developments can be expected in this area in the near future.

PHARMACOGENOMICS

At present, many brain tumors are treated in a similar way regardless of their classification, but this situation is changing as patient responsiveness to various therapies is correlated with genetic changes in the tumor. For example patients with combined 1p and 19q loss may opt for chemotherapy but withhold radiation until recurrence, therefore avoiding the problematic effects of extensive radiation to the brain in long surviving patients. On the other hand, a patient with intact chromosome 1p and EGFR amplification may opt to forego PCV chemotherapy, and have radiation and a novel therapy, thereby avoiding the myelotoxic effects of PCV (Louis, 2006).

The benefit of chemotherapy in glioblastoma and anaplastic astrocytoma is small, with response plus stabilization in 20–50% of patients, because these tumors have intrinsic chemoresistance. Esteller et al. (2000) first described the mechanism by which some gliomas are resistant to nitrosourea alkylating agents such as carmustine (BCNU). These agents kill by alkylation of the O6 position of guanine, thereby crosslinking adjacent DNA strands. These crosslinks can be repaired by the DNA repair enzyme O6-methylguanine-DNA methyltransferase (MGMT), which rapidly reverses alkylation. Around 30% of gliomas lack MGMT, and this correlates closely with chemosensitivity. However, mutations in MGMT are rare, and it was found that methylation of the promoter region of the gene, leading to transcriptional silencing, accounts for the variation. 12 of 19 high-grade glioma patients with methylated MGMT promoters had a partial or complete response to treatment, whereas only one of 28 patients with an unmethylated promoter had a response. MGMT promoter methylation also is linked to responsiveness to temozolomide (Hegi et al., 2005).

A second example of pharmacogenomics is in the use of EGFR kinase inhibitors for glioma treatment. Molecularly targeted therapeutics such as EGFR inhibitors are an attractive option for glioma because of the frequently observed amplification of EGFR in these tumors. However, trials so far have shown only a 20% response rate (Mellinghoff et al., 2005). Molecular determinants of responsiveness were analyzed, and it was found that combined EGFRVIII mutation and the presence of PTEN sensitizes tumor, suggesting that secondarily targeting PI3K signaling may improve this kind of therapy, and that patients with the appropriate profile should be enlisted in further trials for these drugs. As glioma treatment becomes increasingly sophisticated further details and examples of chemoresistance mechanisms, which can affect therapeutic decision making are sure to emerge.

SUMMARY

The prognosis for many brain tumors remains dismal. However, the wealth of data currently being generated by microarray-based studies in particular should have a profound effect on brain tumor management. Headway is currently being made in four main areas:

1. *Identification of robust molecular markers and signatures that define tumor types*: Recent studies have revealed that molecular signatures readily distinguish tumor types, and can also further subdivide histologically similar tumors into previously unknown groups. This opens up the possibility that molecular information will be increasingly useful in brain tumor diagnosis.
2. *Correlation of molecular signatures with patient prognosis*: Molecular information may provide the ability to predict

patient survival more reliably than at present. Recent studies show that molecular classification can improve prediction of patient outcome compared with histology in some cases.

3. *Correlation of molecular data with therapeutic response*: Molecular alterations play a role in drug responsiveness. The identification of these alterations is beginning to impact clinical decision making; 1p/19q is now widely used, and MGMT and EGFR status may be used in the near future. These represent the first steps towards the development of patient-tailored therapies.
4. *Identification of novel therapeutic targets*: Improved understanding of brain tumor biology is allowing the development of new therapeutic strategies based on novel molecular targets revealed by global genetic analyses.

The most promising approaches so far may involve tumor classification by gene expression profiling using a panel of relevant genes. The identification of the *PN*, *Mes* and *Prolif* tumor subgroups (Phillips et al., 2006) provides a strong foundation for such an approach. Microarray studies have identified many candi dates that could be of use in prognosis and monitoring – the most promising of these so far may be YKL-40, which can differentiate astrocytic from oligodendroglial tumors and is associated with poor prognosis. The association between MGMT promoter methylation and improved treatment response in glioblastoma patients has provoked much interest in this area. The incorporation of MGMT expression analysis may therefore soon emerge as a useful predictive clinical tool.

The list of molecular alterations is growing, but is still far from complete. In addition the role of epigenetic changes has barely been studied as yet in gliomas. The major challenge at this point is to translate this increasingly large amount of data into clinically useful tools. This should lead to the development of a new genomic approach to glioma treatment, using molecular signatures to provide accurate diagnosis, and to stratify patients for the most effective therapy, or for targeted therapies. This should finally lead to a better outlook for these cancers.

2009 UPDATE

The most significant recent development in brain tumor genomics is the development of TCGA (Cancer Genome Atlas Research Network, 2008). This freely available resource contains DNA copy number, gene expression, microRNA, and methylation data on 206 glioblastomas so far. Some 600 candidate genes are also being sequenced. In another study, next-generation sequencing as well as profiling was performed on 20,661 genes in 22 glioblastomas (Parsons et al., 2008). These studies identified mutations and alterations in core pathways and mark the beginning of a new era in glioblastoma research and discovery.

Little is known about genetic factors predisposing to glioma. Previous data established a potential inverse relationship between allergy and glioma incidence. This is supported by the demonstration that polymorphisms in the IL4-receptor gene are significantly associated with improved survival (Scheurer et al., 2008a). Effects of combined SNPs in multiple DNA repair genes increases glioma risk (Liu et al., 2008). Evidence is beginning to accumulate suggesting a role of CMV in glioma progression and awaits further investigation (Cobbs et al., 2008; Prins et al., 2008; Scheurer et al., 2008b).

Several groups have reported that high levels of the stem cell marker CD133 are associated with poor prognosis in gliomas (Beier et al., 2008; Rebetz et al., 2008; Zeppernick et al., 2008). Resistance to temozolomide chemotherapy also appears to be linked to a stem cell signature (Murat et al., 2008). Co-deletion of chromosomes 1p and 19q is the major molecular marker currently in wide use. MGMT is still under close study, but some difficulties have been reported in relating immunostaining to patient response (Preusser et al., 2008).

Efforts to classify gliomas based on transcriptional profiling have continued (Petalidis et al., 2008). As described in earlier studies, this data reveals three distinct molecular classes of glioma and suggests that grading based on molecular features can outperform traditional histologic methods. It is increasingly recognized that personalized therapies may be necessary for the effective treatment of glioblastoma. An example of this was outlined in a study describing an oncogenic role for STAT3 by association with EGFRVIII, and a tumor suppressor role for STAT3 in response to PTEN deletion (de la Iglesia, 2008).

An increasing number of microRNAs have been characterized in glioblastoma. MiR-21 antagonism and re-expression of weakly expressed microRNAs, such as miR-7, miR124, and miR-128 all have effects on glioma cell proliferation and/or invasion, and target important genes, such as EGFR (miR-7) (Kefas et al., 2008), CDK6 (miR-124) (Silber et al., 2008), and Bmi1 (miR-128) (Godlewski et al., 2008). Also, miR-296 was identified in endothelial cells as a pro-angiogenic microRNA (Wurdinger et al., 2008).

Anti-angiogenic approaches show promise in early trials. These include the VEGFR inhibitor Cediranib (AZD2171) (Batchelor et al., 2007) and the integrin inhibitor cilengitide (Reardon et al., 2008). The anti-VEGF monoclonal antibody Avastin showed excellent radiographic responses in trials for recurrent glioblastoma in combination with CPT11 (Vredenburgh et al., 2007). It is not yet clear whether these impressive responses will translate into improved survival (Norden et al., 2008). Avastin will now be investigated in newly diagnosed glioblastoma in combination with temozolomide and radiation.

CHAPTER

Targeted Therapies for Cancer

Jeffrey S. Ross

INTRODUCTION

The regulatory approvals in the United States and Europe of trastuzumab (Herceptin®) for the treatment of HER2 overexpressing metastatic breast cancer and imatinib mesylate (Gleevec®) for the treatment of patients with *bcr/abl* translocation positive chronic myelogenous leukemia and gastrointestinal stromal tumors (GISTs) featuring an activating c-*kit* growth factor receptor mutation has created enthusiasm for anticancer targeted therapy in both the scientific and public communities (Mauro and Druker, 2001; O'Dwyer and Druker, 2001). Recent major news magazines and other public media have highlighted interest in new anticancer drugs that exploit disease-specific genetic defects as the target of their mechanism of action (Brown, et al., 2001; Lemonick and Parl, 2001). It is now widely held that the integration of molecular oncology and molecular diagnostics will further revolutionize oncology drug discovery and development; customize the selection, dosing, and route of administration of both previously approved traditional agents and new therapeutics in clinical trials, and individualize medical care for the cancer patient (Amos and Patnaik, 2002; Bottles, 2001; Evans and McLeod, 2003; Weinshilboum, 2003).

TARGETED THERAPIES FOR CANCER

From the regulatory perspective, "targeted therapy" has been defined as a drug in whose approval label there is a specific reference to a simultaneously or previously approved diagnostic test that must be performed before the patient can be considered eligible to receive that specific drug. The co-approvals of the anti-breast cancer antibody trastuzumab (Herceptin®) and the required tissue-based tests for patient eligibility (Herceptest®, Pathway®, InSite®, and Pathvysion®) are examples of this strict definition of targeted therapy. However, for many scientists and oncologists, anticancer drugs are considered to "targeted" when they feature a focused mechanism that specifically acts on a well-defined target or biologic pathway that, when inactivated, causes regression or destruction of the malignant process. Examples of this less rigorous definition of targeted therapy include hormonal-based therapies for breast cancer, small-molecule inhibitors of the epidermal growth factor receptor (EGFR), blockers of invasion and metastasis enabling proteins and enzymes, antiangiogenesis agents, proapoptotic drugs and proteasome inhibitors. Finally, another definition of targeted therapy involves anticancer antibody therapeutics that seek out and kill malignant cells bearing the target antigen.

THE IDEAL TARGET

The ideal cancer target (Table 42.1) can be defined as a macromolecule that is crucial to the malignant phenotype and is not significantly expressed in vital organs and tissues; that has biologic relevance that can be reproducibly measured in readily obtained clinical samples; that is definably correlated with clinical outcome; and that interruption, interference, or inhibition of such a macromolecule yields a clinical response in a significant proportion of patients whose tumors express the target with minimal to absent responses in patients whose tumors do not express the target. For antibody therapeutics, additional important criteria include the use of cell surface targets that when

complexed with the therapeutic naked or conjugated antibody, internalize the antigen–antibody complex by reverse pinocytosis, thus facilitating tumor cell killing.

THE FIRST DIAGNOSTIC-THERAPEUTIC COMBINATION IN CANCER THERAPY: HORMONAL THERAPY FOR BREAST CANCER

Targeted therapy for cancer began in the early 1970s with the introduction of the estrogen receptor (ER) biochemical assay to select patients with painful metastatic breast cancer for surgical ablation of estrogen producing organs (ovaries, adrenals) (Figure 42.1) (Osborne, 1998). The ER assay was followed by a similar dextran coated charcoal biochemical assay for the progesterone receptor (PR) and subsequently converted to an immunohistochemistry (IHC) platform when the decreased size of primary tumors associated with self-examination and mammography-based screening programs prevented the use of the biochemical test (Wilbur et al., 1992). The drug tamoxifen (Nolvadex®), which has both hormonal and nonhormonal mechanisms of action, has been the most widely prescribed antiestrogen for the treatment of metastatic breast cancer and chemoprevention of the disease in high risk women (Ciocca and Elledge, 2000; Jordan, 2003a, b, c). Although, ER and PR testing is the front line for predicting tamoxifen response, additional biomarkers, including HER-2/neu (HER-2) and cathepsin D testing, have been used to further refine therapy selection (Locker, 1998). The introductions of specific estrogen response modulators and aromatase inhibitors such as anastrozole (Arimidex®), letrozole (Femara®), and the combination chemotherapeutic, estramustine (Emcyt®) (Buzdar et al., 2006; Ibrahim and Hortobagyi, 1999; Jordan, 2003a, b, c; Miller et al., 2002) have added new strategies for evaluating tumors for hormonal therapy.

Most recently, the Oncotype Dx® (Genomic Health, Redwood City, CA) multigene RT-PCR multiplex assay using a 21-gene probe set and mRNA extracted from paraffin blocks of stored breast cancer tissues was introduced as a new guide to the use of tamoxifen in ER positive node negative breast cancer patients (Paik et al., 2004). The assay features 16 cancer-related genes and 5 reference genes that were selected based on a series of transcriptional profiling experiments. The cancer-related genes include markers of proliferation including Ki-67, markers of apoptosis including survivin, invasion-associated protease genes including MMP11 and cathepsin L2, ER and HER2/*neu* gene family members, the glutathione-S-transferase genotype M1, CD68, a lysosomal monocyte/macrophage marker and BAG1, a co-chaperone glucocorticoid receptor associated with bcl-2 and apoptosis. Using a cohort of 688 lymph node negative, ER+ tumors obtained from patients enrolled in the NSABP B-14 clinical trial treated with tamoxifen alone, the 21-gene assay produced three prognosis scores of low, intermediate and high risk. The recurrence rates for these patients at 10 years follow-up was 7% for the low risk, 14% for the intermediate risk and 31% for the high risk groups. The difference in relapse rates between the low risk and high risk patients was highly significant ($p < 0.001$). On multivariate analysis this assay predicted adverse outcome independent of tumor size and also predicted overall survival (Paik et al., 2004). Although not currently approved by the FDA, the interest in this new assay has been intense and it has become commercially available in a centralized format for new patients. Recent data presented at the 2005 ASCO Meeting showed that the Oncotype Dx® is also capable of performing as a stand-alone prognostic test based on the test results in an untreated patient population (Paik et al., 2005). Detailed evaluation of the gene set in the Oncotype Dx® assay indicates that the mRNA levels of ER appear to be the most significant predictors in the node-negative ER-positive population (by IHC). Further studies are needed to validate the assay, learn its best uses and limitations given the evolving approach to hormonal therapy with non-tamoxifen drugs, the wide use of cytotoxic agents in the adjuvant setting for node-negative patients and the availability of both RT-PCR based and non-RT-PCR approaches to predicting breast cancer response to anti-estrogen and other anti-neoplastic agents used for treatment of the disease (Bast and Hortobagyi, 2004). In current practice the routine testing of tumor samples for androgen receptor status has not been incorporated into the selection of hormonal therapy for the disease.

DIAGNOSTIC-THERAPEUTIC COMBINATIONS FOR LEUKEMIA AND LYMPHOMA

The introduction of immunophenotyping for leukemia and lymphoma was followed by the first applications of DNA-based assays, the polymerase chain reaction, and RNA-based molecular technologies in these diseases that complemented continuing advances in tumor cytogenetics (Gleissner and Thiel, 2001; Rubnitz et al.,

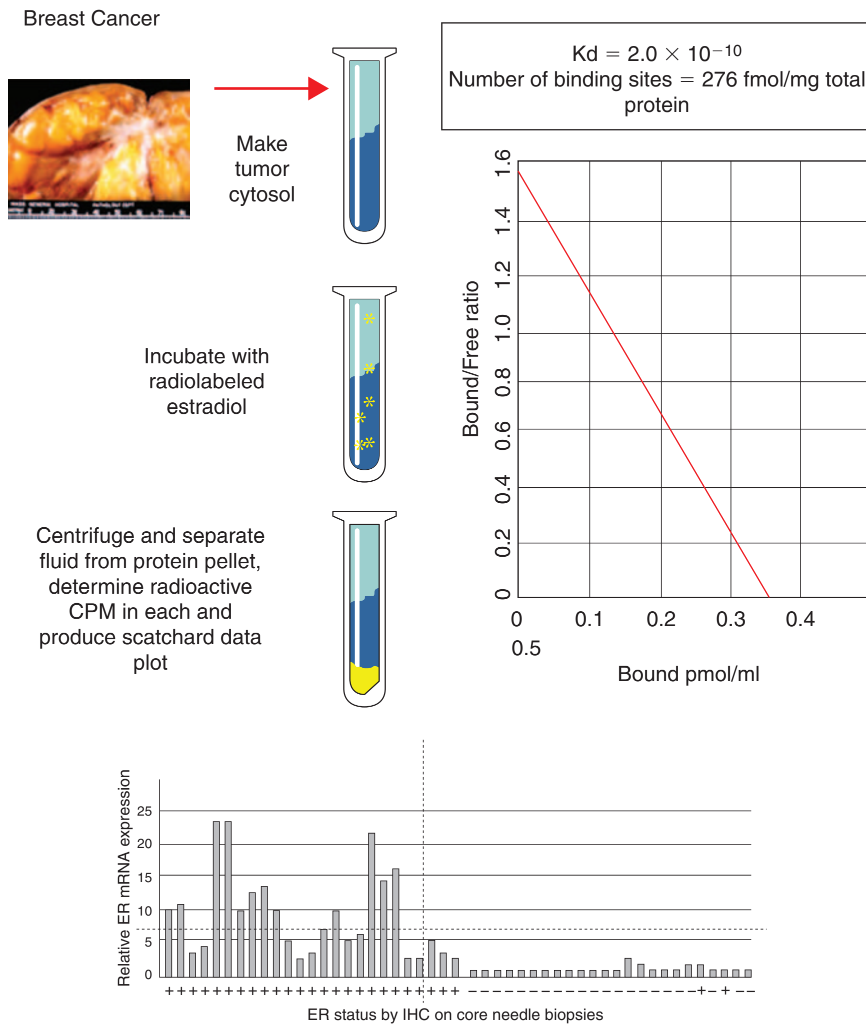

Figure 42.1 ER status determination. (a) Biochemical competitive binding assay for ER status determination. (b) Comparison of ER messenger RNA expression detected by microarray profiling and corresponding ER protein expression measured by IHC. The concordance between ER levels determined by IHC and ER levels determined by gene expression profiling was about 95%. Reprinted from Ross, J.S, Hortobagyi, G.H. eds. *The Molecular Oncology of Breast Cancer*. Jones and Bartlett, Inc., Sudbury, MA with permission by the publisher.

1999). In addition to the imatinib (Gleevec®) targeted therapy for chronic myelogenous leukemia, other molecular targeted therapies in hematologic malignancies includes the use of all-*trans*-retinoic acid (ATRA) for the treatment of acute promyelocytic leukemia (Grimwade and Lo Coco, 2002); anti-CD20 antibody therapeutics targeting non-Hodgkin lymphomas, including rituximab (Rituxan®) (Kiyoi and Naoe, 2005); and the emerging Flt-3 target for a subset of acute myelogenous leukemia patients (see below) (Ross et al., 2003a).

HER-2 POSITIVE BREAST CANCER AND TRASTUZUMAB (HERCEPTIN®)

After the introduction of hormone receptor testing, some 30 years then elapsed before the next major targeted cancer chemotherapy program for a solid tumor was developed. In the mid-1980s, the discovery of the *HER-2* (c-*erb*B2) gene and protein and subsequent association with an adverse outcome in breast cancer provided clinicians with a new biomarker that could be used to guide adjuvant chemotherapy (Slamon et al., 2001). The development of trastuzumab (Herceptin®), a humanized monoclonal antibody designed to treat advanced metastatic breast cancer that had failed first- and second-line chemotherapy, caused a rapid wide adoption of HER-2 testing of the patients' primary tumors (Schnitt and Jacobs, 2001). However, soon after its approval, widespread confusion concerning the most appropriate diagnostic test to determine HER-2 status in formalin-fixed paraffin-embedded breast cancer tissues substantially impacted trastuzumab use (Hayes and Thor, 2002; Hortobagyi, 2001; Masood and Bui, 2002, Paik et al., 2002;

Tanner et al., 2000; Wang et al., 2000, 2001; Zhao et al., 2002). Since its launch in 1998, trastuzumab has become an important therapeutic option for patients with HER-2-positive breast cancer (Bast et al., 2000; Ligibel and Winer, 2002; McKeage and Perry, 2002, Shawver et al., 2002).

In general, when specimens have been carefully fixed, processed and embedded, there has been excellent correlation between *HER-2* gene copy status determined by Fluorescence *In Situ* Hybridization (FISH) and HER-2 protein expression levels determined by IHC (Slamon et al., 2001). The main use of either method in current clinical practice is focused on the negative prediction of response to trastuzumab. Currently, both the American Society of Clinical Oncology and the College of American Pathologists consider HER-2 testing to be part of the standard work-up and management of breast cancer (Hammond et al., 2000; Pawlowski et al., 2000). Recently, the chromogenic (non-fluorescent) *in situ* hybridization technique has been used to determine the *HER-2* gene amplification status with promising results (Hortobagyi, 2001; Zhao et al., 2002). Non-morphologic approaches for determining HER-2 status have also been developed. The RT-PCR technique which has been predominantly used to detect HER-2 mRNA in peripheral blood and bone marrow samples, has correlated more with gene amplification status than IHC levels of primary tumors, but has been less successful as a predictor of survival (Bieche et al., 1999; Dressman et al., 2003; Tubbs et al., 2001). With the advent of laser capture microscopy and the acceptance of RT-PCR as a routine and reproducible laboratory technique, the use of RT-PCR for the determination of HER-2 status may increase in the future. The cDNA microarray-based method of detecting HER-2 mRNA expression levels has recently received interest as an alternative method for measuring HER-2/neu status in breast cancer (Fornier et al., 2005; Pusztai et al., 2003). Finally, the serum HER-2/ELISA test measuring circulating HER-2 (p185neu) protein is an FDA-approved test that has seen increased clinical use as a method for monitoring the response to trastuzumab (Ross et al., 2005). A summary of HER-2 testing methods in breast cancer is shown in Table 42.2.

TABLE 42.2 Methods of detection of HER-2/neu status in breast cancer

Method	Target	FDA-approved	Slide-based
IHC	Protein	Yes[a]	Yes
FISH	Gene	Yes[a]	Yes
CISH	Gene	No	Yes
Southern blot	Gene	No	No
RT-PCR	mRNA	No	No
Microarray TP	mRNA	No	No
Tumor ELISA	Protein	No	No
Serum ELISA	Protein	Yes[b]	No

[b]For monitoring response of breast cancer to treatment

OTHER TARGETED ANTICANCER THERAPIES USING ANTIBODIES

An unprecedented number and variety of targeted small molecule and antibody-based therapeutics are currently in early development and clinical trials for the treatment of cancer. Therapeutic antibodies have become a major strategy in clinical oncology because of their ability to specifically bind to primary and metastatic cancer cells with high affinity and create antitumor effects by complement-mediated cytolysis and antibody-dependent cell-mediated cytotoxicity (naked antibodies) or by the focused delivery of radiation or cellular toxins (conjugated antibodies) (Carter, 2001; Goldenberg, 2002; Hemminki, 2002; Milenic, 2002; Reichert, 2002; Ross et al., 2003b,). Currently, there are eight anticancer therapeutic antibodies approved by the US Food and Drug Administration (FDA) for sale in the United States (Table 42.3). Therapeutic monoclonal antibodies are typically of the IgG class containing two heavy and two light chains. The heavy chains form a fused "Y" structure with two light chains running in parallel to the open portion of the heavy chain. The tips of the heavy-light chain pairs form the antigen binding sites, with the primary antigen recognition regions known as the complementarity determining regions.

The early promise of mouse monoclonal antibodies for the treatment of human cancers was not realized because (1) unfocused target selection led to the identification of target antigens that were not critical for cancer cell survival and progression, (2) there was a low overall potency of naked mouse antibodies as anticancer drugs, (3) antibodies penetrated tumor cells poorly, (4) there was limited success in producing radioisotope and toxin conjugates, and (5) the development of human antimouse antibodies (HAMA) prevented the use of multiple dosing schedules (Reilly et al., 1995).

The next advance in antibody therapeutics began in the early 1980s when recombinant DNA technology was applied to antibody design to reduce the antigenicity of murine and other rodent-derived monoclonal antibodies. Chimeric antibodies were developed where the constant domains of the human IgG molecule were combined with the murine variable regions by transgenic fusion of the immunoglobulin genes; the chimeric monoclonal antibodies were produced from engineered hybridomas and Chinese Hamster Ovary (CHO) cells (Merluzzi et al., 2000; Winter and

Table 42.3 Antibody therapeutics for cancer

Name	FDA approval date	Source *Partners*	Type	Target	Indication(s) (both approved and investigational)
Alemtuzumab *Campath®*	05/01	BTG *ILEX Oncology Schering AG*	Monoclonal antibody, humanized Anticancer, immunological Multiple sclerosis treatment Immunosuppressant	CD52	Cancer, leukemia, chronic lymphocytic Cancer, leukemia, chronic myelogenous Multiple sclerosis, chronic progressive
Daclizumab *Zenapax®*	03/02	Protein Design Labs *Hoffmann-La Roche*	Monoclonal IgG_1 Chimeric Immunosuppressant Antipsoriasis Antidiabetic Ophthalmological Multiple sclerosis treatment	IL2R	Transplant rejection, general Transplant rejection, bone marrow Uveitis Multiple sclerosis, relapsing-remitting Multiple sclerosis, chronic progressive Cancer, leukemia, general Psoriasis Diabetes, type I Asthma Colitis, ulcerative
Rituximab *Rituxan®*	11/97	IDEC *Genentech Hoffmann-La Roche Zenyaku Kogyo*	Monoclonal IgG_1 Chimeric Anticancer, immunological Antiarthritic, immunological Immunosuppressant	CD20	Cancer, lymphoma, non-Hodgkin's Cancer, lymphoma, B-cell Arthritis, rheumatoid Cancer, leukaemia, chronic lymphocytic Thrombocytopenic purpura
Trastuzumab *Herceptin®*	09/98	Genentech *Hoffmann-La Roche ImmunoGen*	Monoclonal IgG_1 Humanized Anticancer, immunological	p185neu	Cancer, breast Cancer, lung, non-small cell Cancer, pancreatic
Gemtuzumab *Mylotarg®*	05/00	Wyeth/AHP	Monoclonal IgG_4 Humanized	CD33 / coleacheamycin	Cancer, leukemia, AML (patients older than 60 years)
Ibritumomab *Zevalin®*	02/02	IDEC	Monoclonal IgG_1 Murine Anticancer	CD20 / ^{90}Yttrium	Cancer, lymphoma, low grade, follicular, Transformed non-Hodgkin's (relapsed or refractory)
Tositomumab *Bexxar®*	06/03	Corixa	Anti-CD 20 Murine Monocolonal antibody with ^{131}I conjugation	CD20	Cancer, lymphoma, non-Hodgkin's
Cetuximab *Erbitux®*	02/04	Imclone Bristol Myers Squibb	Anti-EGFR monoclonal antibody	EGFR	Approved for third line treatment of metatstatic colorectal cancer that has failed primary chemotherapy
Bevacizumab *Avastin®*	02/04	Genentech	Anti-VEGF (ligand)	VEGF	Avastin is approved for use in combination with intravenous 5-fluorouracil-based chemotherapy as a treatment for patients with first-line – or previously untreated – metastatic colorectal cancer.
Edrecolomab *Panorex™*	01/95 (Europe Only, nut FDA-approved)	Glaxo-Smith-Kline	Monoclonal IgG_{2A} Murine Anticancer	Epithelial cell adhesion molecule (EpCAM)	Cancer, colorectal

Harris, 1993). The use of chimeric antibodies significantly reduced the HAMA responses but did notcompletely eliminate them (Kuus-Reichel et al., 1994; Merluzzi et al., 2000). Although several chimeric antibodies achieved regulatory approval, certain targets required humanized antibodies to achieve appropriate dosing. Partially humanized antibodies were then developed where the six complementarity determining regions of the heavy and light chains and a limited number of structural amino acids of the murine monoclonal antibody were grafted by recombinant technology to the complementarity determining region depleted human IgG scaffold (Milenic, 2002). Although this process further reduced or eliminated the HAMA responses, in many cases significant further antibody design procedures were needed to reestablish the required specificity and affinity of the original murine antibody (Jones et al., 1986, Isaacs, 2001; Pimm, 1994; Watkins and Ouwehand, 2000).

A second approach to reducing the immunogenicity of monoclonal antibodies has been to replace immunogenic epitopes in the murine variable domains with benign amino acid sequences, resulting in a deimmunized variable domain. The deimmunized variable domains are genetically linked to human IgG constant domains to yield a deimmunized antibody (Biovation, Aberdeen, Scotland). Additionally, primatized antibodies were subsequently developed that featured a chimeric antibody structure of human and monkey that, as a near exact copy of a human antibody, further reduced immunogenicity and enabled the capability for continuous repeat dosing and chronic therapy (Reff et al., 2002). Finally, fully human antibodies have now been developed using murine sources and transgenic techniques (Reff et al., 2002).

Using modern antibody design and deimmunization technologies, scientists and clinicians have attempted to improve the efficacy and reduce the toxicity of anticancer antibody therapeutics (Carter, 2001; Chester and Hawkins, 1995; Reff Heard, 2001; Reilly et al., 1995; Nielsen and Marks, 2000). The bacteriophage antibody design system has facilitated the development of high affinity antibodies by increasing antigen binding rates and reducing corresponding detachment rates (Nielsen and Marks, 2000). Increased antigen binding is also achieved in bivalent antibodies with multiple attachment sites, a feature known as avidity. Modern antibody design has endeavored to create small antibodies that can penetrate to cancerous sites but maintain their affinity and avidity. A variety of approaches has been used to increase antibody efficacy (Carter, 2001). Clinical trials have recently combined anticancer antibodies with conventional cytotoxic drugs, yielding promising results (Carter, 2001; Goldenberg, 2002; Hemminki, 2002; Milenic, 2002; Reichert, 2002; Ross et al., 2003b). The applications of radioisotope, small molecule cytotoxic drug, and protein toxin conjugation have resulted in promising results in clinical trials and achieved regulatory approval for several drugs now on the market (see below). Antibodies have also been designed to increase their enhancement of effector functions of antibody-dependent cellular cytotoxicity. Another cause of toxicity of conjugated antibodies has been the limitations of the conjugation technology, which can restrict the ratio of the number of toxin molecules per antibody molecule (Carter, 2001; Goldenberg, 2002; Watkins and Ouwehand, 2000). Methods designed to overcome the toxicity of conjugated antibodies include the use of antibody targeted liposomal small molecule drug conjugates and the use antibody conjugates with drugs in nanoparticle formats to enhance bonding strength that enable controlled release of the cytotoxic agent. Another technique that uses site selective prodrug activation to reduce bystander tissue toxicity is the antibody directed enzyme prodrug therapy. An antibody-bound enzyme is targeted to tumor cells. This allows for selective activation of a nontoxic prodrug to a cytotoxic agent at the tumor site for cancer therapy.

A variety of factors can reduce antibody efficacy (Reilly et al., 1995): (1) limited penetration of the antibody into a large solid tumor or into vital regions such as the brain, (2) reduced extravasations of antibodies into target sites due to decreased vascular permeability, (3) cross-reactivity and nonspecific binding of antibody to normal tissues reduces targeting effect, (4) heterogeneous tumor uptake results in untreated zones, (5) increased metabolism of injected antibodies reduces therapeutic effects, and (6) HAMA and human antihuman antibodies form rapidly and inactivate the therapeutic antibody.

Toxicity has been a major obstacle in the development of therapeutic antibodies for cancer [Carter, 2001; Goldenberg, 2002; Ross et al., 2003b; Watkins and Ouwehand, (2000)]. Cross-reactivity with normal tissues can cause significant side effects for unconjugated (naked) antibodies, which can be enhanced when the antibodies are conjugated with toxins or radioisotopes. Immune-mediated complications can include dyspnea from pulmonary toxicity, occasional central and peripheral nervous system complications, and decreased liver and renal function. On occasion, unexpected toxic complications can be seen, such as the cardiotoxicity associated with the HER-2 targeting antibody trastuzumab. Radioimmunotherapy with isotopic-conjugated antibodies can also cause bone marrow suppression (see below).

Unconjugated or naked antibodies include a variety of targeting molecules both on the market and in early and late clinical development. A variety of mechanisms have been cited to explain the therapeutic benefit of these drugs, including enhanced immune effector functions and direct inactivation of the targeted pathways as seen in the antibodies directed at surface receptors such as HER-1 (EGFR) and HER-2 (Amos and Patnaik, 2002; Brown et al., 2001; Lemonick and Parl, 2001; Mauro and Druker, 2001). Surface receptor targeting can reduce intracellular signaling, resulting in decreased cell growth and increased apoptosis (Reff et al., 2002).

As seen in Table 42.3, of the nine anticancer antibodies on the market in the United States, two are conjugated with a radioisotope ^{90}Y-ibritumomab tiuxetan (Zevalin®) and ^{131}I-tositomumab (Bexxar®) and one is conjugated to a complex natural product toxin gemtuzumab ozogamicin (Mylotarg®). Conjugation procedures have been designed to improve antibody therapy efficacy and have used a variety of methods to complex the isotope, toxin, or cytotoxic agent to the antibody (Carter, 2001; Goldenberg, 2002). Cytotoxic small molecule drug conjugates have been widely tested, but enthusiasm for this

approach has been limited by the relatively low potency of these compounds (Carter, 2001). Fungal derived potent toxins have yielded greater success with the calicheamicin conjugated anti-CD33 antibody gemtuzumab ozogamicin approved for the treatment of acute myelogenous leukemia and a variety of antibodies conjugated with the fungal toxin maytansanoid (DM-1) in preclinical development and early clinical trials. The interest in radioimmunotherapy increased significantly in 2001 with the FDA approvals of the ^{90}Y-conjugated anti-CD20 antibody ^{90}Y-ibritumomab tiuxetan and the ^{131}I-conjugated anti-CD20 antibody ^{131}I-tositumomab. A variety of isotopes are under investigation in addition to ^{90}Y as potential conjugates for anticancer antibodies (Goldenberg, 2002). Radioimmunotherapy features the phenomenon of the bystander effect, in which if antigen expression is heterogeneous, extensive tumor cell killing can still take place, even on nonexpressing cells, but can also lead to significant toxicity when the neighboring cells are vital non-neoplastic tissues such as the bone marrow and liver.

Antibody Therapeutics for Hematologic Malignancies

The earliest and most successful clinical use of antibodies in oncology has been for the treatment of hematologic malignancies (Burke et al., 2002; Carter, 2001; Goldenberg, 2002; Linenberger et al., 2002; Reff et al., 2002; Ross et al., 2003b; Stevenson et al., 2002; Watkins and Ouwehand, 2000; Wiseman et al., 2002). By taking advantage of improved recombinant technologies generating more specific and higher affinity monoclonal antibodies with reduced immunogenicity after humanization or deimmunization and the emerging conjugation capabilities, antibody therapeutics have become a major weapon in the treatment of leukemias and lymphomas (Burke et al., 2002; Linenberger et al., 2002; Stevenson et al., 2002; Wiseman et al., 2002).

Rituximab (Rituxan®)

Approved in 1997, rituximab (Rituxan®) is arguably the most commercially successful anticancer drug of any type since the introduction of taxanes. Rituximab sales exceeded $ 700 million in sales in the United States in 2001 (Reichert, 2002). Targeting the CD20 surface receptor common to many B cell non-Hodgkin lymphoma subtypes, rituximab is a chimeric monoclonal IgG_1 antibody that induces apoptosis, antibody-dependent cell cytotoxicity, and complement-mediated cytotoxicity (Reff et al., 2002) and has achieved significantly improved disease-free survival rates compared with patients receiving cytotoxic agents alone (Dillman, 2001; Coiffier, 2002; Grillo-Lopez, 2002; Grillo-Lopez et al., 2002).

^{90}Y-ibritumomab Tiuxetan (Zevalin®)

^{90}Y-ibritumomab tiuxetan (Zevalin®) consists of the murine version of the anti-CD20 chimeric monoclonal antibody, rituximab, which has been covalently linked to the metal chelator, MD-DTPA, permitting stable binding of ^{111}In when used for radionucleotide tumor imaging and ^{90}Y when used to produce enhanced targeted cytotoxicity (Dillman, 2002; Gordon et al., 2002; Krasner and Joyce, 2001; Wagner et al., 2002). In early 2002, ^{90}Y-ibritumomab tiuxetan became the first radioconjugated antibody therapeutic for cancer approved by the FDA. Since its FDA approval, numerous patients who have received ^{90}Y-ibritumomab tiuxetan after becoming refractory to a rituximab-based regimen have achieved significant responses (Dillman, 2001; Gordon et al., 2002).

Gemtuzumab ozogamicin (Mylotarg®)

The approval of gemtuzumab ozogamicin (Mylotarg®) by the FDA in 2000 marked the first introduction of a plant toxin conjugated antibody therapeutic (Bross et al., 2001; Larson et al., 2002; Nabhan and Tallman, 2002; Sievers and Linenberger, 2001; Stadtmauer, 2002). Gemtuzumab ozogamicin is targeted against CD33, a surface marker expressed by 90% of myeloid leukemic blasts but absent from stem cells, armed with calicheamicin, a potent cytotoxic antibiotic that inhibits DNA synthesis and induces apoptosis (Stadtmauer, 2002). The current indication for use of gemtuzumab ozogamicin is in acute myelogenous leukemia patients older than 60 years with the recommendation that before the initiation of therapy, the leukemic blast count is below 30,000/mL (Bross et al., 2001; Nabhan and Tallman, 2002; Sievers and Linenberger, 2001).

Alemtuzumab (Campath®)

Alemtuzumab (Campath®), a humanized monoclonal antibody, was approved in mid-2001 for the treatment of B-cell chronic lymphocytic leukemia in patients who have been treated with alkylating agents and who have failed fludarabine therapy (Dumont, 2002; Pangalis et al., 2001).

Daclizumab (Zenapax®)

Daclizumab (Zenapax®) is a chimeric monoclonal antibody that targets the interleukin-2 receptor. This antibody is primarily used to prevent and treat patients with organ transplant rejection but has also been used in a wide variety of chronic inflammatory conditions, including psoriasis, multiple sclerosis, ulcerative colitis, asthma, type I diabetes mellitus, uveitis, and also in a variety of leukemias (Carswell et al., 2001, Kreitman et al., 1992).

^{131}I-tositumomab (Bexxar®)

^{131}I-tositumomab (Bexxar®) is a radiolabeled anti-CD20 murine monoclonal antibody approved in 2003 for the treatment of relapsed and refractory follicular/low grade and transformed non-Hodgkin lymphoma (Cheson, 2002; Zelenetz, 2003).

Antibody Therapeutics for Solid Tumors

Interest in the development of antibody therapeutics for solid tumors among many commercial organizations and universities has been significantly impacted by the technologic advances in antibody engineering and the approval and recent clinical and commercial success of trastuzumab, the only therapeutic antibody approved by the FDA for the treatment of solid tumors (edrecolomab is approved in Germany, but not in the United States).

Trastuzumab (Herceptin®)

Trastuzumab (Herceptin®) has been described above. During the 6 years since the FDA approval of trastuzumab, two additional antibodies have been approved for the treatment of solid tumors (cetuximab and bevacizumab). In addition, continuing progress has been made in this field, and there are a number of both late stage and early stage products in development which show substantial promise.

Cetuximab (Erbitux®)

The epidermal growth factor receptor (EGFR), also known as HER-1, is the target of two FDA-approved small molecule drugs (see below) and one FDA-approved antibody (Mendelsohn and Baselga, 2000). Cetuximab (Erbitux®) is a chimeric monoclonal antibody that binds to the EGFR with high affinity, blocking growth factor binding, receptor activation, and subsequent signal transduction events and leading to cell proliferation (Baselga, 2001). Cetuximab enhanced the antitumor effects of chemotherapy and radiotherapy in preclinical models by inhibiting cell proliferation, angiogenesis, and metastasis and by promoting apoptosis (Baselga, 2001). Cetuximab has been evaluated both alone and in combination with radiotherapy and various cytotoxic chemotherapeutic agents in a series of phase II/III studies that primarily treated patients with either head and neck or colorectal cancer (Baselga, 2001, Herbst and Langer, 2002). Breast cancer trials are also underway (Leonard et al., 2002). Although the FDA approval process for cetuximab was initially slowed because of concerns over clinical trial design and outcome data management (Reynolds, 2002), the antibody was approved for use in the treatment of advanced metastatic colorectal cancer in February 2004. Similar to trastuzumab, the development of cetuximab also included an immunohistochemical test for determining EGFR overexpression to define patient eligibility to receive the antibody (Wong, 2005). Thus, cetuximab has joined trastuzumab as an FDA-approved targeted therapy featuring an unconjugated antibody. However, there have been conflicting reports suggesting that the use of a pharmacodiagnostic test (EGFR immunostaining) is unnecessary for the selection of cetuximab in colorectal cancer therapy (Saltz, 2005). Recent clinical trials have found significant efficacy for cetuximab in the treatment of head and neck squamous cell cancers often in combination with radiation treatment (Harari and Huang, 2006).

Bevacizumab (Avastin®)

Bevacizumab (rhuMAb-VEGF) is a humanized murine monoclonal antibody targeting the vascular endothelial growth factor ligand (VEGF) approved by the FDA in 2004 for the front line or first line treatment in combination with chemotherapy of metatstatic colorectal cancer. VEGF regulates both vascular proliferation and permeability and functions as an antiapoptotic factor for newly formed blood vessels (Chen et al., 2000; Ferrara, 2005; Rosen, 2002). In addition to its approved indication in colorectal cancer, bevacizumab has shown promising efficacy in combination with cytotoxic drugs for the treatment of non-small cell lung cancer (Wakelee and Belani, 2005), renal cell carcinoma (Stadler, 2005), pancreatic cancer (Bruckner et al., 2005), breast cancer (de Gramont and Van Cutsem, 2005) and prostate cancer (Berry and Eisenberger, 2005). Unlike cetuximab, the development of bevacizumab has not included a diagnostic eligibility test. Neither direct measurement of VEGF expression in tumor, circulating VEGF levels in serum or urine or assessment of tumor microvessel density have been incorporated into the clinical trials or linked to the response rates to the antibody. To date a number of theories have been proposed as to the actual mechanism of action of bevacizumab and the relative contributions of direct anti-angiogenesis and other tumor vasculature stabilization and cytotoxic chemotherapy potentiation effects of the antibody (Blagosklonny, 2005; Hurwitz and Kabbinavar, 2005). In summary, currently used without an integrated diagnostic eligibility test, bevacizumab cannot be considered a true targeted therapy, and further development of this agent for use in prostatic, breast, lung, renal, and other cancers may will be inhibited by the inability to individually select patients who will be more likely to benefit from its use, either alone or in combination with other traditional cytotoxic drugs, antibodies and novel drugs.

Edrecolomab (Panorex®)

Edrecolomab is a murine IgG_{2A} monoclonal antibody that targets the human tumor-associated antigen Ep-CAM (17-1A). Edrecolomab has been approved in Europe (Germany) since 1995 to date has not been approved by the FDA. In a study of 189 patients with resected stage III colorectal cancer, treatment with edrecolomab resulted in a 32% increase in overall survival compared with no treatment ($P < 0.01$) (Schwartzberg, 2001). Edrecolomab's antitumor effects are mediated through antibody-dependent cellular cytotoxicity, complement-mediated cytolysis, and the induction of an antiidiotypic network (Haller, 2001). Edrecolomab is also currently being tested in large multicenter adjuvant phase III studies in stage II/III rectal cancer and stage II colon cancer. Edrecolomab was well tolerated when used as monotherapy and added little to chemotherapy-related side effects when used in combination. Sequential treatment of patients with metastatic breast cancer with edrecolomab after adjuvant chemotherapy reduced levels of disseminated tumor cells in the bone marrow and eliminated Ep-CAM-positive micrometastases (Kirchner et al., 2002).

huJ-591 (Anti-$PSMA_{EXT}$)

Prostate-specific membrane antigen (PSMA) is a membrane-bound glycoprotein restricted to normal prostatic epithelial cells, prostate cancer, and the endothelium of the neovasculature of a wide variety of non-prostatic carcinomas and other solid tumors (Figure 42.2) (Israeli et al., 1994; Liu et al., 1997; Ross, 2005). PSMA expression per cell progressively increases in primary prostate cancer, metastatic hormone sensitive prostate cancer, and hormone refractory metastatic disease. PSMA expression is

increased further in association with clinically advanced prostatic cancer, particularly in hormone refractory disease, and appears to be an ideal molecule for use in targeting prostatic cancer cells. Increasing expression levels of PSMA in resected primary prostate cancer is associated with increased rates of subsequent disease recurrence (Ross et al., 2003c). Humanized and fully human antibodies specific for the extracellular domain of PSMA have been developed. A phase I clinical trial of one these antibodies, huJ591 conjugated with ^{90}Y, has yielded promising results (Milowsky et al., 2004). Programs using toxin conjugates with anti-PSMA antibodies have completed preclinical development (Fracasso et al., 2002) and are currently showing promising results in early stage clinical trials for hormone-refractory advanced metastatic prostate cancer (Milowsky et al., 2005). Finally, antibodies to PSMA have been used as diagnostic imaging agents (Figure 42.2), including the commercially available Prostascint® Freeman et al., 2002).

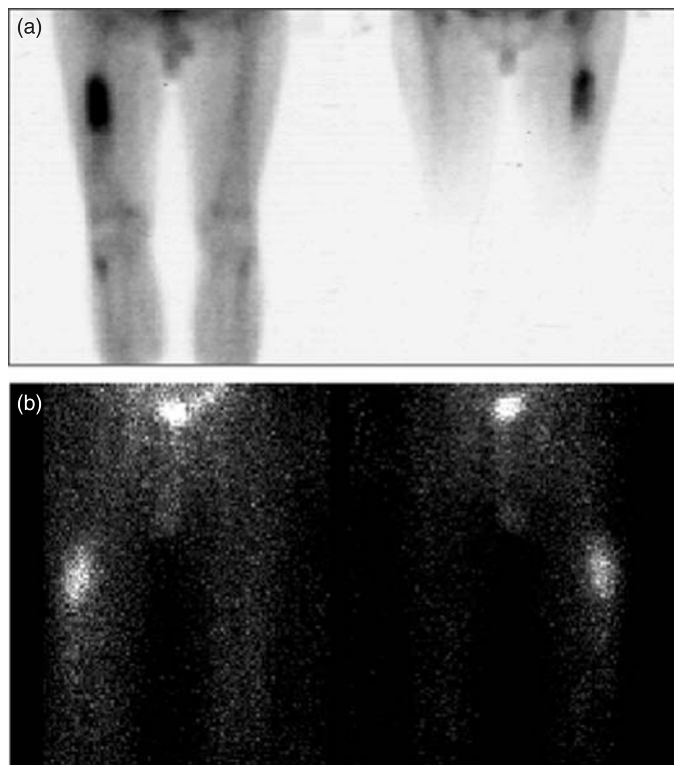

Figure 42.2 PSMA expression in non-prostate cancer. (a) Traditional bone scan demonstrating bilateral activity in the femur indirectly indicating the presence of metastatic renal cell carcinoma. (b) ^{111}I-huJ591$_{EXT}$ diagnostic immunoscintiscan of the same patient showing direct localization of the anti-PSMA antibody conjugate to the sites of metastatic renal cell carcinoma that feature PSMA expression in the tumor neovasculature. SELECTED TARGETED ANTICANCER THERAPIES USING SMALL MOLECULES

Table 42.4 lists selected small molecule drugs designed to target specific genetic events and biologic pathways critical to cancer growth, invasion, and metastasis.

Targeted Small Molecule Drugs for Hematologic Malignancies

ATRA

Arguably the first truly targeted therapy after the development of hormonal therapy for breast cancer was the development of ATRA for the treatment of acute promyelocytic leukemia, a subset of acute nonlymphocytic leukemia featuring a disease-defining retinoic acid receptor activating t(15:17) reciprocal translocation (Fang et al., 2002; Parmar and Tallman, 2003). For these selected patients, direct targeting of the retinoic acid receptor with ATRA has resulted in very high response rates, delay in disease progression, and long-term cures for these patients (Fang et al., 2002; Parmar and Tallman, 2003).

Imatinib (Gleevec®)

The development of imatinib for patients with chronic myelogenous leukemia in 2001 ushered in a new excitement both in the scientific and public communities for targeted anticancer therapy. Imatinib received fast-track approval by the FDA as an ATP-competitive selective inhibitor of *bcr-abl* and has unprecedented efficacy for the treatment of early stage chronic myelogenous leukemia typically achieving durable complete hematologic and complete cytogenetic remissions, with minimal toxicity (Druker, 2003; Goldman and Melo, 2003; O'Brien et al., 2003). Imatinib is a true targeted therapy for leukemia in that a test for the *bcr/abl* translocation must be performed before a patient will be considered as eligible to receive the drug. The prediction of resistance to imatinib in early phase Chronic Myeloid Leukemia (CML) has been the subject of numerous studies (Lange et al., 2005; O'hare et al., 2005). It is the current goal to predict resistance emergence with gene mutation testing and employ novel tyrosine kinase inhibitors to attempt to overcome blast cells that have lost the ability to bind imatinib to the ATP binding pocket of the fusion gene (Lange et al., 2005; O'hare et al., 2005).

Imatinib has also achieved regulatory approval for the treatment of relapsed and metastatic GISTs, which characteristically feature an activating point mutation in the c-*kit* receptor tyrosine kinase gene (von Mehren, 2003). For GISTs, the response to imatinib treatment appears to be predictable based on the location of the c-*kit* mutation (Verweij et al., 2003). The use of imatinib in GIST is also an example of targeted therapy as a measurement of c-*kit* expression usually performed by IHC, required to confirm the diagnosis and render the patient eligible for treatment. Interestingly, most commercially available

TABLE 42.4 Selected small molecule dugs designed to target specific genetic events and biologic pathways critical to cancer growth and progression

Target	Drug	Source	Clinical development status	Comment
PML-RAR-α in PML	ATRA	Promega	Approved	First true targeted therapy since the introduction of ER testing and hormonal therapy for breast cancer
Bcr/abl in CML	Imatinib	Novartis	Approved	Has emerged as standard of care for early stage CML
c-Kit in GIST PDGF-α	Imatinib	Novartis	Approved	Responses in relapsed/metastatic GIST can be predicted by the location of the activating *c-kit* mutation
Flt-3 in AML	SU5416 PKC412 MLN-518	Pfizer Novartis Millennium	Early Stage Clinical Trials	Small molecule drugs that target the *flt-3* internal tandem duplication seen in 30% of AML
EGFR in NSCLC	Gefitinib	Astra Zeneca	Approved/withdrawn	No survival benefit. Returned to clinical trials.
EGFR in NSCLC and pancreatic cancer	Erlotinib	Genentech/OSI	Approved	Survival benefit demonstrated. No diagnostic test current used to select patients.
Anti-angiogenesis in renal cell carcinoma	BAY 43-9006	Bayer	Approved	Raf kinase inhibitor also targets PDGFR and VEGFR.
Anti-angiogenesis in Myelodysplastic Syndrome	Lenolidamide	Celgene	Approved	Also in clinical trials for the treatment of multiple myeloma
Other anti-angiogenesis	Thalidomide Sunitinib	Celgene Pfizer/Sugen	Approved Approved	Multiple myeloma Gastrointestinal tumor
Bcl-2	G3135	Genta	Pending	Anti-sense oligonucleotide targets the anti-apoptotic gene, *bcl-2*
Proteasome in multiple myeloma	Bortezomib	Millennium	Approved	Proteasome inhibition effective in hematologic malignancies, but of uncertain potential for the treatment of solid tumors

Adapted from Ross, J.S. and Hortobagyi, G.H. eds. *The Molecular Oncology of Breast Cancer*. Jones and Bartlett, Inc., Sudbury, MA with permission by the publisher.

antibodies for *c-kit* recognize the total *c-kit* and do not distinguish the activated or phosphorylated version, which is the actual target of imatinib. Currently, the high treatment failure rate is directly linked to the test used to characterize the patients. It is anticipated that either the use of specific antibodies designed to identify the activated *c-kit* gene or directed sequencing of the *c-kit* gene may be required before imatinib is prescribed for patients with recurrent or metastatic GIST. An alternative to *c-kit* mutation testing for the prediction of resistance to imatinib, functional imaging after initial dosing of the drugs has been employed for patients with metastatic GIST (Heinicke et al., 2005). In early 2006, the anti-angiogenesis agent sunitinib was approved by the FDA for the treatment of advanced GIST that has become resistant to imatinib therapy.

Flt-3 Targeted Therapy

In approximately 30% of cases of acute myelogenous leukemia and less frequently in other forms of leukemia, a *flt-3* gene mutation creates an internal tandem duplication that creates an abnormal FLT3 receptor that promotes the growth and survival of the leukemic cells (Advani, 2005; Gilliland and Griffin, 2002; Kelly et al., 2002; Sawyers, 2002). Three small molecule compounds are in clinical trials for the treatment of acute myelogenous leukemia by targeting the *flt-3* internal tandem duplication. These drugs are also examples of potential true targeted therapies in that a test for detecting an internal tandem duplication that causes the *flt-3* gene activation will likely be required and incorporated into the FDA drug approval label should these agents be successful in future clinical trials.

Targeted Small Molecule Drugs for Solid Tumors

Gefitinib (Iressa®)

Gefitinib was originally approved by the FDA in 2003 as a monotherapy for the treatment of patients with locally advanced or metastatic non-small cell lung cancer after failure of both platinum based and docetaxel chemotherapies (Ranson, 2002; Schiller, 2003). Gefitinib is a small molecule drug that targets the EGFR. In contrast with the approval of trastuzumab, this approval of gefitinib did not include an eligibility requirement reference to a specific tumor diagnostic test designed to select patients that were more likely to respond to the drug. Overexpression of EGFR typically identified by IHC is extremely common in both lung and breast cancers (Campiglio et al., 2004; Ranson, 2002; Schiller, 2003), but in contrast with HER-2 overexpression, which is virtually limited to cases with gene amplification, multiple mechanisms of dysregulation of EGFR and associated activation of signaling pathways have been described for both of these tumors (Campiglio et al., 2004; Ranson, 2002; Schiller, 2003). Thus, it has been difficult to develop this drug for expanded indications or combination therapies in the absence of a well-defined efficacy test. However, more recently, two independent groups reported their similar discovery of a specific activating mutation in the tyrosine kinase domain of the EGFR receptor that was associated with a high response of patients with non-small cell lung cancer to gefitinib (Lynch et al., 2004; Paez et al., 2004). Of interest have been the consistent observations that both a bronchioloalveolar histology and a persistent skin rash have been the best clinical signals of gefitinib response in lung cancer (Dudek et al., 2005). In addition, although specific activating mutations in the EGFR gene have been reproduced in a number of studies (Chan et al., 2006), some studies have failed to demonstrate this association and other biomarkers including EGFR gene amplification have also been found to be predictive of tumor response (Carbone, 2004; Kobayashi et al., 2005). Most recently, follow-on studies of gefitinib in lung revealed that the increased response rates that led to the approval of the drug were not accompanied by a clinical survival advantage (Twombly, 2005). This has led to a current withdrawal of the drug while further research and clinical trials are performed. It is possible the gefitinib will reappear on the market for the treatment of lung cancer with an integrated diagnostic test designed to boost the response rates by limiting the treatment to tumors with specific histologic and molecular features.

Erlotinib (Tarceva®)

Erlotinib is another targeted small molecule inhibitor of EGFR that was approved by the FDA in 2005 for the treatment of non-small cell lung cancer and pancreatic cancer (Moore, 2005; Smith, 2005). To date, similar to gefitinib, the clinical trials and FDA approval for erlotinib have not included an assessment of the EGFR status or other diagnostic test for eligibility to receive the drug. In lung cancer the predictors of tumor response including skin rash and brochioloalveolar histology have also applied to erlotinib as have the somewhat conflicting associations of both activating EGFR mutations and EGFR gene amplification as predictors of drug response (Chan et al., 2006; Silvestri and Rivera, 2005). Clinical trials have demonstrated that erlotinib does add a survival benefit to the treatment of both lung and pancreatic cancers and the drug remains on the market currently without an integrated diagnostic eligibility test.

BAY 43-9006 (Sorafenib®)

BAY 43-9006 is a RAF kinase inhibitor that also inhibits the VEGFR and PDGFR growth factor receptors. It is thus considered to be an anti-angiogenesis drug. This oral agent was approved in late 2005 by the FDA for the treatment of metastatic renal cell carcinoma (Staehler et al., 2005). Currently, there are no diagnostic tests associated with the selection of this agent and clinical trials for other types of cancer are on-going.

Other Small Molecule Antiangiogenesis Agents (SU5416, Thalidomide [Thalomid®], Lenalidamide [Revlimid®], Endostatin/Angiostatin, and Marimastat)

A variety of small molecule drugs are currently in clinical trials for the treatment of solid tumors that target the establishment and growth of tumor blood vessels (Khalil et al., 2003; Mendel et al., 2000; Thomas and Kantarjian, 2000; Zogakis and Libutti, 2001). Additional compounds that target matrix metalloproteases, such as the drug marimastat, are also considered to be angiogenesis

inhibitors (Brown, 2000; Dell'Eva et al., 2002; Miller et al., 2002). The anti-angiogenesis drug, lenalidomide (Revlimid®) was approved by the FDA in late 2005 for the treatment of myelodysplastic syndrome (List, 2005). To date, none of these compounds has a linked diagnostic test such as tumor microvessel density or the expression of an angiogenesis promoting gene or protein in their clinical development plans.

G3139 (Genasense®)

Another strategy in anticancer therapy is the targeting of chemotherapy resistance by overcoming the antiapoptosis mechanisms of cancer cells. An example of this approach is the novel antisense oligonucleotide G3139, which targets the antiapoptotic gene *bcl-2* (Tamm et al., 2001; Tolcher, 2002). This agent has been the most widely tested antisense therapy and has been mostly focused in hematologic malignancies (Stein et al., 2005).

Bortezomib (Velcade®)

Recently, drugs targeting the proteasome have been developed that are designed to impact downstream pathways regulating angiogenesis, tumor growth, adhesion, and resistance to apoptosis (Adams, 2002; Elliott and Ross, 2001). One of these agents, bortezomib (PS-341), has recently been approved for the treatment of advanced refractory multiple myeloma (Richardson et al., 2003). Bortezomib has shown both preclinical activity in animal studies and biologic activity in early clinical trials involving patients with a variety of solid tumors, but, to date, no trials using this agent alone or in combination with other drugs has progressed to Phase III. Although pharmacogenomic studies of bortezomib use in multiple myeloma have been conducted, to date, no specific pattern of gene expression or other specific test has emerged that could be a guide to the selection of patients for treatment.

2009 UPDATE

In the past year, targeted therapies featuring combinations of drugs and diagnostics tests have become the standard of care in several approved indications. The resulting high level of uptake, coupled with their premium prices, make targeted therapies the leading therapy class in the oncology market with, according to Datamonitor, global sales growing at a near 33% rate and reaching $17.3 billion in 2007. A number of targeted therapy cancer brands have achieved blockbuster sales and have become important sources of revenue for some of the leading pharmaceutical and biotech companies such as Roche, Genentech, and Novartis. Of note has been the introduction of the anti-HER1/2 tyrosine kinase inhibitor lapatinib in HER2 positive breast cancer; additional indications for use of the antibody therapeutic Trastuzumab in earlier stages of the disease; expansion in the use of the tyrosine kinase inhibitors Gleevec and Dasatinib in chronic myelogenous leukemia; additional indications for use of the anti-EGFR antibody therapies Erbitux and Panitumab; expansion of use of the anti-VEGF ligand antibody Bevacizumab in multiple solid tumors including colon, lung, and breast cancers; and the clinical use of small molecule antiangiogenesis inhibitors such as Sunitinib and Sorafenib (Dy and Adjei, 2008).

During the last year, several significant developments in the clinical management of breast and colorectal cancer featured further refinements in the use of integrated diagnostics. In breast cancer, continued improvement in HER2 test accuracy has been achieved with the widespread adoption of the ASCO-CAP HER2 testing guidelines (Wolff et al., 2007). There has also been continued interest in the preliminary results from HER2 testing of circulating tumor cells, suggesting that HER2-negative primary tumors may evolve into HER2-positive metastatic disease more often than previously believed (Ignatiatis et al., 2008). Finally, testing was reported for the 2D6 haplotype in the cytochrome P450 gene as a means of predicting the failure of a subset of estrogen receptor positive breast cancer patients to activate and subsequently respond to the antiestrogen receptor drug, tamoxifen (Jin et al., 2005).

In colorectal cancer, clinical trial-based data indicated that the presence of a mutation in the K-*ras* oncogene predicted resistance to the anti-EGFR antibody therapeutics Erbitux and Panitumab independent of the original tumor EGFR protein expression, gene copy number, or presence of gene sequence mutations (Karapetis et al., 2008). Widespread testing of colorectal cancer for K-*ras* mutations has now commenced, and it is anticipated that this will also be applied to newly diagnosed non-small cell lung cancers as well.

CHAPTER

Genomics in the Evaluation and Management of Rheumatoid Arthritis

Robert M. Plenge and Michael E. Weinblatt

INTRODUCTION

Rheumatoid arthritis (RA) is a systemic, chronic inflammatory disorder whose root cause is unclear. The clinical hallmark of RA is an inflammatory arthritis with a predilection for specific diarthrodial (freely movable) joints. It is the most common form of inflammatory arthritis, with an estimated prevalence of up to ~1% in the adult population. Females are at greater risk than males for developing the disease, with a female:male ratio of ~2.5:1. While the disease can occur at any age, the peak age on onset is in the 40s, with an increasing incident with age.

As with many complex diseases – those influenced by multiple genes and environmental exposures – there is substantial clinical heterogeneity. The clinical features of new-onset RA are highlighted in Table 43.1. With longstanding disease, articular erosions and joint deformities occur. Autoantibodies (RF and CCP) have important diagnostic and prognostic features, and have proven very useful in clinical management of RA. Most efforts aimed at understanding the molecular basis of RA have focused of genetic studies of disease susceptibility. To date, there are only two genes that have been convincingly demonstrated to influence risk of RA (*PTPN22* and *HLA-DRB1*), although only a small fraction of the genome has been adequately interrogated using available molecular genetic techniques. Other genomic technologies such as large-scale expression and proteomic profiling in RA are less mature, but offer promise in understanding disease etiology.

"Genomic medicine" – translating genomic information into prediction of disease susceptibility, characterization of gene–environment interactions, identification of new therapeutic targets, and development of novel gene-based diagnostics – has had very little impact thus for on the clinical management of patients with RA. The association of susceptibility to *HLA-DRB1*

TABLE 43.1 Common clinical features of new-onset rheumatoid arthritis

Symptoms

- Joint swelling
- Pain/stiffness (commonly in morning and lasting >1 h)
- Fatigue
- Malaise

Articular characteristics

- Palpation tenderness
- Synovial thickening
- Effusion
- Erythema

Distribution

- Symmetrical
- Distal (e.g., hands and feet) more commonly than proximal (e.g., spine)
- PIP, MCP/MTP, wrist/ankle more commonly than elbow/knee, shoulder/hip

PIP = proximal interphalangeal joint, MCP = metacarpophalangeal joint, MTP = metatarsophalangeal joint.

alleles has been known since the 1970s, yet has not translated into novel diagnostics or therapeutic treatments. The most remarkable advancement in the clinical management of RA, which emerged from intense basic science research, is the development of inhibitors of an important cytokine, tumor necrosis factor-alpha (TNFα). Advances in genomic medicine hope to parallel the success of TNFα-inhibitors, thus leading to improved patient care for this debilitating disease.

PREDISPOSITION

Despite decades of research, the root cause of RA is unclear (Firestein, 2003). Genes and environment together contribute to development of RA, although only two genes (*PTPN22* and *HLA-DRB1*), and one environmental factor (smoking), have been associated with RA susceptibility across multiple, independent studies. Antibodies directed against cyclic citrullinated peptides (anti-CCP antibodies) have emerged as a specific marker for RA. That anti-CCP antibodies predate the diagnosis of RA by years suggests that these autoantibodies are pathogenic rather than simply a marker of chronic inflammation. Together, these risk factors suggest a hypothetical model that an environment trigger (e.g., smoking) invokes a generalized inflammatory response in genetically susceptible hosts, which leads to the formation of autoantibodies and eventually RA.

Genetic Basis of RA

The genetic contribution to RA susceptibility in humans has been demonstrated through twin studies (MacGregor et al., 2000), family studies (Bali et al., 1999), and genome-wide linkage scans (Amos et al., 2006; Cornelis et al., 1998; Etzel et al., 2006; Jawaheer et al., 2001, 2003; MacKay et al., 2002; Shiozawa et al., 1998). Heritability refers to the amount of phenotypic variation due to additive genetic factors, rather than common environmental factors, stochastic variation, gene–environment interactions, and gene–gene interactions. One such study demonstrated that approximately 60% of disease variability is inherited (MacGregor et al., 2000). Another measure of genetic contribution to disease activity is to compare prevalence of disease in family members compared to the general population. Whereas the population risk of RA is ~1%, the monozygotic (MZ) twin of a patient with RA has a risk of ~15% (Aho et al., 1986; Jarvinen and Aho, 1994; Silman et al., 1993). Moreover, the relative risk (RR) to the sibling of a proband with RA is ~5 for RA (Deighton et al., 1989; Hasstedt et al., 1994; Wolfe et al., 1988), although the number varies depending on the population studied (Jawaheer et al., 2001).

The MHC-Region and HLA-DRB1 Susceptibility Alleles

The major histocompatibility complex (MHC) region spans ~3.6 megabases (Mb) on the short arm of human chromosome 6, and contains hundreds of genes, including many involved in immune function (Horton et al., 2004; Stewart et al., 2004). It has been estimated that the MHC-region of the human genome accounts for approximately one-third of the overall genetic component of RA risk (Deighton et al., 1989; Rigby et al., 1991). Genome-wide linkage scans using both microsatellite (Cornelis et al., 1998; Jawaheer et al., 2001; MacKay et al., 2002; Shiozawa et al., 1998) and single nucleotide polymorphism (SNP) markers (Amos et al., 2006) have identified consistently this region as important in RA pathogenesis. These genome-wide scans have demonstrated that the MHC region has the largest genetic contribution in RA, and the relative contribution of MHC genes (λMHC) was found to be ~1.75 (Cornelis et al., 1998; Jawaheer et al., 2001).

Much, but probably not all, of the risk attributable to the MHC-region is associated with alleles within the *HLA-DRB1* gene. An association between RA and the Class II HLA proteins was first noted in the 1970s, when the mixed lymphocyte culture (MCL) type Dw4 (related to the serological subtype DR4) was observed to be more common among patients with RA compared to controls (Stastny, 1978; Stastny and Fink, 1977). Subsequently, investigation of the molecular diversity of Class II proteins (subunits of HLA-DR, -DQ and -DP) localized the serological Dw4 subtype to the *HLA-DRB1* gene (Gregersen et al., 1986a, b). When the susceptible DR subtypes were considered as a group, Gregersen et al., noted a shared amino acid (a.a.) sequence at positions 70–74 of the HLA-DRB1 protein (Gregersen et al., 1987). These residues are important in peptide binding, and thus it was hypothesized that RA-associated alleles bind specific peptides, which in turn facilitates the development of auto-reactive T cells. These alleles are now known collectively as "shared epitope" alleles due to the related sequence composition in the third hypervariable region (Table 43.2): the susceptibility alleles result in missense a.a. changes, where the shared susceptibility a.a. motif is ^{70}Q/R-K/R-R-A-A^{74}.

The *HLA-DRB1* gene encodes for a protein that is part of MHC Class II molecules. These molecules, heterodimers of alpha and beta proteins, are found on professional antigen-presenting cells (APCs), and display peptides derived from extracellular proteins to CD4+ T cells (T "helper" cells). The genes that encode the Class II molecules are found in three subregions (DR, DQ, and DP) spanning ~1 Mb within the MHC region. Within the DR subregion, one alpha- and three beta-chain genes have been described; the a-chain gene and two beta-chain genes, DRB1 and DRB2, are clearly expressed. The DQ subregion contains two sets of alpha and beta-chain genes, DX and DQ-alpha and beta. With the exception of DR-alpha, all of the expressed genes display considerable allelic diversity. Classification of HLA-DRB1 molecules includes serological nomenclature (e.g., DR1, DR4, and DR10), MCL nomenclature (e.g., Dw4) and DNA-sequence based nomenclature (see below).

Since the initial observation, a large number of population studies have confirmed the association between RA and allelic variants at *HLA-DRB1* (Ollier and Thomson, 1992). At the level of DNA, the most common (>5% population frequency) *HLA-DRB1* shared epitope susceptibility alleles include *0101,

TABLE 43.2 RA HLA-DRB1 "shared epitope" alleles

Genes associated with RA HLA-DRB1"shared epitope" alleles are classified by amino acid (a.a.) sequence at positions 70–74. The consensus a.a. sequence (QRRAA) is shown at the top; the identical a.a. is indicated by a dash (-) and variable a.a. indicated by appropriate nomenclature. Alleles in bold are associated with RA susceptibility.

*0401, and *0404 in individuals of European ancestry, and *0405 and *0901 in individuals of Asian ancestry; less common shared epitope alleles include *0102, *0104, *0408, *0413, *0416, *1001, and *1402. Of note, the *0901 allele observed among Asian populations does not strictly conform to the SE a.a. sequence motif (^{70}R-R-R-A-E^{74}, see Table 43.3), and the classic SE alleles may not contribute to risk in African-American and Hispanic-American RA populations (McDaniel et al., 1995; Teller et al., 1996). Thus, additional exploration of the molecular basis of *HLA-DRB1* susceptibility alleles is needed in the future.

While *HLA-DRB1* susceptibility alleles are often considered as a group, the strength of the genetic association to RA susceptibility differs across the *DRB1* alleles. There are at least two classes of *HLA-DRB1* risk alleles (high and moderate). In general, DRB1*0401 and *0405 alleles exhibit a high level or risk, with a RR of approximately 3. The DRB1*0101, *0404, *0901, and *1001 alleles exhibit a more moderate RR in the range of 1.5.

It is becoming increasingly clear that *HLA-DRB1* shared epitope alleles only influence the development of seropositive RA, and more specifically anti-CCP+ RA (see below for discussion on autoantibodies) (Huizinga et al., 2005; Irigoyen et al., 2005). Collectively, the shared epitope alleles have an odds ratio (OR) of over 5 if CCP+ RA patients are compared to matched healthy controls. Because these alleles are quite common in the general population (collectively, allele frequency ~40% in individuals of European ancestry), the attributable risk for SE alleles is quite high.

Several investigators have proposed a refined classification of shared epitope alleles, as this hypothesis alone cannot explain all of the genetic risk attributable to the *HLA-DRB1* locus (de Vries et al., 2002; Gao et al., 1991; Michou et al., 2006; Zanelli et al., 1998). No consensus has emerged, however. Some of these studies suggest that a protective allele may be in linkage disequilibrium with the *HLA-DRB1* alleles. It has been hypothesized that the presence of an asparagine amino acid at position 70 of the HLA-DRB1 protein (D70) may be associated with protection from the development of RA (once the effect of the shared epitope alleles has been taking into consideration) (Mattey et al., 2001a; Ruiz-Morales et al., 2004).

Numerous studies have shown that *HLA-DRB1* susceptibility alleles influence disease severity in longstanding disease, particularly the development of bony erosions (e.g., Chen et al., 2002; Gorman et al. 2004; Moxley and Cohen, 2002). More recently, however, it has been suggested that this association is primarily due to the presence of CCP autoantibodies (Huizinga et al., 2005). It remains to be determined whether *HLA-DRB1* alleles contribute additional risk of developing erosive disease independent of CCP autoantibodies (van der Helm-van Mil et al., 2006). This more recent observation may be an important explanation for why some studies have demonstrated that SE alleles predict erosive changes, but only in RF- patients (El-Gabalawy et al., 1999; Mattey et al., 2001b). One hypothesis to explain this observation is that RF- patients in these older studies are actually CCP+ [and it is known that SE alleles have a stronger association with CCP+ than RF+ RA (Irigoyen et al., 2005)]. In

TABLE 43.3 Non-MHC associations in RA

Gene	OR	Comments
PTPN22	1.75	Clear association with missense SNP (rs2476601) and CCP+ RA
CTLA4	1.20	Possible association with CT60 SNP (rs3087243) and RA
PADI4	1.20	Possible association with haplotype tagged by SNP (rs2240340) and RA
SLC22A4	1.25	Possible association with SNP (rs2073838) and RA

the future, it will be important to assess the relationship between *HLA-DRB1* alleles and clinical outcome, controlling for the effect of CCP as well as other important clinical variables.

Despite decades of research, it is not fully known how the *HLA-DRB1* alleles cause risk of RA, and direct functional proof has been difficult (Goronzy and Weyand, 1993; Nepom, 2001). Hypotheses include that the SE alleles influence (1) thresholds for T-cell activation [based on avidity between the T-cell receptor, MHC, and peptide, especially in the context of post-translational modification events important in RA pathogenesis (Hill et al., 2003)]; (2) thymic selection of high-affinity self-reactive T cells (based on the T-cell synovial repertoire) (Yang et al., 1999); and (3) molecular mimicry of microbial antigens (Albani et al., 1992). It is worthwhile noting that the third hypervariable region of the protein (location of SE allelic variants) contains a peptide-binding groove that serves to present peptides to CD4+ T cells (Seyfried et al., 1988), and that citrullination of certain peptides triggers a strong immune response to citrullinated peptides in *HLA-DRB1* *0401 transgenic mice (Hill et al., 2003).

Other MHC-Region Genes

Several studies suggest that additional genes within the MHC likely contribute to disease susceptibility, once the effect of *HLA-DRB1* has been taken into consideration (Jawaheer et al., 2002; Kochi et al., 2004; Mulcahy et al., 1996; Singal et al., 1999; Zanelli et al., 2001). For example, an extended haplotype that includes *HLA-DRB1* DR3 alleles may be associated with RA (Jawaheer et al., 2002). The associated haplotype spans ~500 kb, and contains Class III MHC genes, including the TNF-alpha region implicated in other studies (Mulcahy et al., 1996; Ota et al., 2001; Waldron-Lynch et al., 2001). One study suggests that this association is restricted to CCP- patients (Irigoyen et al., 2005).

No single study has tested comprehensively DNA variants within the MHC in a patient population large enough to detect subtle effects beyond *HLA-DRB1* alleles. Only recently have genetic linkage disequilibrium maps become available to thoroughly test the hypothesis that non-*HLA-DRB1* alleles influence the risk of developing RA (Miretti et al., 2005; Walsh et al., 2003). Application of high-density SNP genotyping in large patient collections should provide additional insight into the role of the MHC region in susceptibility and severity of RA.

Non-MHC Genes

The identity of genes contributing to RA that lie outside the MHC region has been more elusive. A sizeable portion of genetic variation is attributable to such non-HLA genes – up to two-thirds in some studies. The gene with the most convincing evidence of replication, *PTPN22*, influences threshold of T-cell activation (Begovich et al., 2004; Vang et al., 2005). The statistical evidence of association for other genes (e.g., *CTLA4*, *PADI4*, and *SLC22A4*) is not yet conclusive, and therefore it is not possible to draw broader conclusions on functional classification of genes associated with RA beyond *HLA-DRB1* and *PTPN22* (which implicate class II presentation and T-cell activation).

The most convincing non-HLA gene associated with RA is *PTPN22* (Begovich et al., 2004), a finding that has been replicated across multiple independent studies (e.g., Dieude et al., 2005; Harrison et al., 2006; Hinks et al., 2005; Lee et al., 2005; Orozco et al., 2005; Plenge et al., 2005; Steer et al., 2005; Viken et al., 2005; Zhernakova et al., 2005). The susceptibility allele is a missense variant that changes an arginine to tryptophan amino acid (R620W), resulting in alteration of T-cell activation (Begovich et al., 2004; Vang et al., 2005). The magnitude of the genetic effect, as measured by the OR, is substantially less than for HLA-DRB1*0401 but similar to other SE alleles (*PTPN22* OR ~1.75). Interestingly, this allele is absent in East Asians, and thus not associated with susceptibility in Japanese populations (Ikari et al., 2006).

Extensive genotype-phenotype correlations have not been conducted for *PTPN22* (as they have for *HLA-DRB1*). Like *HLA-DRB1* alleles, *PTPN22* only associates with seropositive RA. There is some evidence that *PTPN22* influences age of onset (Plenge et al., 2005), and may have a more significant effect in males compared to females (Pierer et al. 2006; Plenge et al., 2005), but no evidence that it influences disease activity or radiographic erosions (Harrison et al., 2006; Wesoly et al., 2005).

Additional genes have been implicated in genetic association studies of RA, but have not yet reached the level of statistical significance required to solidify their position as true RA-susceptibility genes (see Table 43.3). Some encouraging candidate genes include *CTLA4*, *PADI4*, and *SLC22A4*.

1. The association between variants with *CTLA4* and susceptibility to autoimmunity is most convincing in type 1 diabetes and autoimmune thyroiditis (Ueda et al., 2003). CTLA4 is a negative regulator of T-cell activation. In these diseases, an allele in the 3′ untranslated region (UTR) of the gene causes a modest increase in disease risk (OR ~1.2–1.5). Several studies have extended these findings to RA (Lei et al., 2005; Plenge et al., 2005), where the magnitude of the genetic effect is again modest (~1.20).
2. *PADI4* encodes for an enzyme that post-translationally modifies arginine to citrulline, and may therefore be important in generating anti-CCP autoantibodies. An initial report in Japanese patients implicated a common variant (population allele frequency ~35%) in disease risk (Suzuki et al., 2003); subsequent reports have been less convincing

statistically, but nonetheless support an association with RA susceptibility (Iwamoto et al., 2006).

3. Finally, a common allele within the *SLC22A4* gene may be associated with RA susceptibility in East Asian populations (Tokuhiro et al., 2003), but this result has not been replicated in RA patients of European ancestry (Plenge et al., 2005). The protein product of *SLC22A4* is an organic cation transporter expressed in hematological and immunological tissues. Of note, the putative causal allele, which disrupts a RUNX1-binding site, is at reduced population frequency in RA patients of European ancestry compared to East Asian ancestry (0.08 versus 0.30 minor allele frequency), thus limiting power to detect an association in RA patients with European ancestry.

Candidate gene studies in RA, as with many other complex diseases, highlight the current challenge of genetic association studies (Plenge and Rioux, 2006). First, most studies to date have tested a small fraction of genetic variation in the human genome. It is estimated that over 10 million common variants (population allele frequency >1%) exist in the human genome, yet most studies test a vanishingly small fraction of these variants. Second, the expected genetic effect for most disease alleles is quite modest (OR <1.5). Therefore, thousands of patients are required to detect the genetic effect – and most studies have been conducted on far fewer, limiting power to detect a true positive association.

In the immediate future, genome-wide association studies, which test the majority of common genetic variants in the human genome, will be conducted in RA and other autoimmune diseases. If appropriately designed and interpreted (Hirschhorn and Daly, 2005), it is expected that these studies will greatly expand the list of RA-susceptibility genes. Several genome-wide association studies are underway with genotyping platforms that capture >60% of common genetic variants (as estimated by Phase II HapMap).

Non-Genetic Risk Factors

Sex Bias and Hormonal Factors

Perhaps the strongest non-genetic risk factor for the development of RA is female sex: females are more than twice as likely to develop RA compared to males, and this disparity is even greater at a younger age (Linos et al., 1980; Symmons et al., 1994). In females, the risk of developing RA increases with age and peaks around the time of menopause (Doran et al., 2002; Goemaere et al., 1990; Karlson et al., 2004). These observations have lead to considerable effort in examining the role of hormonal and pregnancy factors in disease occurrence. These studies include:

1. Conditions associated with excess estrogen and/or progesterone may be protective against developing RA. The risk of developing RA is increased in the 12-month postpartum period (when serum hormone levels fall) (Silman et al., 1992), and symptoms are less severe during the post-ovulatory phase of the menstrual cycle and during pregnancy (when levels are elevated) (Latman, 1983; Ostensen et al., 1983).
2. Duration of breast-feeding may be associated with risk of developing RA. Women with >24 total months of breast-feeding have a twofold reduced risk of developing RA (Karlson et al., 2004).
3. Cross-sectional studies of serum androgen levels consistently demonstrate lower serum testosterone levels in RA patients (Cutolo and Accardo, 1991; Masi et al., 1995).
4. The hypothalamic-pituitary axis (HPA) is altered in RA patients (Chikanza et al., 1992), and conditions leading to panhypopituitarism and hypoadrenalism are associated with the onset of RA (Wilder, 1996).
5. Castration of female mice exaggerates arthritis (Holmdahl et al., 1986), and estrogen replacement therapy suppresses arthritis in the collagen-induced mouse model of arthritis (Holmdahl et al., 1987) and in adjuvant arthritis in the rat (Kappas et al., 1963), consistent with the role of estrogen in the human.
6. Finally, a subset of RA patients undergoes striking remission during pregnancy. Although fetal-maternal genetic relationships have been invoked to explain this phenomenon (Nelson et al., 1993), other data fails to fully support this hypothesis (Brennan et al., 2000; Gregersen, 2000), and thus it is likely that hormonal changes during pregnancy at least partially explain disease remission in pregnancy.

While it has been proposed that genes within sex steroid hormone pathways may contribute to RA inherited risk, no gene has been conclusively identified to date.

Environmental Factors

Smoking is the environmental risk factor with strongest association with developing RA. Over the past 20 years, many studies have convincingly shown that smoking increases risk of developing RA in both males and females by a factor of ~2.0 (Gorman, 2006; Stolt et al., 2003). Most of these studies demonstrate that the increase risk is in developing autoantibody positive RA, and that the risk is greatest for heavy, current smokers; the risk remains, however, for >10 years following smoking cessation. Because the link between smoking and autoantibody positive RA is reminiscent of the genetic association between *HLA-DRB1* "shared epitope" alleles and autoantibody positive RA, Padyukov et al. investigated the risk of developing disease in carriers of these two established risk factors: a 16-fold risk of developing RF+ RA in smokers who carry two copies of the SE alleles was observed (Padyukov et al., 2004).

Other putative environmental risk factors that have not been as widely replicated as smoking include blood transfusions, obesity, occupational silica and mineral oil exposure, and socioeconomic class (Silman and Pearson, 2002; Symmons, 2003). It is interesting that several of these putative environmental factors are inhaled through the lungs. Silica dust and mineral oil exposure, similar to exposure to cigarette smoke, was a risk factor only for seropositive RA. Mineral oil can also act as an adjuvant capable of inducing experimental arthritis in rodent models.

Infectious Agents

There is indirect, but certainly not conclusive evidence that exposure to an infectious agent(s) may trigger the development of RA (Silman and Pearson, 2002). Despite decades of investigation, however, no single infectious agent has emerged as influencing risk of RA.

Support for an infectious etiology contributing to RA risk include: (a) certain forms of arthritides in humans are triggered by bacteria, including enterogenic and urogenic infections (e.g., reactive arthritis, rheumatic fever, Lyme disease, and Whipple's disease); (b) bacterial components are able to induce chronic arthritis closely resembling RA in animal models; (c) antibodies, T-cell clones, or cellular immune responses specific to certain bacteria as well as bacterial components have been observed in synovial fluid or peripheral blood in patients with RA; and (d) and paleontological (Rothschild et al., 1988) and epidemiological data (Doran et al., 2002; Kaipiainen-Seppanen et al., 1996; Shichikawa et al., 1999) demonstrating the first appearance of RA in modern man, yet with a decrease in incidence over the last 40 years (with the improvement in public health measures and the widespread use of antimicrobial therapy).

If an infectious agent is causal, one could imagine different mechanisms by which it might lead to RA. Exposure might lead to a generalized over-active immune system, thus clearing the infection but resulting in autoimmunity later in life. A more specific response to a single infectious agent might induce an immunological response against the infection, yet lead to cross-reactivity with antigens in human synovial tissue ("molecular mimcry").

Autoantibodies

RF and CCP Autoantibodies

Autoantibodies have proven useful in the diagnosis and prognosis of RA patients. Autoantibodies are detected in approximately two-thirds of patients with RA and predict severe disease. The two major types of autoantibodies used clinically to create RA subsets are RF, which is an immunoglobulin specific to the Fc region of IgG, and anti-cyclic citrullinated peptide (CCP) antibodies, which are antibodies directed against peptides that have arginine posttranslationally modified to citrulline (Schellekens et al., 2000). These autoantibodies are strongly correlated but may represent distinct clinical subsets of RA.

RF autoantibodies are part of the diagnostic criteria for RA (Arnett et al., 1988). The RF assay, however, remains suboptimal as a diagnostic test, as it lacks sensitivity (50–90%) and specificity (50–90%) (Shmerling and Delbanco, 1991). Furthermore, it is present in many other disease states (including those that mimic RA) and patients that smoke, and its incidence increases with age. In contrast, anti-CCP antibodies have moderate sensitivity (60–80%) but increased specificity for RA (>90%), and predict functional status and radiographic erosions in patients with early-onset RA (van Jaarsveld et al., 1999; van Zeben et al., 1992; Kroot et al., 2000).

There has been much debate about whether these autoantibodies are causal or whether they represent a non-specific response to systemic inflammation. Several lines of evidence suggest that these autoantibodies – and CCP in particular – are pathogenic: (1) anti-CCP antibodies appear before disease onset (Rantapaa-Dahlqvist et al., 2003; Schellekens et al., 2000); (2) the presence of CCP is very specific to RA; (3) antibodies against citrullinated proteins enhance tissue injury in a murine model of arthritis (collagen-induced arthritis) (Kuhn et al., 2006); and (4) genetic variation in an enzyme, *PADI4*, involved in the citrullination pathway appears associated with RA susceptibility (Suzuki et al., 2003) and see "*Non-MHC genes*" above).

Finally, presence of RF and CCP antibodies may facilitate the identification of genes in RA. As with other complex human diseases, substantial clinical heterogeneity exists. Because presence or absence of RF and CCP antibodies provides a rationale clinical subset, these have been used to subset patients in the search for RA genes. Indeed, the two genes with a clear association to RA (*HLA-DRB1* and *PTPN22*) are both association with CCP+ patients, but not CCP- patients.

Hypothetical Model of RA Predisposition

Based upon the above information, it is tempting to speculate about a hypothetical model of RA pathogenesis. One model, put forth by Klareskog et al (Klareskog et al., 2006), is that smoking or other air pollutants lead to inflammation and citrullination of proteins in the lungs in genetically susceptible individuals. This event leads to the formation of anti-CCP antibodies, which have a direct pathogenic role in the joint. Under this hypothesis, citrullinated proteins are presented in class II MHC molecules to induce an immune response, and *HLA-DRB1* variants augment the autoimmune response. The *PTPN22* missense allele may also augment the autoimmune response, or may allow autoreactive T-cells to escape selection in the thymus.

While aspects of this model may be correct, it almost certainly does not explain RA pathogenesis in all patients. Continued integration of clinical and basic science research is necessary to revise, or refine, models of RA pathogenesis. The advent of genome-wide association studies should facilitate identification of new RA-related genes, facilitating our understanding of disease pathogenesis.

Other Genomic Studies

Other genomic resources are available to study predisposition to RA, including mRNA expression profiling and examination of serum protein levels, although neither has been widely implemented in large patient collections. The field of proteomics is still limited by the availability of cost-effective, high-throughput assays. The search for auto-antigens that predispose to RA has also been challenging. The goals of these efforts include identifying novel biomarkers that allow early and specific disease diagnosis or predict severe disease, or biomarkers that may serve as therapeutic targets. The success of RF and anti-CCP autoantibodies provide proof-of-concept that a novel biomarker might have direct clinical utility.

mRNA Expression Profiling

Genome-wide analysis of mRNA expression patterns has been performed in peripheral blood and synovial fluid derived from RA patients. This approach has proven insightful in the peripheral blood of patients with systemic lupus erythematosis (SLE) (Baechler et al., 2003), but has been less fruitful to date in RA. Studies in peripheral blood have compared RA patients versus normal controls (Batliwalla et al., 2005; van der Pouw Kraan et al., 2007), RF+ versus RF- patients (Bovin et al., 2004), and early versus chronic RA (Olsen et al., 2004). Similar techniques have been applied to synvovial tissue, where inflammatory RA synovium is compared to non-inflammatory OA synovium (Devauchelle et al., 2004; van der Pouw Kraan et al., 2003a, b). No clear consensus has emerged from these studies, but there is some evidence that there may be an alteration in the number or activation state of monocytes (Batliwalla et al., 2005) or a type I interferon signature (similar to SLE, [van der Pouw Kraan et al., 2007]). Many studies are too small (e.g., <15 patients) to draw any significant conclusions given the large number of hypotheses (i.e., expressed genes) tested (Bovin et al., 2004; Devauchelle et al., 2004; Haas et al., 2006; Szodoray et al., 2006).

Proteomics

Genome-wide genetic association studies and mRNA expression profiling allow for exploration of novel hypotheses, effectively exploring hundreds of thousands of genes for influence on disease risk. These platforms are becoming increasingly cost-effective and robust. In contrast, the field of proteomics has been hampered by equivalent technical capacity. Mass spectrometry offers such a platform, but is not yet widely in use (Domon and Aebersold, 2006). Consequently, most "proteomics" research in RA and other complex diseases has been limited to ELISA-based methodologies that are not capable of high-throughput multiplexing – and thus limited to a small number (hundreds not thousands) of proteins of known relevance.

It is clear that cytokines play a crucial role in RA pathogenesis (Lee and Weinblatt, 2001). Cytokines are small soluble proteins that mediate intercellular communication within the immune system. Important examples include the proinflammatory cytokines interleukin 1 (IL1) and tumor necrosis factor alpha (TNF-alpha), as well as their soluble receptors (p55 and p75 for TNF; IL1R1, IL1R2, and IL1Ra for IL1). These cytokines are secreted primarily by macrophages within the synovium, and lead to inflammation and stimulation of synovial tissue effector functions (e.g., cellular proliferation, expression of metalloproteinases and adhesion-molecules, and secretion of prostaglandins and other cytokines). Perhaps the most incriminating evidence for the role of cytokines in RA pathogenesis is in neutralizing therapies directed at the proteins themselves in patients with active RA: antibodies directed against TNF-alpha (or its soluble receptor) have been remarkably useful in the treatment of RA; anti-IL1 therapies are somewhat effective, but not to the same degree as anti-TNF-alpha therapies.

While cytokines are important in RA, what is not clear is whether alterations in cytokine secretion *per se* leads to the development of RA, or whether dysfunction is simply the result of an over-active immune system. No longitudinal cohort study has yet demonstrated alterations in these molecules prior to the development of RA – evidence that would be necessary to establish causality. An alternate strategy to establish causality would be to demonstrate that genetic variation within a cytokine gene leads to the development of RA. Numerous studies have suggested that alleles within the *TNF* gene influence RA risk, but it has yet to be conclusively shown that this effect is independent of linkage disequilibrium with *HLA-DRB1* or neighboring genes within the 3.6 Mb MHC region. In theory, all alleles that influence secretion of a given cytokine could be mapped and then tested to determine whether these alleles also influence the development of RA. To date, no such comprehensive list of alleles exists.

It is worth highlighting studies that have implemented newer proteomic techniques such as mass spectrometry (Saulot et al., 2002; de Seny et al., 2005; Liao et al., 2004; Uchida et al., 2002), multiplex cytokine arrays (Hueber et al., 2006) and antigen microarrays (Hueber et al., 2005) to analyze synovial fluid and serum in RA patients. A study by Liao et al. used a two-step mass spectrometry approach to generate protein profiles of synovial fluid from patients with either erosive or non-erosive RA (Liao et al., 2004). Among 33 proteins elevated in the synovial fluid of patients with erosive RA were C-reactive protein (CRP) and 6 members of the S100 protein family of calcium-binding proteins. The authors demonstrated that levels of CRP, S100A8 (calgranulin A), S100A9 (calgranulin B), and S100A12 (calgranulin C) proteins were also elevated in the serum of patients with erosive RA. A different study by de Seny et al., which included 34 patients with longstanding disease, identified 5 proteins elevated in the serum of patients with CCP+ RA (compared to patients with other inflammatory diseases), one of which was hypothesized to be myeloid-related protein 8 (MRP8) (de Seny et al., 2005). The MRP8 protein may be enriched in the synovial fluid of RA compared to osteoarthritis patients (Uchida et al., 2002). Finally, Hueber et al. used microarrays in a set of early RA patients to show that autoantibody reactivity against citrullinated epitopes is more common in patients with high-serum levels of TNFα, IL-1β, IL-6, IL-13, IL-15, and GM-CSF (Hueber et al., 2006).

SCREENING

No reliable methods to screen a population prior to disease onset exist for RA. It may be that the presence of CCP autoantibodies together with genetic susceptibility variants (*PTPN22* and *HLA-DRB1*) will increase risk substantially to the point where screening the healthy population because cost-effective (Berglin et al., 2004; Johansson et al., 2005). Under this scenario, it remains to be determined whether effective intervention to prevent RA will emerge – currently, RA therapies are directed at symptoms rather than a cure. Moreover, this simple approach does nothing to screen the 1/3 of RA patients who develop

autoantibody negative disease. Overall, no clear paradigm has emerged as to how screening the population would influence clinical decision-making, and additional attention should be paid to this area in the future.

DIAGNOSIS, PROGNOSIS, AND MONITORING

The diagnosis of RA is based on established clinical criteria (Arnett et al., 1988). The clinical course for any individual patient is highly variable. Extent of synovial inflammation and presence of autoantibodies at the time of initial diagnosis portend a poor prognosis, but cannot alone predict prognosis in any individual patient. Similarly, the presence of *HLA-DRB1* SE alleles predicts more severe disease, but does not routinely enter into decision-making in clinical patient care. Because treatment strategies have improved dramatically over the last decade with the advent of TNF-alpha inhibitors, prognosis is more influenced by response to treatment rather than aggressiveness of the underlying disease in an untreated patient.

A major goal of therapy is early institution of *d*isease-*m*odifying *a*nti-*r*heumatic *d*rugs, or DMARDs. The most popular disease-modifying therapy is low dose weekly methotrexate (MTX). This drug is used as a mono-therapy or in combination with other synthetic molecules (antimalarials, sulfasalazine, leflunomide) or with biologic response modifiers. Biologics that neutralize the pro-inflammatory cytokine TNF-alpha have been a major advance in the therapy of RA. Monoclonal antibodies (infliximab and adalimumab) or the p75 TNF-alpha soluble receptor fusion protein (etanercept) are effective as a mono-therapy or in combination with MTX in reducing the signs and symptoms of the disease, as well as improving quality of life and slowing the rate of radiographic progression. These therapies are very effective when combined with MTX. Newer biologics recently approved for use in RA include abatacept (blocks the CTLA4 co-stimulation pathway) and rituximab (a B-cell depleting strategy). Early intervention with MTX and combination therapy (including anti-TNF-alpha therapy) have had a major impact on this disease.

2009 UPDATE

The last two years has observed a dramatic increase in the number of validated risk alleles for complex traits, in large part due to the implementation of genome-wide association studies and related methodologies (Altshuler et al., 2008). In RA genetics, the greatest recent advance has been the discovery and validation of RA risk alleles outside of the MHC (Barton et al., 2008a, b; Chang et al., 2008; Consortium, 2007; Kurreeman et al., 2007; Plenge et al., 2007a, b; Raychaudhuri et al., 2008; Remmers et al., 2007; Suzuki et al., 2008; Thomson et al., 2007; Zhernakova et al., 2007). In addition, large-scale SNP genotyping across the MHC provides continued support for additional alleles, including alleles that are found on the conserved A1-B8-DR3 (8.1) haplotype and alleles near the *HLA-DPB1* gene (Lee et al., 2008).

There are six new validated non-MHC RA risk loci (overall $p < 5 \times 10^{-8}$ with independent replication), including 2q32/*STAT4* (Barton et al., 2008a; Kobayashi et al., 2008; Lee et al., 2007; Martinez et al., 2008; Orozco et al., 2008; Palomino-Morales et al., 2008; Remmers et al., 2007; Zervou et al., 2008), 9q33/*TRAF1-C5* (Barton et al., 2008a; Chang et al., 2008; Kurreeman et al., 2008; Plenge et al., 2007b; Zervou et al., 2008), 6q23/*TNFAIP3* (Plenge et al., 2007a; Thomson et al., 2007), 20q13/*CD40* (Raychaudhuri et al., 2008), 10p15/*PRKCQ* (Barton et al., 2008b; Raychaudhuri et al., 2008), and 12q13/*PIP4K2C* (Barton et al., 2008b; Raychaudhuri et al., 2008). There are at least six "highly suggestive" RA risk loci ($10^{-6} < p < 5 \times 10^{-8}$), which require additional replication before they can be considered validated RA risk loci: 2q33/*CTLA4* (Raychaudhuri et al., 2008), 4q27/*IL2-IL21* (Raychaudhuri et al., 2008; Zhernakova et al., 2007), 9p13/*CCL21* (Raychaudhuri et al., 2008), 1p36/*TNFRSF14* (Barton et al., 2008b; Raychaudhuri et al., 2008), 22q13/*IL2RB* (Barton et al., 2008b), and 1q22/*CD244* (Suzuki et al., 2008). For each of these loci, the causal allele and causal gene has not yet been definitively identified, indicating the need for fine-mapping and functional studies. The non-MHC risk alleles contribute between 3–5% of the genetic burden of RA (Raychaudhuri et al., 2008), compared to approximately one-third for the MHC (Cornelis et al., 1998; Deighton et al., 1989; Jawaheer et al., 2001; Rigby et al., 1991). Among individuals of European ancestry, the *PTPN22* locus (Begovich et al., 2004) continues to be the non-MHC region with the strongest effect, as estimated by the OR. All other non-MHC risk alleles are common in the general population and have modest effect on disease risk (OR $\sim$ 1.10).

The success in mapping RA risk loci has been paralleled by the success in other autoimmune and inflammatory diseases, including type 1 diabetes (Smyth et al., 2008; Todd et al., 2007), celiac disease (Smyth et al., 2008; van Heel et al., 2007), SLE (Graham et al., 2008; Harley et al., 2008; Hom et al., 2008), inflammatory bowel disease (Barrett et al., 2008), and multiple sclerosis (Hafler et al., 2007). An emerging theme is that many of the validated autoimmune risk loci predispose to more than one autoimmune disease (Behrens et al.,

2008; Consortium, 2008; Fung et al., 2008; Plenge, 2008; Raychaudhuri et al., 2008; Remmers et al., 2007; Smyth et al., 2008; Zhernakova et al., 2007). In RA, up to half of the known non-MHC risk loci also appear to confer risk to at least one additional autoimmune disease. In most examples, it is the same allele that is associated with risk in both diseases (e.g., a common allele at the *STAT4* gene locus and risk of both RA and SLE [Remmers et al., 2007]). There are gene loci, however, that appear to have multiple autoimmune alleles (e.g., the *6q23/TNFAIP3* locus and risk of both RA and SLE [Graham et al., 2008; Musone et al., 2008; Plenge et al., 2007a; Thomson et al., 2007]). Finally, there are loci, such as *PTPN22*, in which an allele *predisposes* to one autoimmune disease (e.g., RA [Begovich et al., 2004]), but the same allele is *protective* in another autoimmune disease (e.g., Crohn's disease [Barrett et al., 2008]).

These human genetic discoveries have identified pathways that are important in RA pathogenesis. One is the nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) signaling pathway (Hammaker et al., 2003; Sen and Baltimore, 1986). NF-κB, a protein complex that acts as a transcription factor, is found in almost all cell types and is involved in a variety of cellular responses to stimuli. Both TNF and CD40 signal through NF-κB to exert their effects on the immune system. Several of the RA risk loci contain genes that are involved in NF-κB signaling, including *CD40*, *TRAF1*, *TNFAIP3*, *PRKCQ*, and *TNFRSF14*.

CHAPTER

Genomic Evaluation of Multiple Sclerosis

Francisco J. Quintana and Howard L. Weiner

INTRODUCTION

Multiple sclerosis (MS) is an autoimmune disorder in which the central nervous system (CNS) is targeted by the dysregulated activity of the immune system, resulting in focal lesions and progressive neurological dysfunction. MS is heterogeneous in its clinical symptoms, rate of progression and response to therapy, probably reflecting the existence of several pathogenic mechanisms that make different contributions to the disease. MS is a T cell-mediated autoimmune disease thought to result from a combination of genetic and environmental factors (Weiner, 2004). In this chapter we will analyze the contribution of genomics, transcriptomics, immunomics and proteomics in delineating these factors, as well as their utility for monitoring disease progression and response to therapy, identifying new targets for therapeutic intervention and detecting individuals at risk of developing the disease later on in life.

GENOMICS IN MS

The first observation suggesting a genetic contribution to MS susceptibility was the identification of familial aggregation: first, second and third degree relatives of MS patients have an increased risk of developing the disease (Mackay, 1950); a sibling of an MS patient, for example, has a 20-times greater lifetime risk of developing MS than an individual from the general population (Sawcer et al., 2005). Further studies have showed that familial aggregation in MS results from sharing predisposing genetic elements and not from the exposure to environmental factors (Dyment et al., 2004).

MS is considered a complex genetic disease in which many polymorphic genes have small or at most moderate effects on the overall MS risk, disease severity, rate of progression and age of onset among several clinical outcomes. To date, the major histocompatibility complex (MHC) locus on chromosome 6p21 MHC remains the strongest and most convincingly chromosomal region linked to MS: The DRB1*15 and the CRB1*17 alleles increase the risk for MS while the CRB1*14 has a disease-protective effect (Games, 2003; Jersild et al., 1972; Oksenberg and Barcellos, 2005). Several non-MHC candidate loci have also been linked to MS (Oksenberg and Barcellos, 2005), but it has proven difficult to validate their association in independent studies. The difficulty in the identification of non-MHC genes associated to MS might result from the genetic heterogeneity existing among MS patients, meaning that different combinations of genes might lead to the same end phenotype: MS. In this scenario, methods like linkage analysis might not be sensitive enough for the detection of genes bearing only modest effects on MS susceptibility, and thus association studies in large cohorts of patients and controls might be needed.

Briefly, two approaches are used for the identification of genes linked to MS pathogenesis and progression: linkage and association mapping.

Linkage mapping is based on the study of the co-inheritance of genetic markers and phenotypes in families over several generations. Linkage mapping is successful in finding genes for rare

Mendelian monogenic diseases inherited in a dominant fashion. However, in diseases like MS where several loci have a small contribution to the phenotype under study, linkage studies only identify those loci that have the strongest influence. In addition, one of the premises implicit in linkage studies is that all the families studied have their susceptibility determined by the same genes, an assumption at odds with mounting evidence suggesting that the susceptibility to MS is genetically heterogeneous.

A recent study used 4506 genetic markers to analyze 2692 individuals in 730 families of Northern European descent looking for the co-inheritance of genetic markers and MS (Sawcer et al., 2005). Multipoint non-parametric linkage analysis could only find one significant linkage, which unsurprisingly pointed to the MHC locus on chromosome 6p21. This study therefore confirms the identification of the MHC locus as a genetic determinant of the susceptibility to MS, but it also highlights two limitations of linkage mapping. First, linkage mapping tends to identify large chromosomal fragments because of the small number of recombination events analyzed in familial pedigrees; the MHC locus, for example, contains more than 200 genes. Second, the authors also found suggestive linkage on chromosomes 17q23 and 5q33 and 19p13, but the data were inconclusive about these loci even when a high density of genetic markers was used. Other mapping strategies are needed to identify loci with modest effects on MS.

Association mapping looks for genetic markers with higher frequencies in MS patients than controls, suggesting an association between a disease phenotype and allelic variation (Hafler and De Jager, 2005).

Although genetic susceptibility to MS has been linked to the MHC locus, the particular gene or genes underlying susceptibility to MS within this locus are a matter of discussion, particularly because of the punctuated pattern of linkage disequilibrium observed for this chromosomal location (Jeffreys et al., 2001). As a result, other genes within the MHC locus besides HLA-DRB1 might be associated with MS; *tnf* and other loci in HLA class III and HLA class I are logical candidates. Lincoln and coworkers genotyped 4203 individuals from Finland and Canada with a high-density SNP panel to identify the gene or genes in the MHC locus responsible for the increased susceptibility to MS (Lincoln et al., 2005). Their results identified the DRB1 allele in the HLA class II region as the single major susceptibility locus in the MHC region, although there is still a small chance that a closely adjacent locus contains the true susceptibility variant. Thus, association mapping confined the MS susceptibility to the approximately 100 kb of sequence flanking HLA-DRB1. On the one hand, this work illustrates the increased power of association over linkage mapping studies. On the other hand, it highlights the dependency of association mapping on linkage disequilibrium: the uneven distribution of recombination events in this region leads to the identification of a locus for MS susceptibility big enough to contain several genes.

Admixture mapping is an association mapping strategy based on: (a) a difference on the prevalence of a disease between two ethnic groups and (b) the existence of a third admixed population (Smith and O'Brien, 2005). Northern Europeans and Africans have different susceptibilities to many autoimmune, circulatory and metabolic disorders, among them MS (Smith and O'Brien, 2005). This differential susceptibility is also reflected in North America where MS is more prevalent in European Americans than African Americans. On average, there have been only six generations since African and European populations came into contact in North America, resulting in little recombination between chromosomes of African and European ancestry in the history of African American populations. Thus, the chromosomal segments of one or the other ancestry are long in the admixed population, and few genetic markers can be used to classify the genome of an African American into sections with African or European origins. It is therefore possible to study African Americans to identify genomic regions where individuals with MS tend to have an unusually high proportion of ancestry from either Europeans or Africans, indicative of the presence of an MS variant that differs in frequency between the two ancestral populations. This mapping strategy was initially suggested several years ago (Chakraborty and Weiss, 1988), but it could only be fully implemented with the recent advent of genetic markers that identify human populations of different ancestry (Sachidanandam et al., 2001).

Admixture mapping led to the identification of a new locus associated with MS risk around the chromosome 1 centromere as a result of the analysis of 1166 genetic markers in 1648 samples (605 MS patients and 1043 controls) (Reich et al., 2005). Notably, this linkage could not be replicated using an independent set of 143 African Caribbeans with MS from Martinique and the United Kingdom, suggesting that either the locus in chromosome 1 does not have a role in African Caribbean populations or that the African Caribbean cohort was not large enough. Future studies should attempt to clone the susceptibility gene on chromosome 1.

Genome scans aimed at identifying non-MHC genes linked to MS usually fail when initial promising candidates cannot be validated on independent populations. New experimental techniques and analytical methods, however, are trying to change this trend. A recently published study combined the results of whole genome screens for linkage or association in 18 populations and superimposed them in a combined genomic map (Abdeen et al., 2006). The regions identified by this meta-analysis were then verified in a different set of samples (Abdeen et al., 2006), leading to the identification of several non-MHC candidate genes that modify the risk for MS. The list of candidates includes genes involved in CNS development and regeneration (NTN1, NCAM1, ADAM22 and ADAMTS10) in addition to genes directly linked to inflammation (TGFA, TGFBR, IL18 and IL10RA) (Abdeen et al., 2006). Although these new gene candidates are still awaiting independent validation, the meta-analysis used for their identification might constitute a new method for shortlisting new candidates to be targeted in independent replication studies.

TRANSCRIPTOMICS IN MS

Large-scale studies of mRNA expression in MS have been directed at characterizing the two main components of the disease: the lesion and the immune response.

Characterization of the Lesion

The hallmark of MS is the presence of demyelinated plaques in the white matter area of the CNS (Lassmann, 1998). These lesions are heterogeneous, reflecting the contribution of diverse mechanisms to disease progression (Lassmann et al., 2001). The study of the transcriptional activity in the lesions is therefore of importance for the characterization of the processes that drive MS, and for the identification of new targets of immune intervention.

Lindberg and coworkers studied the transcriptional activity of lesions and normal appearing white matter (NAWM) in samples taken from 6 secondary progressive MS (SPMS) patients and 12 matched controls (Lindberg et al., 2004). Within the lesion, only 21% of the upregulated genes were associated to the immune response; 77% of those immune-related transcripts corresponded to the cellular response. However, the Four most significant immune upregulated genes were linked to humoral immunity (immunoglobulins). Notably, tertiary lymph nodes that support the maturation of antibody-secreting plasma cells within the CNS have been identified in SPMS brains (Aloisi and Pujol-Borrell, 2006; Corcione et al., 2005). In addition, those genes that showed a decreased expression mainly belonged to one of two categories: genes with well-known anti-inflammatory activities (pointing to a deficit in immunoregulatory mechanisms), and genes involved in neural homeostasis. Interestingly, the NAWM showed a significant upregulation in immune-related genes, mainly involved in signaling and effector functions like blood–brain barrier (BBB) disruption and lymphocyte activation. These data provide a molecular insight into the pathological mechanisms driving MS and confirm the presence of physiological abnormalities on NAWM.

The study of the transcriptional profile in the MS lesion can lead to the identification of new targets for immuno intervention. Lock and coworkers studied the expression profile in the acute MS lesions (with signs of inflammation) and in silent lesions (without inflammation but showing clear signs of demyelination and scarring) (Lock et al., 2002). Both types of lesions showed an upregulated expression of genes associated with MHC class II antigen presentation, immunoglobulin synthesis, complement and pro-inflammatory cytokines. Neuron-associated genes and those associated with myelin production were underexpressed.

Different expression profiles were found in active and silent lesions. α-integrin was found to be elevated in chronic silent MS lesions; notably antibodies to α4-integrin reverse and reduce the rate of relapse in relapsing-remitting experimental autoimmune encephalomyelitis (EAE) (Yednock et al., 1992), and a humanized version of this antibody showed promising effects in the treatment of human MS (Polman et al., 2006).

The expression of IgE and IgG Fc receptors was upregulated in chronic silent MS lesions (Lock et al., 2002). Accordingly, mice harboring impaired IgE and IgG Fc receptors develop a milder EAE than their wild type counterparts (Lock et al., 2002). These effects were stronger from day 20 onwards following the induction of the disease, in accordance with microarray data showing that Fc receptor transcripts are elevated in chronic but not acute MS lesions. Granulocyte colony-stimulating factor (GCSF) was found to be upregulated in acute active lesions; its administration to mice before challenge with an encephalopathogenic peptide also leads to an amelioration of the disease, suggesting that endogenous GCSF might participate of the natural regulation of acute attacks (Lock et al., 2002).

In a separate study, the large-scale sequencing of non-normalized cDNA libraries derived from plaques dissected from brains of patients with MS showed an increased frequency of transcripts coding for osteopontin (OPN), a Th1 cytokine involved in the immune response to infectious diseases (Chabas et al., 2001). OPN transcripts were detected exclusively in the MS mRNA population but not in control brain mRNA. The upregulated expression of OPN was confirmed by immuno-histochemistry in human MS plaques, which showed OPN expression in microvascular endothelial cells and macrophages, and in the white matter areas adjacent to plaques. Similar patterns of expression were seen in mice and rats representing a model of relapsing remitting and monophasic EAE, respectively. To test the relevance of OPN in MS, OPN-deficient mice were generated. These mice showed a reduced severity in EAE. Moreover, neutralization of OPN with neutralizing antibodies also led to an amelioration of EAE (Blom et al., 2003), validating the use of cDNA microarrays in the search for new therapeutic targets for MS. The upregulation of OPN levels in MS plaques (Tajouri et al., 2005) and in the circulation (Comabella et al., 2005; Vogt et al., 2003, 2004) of MS patients was replicated in independent studies, prompting the search for polymorphisms in the *opn* gene associated with MS. Although some controversy still remains (Caillier et al., 2003) polymorphisms in the *opn* locus have been associated with increased levels of circulating OPN and disease course (Chiocchetti et al., 2005). OPN is therefore an example of how results obtained in transcriptomics studies might lead to the identification of genetic polymorphisms linked to MS.

Characterization of the Immune Response

The analysis of the transcriptional profile could also be applied to study the immune response in MS, to monitor the progression of the disease and the response to therapy. Two points, however, should be kept in mind when considering the use of cDNA arrays for the analysis of the immune response in MS patients: First, these studies assume that changes in the periphery somehow reflect the ongoing situation within the CNS. Second, these studies are limited by the normal "noise" that exists in basal gene expression, originated from diverse factors such as the relative proportion of different blood cell subsets, gender, age and the time of day at which the sample was taken (Whitney et al., 2003). This variation is likely to impose severe limitations for the use of cDNA microarrays in a clinical setting.

Follow up of Disease Activity

A recent study by Achiron and co-workers followed the transcriptional activity of peripheral blood mononuclear cells (PBMC) prepared from relapsing-remitting MS (RRMS) patients during the relapses and remission of MS (Achiron et al., 2004). The authors identified a transcriptional signature associated to the relapse, that included genes involved in the recruitment of immune cells, epitope spreading and escape from immune-regulation. Although encouraging, these results should be validated using an independent set of samples and in longitudinal studies to asses their predictive value.

Response to Therapy

Gene expression profiling can also be used to classify patients according to different clinical criteria, such as responder or non-responders to therapy. β−Interferon (β−IFN) is widely used for the treatment of MS (Kappos and Hartung, 2005), however, its precise mechanism of action is not known, and neither are biomarkers that would allow the identification of patients that will benefit from it. Weinstock-Guttman and colleagues used cDNA microarrays to study the effects of IFNβ therapy on the transcriptional activity of monocyte-depleted PBMC (Weinstock-Guttman et al., 2003). This pharmaco-dynamic study found that upon 1 h of IFNβ administration, significant changes are detected in the expression of genes involved in the antiviral response, β−IFN signaling and markers of lymphocyte activation. These studies provided a molecular description of the effects of β−IFN on RRMS patients and were later on extended to identify transcriptional signatures associated with a favorable response to treatment with IFNβ (Sturzebecher et al., 2003). Moreover, they demonstrated that MS patients showing a positive response to treatment with β−IFN, as assessed by longitudinal gadolinium-enhanced MRI scans and clinical disease activity, are characterized by specific patterns of gene expression (Sturzebecher et al., 2003). Based on these observations, Oksenberg and coworkers identified groups of genes whose expression has a prognostic value for the identification of MS patients likely to respond to treatment with β−IFN (Baranzini et al., 2005). The work of Oksenberg and coworkers is remarkable for two reasons: First, it demonstrates that gene expression profiling can be used in the management of MS to select a therapeutic regime suited to the patient's metabolism. Second, it used a methodology (RT-PCR) accessible to clinical laboratories, facilitating the translation of their results into daily medical practice.

The combination of the data generated in transcriptomics and genomics studies can be an invaluable source of information and new hypotheses. Aune et al. compared the genes differentially expressed by lymphocytes in rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), insulin-dependent diabetes mellitus (IDDM) and MS, concluding that they are clustered within chromosomal domains in the genome (Aune et al., 2004). Strikingly, they found that the chromosomal domains containing the genes differentially expressed in autoimmune disorders could be mapped to disease susceptibility loci associated to those diseases by genetic linkage studies (Aune et al., 2004). These results suggest that the expression of disease-associated genes is co-regulated as a result of shared genetic regulatory elements or local patterns of chromatin condensation. Recently Baranzini and coworkers studied the genetic concordance between gene expression and genetic linkage in MS (Fernald et al., 2005). They first compiled the data on gene expression available for MS and EAE, and superimposed it with the all the known susceptibility loci identified in MS and EAE. In their study, Baranzini and coworkers identified the MS susceptibility genes located in the MHC locus as overlapping with clusters of differentially expressed genes in MS and murine EAE. However, they could also identify an interesting region on chromosome X that might contribute to the sexual dimorphism observed in MS. The integration of the data generated by different platforms, like transcriptomics, genomics and proteomics, is therefore likely to deepen our understanding of the mechanisms driving MS.

IMMUNOMICS IN MS

The autoimmune nature of MS suggests that the study of the immune response should be useful for the early diagnosis, prognosis and monitoring of MS patients. With this aim, new tools have been developed, allowing a high-throughput analysis of the T cell- and antibody-mediated immune response.

T Cell Response

MHC arrays have been recently developed based on the immobilization of peptide/MHC tetramers used to activate peptide-specific T cells and follow cytokine secretion or adhesion (Chen et al., 2005; Soen et al., 2003). Their use for the study of human immunology is limited by the high frequency of polymorphisms existing on the MHC locus. Nevertheless, these arrays have been recently used to characterize the cellular response in tumor-vaccinated humans (Chen et al., 2005).

Reverse phase arrays consist of arrays of spotted lysates prepared from primary cells, which are interrogated with antibodies specific for phosphorylated or de-phosphorylated proteins involved in signaling transduction pathways of interest (Chan et al., 2004). By combining different antibodies and inhibitors of specific signal transduction pathways, detailed signaling maps can be constructed describing the molecular events that lead to the activation of a specific cell population. This approach have been recently be used to study $CD4^+CD25^+$ regulatory T cells (Treg) (Chan et al., 2004). Since defects in Treg function have been described in MS patients (Viglietta et al., 2004), these arrays could be useful in the identification of signaling defects in the immune system of MS patients, and how these pathways are modified in immuno-modulatory regimes.

Multidimensional FACS is based on the simultaneous computation of the signals produced by more than 16 colors, and their analysis using advance mathematical algorithms (Perfetto et al., 2004). This technique could be useful to interrogate the immune response to specific antigens using a combination of tetramers, intracellular cytokine staining and surface markers (Chattopadhyay et al., 2005).

Cell migration arrays (Kuschel et al., 2006). To reach the CNS and cause tissue destruction, autoimmune T-cells have to express surface molecules that allow them to cross the BBB and initiate inflammation (Luster et al., 2005). The importance of this process for MS progression is shown by the beneficial effects that natalizumab, a humanized antibody to α4 integrin that interferes with T cell extravasation to the CNS and has showed promising preliminary results in the treatment of MS (Polman et al., 2006). Thus, the characterization of the adhesion properties exhibited by the different cell populations in MS patients might be of help to predict and monitor response to treatment and predict and prevent the development of relapses.

B Cell Response

Antibodies are of interest in MS because they might have a pathological role in MS (Genain et al., 1995), and more importantly, because antibody responses are thought to reflect the activity of the T cell compartment (Robinson et al., 2002b). These antibodies can be produced by B cells in the periphery and make their way to the inflamed CNS via the disrupted BBB, but they are also produced by intrathecal germinal centers that seem to form tertiary lymph nodes (Aloisi and Pujol-Borrell, 2006; Corcione et al., 2005). It is easier to assay antibody reactivity than to follow antigen-specific T-cell responses, thus new efforts have been invested in the development of new technologies for monitoring the humoral response in MS patients and autoimmunity (Quintana et al., 2004; Robinson et al., 2002a).

Antigen arrays can be used to detect changes in the repertoire of antibodies reflecting the antigen spreading that accompanies EAE progression (Robinson et al., 2003). The information obtained about the degree of antigen spreading observed in each mouse was used to design tailored immunomodulatory vaccines to control EAE (Robinson et al., 2003). In humans, have been used to identify new lipid targets of antibodies present in the CSF of MS patients; some of the new lipid targets found were also validated on EAE (Kanter et al., 2006). Future experiments should study the antibody response in the serum of MS patients, searching for patterns of antibody reactivity that predict the progression of MS or the response to therapy, as has been shown for other autoimmune disorders, such as RA (Hueber et al., 2005), autoimmune diabetes (Quintana et al., 2004) and SLE (Li et al., 2005). Antigen arrays have also been shown to identify the individual mice that will develop autoimmune diabetes later in life by studying an experimental model that shows incomplete penetrance. Thus, antigen arrays might be useful for the identification of patients at risk of developing MS, before the overt onset of the symptoms (Quintana et al., 2004). In addition, antigen arrays might be used to interrogate the antibody repertoire in the search of new targets of the MS autoimmune attack and therefore, new targets for immuno-modulation. Indeed, we have preliminary data suggesting that antigen arrays might be used to identify antibody patterns linked to the different forms of MS and the pathology at the site of the lesion (Quintana and Weiner, unpublished results).

PROTEOMICS IN MS

Proteomic studies in MS can identify new targets of the autoimmune process complementing the information provided by antigen array; they can also identify new processes contributing to disease pathology, and biomarkers for the early diagnosis and monitoring of MS patients.

Identification of New Targets of Autoimmunity

Using 2D gels on brain extracts, Almeras and coworkers identified 14 new targets recognized by antibodies present in CSF (Almeras et al., 2004). The targets identified by this study included heat shock proteins, structural proteins and enzymes involved in glucose metabolism (Almeras et al., 2004); although these results have been partially validated in the experimental model of MS EAE (Zephir et al., 2006), they are still waiting validation in an independent patient cohort.

Identification of New Pathogenic Processes

Proteomic studies have also identified new mechanisms that contribute to MS pathology. The existence of a link between Epstein-Barr Virus infection (EBV) and MS has been recently strengthened by the work of Cepok and co-workers, who used protein expression arrays to characterize the reactivity of antibodies in the CSF of MS patients, most of those antibodies recognized EBV epitopes (Cepok et al., 2005). These results suggest that EBV reactivation might elicit and abnormal immune response in susceptible individuals that contributes to MS (Sundstrom et al., 2004).

Brinkmeier and coworkers analyzed the CSF of MS and Guillain-Barre Syndrome (GBS) patients to characterize molecules that might affect ion-channel function (Brinkmeier et al., 2000). They identified and endogenous pentapetide (QYNAD) that works as a reversible Na^+ channel blocker (Brinkmeier et al., 2000). This pentapetide is present in the CSF of healthy individuals, but its levels are upregulated 3–14-fold in MS and GBS patients. This blocking peptide might be involved in the fast exacerbations and relapses commonly seen in demyelinating autoimmune diseases. Moreover, it might become a valuable marker of disease activity, and the target of future therapeutic interventions. These observations, however, could not be replicated by independent researchers (Cummins et al., 2003), highlighting the need for independent validation of proteomic findings.

Identification of Biomarkers

Proteomics can identify biomarkers useful in the monitoring of the different processes that contribute to MS pathology. In this direction, several studies have suggested that cytokines, chemokines, complement and adhesion molecules can be used as indicators of the inflammatory process in MS; while the levels of actin, tubulin, neurofilaments, tau, GFAP and S-100 proteins can be takes as indicators of axonal loss and gliosis (reviewed in Bielekova and Martin, 2004; Miller, 2004; Teunissen et al., 2005). However, for these to be of widespread clinical use, these markers should be easy to collect and provide reproducible results. This

motivation has boosted efforts aimed at finding markers of inflammation and neurodegeneration detectable in blood (Bielekova and Martin, 2004), urine (Bielekova and Martin, 2004) and tears (Devos et al., 2001); and simultaneously it has fostered the development of new technologies aimed at detecting minute amounts of proteins in body fluids (Zhang et al., 2006).

2009 UPDATE

Polymorphisms in the α chain of the IL-7 receptor (IL-7Ra) have been recently associated with MS (Gregory et al., 2007; Hafler et al., 2007; Lundmark et al., 2007). Although these polymorphisms make only a small contribution to the overall genetic susceptibility to MS, they are a significant step towards the identification of genetic determinants for MS outside the MHC locus. The IL-7Ra allele associated with MS favors a relative decrease in the membrane-bound IL-7Ra (Gregory et al., 2007). IL-7 is produced by stromal cells in lymphoid tissues and its availability is controlled through its uptake by the membrane-bound IL-7R on T cells (Mazzucchelli and Durum, 2007). Thus, considering the positive effects that IL-7 has on lymphocyte survival and proliferation (Mazzucchelli and Durum, 2007), the decrease in membrane IL-7R might result in increased levels of IL-7 available to fuel the inflammatory T cell response in MS.

The α chain IL-2 receptor (IL-2Ra) gene has also been recently linked to MS (Hafler et al., 2007). IL-2Ra allelic variation has been previously associated to other autoimmune diseases such as type I diabetes, but at a different genomic position (Lowe et al., 2007). IL-2 is required for the development of regulatory T cells (T_{reg}) (Malek, 2008; Suzuki et al., 1995) and, indeed, deficits in T_{reg} activity characterize relapsing–remitting MS (Viglietta et al., 2004); thus the IL2Ra polymorphisms might be related to the immune dysregulation observed in MS. Notably, IL2Ra-specific antibodies have shown promising beneficial effects for the treatment of MS on phase 2 clinical trials (Bielekova et al., 2004; Rose et al., 2004). Although the link between IL-2Rapolymorphisms and MS is still awaiting further validation, the association of IL-7Raand IL-2Ra variants to MS supports the use of genome-wide studies to delineate pathways contributing to disease pathogenesis.

The transcriptional profiling of $CD4^+$ T cells in MS has been recently used to predict the conversion of clinically isolated syndrome (CIS) patients to definite MS (Corvol et al., 2008). Baranzini and coworkers identified a set of genes whose expression is linked to the conversion to definite MS in less than a year. One of those genes is TOB1, a critical regulator of cell proliferation as a potential player in MS pathogenesis. Decreased TOB1 expression at the RNA and protein levels was found in MS patients and also in EAE. Moreover, a genetic association was observed between TOB1 variation and MS progression. All in all, these results link alterations in the regulation of $CD4^+$T cell quiescence to the progression of MS (Corvol et al., 2008).

A large proteomic study of MS lesions by Steinman and coworkers has recently identified the dysregulation of the clotting cascade as a new player in MS pathogenesis (Han et al., 2008). *In vivo* administration of hirudin or recombinant activated protein C reduced disease severity in EAE and suppressed T_H1 and T_H17 cytokines in astrocytes and immune cells (Han et al., 2008). Administration of mutant forms of recombinant activated protein C showed that both its anticoagulant and its signaling functions were essential for optimal amelioration of EAE (Han et al., 2008). Thus, the coagulation cascade might constitute a new therapeutic target for MS.

Using antigen arrays, we characterized patterns of antibody reactivity in MS serum against a panel of CNS protein, and lipid autoantigens, and heat shock proteins (Quintana et al., 2008b). We found unique autoantibody patterns that distinguished RRMS, SPMS and primary progressive (PPMS) MS from both healthy controls and other neurologic or autoimmune driven diseases, including Alzheimer's disease, adrenoleukodystropy and lupus erythematosus. RRMS was characterized by autoantibodies to heat shock proteins that were not observed in PPMS or SPMS. In addition, RRMS, SPMS and PPMS were characterized by unique patterns of reactivity to CNS antigens (Quintana et al., 2008b). Furthermore, we examined sera from patients with different immunopathologic patterns of MS as determined by brain biopsy, and we identified unique antibody patterns to lipids and CNS-derived peptides that were linked to each type of pathology (Quintana et al., 2008b). A further characterization of the role of these lipids in EAE identified them as direct effectors in MS pathogenesis by the activation of the innate immune system in the CNS (Quintana et al., 2008b). The demonstration of unique serum immune signatures linked to different stages and pathologic processes in MS provides an avenue to monitor MS and to characterize immunopathogenic mechanisms and therapeutic targets in the disease.

Screenings aimed at identifying genes or drugs controlling the immune response cannot be easily undertaken in mice because they are based on crossing, maintaining and screening large numbers of animals, an expensive time-, space- and labor-intensive task; new experimental models are needed. The zebrafish (*Daniorerio*) harbors an adaptive immune system that resembles the mammalian immune system (Langenau and Zon, 2005) and offers several experimental advantages for the study of pathways controlling vertebrate processes of interest. As part of our work on the zebrafish to identify pathways controlling immunity, we have identified the ligand-activated transcription

factor aryl hydrocarbon receptor (AHR) as a regulator of the generation of T_{reg} and T_H17 cells (Quintana et al., 2008a). AHR activation by its ligand 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD) results in the generation of functional T_{reg} that inhibit the development of EAE by a TGFβ1-dependent mechanism. Surprisingly, AHR activation by an alternative ligand, 6-formylindolo [3, 2-b]carbazole, interferes with T_{reg} differentiation, boosts T_H17 differentiation and worsens EAE. Thus, AHR regulates both T_{reg} and T_H17 differentiation in a ligand-specific fashion, constituting a unique target for therapeutic immunomodulation. Moreover, our findings suggest that the experimental advantages offered by the zebrafish can be exploited to characterize metabolic pathways controlling immunity in vertebrates and to identify new targets for therapeutic intervention..

CHAPTER

Genomic Assessment of Inflammatory Bowel Disease

Ad A. van Bodegraven and Cisca Wijmenga

INTRODUCTION

Inflammatory bowel diseases (IBD) are a group of chronic inflammatory disorders of the gastrointestinal tract of unknown origin; they comprise three main entities: ulcerative colitis (UC), Crohn's disease (CD), and indeterminate colitis. Indeterminate colitis represents a patient group that cannot be classified as either UC or CD, but which constitutes about 10% of IBD patients. Follow-up studies have shown that the majority of these patients eventually develop the features of UC. In addition, collagenous colitis and microscopic colitis have been described, although they will not be discussed in this chapter. Celiac disease is also a chronic inflammatory disorder of the gastrointestinal tract, but this disease is not usually included in IBD.

The incidence of CD has increased 8- to 10-fold over the past 50 years (Bach, 2002), whereas the incidence of UC has remained stable. CD is mainly seen in urbanized, developed countries and the change in incidence is associated with improved hygiene or social standards in Western societies. In contrast, UC is a more global disease (Karlinger et al., 2000). The median age of patients with IBD at diagnosis has increased over time, partly due to a higher proportion of elderly patients (>65 years of age), especially in UC. However, the incidence of CD is also increasing in patients younger than 17 years of age. The lifetime risk for Caucasians to develop UC is twice that of developing CD (0.15%) (Schreiber et al., 2005). Hence, the incidence of IBD varies with geographic location, industrialization and the availability of diagnostic means. It ranges from 0.5 to 24.5 per 100,000 people per year for UC, and from 0.1 to 10 per 100,000 per year for CD (Gallop et al., 1988; Moum et al., 1996; Russel et al., 1998). There is an evident north–south gradient, with the highest incidence of IBD occurring in northern countries, such as Scandinavia and Scotland, followed by Northwest Europe (the Netherlands, United Kingdom) and the United States, and with the lowest reported incidences in southern, Mediterranean Europe (Greece, Crete, Italy). Recent data from developing countries show similar trends (Jiang et al., 2006). Apart from the differences in incidence rates of IBD around the world, national, and regional differences have also been observed (Ekbom et al., 1991; Latour et al., 1998; Timmer and Goebell, 1999; Timmer et al., 1999). Reported prevalence rates of UC and CD also vary widely in different studies, ranging from 21 to 234 per 100,000 for UC and from 12 to 146 per 100,000 for CD. Colorectal CD seems to be increasing, and in UC, proctitis and left-sided UC seem to be becoming more prevalent.

Both diseases show variation in the individual clinical presentation and outcome that is most likely due to differences in genetic susceptibility, exposure to environmental factors, the commensal bacteria in the intestine, and the intestinal immune system. Even though CD and UC share some features, they also show major differences and it is still not clear whether both disorders are related at the molecular level, which would justify lumping them together as IBD. However, more and more evidence is emerging that a dysregulated mucosal immune response underlies the chronic intestinal inflammation, potentially initiated by a dysfunctional (immunological) intestinal barrier.

PREDISPOSITION (GENETIC AND NON-GENETIC)

Current theories suggest that multiple factors, each of relatively weak effect, may act together to influence disease risk in IBD. Apart from genetic factors, there is evidence that supports an association between IBD and a large number of seemingly unrelated environmental factors, including smoking, oral contraception, diet, breastfeeding, drugs, geographical and social status, stress, microbial agents, intestinal permeability, and appendectomy (Corrao et al., 1998; Danese et al., 2004; Garcia Rodriguez et al., 2005; Loftus, 2004). However, only smoking has been confirmed as a clear environmental risk factor for IBD, protecting against UC but increasing the risk for CD (Cosnes, 2004).

In addition, IBD has a strong genetic component, although this seems to be more pronounced in CD than in UC. The derived heritability in CD is higher than for many other common complex diseases. Evidence for a strong inherited predisposition to IBD susceptibility comes from twin studies and studies of familial aggregation (Peeters et al., 1996; Satsangi et al., 1994; Tysk et al., 1988). There is, however, no discernable Mendelian inheritance pattern; thus we must assume a complex pattern of inheritance in which both susceptibility genes and environmental factors may contribute to IBD pathogenesis.

Twin studies provide a powerful means of assessing the contribution of both genetic and environmental factors to disease susceptibility (Martin et al., 1997). There are different measures of concordance used in such studies, but those based on National Twin Registries allow the individual twins to be selected independently of disease, so that they can then be assessed separately. In a recent study based on 38,507 identified twins born in Denmark from 1953 to 1982, the proband-wise concordance rates for UC and CD among monozygotic and dizygotic twins were estimated and found to be 58.3% for CD and 18.2% for UC among the monozygotic pairs, and 0% and 4.5%, respectively among the dizygotic pairs (Halfvarson et al., 2003; Orholm et al., 2000).

The sibling relative risk provides a further measure of the heritability of IBD and is defined as the risk to an affected patient's sibling divided by the population risk (prevalence). Estimates from German (Kuster et al., 1989) and northern France/Belgium (Laharie et al., 2001) populations suggest sibling relative risks for CD of 15–35. For a sibling of an UC patient, this risk is substantially lower: a Danish (Orholm et al., 1991) and Italian (Meucci et al., 1992) study showed relative sibling risks of 6–9 for UC. Another argument for a genetic contribution to IBD pathogenesis stems from differences in prevalence among different ethnic groups, with the highest rates found amongst Caucasians and people with an Ashkenazi Jewish background (Roth et al., 1989; Yang et al., 1993).

Over the past 10 years substantial progress has been made in identifying susceptibility genes for IBD, using both genome-wide linkage scans in affected sibling pairs and genetic association studies. To date, 14 genome-wide linkage scans have been conducted that have resulted in the identification of at least 9 loci (*IBD1-IBD9*). A recent meta-analysis on data from 10 genome-wide scans also revealed the *IBD1*, *IBD3*, *IBD5*, and *IBD6* loci, as well as many novel loci (Van Heel et al., 2004). Unfortunately not all IBD susceptibility loci have been replicated consistently. Silverberg and colleagues showed that IBD is frequently misdiagnosed, thereby reducing the ability to detect linkage (Silverberg et al., 2001). A recent study using a phenotyped cohort of 904 affected relative pairs uncovered novel loci and also demonstrated that the *IBD2* locus is an extensive UC locus (Achkar et al., 2006). The next step, to go from a linkage region to a disease susceptibility gene, has also proved to be difficult. The usual course is to switch from a family-based linkage design to a population-based genetic association design (Wild and Rioux, 2004). The latter requires large numbers of case/control pairs and polymorphic markers able to capture all the genetic variation. The identification of the vast majority of common (>1%) single nucleotide polymorphisms (SNP) and the correlation between them ("HapMap") (Altshuler et al., 2005) will revolutionize such studies in future. From the established IBD linkage regions, only the disease susceptibility genes from *IBD1* (*CARD15/NOD2*) and *IBD5* (*SLC22A4/SLC22A5*) have been uncovered (Table 45.1). Both these genes confer risk of CD. The current status of genetic research in IBD has been discussed in excellent reviews by Bonen and Cho (2003), Wild and Rioux (2004), Newman and Siminovitch (2005), and Vermeire and Rutgeerts (2005).

The *CARD15/NOD2* gene was identified through both a classical positional cloning strategy (Hugot et al., 2001) and a positional and functional candidate gene approach (Hampe et al., 2001; Ogura et al., 2001). Mutations in *CARD15/NOD2* are found in approximately 30% of CD patients. Although multiple variants in the gene can increase susceptibility only to CD, the most commonly identified mutations are the R702W, G908R, and L1007fsinsC. The increased risk conferred by mutations in the *CARD15/NOD2* gene depends on the number of mutant alleles: heterozygosity increases the risk 2- to 3-fold, whereas homozygosity is associated with a 20- to 40-fold higher risk of developing CD. However, the frequencies of mutant *CARD15/NOD2* alleles vary considerably across European populations (Arnott et al., 2004) and show low frequencies in northern European countries (Arnott et al., 2004; Helio et al., 2003; Medici et al., 2006; Thjodleifsson et al., 2003). *CARD15/NOD2* mutations are associated with a more severe form of the disease, an early age at onset, and ileal lesions (Abreu et al., 2002; Hampe et al., 2002; Lesage et al., 2002). *CARD15*, the caspase recruitment domain (CARD) family member 15 protein, is a member of the Nod1/Apaf-1 family and encodes a protein with two CARDs and six leucine-rich repeats (LRRs). The protein is primarily expressed in the peripheral blood leukocytes, but also in the intestinal epithelial layer, in particular in Paneth cells and associated with mucosal alpha-defensin expression (Ogura et al., 2003; Wehkamp et al., 2004). It plays also a role in the immune response to intracellular bacterial lipopolysaccharides (LPS) by recognizing the muramyl dipeptide (MDP) derived from them and activating the NF-kB protein. Although its role in CD is

Table 45.1 Genes known or suspected of being involved in IBD pathogenesis

Replicated IBD genes/loci	Chromosomal location	Disease	Relative risk heterozygote/ homozygote	Alleged mechanism of action	Genotype/ phenotype correlation
CARD15/NOD2 (IBD1)	16q13	CD	2–4 versus 20–40	Innate immunity, balance of immunological response	Ileal involvement and earlier clinical presentation
DLG5	10q23	CD	~1.5	Maintenance of epithelial barrier integrity	Ileal (combined with peri-anal)
SLC22A4/OCTN1, SLC22A5/OCTN2 (IBD5)	5q31–q33	CD	2.5 versus 4	Epithelial barrier	Multi-site, more severe phenotype
MYO9B	19p13	UC	1.2	Epithelial barrier	
IL23R	1p31	IBD	0.26	Innate immunity	Both small intestinal (ileal CD) and large intestinal (UC) inflammation
ATG16L1	2q37.1	CD	1.45	Mediating innate immune response to bacteria, interaction with NOD2	
Suggested IBD genes/loci					
IBD2	12q14	UC		?	Extensive UC
IBD3	6p21			MHC associated immunological responses	Both small intestine and colonic disease locations
IBD4	14q11–12	CD			Interaction with smoking
MDR1/ABCB1	7q22	IBD?		Membrane transporter (xenobiotic handling)	Refractory (and extensive) disease
PXR		IBD		Response to xenobiotics	
NOD1/CARD4	7p14	IBD		Innate immunity	Early age at onset (<25 y)
TLR-9	3p21			Mediating innate response, interaction with NOD2	
TLR-4		IBD		Mediating innate immune response to gram-negative bacteria. Interaction with NOD2	
TLR-5				Mediating innate immune response to flagellin	
NF-kB1	4q	IBD		Pivotal mediator of generation pro-inflammatory cytokines	
ICAM-1 (IBD6?)	19p13	IBD		Function of pivotal adhesion molecule	In CD: fistulizing disease. In UC: limited disease extent
PPARg (IBD9?)		IBD		Innate response to intestinal bacteria	
COX2		IBD		Inflammatory response	
TNFSF15				Pivotal pro-inflammatory cytokine	

not entirely elucidated, many leads point at involvement with the innate immune response.

Fine-mapping of the *IBD5* locus initially led to the identification of a unique haplotype of 250 kb (Rioux et al., 2001). Since the SNPs within the haplotype were in strong linkage disequilibrium, they all conferred risk to CD. The association to the 250 kb haplotype has been replicated extensively, thereby confirming the importance of the *IBD5* locus. Subsequently, extensive sequence analysis revealed two variants within the organic cation transport genes *SLC22A4/OCTN1* and *SLC22A5/OCTN2,* which have been proposed to alter the gene function and expression and to form a haplotype associated with CD risk (Peltekova et al., 2004). Because of the strong linkage disequilibrium across the entire 250 kb haplotype, it remains to be proven if the two identified variants act independently of the surrounding SNPs (reviewed in Reinhard and Rioux, 2006). *SLC22A4/OCTN1* and *SLC22A5/OCTN2* are involved in the active cellular uptake of carnitine across the intestinal epithelial layer. The role of the *SLC22A4/OCTN1* and *SLC22A5/OCTN2* genes in CD pathology is not clear, but they are thought to act through an inappropriate inflammatory host response to commensal flora.

The fine-mapping of an IBD locus on 10q23 (Hampe et al., 1999) resulted in the identification of the *DLG5* gene, a member of the family of discs large (DLG) homologs (Stoll et al., 2004) and the membrane-associated guanylate kinase (MAGUK) superfamily. DLG5 localizes to the plasma membrane and cytoplasm and interacts with components of adherens junctions and the cytoskeleton. A function in the transmission of extracellular signals to the cytoskeleton and in maintaining epithelial cell structure has been proposed. The association with *DLG5* varies significantly across populations (Buning et al., 2006; Daly et al., 2005; Ferraris et al., 2006; Gazouli et al., 2005; Medici et al., 2006; Newman et al., 2006; Noble et al., 2000a; Tenesa et al., 2006; Torok et al., 2005; Tremelling et al., 2006; Vermeire et al., 2005; Yamazaki et al., 2004).

More recently, the celiac disease-associated gene *MYO9B* (Monsuur et al., 2005), which localizes to the *IBD6* locus, was shown to be associated with IBD in four different populations (Van Bodegraven et al., 2006). Table 45.1 gives an overview of the different genes known or suspected of being involved in IBD pathogenesis. The picture that is emerging suggests that genes involved in IBD are either important in the innate immune response to commensal bacteria or involved in the maintenance of the epithelial barrier.

More recently it has become possible to perform genome-wide genetic association studies. Using 300,000 SNPs a highly significant association was found between CD and SNPs in the gene encoding a subunit of the proinflammatory cytokine IL23 (*IL-23R)* (Duerr et al., 2006). An uncommon coding variant within the *IL-23R* gene strongly protects against CD. The proinflammatory cytokine IL23 is considered to be a driver of innate immune pathology in the intestine. A second genome-wide study using nearly 20,000 nonsynonymous SNPs, found a strong association between CD and the autophagy-related 16-like 1 gene (*ATG16L1*) encoding a protein in the autophagosome pathway that processes intracellular bacteria (Hampe et al., 2007). The association of both IL23R and *ATG16L1* to CD fits in the emerging picture that genes involved in IBD are important in the innate immune response to commensal bacteria.

SCREENING

Screening for IBD can either be performed in high-risk families, or in the population at large. Apart from the general remarks on screening in a specific cohort, in particular for a disease with no known cure, risk factors have to be available. In affected families we can use the genetic risk factors to identify people at risk of developing IBD. A number of potential genetic risk factors have already been described that predispose to IBD, with *CARD15/NOD2* being the most commonly-associated gene. Unfortunately, the three common *CARD15/NOD2* risk variants have low sensitivity (38.5%) and rather low specificity (88.6%) for preventive screening of CD (Chamaillard et al., 2006). As there are no strategies for influencing the risk profile to attract disease, screening for this or any other risk gene does not yet contribute to diagnostic or treatment strategies for a (potential) patient.

In addition, several biomarkers have been described that are present in both IBD patients and in unaffected family members; these include increased intestinal permeability, anti-*Saccharomyces cerevisiae* antibodies (ASCA), and perinuclear antineutrophil cytoplasmatic antibodies (pANCA). In addition to these three markers, antibodies against microbial substances such as anaerobic coccoid rods, *Pseudomonas fluorescens* (I2), flagellins, and the outer membrane porin C of *Escherichia coli* (OmpC) have also been described in affected IBD patients (Bouma et al., 1999; Oudkerk Pool et al., 1993; Shanahan et al., 1992; Vermeire et al., 2001). It is interesting that these markers all point to the underlying etiopathogenetic hypothesis of IBD, namely a dysfunctional intestinal barrier function, leading to a dysfunctional handling of macromolecules and (intestinal) bacterial antigens, finally leading to an exaggerated immunological intestinal mucosal response, whether at the level of antigen-presenting cells or of cells involved in acquired immunological reactions (Fasano et al., 2005; Schreiber et al., 2005). Whereas serum pANCAs are mainly associated with UC (Oudkerk Pool et al., 1993), ASCA have particularly been associated with CD. *S. cerevisiae*, present in baker's yeast, is found in a wide variety of foods, and thus are an antigenic challenge to most people. Although it has been hypothesized that individuals characterized by an increased leakage of *S. cerevisiae* antigens generate ASCA, this hypothesis does not hold true for other commonly present, similar antigens, such as *Candida albicans*, which are not regularly found in CD patients.

Although these markers can be used in combination for some degree of differentiation between UC and CD (see also the Diagnosis section below), the presence of these types of markers has not been associated with a particular course of the disease, nor do they have enough sensitivity and specificity to help delineate non-affected people at risk of developing IBD (Yang et al., 1995).

DIAGNOSIS

UC and CD are clinically distinct disorders that are also differentially diagnosed. Recent research is aimed at genotype–phenotype associations in order to improve clinical assessment and treatment of patients. To interpret these genotype–phenotype data, phenotypical assessment has to be of outstanding and reproducible quality. Efforts to clearly define different subtypes of IBD have been undertaken by a group of IBD-experts at the World Congress of Gastroenterology 2005, Montreal, leading to the Montreal classification (Silverberg et al., 2005).

Ulcerative Colitis

UC is clinically characterized by urgency, bloody stools, a high-defecation frequency and abdominal discomfort, and it is commonly associated with fever and weight loss. In general, the severity of symptoms parallels the intensity and extent of inflammation. The inflammatory reaction primarily involves the mucosa of the large bowel, characteristically appearing as a continuous inflammation from the anal verge to the more proximal colon with a sharp demarcation to apparently normal mucosa. Microscopic examination reveals erosions, ulcerations, cryptitis, crypt abscesses, and infiltration of polymorphonuclear granulocytes, plasma cells, lymphocytes, and eosinophils in the lamina propria, accompanied by mucin depletion.

UC can be diagnosed by a combination of characteristic clinical, endoscopic, and pathohistological findings. Corroborating findings may be observed in blood chemistry (inflammatory response, iron-deficiency or chronic-disease associated anemia), in feces analysis (markers of inflammation, such as calprotectin), in the absence of microbial pathogens, and in serological findings, in particular the presence of pANCA. Endoscopic findings are invaluable for the subclassification of the disease, because this depends on disease extent. The role of radiological examination is limited in UC patients (Hanauer, 2004).

Classification of UC depends on disease extent, with subclasses of distal disease confined to the rectum (proctitis) or rectum and sigmoid colon (proctosigmoiditis), left-sided disease (from anal verge to splenic flexure), and universal or pancolitis, referring to disease proximal to the splenic flexure and usually involving the complete colon (pancolitis), in the new Montreal classification referred as E1-3. Severity of disease is classically assessed by the Truelove and Witts score, but several other combined scores are available.

Crohn's Disease

CD is an inflammatory disease of the whole intestinal tract, thus leading to a broad spectrum of clinical presentations. Its most classical course is a localized inflammation of the terminal ileum, causing periods of relapsing abdominal pain with gradual weight loss, followed after months to years by postprandial pain with colitis due to intestinal obstruction. Involvement is limited to the colon, which was only acknowledged in the middle of the 20th century, although it presents with the same symptoms as UC, except that rectal bleeding is less pronounced. Increasingly, colorectal disease has been reported over time in several epidemiological studies. Furthermore, oral (granulomatous) ulceration or cheilitis, esophageal inflammation with difficulty of food passage and retrosternal pain, epigastrial pain and nausea due to gastritis or duodenal inflammation may all occur. Inflammation due to CD may extend over the whole bowel wall, but is frequently discontinuous, with alternating normal and affected areas. The transmural inflammation may lead to fistula formation between bowel segments, or between bowel and skin, bladder, or vagina. Peri-anal fistulas are relatively common. The macroscopic appearance encompasses areas of inflammation with erythema, exudate and aphtoid ulceration that may confluence and form large, deep tramline ulcers, or – when ulcers fuse transversely – cobblestones. Subsequent healing may lead to strictures. Characteristically, these areas of inflammation are patchy, whereas continuous inflammation, especially of the colon, may occur. The hallmark early microscopic lesion is an aphtoid ulcer; histopathologic ulcer features in a surrounding with unaffected, adjacent crypts. Focal mucosal disease is a pivotal histopathologic finding: focal cryptitis, focal chronic inflammation, isolated (acute) terminal ileitis all fit in with CD. Granulomas, localized well-formed aggregates of epitheloid histiocytes preferably in the presence of giant cells or a surrounding cuff of lymphocytes, are regularly found.

CD can be diagnosed by the combination of characteristic clinical, endoscopic, and pathohistological findings. Again, additional findings may be found in blood chemistry (inflammatory response, iron deficiency or chronic disease-associated anemia), in feces (calprotectin), in the absence of microbial pathogens, and in serological findings, in particular the presence of ASCA. The role of radiological examination is complimentary to endoscopic findings in CD patients. Small bowel diagnostics still rely on classical radiological methods such as small bowel follow-through and enteroclysis. Recently, newer techniques have begun replacing the old ones. These new techniques include CT scans and MRI scans, preferentially enhanced by intra-intestinal and vascular contrast. In addition, a video capsule has been developed, introducing visual assessment of the small bowel and leading to a more accurate small bowel assessment, while double-balloon endoscopy has provided endoscopic access to the complete small bowel since 2001, allowing sampling for biopsy specimens as well as visual assessment.

CD is usually classified by a combination of age, disease localization, and disease behavior, detailed in the Vienna classification (Gasche et al., 2000). In 2005 the Vienna classification was updated to become the Montreal classification (Silverberg et al., 2005). Severity of CD is most commonly assessed by the CD activity index (CDAI), a score that calculates disease activity for eight components, some of which are monitored over 7 days: stool frequency, general well-being, abdominal discomfort, erythrocyte sedimentation rate (ESR), weight, extra intestinal symptoms, use of antidiarrheal drugs, and fever. The validity of such a subjective, 7 days' score has been discussed extensively. An instant bedside or bureau-side method is the Harvey-Bradshaw (HB) score that is highly related with CDAI, comprising frequency of liquid stools,

general well-being, abdominal pain, complications (extra-intestinal symptoms), and presence of an abdominal mass. This handy score is less widely used than CDAI in clinical (scientific) practice, partly due to EMEA and FDA regulations on drug registration. In order to avoid any subjective measure in a severity assessment score, a Disease activity score (DAI) of laboratory values and calculable physical signs was drawn up. The main problem with this score is its cumbersome calculation. CDAI and DAI are only related to a small extent. It is of interest that in recent clinical trials with biologicals patients were stratified for elevated CDAI score as well as an increased C-reactive protein (CRP) concentration as an indicator the acute phase response. Apparently, CDAI calculation underscores inflammatory variables. A solely subjective score reflecting the quality of life of IBD patients has been validated with the same purpose; assessment of disease activity and response to therapy. The most regularly used score is the Inflammatory Bowel Disease Questionnaire (IBDQ) a 32-item questionnaire that evaluates quality of life using four dimensions: bowel complaints, general malaise, social impact, and emotional burden.

Serological markers may be helpful in identifying patients with IBD. pANCA is expressed in the majority of UC patients, varying from 30–85%, whereas only 4–30% of CD patients show this profile, and then, particularly, in patients with CD confined to the colon, making differentiation between UC and CD more difficult. Patients suffering from concurrent primary sclerosing cholangitis (PSC) have a higher prevalence of pANCA. Positive reactions against ASCA, identifying antibodies against yeast cell wall phosphopeptidomains, are more commonly found in CD patients (50–70%) than in UC patients (6–14%), and healthy controls (0–5%). IgA type antibodies appear to have a higher specificity for CD, but ASCA is also present in celiac disease (up to 30%), ankylosing spondylitis, autoimmune hepatitis, and others.

The presence in various IBD populations – and their family members – of other detected microbial antibodies, such as against the outer membrane porin C of *E. coli* (OmpC), antibodies against *P. fluorescens* (I2) and several more has not been studied sufficiently to be of use in diagnosing disease. The origin and significance of these antibodies are yet unknown.

The genetic background of IBD patients varies greatly, making the presence of the susceptibility genes already described insufficient to diagnose IBD, even in cohorts of people at risk, such as family members. Two well-described examples of these risk genes that are (as yet) unsuitable for establishing a diagnosis are *HLA-DRB1*0103* for UC in Caucasians, *HLA-DRB1*1502* in Japanese and *CARD15/NOD2* in CD. Genetic markers are therefore not currently used in the diagnostic process of IBD.

Despite the differences in clinical characteristics between CD and UC, some 10% of patients are diagnosed as unclassified or indeterminate colitis (depending on whether surgery, i.e., proctocolectomy, has been performed) as they cannot be classified as either CD or UC. Up till now, no serological, genetic or other characteristics can distinguish with enough accuracy between the three IBD-diagnoses, UC, CD, and unclassified colitis. A recent study showed that gene expression on peripheral blood monocytes can provide biomarkers to distinguish CD and UC patients (Burczynski et al., 2006). Although these results need to be validated and replicated in independent and prospective cohorts, this type of diagnostic tools holds great promise for the future.

PROGNOSIS

The course of UC is usually relapsing, a disease pattern occurring in about 90% (Langholz et al., 1994). About 10% will have only one period of active disease in a 25-year time span and the probability of chronic active UC is also low (<20%) (Langholz et al., 1994; Witte et al., 2000). Risk factors precipitating relapses are use of aspirin or NSAID, enteric infection, and seasonal variation, possibly related to stimulation of the (eosinophils-mediated) immune system. Smoking and appendectomy appear to be protective (Andres and Friedman, 1999). About 25–40% of UC patients will require surgery in the short- or long-term (Turner et al., 2007). Chronic active, medical-therapy refractory UC is considered to be a proper indication for surgery, usually proctocolectomy in combination with an ileo-anal pouch reconstruction. Prior to surgery, high-dose intravenous corticosteroid therapy up to 60 mg prednisolone-equivalents daily is usual and well-documented to be effective in about two-third of patients (Turner et al., 2007). Predictors of surgical intervention are disease extent, clinical signs of severe systemic disease involvement (such as stool frequency, temperature, heart rate), and inflammatory variables like serum CRP and albumin concentration, whereas fecal calprotectin concentration holds promise for the future (Turner et al., 2007). In addition, fulminant active disease, concurrent development of colonic adenocarcinoma, and complications due to active disease such as intractable colonic bleeding or stenosis are other indications for surgery. Although observed in large cohorts, the increased risk of developing colonic adenocarcinoma is relatively limited. Risk factors for colonic adenocarcinoma comprise the presence of primary sclerosing cholangitis (PSC), and non-responsive disease of the universal colon. This increased risk comes on top of general markers of an increased risk for the development of colonic carcinoma, such as a positive family history. The debate of an increased risk of lymphoma in IBD patients is still ongoing, with confounding factors of chronic disease, use of immunosuppressive and other methodological difficulties.

Markers for the course of UC comprise both serological and genetic markers. Although the presence of pANCA has neither been associated with disease localization, disease severity, nor response to therapy, it is more commonly found in patients with concurrent PSC. The latter has been associated with development of colonic (and cholangio-) adenocarcinoma. Genetic markers of disease severity include *HLA DRB1*0103*, *IKBL+738*, and *hMLH1* 655A > G. The *HLA DRB1*0103*-allele has been associated with a severe course of UC, including non-response to corticosteroids and necessity of surgery (Satsangi et al., 1996; Roussomoustakaki et al., 1997), and similar findings were reported in a Spanish UC cohort for the presence of *IKBL+738* (de la Concha et al., 2000). The *hMLH1* gene

might be involved in genetic susceptibility to refractory UC as the GG genotype at position 655 of the *hMLH1* gene was almost 5 times more frequent in refractory UC patients compared with nonrefractory patients (Bagnoli et al., 2004). These and other combinations of genes have been associated with clinical course; however most studies could not be reproduced or concerned rather small patient cohorts, limiting the clinical significance in daily practice.

The course and prognosis of CD has been described extensively by Munkholm et al., based on large population-based cohorts from Denmark (Munkholm et al., 1994, 1997; Langholz et al., 1997). These population studies are excellent for extracting data on disease course, but refer mainly to this particular Nordic population so that extrapolation to other populations remains difficult. Nevertheless, these data reveal that the course of disease during the first year after diagnosis predicts the course in the following 5 years. Being quiescent in the first year gives rise to a quiescent disease course in subsequent years in 44% of CD patients; only 8% have an active course of disease. The remaining 48% suffers from a relapsing disease course. In patients with an active disease in the first year following diagnosis, these numbers are 5% and 45%, with 50% having a relapsing course. A second approach is to subclassify according to the proposals from a working group of IBD experts in Vienna, the so-called Vienna classification (Gasche et al., 2000), later updated in Montreal (Silverberg et al., 2005). In particular, patients with a diagnosis at young age and those suffering from penetrating disease have a worse disease outcome. Surgery, as a measure of failure of medical therapy, and thus of a disadvantageous course of CD, is still necessary in about 70% of patients. This high percentage has not yet dropped, notwithstanding new therapies, showing that truly disease-modifying treatment approaches still need to be developed.

Many efforts have been undertaken to identify predictors of disease course allowing for adapted therapeutic approaches. Most, however, have restricted clinical value. ASCA positivity is associated with small intestinal localization of disease (terminal ileum), and correlated with young age of diagnosis of CD. Presence of IgG and IgA antibodies is associated with a stenotizing or penetrating type of disease behavior and less often with a chronic inflammatory colonic type of CD (Abreu et al., 2002; Mow et al., 2004).

In phenotype-genotype studies, the course of CD is usually classified according to anatomic localization, disease behavior, and age of onset (according to the Vienna classification). There is no evidence, however, that this subclassification constitutes nosologic entities. In addition, the Vienna classification varies over time due to the developing course of disease (Louis et al., 2001). However, the validity and rigor of phenotyping are major factors in the adequate interpretation of correlations with an alleged genetic background. Thus interpretation of genotype studies to predict disease course is proving difficult, and fixed time spans have been suggested in the Montreal classification before a phenotype can be reliably assessed. Immediately following the description of *CARD15/NOD2*, several groups reported a phenotypic correlation of one of the major mutated *CARD15/NOD2* alleles with localization of CD in the ileum, a finding that has been corroborated repeatedly. Surgery and a stricturing phenotype of CD have also been reported in several series (Alvarez-Lobos et al., 2005; Russell et al., 2005), whereas, interestingly, the *CARD15/NOD2* genotype did not predict response to the potent anti-TNF-alpha drug infliximab. Other genes reported to be associated with CD, including the infrequent *HLA-DRB1*03*, *SLC22A4/OTCN1* and *SLC22A5/OCTN2* (Noble et al., 2005; Vermeire et al., 2005), and the *IBD 5* (Latiano et al., 2006) locus, have been related to a variety of phenotypes, including earlier age of disease onset, peri-anal (fistulizing) disease, ileal or colonic disease, or reduced need of surgery; there are no corroborating data from large cohorts.

Extra-intestinal manifestations have been reported since the very beginning that IBD has been recognized as a disease entity. Extra-intestinal complications comprise inflammatory changes of joints, eyes, cutis, and liver, but also thrombo-embolic manifestations and osteoporosis. Several studies have reported an overall incidence in 25–35% of IBD patients. Symptoms may be confined to any single organ system, although combinations of organ systems can also occur. A wide variety of rare manifestations have been reported. Most frequently the joints are affected with arthralgia and peripheral or axial arthritis. Other regular manifestations involve the skin, showing erythema nodosum or pyoderma gangrenosum, the eyes with inflammatory reactions such as (epi)scleritis and uveitis, the bone with osteopenia or even osteoporosis, the liver with PSC, leading to an increased risk of cholangiocarcinoma, the hematological tract with anemia and thrombocytopenia, and finally the vascular system with thrombo-embolic events. In addition, many autoimmune disorders may be associated with IBD. Some of these manifestations or concurrent diseases may reflect a common intestinal pathology, with a common pathway immunological response. Hence, IBD might be considered a systemic disorder disease, which may have implications for the proper recognition of patients at risk for IBD, especially when the extra-intestinal manifestations or concurrent diseases precede the development of IBD.

It is likely that genetic factors contribute to expression of this highly variable clinical picture, but few studies have been published. A correlation between the phenotype of IBD-associated arthropathy and HLA alleles has been reported, with *HLA-B27* and *HLA-B35* related to complaints of large joints and *HLA-B44* to small joints (Orchard et al., 2000). The same group of investigators ascribed a role for HLA alleles in the occurrence of ocular and cutaneous symptoms (Orchard et al., 2002). Other genetic factors have been associated with bone loss in IBD patients. Non-carriage of the 240-base pair allele of the *IL-1ra* gene and carriage of the 130-base pair allele of *IL-6* were independent of clinical severity of disease and application of corticosteroids associated with increased bone loss in a group of 83 IBD patients (Schulte et al., 2000).

It is likely that larger, well-phenotyped cohorts of IBD patients will allow for better study of genetic markers for extraintestinal manifestations, as may be deduced from efforts with specific IBD-associated containing chips, the so-called "IBDChip" (Sans et al., 2006). The IBDchip is the world's first diagnostic

DNA chip and is currently being validated in the European community. The chip contains 61 known polymorphic alleles, with alleged association with diagnosis and course of IBD and is aimed at a better prediction of prognosis and response to therapy of patients suffering from IBD.

PHARMACOGENOMICS

A broader understanding of the IBD disease pathology will deliver novel drug targets for disease intervention. It is anticipated that genomics and proteomics technologies will assist in compound identification in drug discovery. Infliximab, a chimeric monoclonal antibody against TNF-alpha, is such a target that neutralizes one of the critical inflammatory mediators in IBD. Nevertheless, the drug is only effective in 40–66% of patients after 2 years of treatment (Hanauer et al., 2002; Present et al., 1999; Sands et al., 2004). It is clear that drug response, in general, is partly genetically determined. Carriage of *CARD15/NOD2* seems to play no role in response to infliximab (Mascheretti et al., 2002; Vermeire et al., 2002), whereas another study on CD patients who had received infliximab showed that patients homozygous for the V allele of the *FcgammaRIIIa-158* polymorphism had a better biological and possibly better clinical response to infliximab (Louis et al., 2004). In addition, there has been a suggestion that the *IBD5* locus is involved in response to infliximab (Urcelay et al., 2005). Recently there has also been a report suggesting that the lack of response to infliximab can, in part, be attributed to certain genetic polymorphisms in two apoptosis genes, Fas ligand and caspase-9 (Hlavaty et al., 2005). Additional studies are needed to corroborate these findings.

IBD patients homozygous for the methylenetetrahydrofolate reductase (*MTHFR*) 1298C allele are more likely to experience side effects than patients homozygous for the wild-type A allele (21.0% versus 6.3%, $P < 0.05$) when treated with the immunosuppressor methotrexate (MTX) (Herrlinger et al., 2005). This is in contrast to what was found in patients with rheumatoid arthritis where the *MTHFR* 1298A allele was associated with MTX-related adverse events in both Caucasians and African-Americans (Odds Ratio [OR] 15.86, 95% CI 1.51-167.01; $p = 0.021$) (Hughes et al., 2006). Similar results were observed in a Japanese study on rheumatoid arthritis, which showed that subjects with the 1298A allele had a higher frequency of side effects from MTX ($P < 0.05$, RR = 1.42, 95% CI 1.11-1.82) (Urano et al., 2002). These conflicting results raise some concern and require additional validation studies as well as a better understanding of how MTX works.

A more well-established polymorphism influencing drug response is the thiopurine methyl transferase gene (*TPMT*) in relation to the outcome of therapy with thiopurines, of which azathioprine and 6-mercaptopurine are frequently used in IBD patients. The metabolism of azathioprine or 6-mercaptopurine is rather complicated, involving various enzymatic steps with interindividual differences in genotype and phenotype. Essentially, the therapeutic activity of thiopurines is related to the concentration of the metabolite 6-thioguanine nucleosides (6-TGN), probably mediated by the phosphorylated forms of this metabolite (Neurath et al., 2005; Poppe et al., 2006). The pivotal enzyme TPMT methylates 6-mercaptopurine and its metabolite 6-thioinosinemonophosphate (6-TIMP) into 6-methylmercaptopurine (6-MMP) and 6-methyl-thioinosinemonophosphate (6-MTIMP), respectively. The activity of TPMT is genetically regulated (Krynetski et al., 1996; Yates et al., 1997). Approximately 1 in 9 patients is heterozygous for the common polymorphisms, and 1 in 300 patients is homozygous. Patients with one mutant (dysfunctional) TPMT allele have a diminished TPMT activity and patients with two non-functional mutant alleles have no TPMT activity. Low TPMT activity will result in an increased amount of azathioprine or 6-mercaptopurine being metabolized by hypoxanthine phosphoribosyl transferase (HGPRT), resulting in high levels of 6TGN. Hence, TPMT deficiency leads to a potentially life-threatening myelo-suppression as 6-TGN accumulates. TPMT with a higher than average activity leads to generation of high levels of 6-MMP, which has been associated with hepatotoxicity in one study in a specific group of children suffering from CD (Dubinsky et al., 2000), and 6-MTIMP, and low levels of 6TGN. This is associated with therapeutic inefficacy. Taken together, determination of the TPMT alleles may be helpful in predicting response to thiopurine therapy and in assessment of risk of myelotoxicity or hepatotoxicity. Its determination prior to treatment with thiopurines has therefore been advocated. Nevertheless, other factors contribute to adverse events of thiopurines, as has been shown by retrospective analysis of more than 40 IBD patients in whom thiopurines had to be withdrawn due to myelotoxicity. Of these the majority had wild-type TPMT alleles, although most patients with myelodepression in the first weeks of treatment were homozygous for mutant alleles (Colombel et al., 2000).

The response to glucocorticosteroids also seems to be partly genetically determined. Polymorphisms in the multidrug-resistance gene 1 (*MDR-1*) are excellent candidates to affect the absorption and concentrations of MDR-1 substrates (Farrell et al., 2000; Hoffmeyer et al., 2000). In a study in Hungarian patients it has been suggested that the *DLG5* 113A allele – which was shown not to be associated with disease susceptibility – may confer resistance to steroids (Lakatos et al., 2006).

With the advanced understanding of human genetic variation, it is now possible to perform genome-wide association studies (GWAS) in large cohorts of responders and non-responders to identify genetic risk and efficacy factors that are related to the effects of such drugs; this is similar to what is being done to identify disease susceptibility genes. Such research may have broad implications since it is likely that the response to a particular drug will not be restricted to the IBD phenotype. Hence, in future, these genetic profiles may help tailor disease treatment and patient care by increasing efficacy and preventing adverse drug reactions (Egan et al., 2006).

2009 UPDATE

With improved genotyping technologies and the completion of the human genome sequence, GWAS have recently become possible and were declared the breakthrough of the year in 2007 (Pennisi, 2007). Not only has the first successful GWAS been performed in CD (Duerr et al., 2006), but inflammatory bowel disease (IBD) has been studied very extensively and also very successfully with nine GWAS for CD (Duerr et al., 2006; Franke et al., 2007; Hampe et al., 2007; Kugathasan et al., 2008; Libioulle et al., 2007; Raelson et al., 2007; Rioux et al., 2007; Wellcome Trust Case Control Consortium, 2007; Yamazaki et al., 2005) and a subsequent meta-analysis of three of these studies (Barrett et al., 2008). There are currently more than 30 CD-associated loci. To date three GWAS for UC have been performed in addition, revealing more than 10 UC-associated loci (Fisher et al., 2008; Franke et al., 2008; Silverberg et al., 2009). This has put IBD at the forefront of complex disease genetic research.

The first GWAS (Duerr et al., 2006) identified the gene encoding a subunit of the interleukin 23 receptor (*IL23R*) on chromosome 1p31 as a susceptibility gene for CD in a population of non-Jewish patients of European ancestry with ileal CD. An uncommon variant, Arg381Gln, was shown to have a strong protective effect for CD, and other noncoding *IL23R* variants were independently associated. This association was confirmed in independent cohorts and, although less strongly, is also associated with UC susceptibility (Weersma et al., 2008c). Since the proinflammatory cytokine IL23 is increasingly being recognized as involved in gut inflammation, this finding is of great importance in elucidating the pathogenetic background of IBD.

The second study (Hampe et al, 2007) found a strong association between CD and the autophagy-related 16-like 1 gene (*ATG16L1*) encoding a protein in the autophagosome pathway, which processes intracellular bacteria. A coding SNP (Thr300Ala) was strongly associated with susceptibility for CD. A third GWAS by the US NIDDK consortium in CD identified the same SNP in *ATG16L1* to be associated with CD and demonstrated that functional knockdown of the gene abrogates autophagy of *Salmonella typhimurium,* suggesting that autophagy and host cell responses to intracellular microbes are involved in the pathogenesis of CD (Rioux et al., 2007). A large GWAS including 14,000 cases (including 2000 CD patients) and 3000 controls by the Wellcome Trust Case Control Consortium (WTCCC, 2007) and a follow-up study (Parkes et al., 2007) identified variants in *IRGM*, which, like *ATG16L1*, is also involved in autophagy, to be associated with CD susceptibility. The finding that autophagy is involved in CD pathogenesis is compatible with the reported therapeutically beneficial administration of the autophagy-inducing mTOR inhibitors sirolimus and everolimus to refractory IBD-patients (Dumortier et al., 2008; Massey et al., 2008).

The WTCCC study and the follow-up study identified 12 loci, including *IRGM* that met the criteria for genome-wide significance. These included SNPs at 1q24, 1q31, 3p21 (harboring the macrophage stimulating-1 *MST-1* gene), *IL12B*, *NKX2-3*, and 21q22. Furthermore, the previously known *IBD5* locus at 5q31 and the gene desert on 5p13, identified by a French–Belgian GWAS, were confirmed (Libioulle, et al., 2007; Parkes et al., 2007; Rioux, 2001; WTCCC, 2007). Of interest is that the Protein Tyrosine Phosphatase 2 (*PTPN2*) gene is not only associated with CD, but also with type 1 diabetes, which reflects the partly shared pathogenesis of these distinct immune-related diseases (Zhernakova et al., 2009). Furthermore it is interesting that in the WTCCC study, CD was by far the most informative disease with regard to associated genes when compared to the other diseases that were studied, such as hypertension, bipolar disorder, and coronary heart disease.

Additional loci that were identified by GWAS were the nel-like precursor encoding gene (*NELL1*), paired-like homeobox 2B (*PHOX2B*), 10q21, and 16q24 (Franke et al., 2007; Rioux et al., 2007). Furthermore, an extensive three-stage analysis of genes involved in innate immunity identified two loci harboring *CARD9* and *IL18RAP* to be associated with both CD and UC (Zhernakova et al., 2008). Two loci on 20q13 and 21q22 were found to be associated with pediatric onset IBD in yet another GWAS (Kugathasan et al., 2008). A candidate gene study identified SNPs located in a predicted regulatory region on chromosome 1q44 downstream of *NLRP3* (Villani et al., 2008).

In 2008 a meta-analysis was performed, combining data from the UK–WTCCC, French–Belgian, and US–NIDDK studies. This has been a tremendously successful effort with 19 newly identified loci, which were replicated in an independent cohort, and confirmation of 11 previously published loci. These new loci included, amongst others, *PTPN22, JAK2, STAT3*, and *CDKAL1* (Barrett et al, 2008).

Despite the fact that many novel genes were identified to be involved in CD pathogenesis, until recently relatively little was known about UC. Most studies so far in UC focused on known CD risk variants. These studies showed that several risk loci are common to both CD and UC, while others – such as *ATG16L1*, *IRGM*, and *CARD15* – were specific for CD. Confirmed common CD–UC risk factors include variants in *MST1*, *NKX2-3*, *IL23R*, *IL12B*, and *CCNY* (Fisher et al., 2008; Franke et al., 2008). A genome-wide candidate gene experiment investigating 10,886 nonsynonymous SNPs in 905 British UC patients and 1465 controls identified the Extracellular Matrix Protein 1 (*ECM1*) on 1q21.2 as a UC-specific susceptibility gene (Fisher et al., 2008). ECM1 is known to strongly activate NF-κ B signaling which is a recognized key mediator in IBD. Another comprehensive genetic association analysis of 41

genes from the tight junction pathway, represented by 197 tag SNPs, showed association with *PARD3* (involved in cell polarity) and *MAGI2* (a scaffolding protein) for both UC and celiac disease, delineating the apparently shared genetic background of these diseases (Festen et al., 2008; Van Bodegraven et al., 2006; Wapenaar et al., 2008; Zhernakova et al., 2009).

In 2008, a European GWAS in UC was performed that identified several novel genetic variants that contribute to UC susceptibility. The most strongly replicated signals showed association to *IL10, ARPC2*, and the *HLA-BTNL2* region. IL10 is an immune-response inhibiting cytokine which has been investigated for many years in IBD. Notably, *IL10-/-* mice are known to develop a spontaneous colitis, indicating the probable important role of IL10 in UC (Franke et al., 2008). Another GWAS in UC from the United States confirmed *IL23R* and the *HLA-BTNL2* region and identified two additional loci on chromosomes 1p36 and 12q15 (Silverberg et al., 2009).

Although the genetics of IBD is only scratching the surface and many more variants remain to be identified, the first studies have been initiated to look at predictive value of molecular markers for disease diagnosis and prognosis (Weersma et al., 2008a, b).

CHAPTER

Asthma Genomics

Scott T. Weiss, Benjamin A. Raby and Juan C. Celedón

INTRODUCTION

Asthma is a complex disease affecting over 300 million individuals in the developed world (Palmer and Cookson, 2000). Ninety percent of all asthma cases, including asthma in adults, have their origin in childhood. Of concern are the increases in asthma prevalence (CDC, 1995) and hospitalization rates (Weiss et al., 1993). Between 1980 and 1994, the self-reported prevalence of asthma in the United States of America increased from 30.7 to 53.8 per 1000, an increase of 75% (CDC, 1995). This increase has been accompanied by a similar increase in health care utilization and mortality over the same time period (CDC, 1995). An estimated 12.6 billion dollars were spent on the diagnosis and management of asthma in the United States in 1998, of which 58% were direct medical expenditures (Sullivan and Strassels, 2002). Despite the availability of several classes of therapeutic agents for asthma, it has been estimated that as many as one-half of asthmatic patients do not respond to treatment with β_2-agonists, leukotriene antagonists, or inhaled corticosteroids (Drazen et al., 2000; Liggett, 2001; Silverman et al., 2002). It is quite likely that genetics and genomics will significantly impact asthma in the next 5 years particularly in the area of prediction of clinical events.

ASTHMA: BASIC PATHOBIOLOGY

Asthma is a clinical syndrome of unknown etiology characterized by reversible episodes of airflow obstruction, airway hyperresponsiveness, and a chronic inflammatory process of the airways of which mast cells, eosinophils, T-lymphocytes, epithelial cells, and airway smooth muscle cells play a prominent role (Elias et al., 2003). Figure 46.1 shows important pathobiologic features of asthma. $CD4^+$ lymphocytes produce IL-3, IL-4, IL-5, IL-13, and GM-CSF and thereby promote the synthesis of IgE, an important allergic effector molecule. Chemokines, such as eotaxin, RANTES, and IL-8 produced by epithelial and inflammatory cells, serve to amplify and perpetuate the inflammatory events. Several bronchoactive mediators, such as histamine, leukotrienes, and neuropeptides are released into the airways and precipitate an asthma attack by causing airway smooth muscle constriction, mucus secretion, and edema. Over time, there is smooth muscle growth and the deposition of subepithelial connective tissue, a process referred to as airway remodeling. Clinically, asthmatics have difficulty exhaling air because of an increase in airway resistance that is a consequence of smooth muscle contraction, inflammation, and remodeling (Figure 46.2). Physiological impairment is quantitated most commonly by the forced expiratory volume in 1 s (FEV_1) (Figure 46.2). FEV_1 is the volume of air a person can "blow out" in 1 s and is very useful as a measurement of lung function because it is easily obtained, reproducible, and correlated with asthma severity and therapeutic responses (ATS, 1987). While it is difficult to be precise, it is reasonable to estimate that although there is general agreement on the physiology described above, the actual genetic and genomic architecture of these events is just beginning to be described. The above description of events, while true, is likely

to only represent 15–20% of the total pathobiology that will be ultimately elucidated by genomic methods.

PREDISPOSITION (GENETIC AND NON-GENETIC) TO ASTHMA

Non-Genetic Predisposition

Eighty percent of childhood asthmatics exhibit hypersensitivity to indoor aeroallergens (Sears et al., 1991), and high concentrations of indoor allergens can worsen asthma symptoms in sensitized individuals (Rosenstreich et al., 1997). In a small follow-up study of atopic children of atopic parents, exposure to high concentrations of dust mite allergen in the first year of life was associated with higher risk for sensitization and asthma at age 11 (Sporik et al., 1990). Although certain home characteristics are significant predictors of dust mite, cat, and cockroach allergen exposure, they may be poor at predicting whether low levels of allergen are present in a home (Chew et al., 1998). Since "low levels" of indoor allergens may lead to sensitization in susceptible individuals, direct measurement of allergen concentrations in house dust have been recommended for use in epidemiologic studies (Chew et al., 1998).Viral respiratory infections are a cause of asthma exacerbations but not a proven cause of disease onset. Passive (primarily *in utero*) and active cigarette smoking are the other major environmental cause of the disease. It is likely that the response to these environmental exposures has a genetic and or genomic basis; however, virtually nothing is known about the important genetic predictors of adverse response to these environmental agents. Polymorphisms in IL13 and ADRB2 seem to predict response to passive and active cigarette smoking, respectively, but nothing is known about the relationship of genetic polymorphisms to other important environmental exposures.

Genetic Predisposition

Data from a significant number of studies indicate familial aggregation of asthma (Jenkins et al., 1997; Van Arsdel and Motulsky, 1959). A method frequently used to establish the existence of familial aggregation of a trait is to calculate the recurrence risk to relatives of type R (λ). Using data from Sibbald et al. (1980) resulted in a λ of 3.3 for asthma. Familial aggregation, however, could result from genetic factors or a shared environment. Estimates of the heritability of asthma in several twin studies conducted around the world have ranged from 36% to 79% (Duffy et al., 1990; Edfors-Lubs, 1971; Hopp et al., 1984; Lubs, 1972; Nieminen et al., 1991; Sibbald et al., 1980), with the highest values coming from studies that had a more comprehensive phenotypic assessment of asthma (Sandford et al., 1996).

GENOME-WIDE LINKAGE ANALYSES OF ASTHMA AND ITS INTERMEDIATE PHENOTYPES

To date, 16 groups have reported results of genome-wide linkage analysis for asthma phenotypes (Table 46.1) (Bleecker et al., 1999; Celedon et al., 2007; CSGA, 1997; Daniels et al., 1996; Dizier et al., 2000; Evans et al., 2004; Ferreira et al., 2005; Haagerup et al., 2002; Hakonarson et al., 2002; Hersh et al., 2007b; Koppelman et al., 2002; Laitinen et al., 2001; Ober et al., 1998; Pillai et al., 2006; Wjst et al., 1999; Xu et al., 2000, 2001a, b; Yokouchi et al., 2000). Several of these groups have published second-generation surveys with larger numbers of subjects and/or markers (Blumenthal et al., 2004; Brasch-Andersen et al., 2006; Dizier et al., 2005; Huang et al., 2003; Meyers et al., 2005; Ober et al., 2000a, b; Xu et al., 2001a, b). In spite of obvious heterogeneity in the design of these studies, 13 regions have shown significant evidence of linkage to asthma or its intermediate phenotypes: chromosomes 2p16 (to airway hyperresponsiveness (AHR), in families from Europe, Australia, and the United States) (Pillai et al., 2006), 2p25 (to AHR, in Chinese families) (Xu et al., 2001a, b), 2q33 (to eosinophil count in Australian

Table 46.1 Results of genome-wide linkage analyses of asthma and/or its intermediate phenotypes[a]

Reference	Population	Number of families (subjects)	Linkage to asthma**	Linkage to intermediate phenotypes of asthma
Daniels et al. (1996)	Australian	80 (363)	Not assessed	Skin test index=**11q12**; AHR[b] = 4q, 7p; eosinophil count = 6p; atopy = 6p, 13q; total serum IgE= 16q

Van Eerdewegh et al. (2002)	North American and British	460 (920)	**20p13**	Not assessed (results for AHR not presented separately from asthma)
Ferreira et al. (2005)	Australian	202 (591)	1q, 4p, 11p, 17q, 18p, 19p	AHR = 6p, 20q; atopy = 2q, 3q, 6p, 17q, 20q; dust mite allergy=**20q13**; total serum IgE = 10q
Evans et al. (2004)	Australian	539 (2360)	Not assessed	Eosinophil count=**2q33**, 8q
Pillai et al. (2006)	North American, European, Australian	414 (1555)		AHR=**2p16**, 4p
Celedon et al. (2007); Raby et al. (2007)	Costa Rican	8 (638)	12q	AHR=**12q24** (nonsmokers); total serum IgE=**20p12** (males)

** Complete linkage results for all chromosomes not published.

[a] Only regions showing suggestive or significant evidence of linkage (as defined by Lander and Kruglyak) to asthma and/or its intermediate phenotypes (other than measures of lung function) are shown. Regions with significant evidence of linkage to asthma and/or its intermediate phenotypes are **bold**.

[b] AHR = airway hyperresponsiveness.

[c] Large pedigree divided into 10–20 sub-pedigrees for data analysis.

twins) (Evans et al., 2004), 5q31-q33 (to mite-sensitive asthma in a Japanese population) (Yokouchi et al., 2000), 7p14-p15 (to total serum IgE in a Finnish population) (Laitinen et al., 2004), 7q21 (to total serum IgE in a Dutch population) (Xu et al., 2000), 11q12-q13 (to atopy in Australians and asthma in African Americans) (Huang et al., 2003; Laitinen et al., 2004), 12q24 (to asthma in Denmark (Brasch-Andersen et al., 2006) and AHR in Costa Rica (Celedon et al., 2007), 14q24 (to asthma in an Icelandic population) (Hakonarson et al., 2002), 19p13 (to dust mite allergy in whites in the United States) (Blumenthal et al., 2004), 20p12 (to total IgE among Costa Rican males) (Raby et al., 2007), 20p13 (to asthma in families from the United States and United Kingdom) (Van Eerdewegh et al., 2002), and 20q13 (to dust mite allergy in Australians) (Ferreira et al., 2005).

In spite of the relatively large number of genomic regions linked to asthma-related phenotypes, only five potential asthma-susceptibility genes (PDH finger protein 11 [*PHF11*], dipeptidylpeptidase 10 [*DPP10*], disintegrin and metalloprotease 33 [*ADAM 33*], G protein-coupled receptor for asthma susceptibility [*GPR154* or *NPSR1*], and human leukocyte antigen G [*HLA-G*]) have been identified by a positional cloning approach (Allen et al., 2003; Laitinen et al., 2004; Nicolae et al., 2005; Van Eerdewegh et al., 2002; Zhang et al., 2003). In all cases, significant linkage between a chromosomal region and asthma phenotypes in a genome-wide linkage analysis was followed by fine-mapping studies of linkage and association in the linked region. Replication studies of the association between asthma phenotypes and these potential asthma-susceptibility genes have yielded inconsistent results, and no specific asthma-susceptibility variants have been identified within these genes (Hersh et al., 2007a, b). However, results of multiple association studies (Hersh et al., 2007a, b), as well as functional data in rodents and humans provide strong support for a significant role of GPR154 in asthma pathogenesis (Laitinen et al., 2004).

CANDIDATE-GENE ASSOCIATION STUDIES OF ASTHMA

Although there are more than 500 genetic association studies for asthma, most suffer from methodological problems including small sample size, non-comprehensive coverage of the gene(s) of interest, failure to correct for multiple testing, and (for case-control studies) lack of adjustment for population stratification. To date, there have been reports of positive associations between variants in over 100 genes and asthma phenotypes (Ober and Hoffjan, 2006). Using the gene as the unit of replication (a very liberal criterion), more than 40 associations were replicated in at least two populations and 17 associations were replicated in at least 5 populations (Allen et al., 2003; Hersh et al., 2007a, b; Ober and Hoffjan, 2006). On the other hand, few associations have been replicated for specific polymorphisms in genes for a particular phenotype and in the same direction, suggesting that LD with adjacent variants and/or bias explains a significant proportion of these findings.

Variants in nine positional candidate genes (IL4, IL4RA, IL13, ADRB2, CD14, TNFA, HLA-DRB1, HLA-DQB1, and FCERIB) have been associated with asthma phenotypes in at least ten populations (Ober and Hoffjan, 2006). Through activation of its receptor, interleukin 4 (IL4) stimulates production of total serum IgE. The IL4 and IL4 receptor α chain (IL4RA) loci are on genomic regions linked to asthma phenotypes (5q31 for IL4 and 16p12 for ILRA). A functional SNP in the promoter of IL4 has been associated with total serum IgE (Rosenwasser et al., 1995), asthma (Rosenwasser et al., 1995), rhinitis (Zhu et al., 2000), asthma severity (Sandford et al., 2000), and atopic dermatitis (Novak et al., 2002). SNPs in exons of IL4RA have been associated with asthma (Mitsuyasu et al., 1998), total serum IgE (Howard et al., 2002), atopic dermatitis (Hershey et al., 1997), and asthma severity (Rosa-Rosa et al., 1999). The interleukin 13 (IL13) and monocyte differentiation antigen CD14 (CD14) genes are on chromosome 5q31-33, a region linked to asthma phenotypes. Experiments in rodents and humans support a critical role of interleukin 13 in asthma pathogenesis (Grunig et al., 1998). Functional SNPs in the promoter and coding regions of IL13 have been associated with asthma (Heinzmann et al., 2003; Howard et al., 2001; van der Pouw Kraan et al., 1999), airway responsiveness (Howard et al., 2001), atopy (DeMeo et al.,2002; Howard et al., 2001), eosinophilia (Hunninghake et al., 2007), and total serum IgE (Graves et al., 2000; Hunninghake et al., 2007). CD14 is a receptor for bacterial cell wall components that may influence immune responses (Guerra et al., 2004). A functional SNP in the promoter of CD14 has been associated with total serum IgE (Baldini et al., 1999), atopy (Ober et al., 2000a, b), food allergy and non-atopic asthma (Woo et al., 2003), and airway responsiveness (O'Donnell et al., 2004). Tumor necrosis factor alpha (TNFA) is a proinflammatory cytokine (Wang et al., 2004), and HLA class II molecules are candidates for controlling immune responses to allergens. The TNFA and human leukocyte antigen DRB1 (HLA-DRB1) genes are on chromosome 6p21, a genomic region linked to asthma phenotypes. A functional variant in the promoter of TNFA has been associated with asthma (Moffatt and Cookson, 1997), airway responsiveness (Moffatt and Cookson, 1997), atopy (Castro et al., 2000), and total serum IgE (Shin et al., 2004). Functional SNPs and/or haplotypes in HLA-DRB1 have been associated with sensitization to specific allergens (Ansari et al., 1989), atopy (Aron et al., 1996), asthma (Di Somma et al., 2003), and total serum IgE (Moffatt et al., 2001). The gene for the beta chain of the high affinity receptor for IgE (FCERIB) is on chromosome 11q13, a genomic region linked to atopy. SNPs and/or haplotypes in FCERIB have been associated with asthma (Cox et al., 1998; Green et al., 1998), total serum IgE (Li and Hopkin, 1997; Shirakawa et al., 1994), and atopy (Shirakawa et al., 1994). Although there are studies refuting the association between each of these nine positional candidate genes and asthma phenotypes, many of these negative studies lacked adequate statistical power to exclude weak-to-moderate genetic effects. In addition, multiple studies have found an association between known functional SNPs in seven

of these genes (IL4, IL4RA, CD14, IL13, TNFA, ADRB2, and HLA-DRB1) and asthma phenotypes. Thus, current evidence suggests that these genes influence asthma pathogenesis.

GENOME-WIDE ASSOCIATION STUDIES OF ASTHMA

To date, only one genome-wide association study of asthma has been published (Moffatt et al., 2007) After testing for association between a panel of 317,000 SNPs and asthma in subjects with and without asthma, Cookson and coworkers identified a gene on chromosome 17q21 (ORMDL3) as a potential susceptibility gene for asthma. These findings were then replicated in two independent cohorts. Other genome-wide association studies of asthma and its intermediate phenotypes are ongoing.

ASTHMA GENOMICS

Complementing these genetic surveys are a handful of studies examining global gene expression patterns in experimental models of asthma and allergic inflammation, in addition to several clinical studies (Brutsche et al., 2002; Guajardo et al., 2005; Hansel et al., 2005; Karp et al., 2000; Laprise et al., 2004; Lilly et al., 2005; Zimmermann et al., 2003; Zou et al., 2002a, b). Akin to genome-wide SNP association studies, the primary strength of genome-wide microarray surveys of gene expression is that they are hypothesis-free in that no assumptions regarding the underlying pathobiology of the conditions under study are placed on data gathering, analysis or interpretation. As such, these approaches have the potential to reveal previously unsuspected molecules or pathways relating to asthma and allergy. Table 46.2 summarizes microarray studies in asthma assessing *in vivo* gene expression (studies of cultured asthma-relevant cells, transgenic mouse models of asthma, or pharmacogenetics are not included). In one of the first studies, Karp and colleagues combined pulmonary tissue gene expression data with SNP genotypes (an example of integrative genomics) in segregating backcross mice to identify C5 as a primary mediator of allergic response (Karp et al., 2000). They demonstrated that: (1) C5 was the only differentially expressed gene following allergen challenge among high- (A/J) and low- (C3H/HeJ) responder mice that also mapped to an AHR locus on chromosome 2; (2) C5 expression is strain dependent and correlates with a 2-bp missense mutation; and (3) blockade of C5 signaling inhibits allergen-mediated responses. Human studies suggest that C5 expression is increased in allergic airway inflammation (Krug et al., 2001) and that C5 genetic variation influences asthma susceptibility (Hasegawa et al., 2004). In a second study, Zimmermann and colleagues (2003) studied patterns of differential gene expression in two models of allergic pulmonary inflammation and identified a common set of differentially expressed genes relating to arginine metabolism, thus implicating this previously unsuspected pathway in the pathogenesis of allergic inflammation. It is interesting that initial genetic association studies of arginase I and II suggest that genetic variants in this pathway are also related to asthma susceptibility (Li et al., 2006).

In contrast to the studies in mouse models, the results from six published studies of gene expression in human populations of asthmatics have been somewhat less exciting in that few truly novel biologic pathways have been reported. We note that these studies evaluated relatively small number of individuals and varied greatly in the tissues studied, analytic methods used, and definitions of significant differential gene expression. It is, therefore, not surprising that the gene signatures identified have little in common with each other. However, it is notable that each of these studies identified genes previously implicated in asthma pathobiology, and several of these genes harbor genetic variation previously associated with asthma-susceptibility and severity (see Table 46.2). It is therefore likely that many of the other genes identified in these studies play previously unrecognized roles in the pathogenesis of asthma. The challenge remains separating the wheat from the chaff. Given the size of these differentially expressed asthma gene sets – as many as 324 genes in one study of nasal epithelium (Guajardo et al., 2005) – experimental validation using animal models is not feasible on a large scale. One approach would be to test all of the identified genes for evidence of genetic association in asthma cohorts. As an example, Laprise and colleagues have demonstrated association to asthma with five polymorphisms (including one non-synonymous variant) in the CX3CR1 fractalkine receptor (Tremblay et al., 2006). This gene was among those demonstrating greatest differential expression in bronchial epithelium derived from asthmatics (Laprise et al., 2004).

The most important cumulative result of these early studies is that together they demonstrate the feasibility of using expression profiling for the study of asthma, and should prompt a second generation of genomic epidemiologic studies. We suggest that the first step include repeating some of these earlier study designs but using considerably larger sample size, with a focus on identifying gene expression signatures and global patterns of gene expression (rather than specific genes). These studies should be large enough to enable splitting of the cohort in two to allow follow-up validation studies of the predictive accuracy of any identified signatures – such as assessment of the predictive power of identified sets in differentiating asthma affection status, atopic status, or disease severity. In addition, these studies should include collection of DNA from all subjects to enable integration of gene expression data with SNP genotype data for the identification of asthma-associated regulatory variation. In this way, investigators will not only have a catalog of differentially expressed asthma genes, but also a set of putative functional variants for follow-up in well-designed genetic association studies.

PHARMACOGENETICS

The two main types of asthma drugs are the so-called "reliever" drugs that target the acute bronchoconstriction and the so-called

Table 46.2 Published expression microarray studies in asthma**

Study	Organism	Tissue/cell type	Phenotype assessed	Sample size	Major findings
Karp et al. (2000)	A/J and C3H/HeJ mice	Lung tissue	Ovalbumin challenge	4 A/J, C3H/HeJ, F1 8 F1xA/J backcross	21 genes overlapping all cross-strain comparisons, including C5, on chromosome 2 (airways responsiveness QTL)
Zou et al. (2002a, b)	Cynomolgus monkeys	Lung tissue	IL4 or Ascaris suum inhalational challenge	Controls = 6 IL4 = 1, Ascaris = 6	149 genes (2.5-fold change), including eotaxin, MCP-1, PARC, COL2A1
Zimmermann et al. (2003); Munitz et al. (2007)	Balb/c mice	Lung tissue	Allergen challenge with ovalbumin or A. Fumigatus	Ova = 3 A. Fumigatus = 3 Control = 5	291 genes overlapping. l-arginine metabolism genes identified: CAT2, Arginase I and Arginase II. CD48 antigen later implicated following allergen challenge
Brutsche et al. (2002)	Human	Peripheral blood mononuclear cells	Atopic status	Atopy and Asthma = 18 Atopy, no asthma = 8 Controls = 14	Developed composite score (10 genes) with 96% sensitivity and 92% specificity for differentiating atopy from controls. Included IL1RA1, IL6, RET, CD71
Laprise et al. (2004)	Human	Bronchial wall	Asthma versus normal pre- and post-ICS	Asthma = 4 Normal = 4	79 genes, including 21 previously implicated in asthma, including ALOX15, NOS2A, TRAa, MUC5A, COL2A1
Hansel et al. (2005)	Human	Peripheral blood $CD4^+$ lymphocytes	Asthma severity	Mild, no ICS = 5 Mild, ICS = 5 Severe = 5	40 genes, including TGFB1, UTS2, TRDa@, JUND
Guajardo et al. (2005)	Human	Nasal epithelium	Asthma exacerbation	Control = 10 Stable = 10 Exacerbation = 10	324 genes (2-fold change) including IL1b, Defensinb1, IL1R1, retinoic acid receptor
Lilly et al. (2005)	Human	Bronchial epithelium	Segmental airway allergen challenge	5 asthmatics pre- and post- challenge	149 genes (2-fold change) including IL1RN, IL1b, PTGFR, MCP-1, NFKB, MIP1b
Youssef et al. (2007)	Human	Peripheral blood basophils	Response to IgE receptor cross-linking	3 nonreleasers and 5 releasers, pre- and post- cross-linking	253 differentially expressed genes following “releaser” basophil stimulation, including RANTES, MIP1β, VEGF, heat-shock proteins

**Studies of cultured asthma-relevant cells, transgenic mouse models of asthma, or pharmacogenetics are not included.

"controller" drugs that are used to reduce the severity of airway inflammation and the severity and frequency of obstruction (CSGA, 1997). The main reliever drugs are rapid-acting β_2-agonists (e.g., albuterol, metaproterenol, pirbuterol, levalbuterol), which relax the bronchial smooth muscle by activating β_2-adrenergic receptors. This is the treatment of choice for very mild asthma. For moderate and severe asthma, the reliever treatment is usually combined with controller treatment. The two commonly used classes of controller agents are the inhaled glucocorticoids and the leukotriene inhibitors. Inhaled glucocorticoids (e.g., budesonide, beclomethasone, flunisolide, and fluticasone) and leukotriene inhibitors (e.g., montelukast and zafirlukast) modify the inflammatory micro-environment of the airway to reduce airway obstruction and hyperresponsiveness.

There is large interindividual variation in the treatment response to asthma medications (Drazen et al., 2000; Szefler et al., 2002). For example, in a study by Malmstrom and colleagues comparing the efficacy of the inhaled steroid beclomethasone (200ug bid) with the leukotriene antagonist montelukast (10 mg/qd), it is clear that both drugs are effective over a 12-week course of treatment with a mean increase in FEV_1 of 13.1% for the beclomethasone group and 7.4 % for the montelukast group (Figure 46.3a) (Malmstrom et al., 1999). However, when these same data are viewed from a different perspective, focusing on the number of individuals as a function of percent change in FEV_1 from baseline, it is clear that many patients had little response (Figure 46.3b). In fact, 22% of patients appear to have had an adverse response to treatment with a decline in FEV_1 at 12 weeks compared with baseline. The mean therapeutic improvement in FEV_1 for all patients is driven by a dramatic increase in FEV_1 in a minority of trial subjects. In a similar study, 38% of patients randomized to inhaled budesonide or fluticasone demonstrated improvements in FEV_1 of under 5% over the course of 24 weeks (Szefler et al., 2002). A unique subset of up to 25% of the non-responders can be classified as having glucocorticoid-resistant asthma (Chan et al., 1998). These patients are non-responsive to even high doses of oral steroids. Furthermore, a careful analysis of these studies indicates that individuals responsive to one class of asthma drug may not necessarily be the individuals responsive to a different class of asthma drug. Despite these studies, there is no universally accepted definition of a steroid (or β_2-agonist) non-responder. These types of data illustrating variable drug efficacy are not limited to asthma drug trials but can be found for almost all classes of drugs. The degree to which this interindividual variability is genetic remains uncertain and probably differs with each class of asthma drug. Moreover, interindividual variability may depend on the particular preparation within a class of asthma drug. Calculations of the repeatability (r) of the treatment response for all three classes of asthma drugs, defined as the fraction of the total population variance that results from within individual differences, show values for r between 60% and 80% indicating the upper limit of the genetic component and suggesting that a substantial fraction of the variance of the treatment response could be genetic (Drazen et al., 2000).

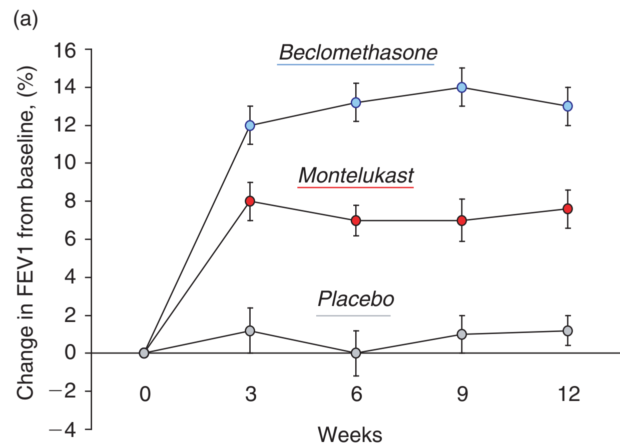

Figure 46.3a Standard approach to clinical trials data showing mean effect by treatment group.

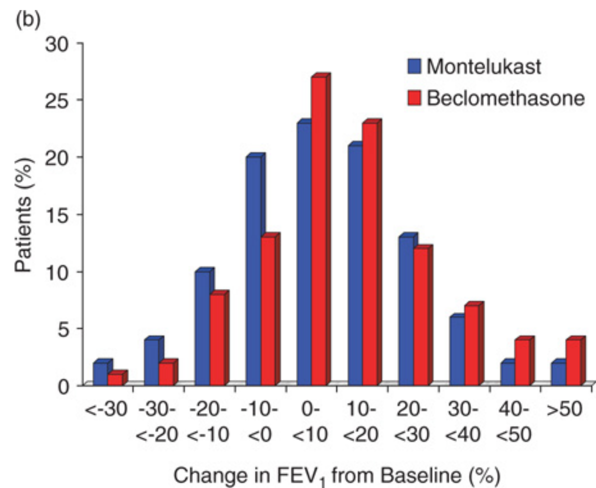

Figure 46.3b Histogram of individual response to beclomethasone subjects in first arm of 3a.

The leukotrienes (LT) are a family of lipoxygenated eicosatetraenoic acids derived from arachidonic acid and produced in the airways of asthmatics that are potent bronchoconstrictors. Of the many enzymes involved in the formation of the leukotrienes, polymorphisms in two, ALOX5 and LTC4S have been associated with altered response to LT inhibitors. ALOX5 catalyzes the conversion of arachidonic acid to LTA4, which is a rate limiting step involved in the synthesis of all leukotrienes (Silverman and Drazen, 1999). In 221 patients with asthma who received either high-dose ABT-761, an ALOX5 inhibitor similar to zileuton, (n=114) or placebo (n=107) treatment, we found that approximately 6% of asthmatic patients had no wild-type allele at the ALOX5 promoter locus and had a diminished response to ABT-761 treatment (Drazen et al., 1999). These findings were consistent with the hypothesis that repeats of the

–GGGCGG- sequence other than the wild type are associated with decreased gene transcription and ALOX5 product production. This has recently been confirmed in cells obtained from patients with asthma (Kalayci et al., 2003, 2006).

Another enzyme of the leukotriene pathway, LTC4S, is responsible for the adduction of glutathione at the C-6 position of the arachidonic acid backbone to form LTC4, a potent bronchoconstrictor. There is a known SNP in the LTC4S promoter, A-444C, with a C allele frequency of 0.19 in normal subjects and of 0.27 in patients with severe asthma (Sayers et al., 2003). The −444C allele creates an activator protein-2 binding sequence that appears to be functional (Sayers et al., 2003), suggesting that the −444C variant is associated with enhanced cysteinyl leukotriene production. Sampson and colleagues found that, among asthmatic subjects treated with zafirlukast (20 mg bid), those homozygous for the A allele ($n=10$) at the −444 locus had a lower FEV_1 response than those with the C/C or C/A ($n=13$) genotype (Sampson et al., 2000). These findings provide possible evidence of a second pharmacogenetic locus in addition to the ALOX5 promoter locus modulating the leukotriene pathway.

Studies evaluating the β_2-agonist pathway have focused largely on the β_2-adrenergic receptor gene (ADRB2). Numerous clinical (Israel et al., 2000, 2001; Reihsaus et al., 1993) and cellular (Liggett, 2000) studies, including one recent prospective, genotype-stratified, clinical trial (Israel et al., 2004), support the association of variation in this gene with response to inhaled β_2-agonist therapy. Other genes in the β_2-agonist pathway are now being actively investigated (Tantisira et al., 2005).

Genetic associations have also been reported for response to corticosteroids in asthma with the following phenotypes: lung function change (Tantisira et al., 2004b), airway constriction (Tantisira et al., 2004a) and relaxation (Tantisira et al., 2005), severe exacerbations (Tantisira et al., 2005), and steroid resistance.

2009 UPDATE

In 2008, substantial additional evidence emerged implicating filaggrin as an important gene in atipic eczema and in asthma associated with this disease. There is, however, no evidence that filaggrin is a risk factor for asthma in the absence of its association with atopic dermatitis (Brown et al., 2008; de Jongh et al., 2008; Henderson et al., 2008; Weidinger et al., 2008a, b).

Confirmation emerged for *ORMDL3* as an asthma locus, although there is controversy as to the importance of its nearest neighbor *GSDML* (Gasmin-like), which is in linkage disequilibrium with *ORMDL3* and may be coexpressed with it (Galanter et al., 2008; Wu et al., 2009). There is likely more to this story, and it will take some time to sort out.

A number of candidate genes have been initially associated with asthma including *IL17RB*, *LKX1*, *IL1RL1*, *IL18R1*, and *IL18RAP*.

Arginase 1 was identified as a gene determining the pharmacogenetic trait of short-acting response to bronchodilator, moving the focus away from *ADRB2* (Litonjua et al., 2008).

CHAPTER

Genomics in the Evaluation and Management of Chronic Obstructive Pulmonary Disease

Peter J. Barnes

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is characterized by progressive development of airflow limitation that is not fully reversible (Barnes, 2000a). The term COPD encompasses chronic obstructive bronchiolitis with obstruction of small airways and emphysema with enlargement of airspaces and destruction of lung parenchyma, loss of lung elasticity and closure of small airways (Hogg, 2004). Chronic bronchitis, by contrast, is defined by a productive cough of more than 3 months duration for more than 2 successive years; this reflects mucous hypersecretion and is not necessarily associated with airflow limitation.

COPD is common and is increasing globally. It is now the fourth leading cause of death in the United States and the only common cause of death that is increasing. This is likely to be an underestimate as COPD is likely to be contributory to other common causes of death. It is predicted to become the third most common cause of death and the fifth most common cause of chronic disability worldwide in the next few years (Lopez et al., 2006). It currently affects more than 5% of the adult population and is underdiagnosed in the community (Chapman et al., 2006). COPD consumes an increasing proportion of health care resources, which currently exceed those devoted to asthma by more than threefold.

There is persuasive evidence that the susceptibility to develop COPD is genetically determined, although the genes have not yet been identified. Genomics and proteomics are currently in use to understand the abnormal protein expression in this disease as a way of understanding its complex pathophysiology. There are clearly different phenotypes of COPD that need to be better defined. Finally pharmacogenomics may have an impact on COPD therapy in the future. This chapter gives an overview of COPD and highlights where genomic medicine is relevant to the future understanding and management of this common disease.

PREDISPOSITION

Several environmental and endogenous factors, including genes, increase the risk of developing COPD (Table 47.1).

Environmental Factors

In industrialized countries, cigarette smoking accounts for most cases of COPD, but in developing countries other environmental pollutants, such as particulates associated with cooking in confined spaces, are important causes. It is likely that there are important interactions between environmental factors and a genetic predisposition to develop the disease. Air pollution

TABLE 47.1 Risk factors for COPD

Environmental factors	Endogenous (host) factors
Cigarette smoking	α_1-Antitrypsin deficiency
Active	Other genetic factors
Passive	Ethnic factors
Maternal	
Air pollution	Airway hyperresponsiveness?
Outdoor	
Indoor: biomass fuels	
Occupational exposure	Low birth weight
Dietary factors	
High salt	
Low antioxidant vitamins	
Low unsaturated fatty acids	
Infections	

(particularly sulfur dioxide and particulates), exposure to certain occupational chemicals such as cadmium and passive smoking may all be additional risk factors. The role of airway hyperresponsiveness and allergy as risk factors for COPD is still uncertain. Atopy, serum IgE and blood eosinophilia are not important risk factors. However, this is not necessarily the same type of abnormal airway responsiveness that is seen in asthma. Low birth weight is also a risk factor for COPD, probably because poor nutrition in fetal life results in small lungs, so that decline in lung function with age starts from a lower peak value.

Genetic Factors

Longitudinal monitoring of lung function in cigarette smokers reveals that only a minority (15–40% depending on definition) develop significant airflow obstruction due to an accelerated decline in lung function (2- to 5-fold higher than the normal decline of 15–30 ml FEV_1/year) compared to the normal population and the remainder of smokers who have consumed an equivalent number of cigarettes (Figure 47.1). The rate of decline in lung function in the general population (Framingham Study) has a heritability of about 50% (Gottlieb et al., 2001). This strongly suggests that genetic factors may determine which smokers are susceptible and develop airflow limitation. Further evidence that genetic factors are important is the familial clustering of patients with early onset COPD and the differences in COPD prevalence between different ethnic groups (Sandford and Silverman, 2002). Patients with α_1-antitrypsin deficiency (proteinase inhibitor (Pi) ZZ phenotype with α_1-antitrypsin levels $<$10% of normal values) develop early emphysema that is exacerbated by smoking, indicating a clear genetic predisposition to COPD (Carrell and Lomas, 2002). However, α_1-antitrypsin deficiency accounts for $<$1% of patients with COPD, and many other genetic variants of α_1-antitrypsin that are associated with lower than normal serum levels of this proteinase inhibitor have not been clearly associated with an increased risk of COPD, although analysis of several studies indicates a small risk, with an odds ratio from COPD in Pi MZ versus Pi MM individuals of approximately two (Hersh et al., 2004).

This has lead to a search for associations between COPD and single nucleotide polymorphisms (SNPs) of other candidate genes that may be involved in its pathophysiology (Cookson, 2006). Various SNPs have been associated with COPD, as defined by a reduced FEV_1, but there is emerging evidence that different aspects of COPD may relate to different genotypes (Demeo et al., 2007; Hersh et al., 2006a). For example, a reduction in gas diffusion is correlated with SNPs of the microsomal epoxide hydrolase gene, reduced exercise performance is correlated with SNPs of the latent transforming growth factor-beta binding protein-4 (LTBP4), whereas dyspnea was linked to three SNPs in transforming growth factor β1 (TGF-β1). This suggests that more careful phenotyping is required in the future to sort out susceptibility genes. A 10-fold increased risk of COPD in individuals who have a polymorphism in the promoter region of the gene for tumor necrosis factor-α (TNF-α) that is associated with increased TNF-α production has been reported in a Taiwanese population but not confirmed in Caucasian populations. So far, few significant associations have been detected between SNPs and disease, and even those reported have not usually been replicated in other studies or have no obvious functional effects. Several other genes have been implicated in COPD, but few have been replicated in different populations. One SNP that has been replicated is heme oxygenase-1 (HMOX1), which is linked to protection against oxidative stress (Hersh et al., 2005) (Table 47.2). In addition to candidate genes that have been linked to the progressive lung disease, genetic factors are also important in addictive behavior, such as the nicotine addition of smokers, which has a high degree of heritability (Goldman et al., 2005). For example, SNPs of the dopamine transporter gene *SLC6A3* and the dopamine receptor 2 gene have been associated with nicotine addiction and inability to quit (Erblich et al., 2005).

Positional cloning is more likely to identify novel genes, and genome-wide linkage studies have identified some areas of weak linkage. The most convincing evidence is for linkage on chromosome 2q in the region of the *SERPINE2* gene, which encodes an antiprotease (Demeo et al., 2006). Several SNPs of the *SERPINE2* gene have been associated with increased susceptibility to COPD. Various high density genome-wide screens are currently in progress, with the aim of identifying novel genes involved in COPD susceptibility. This approach is now possible with high throughput genotyping of thousands of SNPs in very large populations.

PATHOPHYSIOLOGY

COPD includes chronic obstructive bronchiolitis with fibrosis and obstruction of small airways, and emphysema with enlargement of airspaces and destruction of lung parenchyma, loss of lung elasticity and closure of small airways. Chronic bronchitis, by contrast, is defined by a productive cough of more than 3 months duration for more than 2 successive years; this reflects mucous hypersecretion and is not necessarily associated with airflow limitation. Most patients with COPD have all three pathological mechanisms

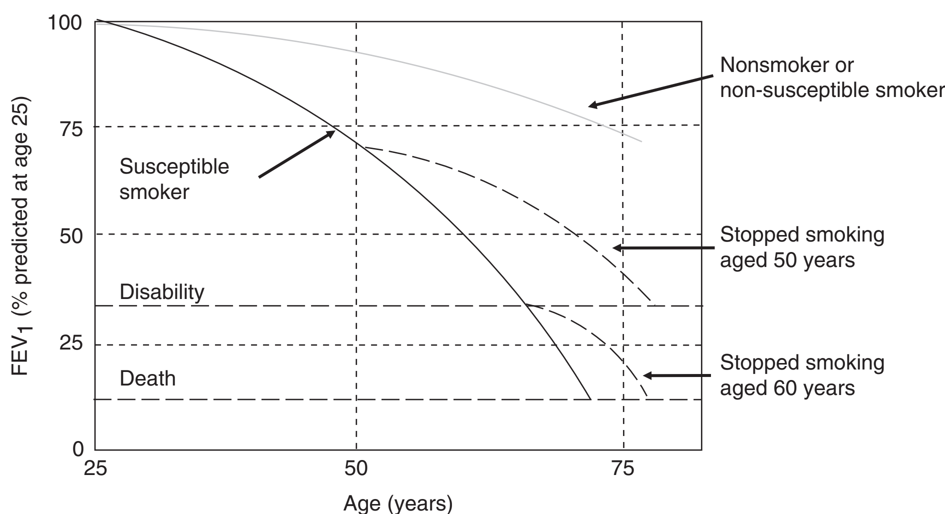

Figure 47.1 Natural history of COPD. Annual decline in airway function showing accelerated decline in susceptible smokers and effects of smoking cessation. Patients with COPD usually show an accelerated annual decline in forced expiratory volume in 1 second (FEV_1), often greater than 50 ml/year, compared to the normal decline of approximately 20 ml/year, although this is variable between patients. The classic studies of Fletcher and Peto established that 10–20% of cigarette smokers are susceptible to this rapid decline. However, with longer follow-up more smokers may develop COPD. The propensity to develop COPD amongst smokers is only weakly related to the amount of cigarettes smoked and this suggests that other factors play an important role in determining susceptibility. Most evidence points toward genetic factors, although the genes determining susceptibility have not yet been determined.

Table 47.2 Some of the genes associated with COPD susceptibility

Candidate genes	Risk
α_1-Antitrypsin	ZZ genotype high risk
	MZ, SZ genotypes small risk
α_1-Chymptrypsin	Associated in some populations
Matrix metalloproteinase-1, −2, −9, −12	Associated in some studies
Microsomal epoxide hydrolase	Increased risk
Glutathione S-transferase	Increased risk
Heme oxygenase-1	Small risk but consistent
Interleukin-13	Small risk
Vitamin D binding protein	Inconsistent
TNF-α promoter	Inconsistent
TGF-β promoter	Inconsistent

(chronic obstructive bronchitis, emphysema and mucus plugging) as all are induced by smoking, but may differ in the proportion of emphysema and obstructive bronchitis (Figure 47.2).

Small Airways

There has been debate about the predominant mechanism of progressive airflow limitation and recent pathological studies suggest that is closely related to the degree of inflammation, narrowing and fibrosis in small airways (Barnes, 2004c; Hogg et al., 2004). Emphysema may contribute to the airway narrowing in the more advanced stages of the disease, with disruption of alveolar attachments facilitating small airway closure and gas trapping. This combined effect of small airway disease and early closure on expiration results in lung hyperinflation, which results in progressive exertional dyspnea, the predominant symptom of COPD.

Emphysema

Emphysema describes loss of alveolar walls due to destruction of matrix proteins (predominantly elastin) and loss of type 1 pneumocytes as a result of apoptosis. Several patterns of emphysema are recognized: centriacinar emphysema radiates from the terminal bronchiole; panacinar emphysema involves more widespread destruction and bullae are large airspaces. Emphysema results in airway obstruction by loss of elastic recoil so that intrapulmonary airways close more readily during expiration. Emphysema with loss of gas-exchanging surface also leads to progressive hypoxia and eventually to respiratory failure.

Pulmonary Hypertension

Chronic hypoxia may lead to hypoxic vasoconstriction, with structural changes in pulmonary vessels that eventually lead to secondary pulmonary hypertension (Naeije, 2005). Inflammatory changes similar to those seen in small airways are also seen in pulmonary arterioles. Only a small proportion of COPD patients develop pulmonary hypertension, and it is likely that genetic susceptibility may play a role.

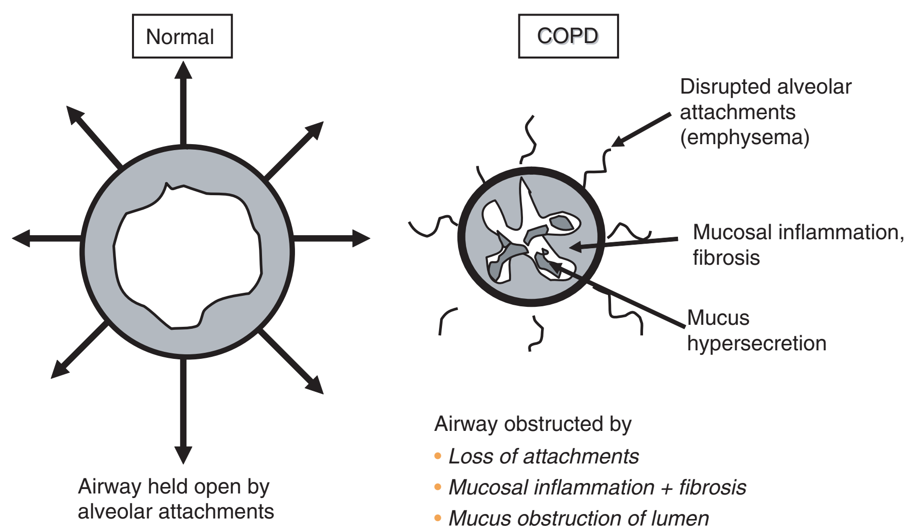

Figure 47.2 Mechanisms of airflow limitation in COPD. The airway in normal subjects is distended by alveolar attachments during expiration, allowing alveolar emptying and lung deflation. In COPD these attachments are disrupted because of emphysema thus contributing to airway closure during expiration, trapping gas in the alveoli and resulting in hyperinflation (Hogg, 2001). Peripheral airways are also obstructed and distorted by airways inflammation and fibrosis (chronic obstructive bronchiolitis) and by occlusion of the airway lumen by mucous secretions which may be trapped in the airways because of poor mucociliary clearance.

Systemic Features

Patients with severe COPD also develop systemic features, which may have an adverse effect on prognosis (Agusti et al., 2003). The most common systemic feature is weight loss due to loss of skeletal muscle bulk. This may contribute to the muscle weaknesses as a result of impaired mobility due to dyspnea. Other systemic features include osteoporosis and depression. These systemic features may be due to overspill of inflammatory mediators from the lung into the systemic circulation. There appears to be a difference in susceptibility to systemic features between patients as they do not always correlate with disease severity and this may be genetically determined. Patients with COPD also have comorbidities, particularly cardiovascular diseases. Smoking is a common risk factor for ischemic heart disease and COPD, but there may be shared genetic susceptibilities. There may be common genetic predispositions to COPD and cardiovascular diseases. COPD patients with coexisting cardiovascular disease have increased circulating levels of C-reactive protein (CRP) (Gan et al., 2004). There is evidence for genetic determinants of plasma CRP concentrations in COPD patients (Hersh et al., 2006b).

Exacerbations

An important feature of COPD are exacerbations, with worsening of dyspnea and an increase in sputum production. This may lead to hospitalization and accounts for a high proportion of the costs of COPD. Exacerbations are usually due to infections, either due to bacteria (especially *Haemophilus influenzae* or *Steptococcus pneumoniae*) or to upper respiratory tract virus infections (especially rhinovirus or respiratory syncytial virus) (Papi et al., 2006). Exacerbations of COPD tend to increase as the disease progresses, but some patients appear to have more frequent exacerbations than others, which may suggest genetic predisposing factors.

CELLULAR AND MOLECULAR MECHANISMS

There is chronic inflammation predominantly in small airways and the lung parenchyma, with an increase in numbers of macrophages and neutrophils in early stages of the disease indicating an enhanced innate immune response, but in more advanced stages of the disease there is an increase in lymphocytes (particularly cytotoxic $CD8^+$ T cells), including lymphoid follicles that contain B- and T-lymphocytes, indicating acquired immunity (Hogg et al., 2004) (Figure 47.3).

Macrophages

Alveolar macrophages play a critical role in the orchestration of this pulmonary inflammation, since they are activated by inhaled irritants such as cigarette smoke and release chemokines that attract inflammatory cells, such as monocytes, neutrophils and T cells, into the lungs (Barnes, 2004a; Barnes et al., 2003). Monocytes are attracted into the lung to differentiate into tissue and alveolar macrophages, the number of which are increased more than 20-fold in COPD compared to cigarette smokers without COPD (Retamales et al., 2001). These cells then

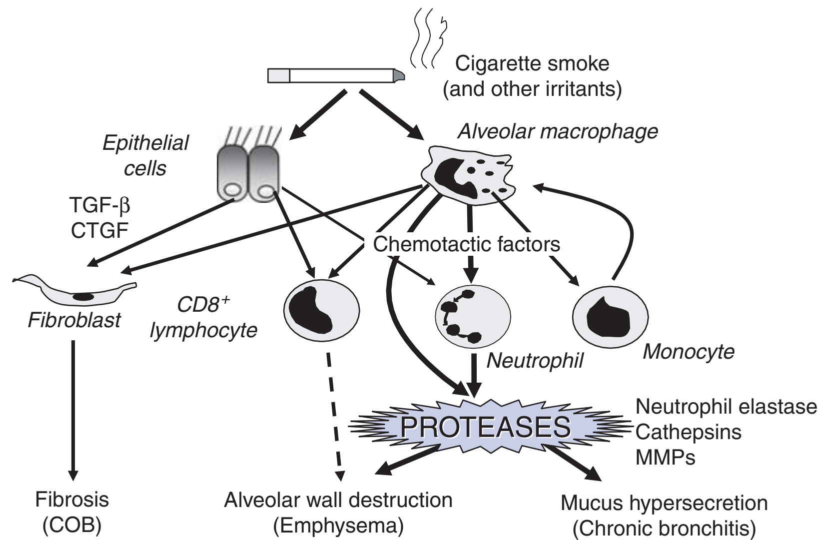

Figure 47.3 Inflammatory mechanisms in COPD. Cigarette smoke (and other irritants) activate macrophages in the respiratory tract that release neutrophil chemotactic factors, including interleukin-8 (IL-8) and leukotriene B4 (LTB4). These cells then release proteases that break down connective tissue in the lung parenchyma, resulting in emphysema, and also stimulate mucus hypersecretion. These enzymes are normally counteracted by protease inhibitors, including α1-antitrypsin, secretory leukoprotease inhibitor (SLPI) and tissue inhibitor of matrix metalloproteinases (TIMP). Cytotoxic T cells ($CD8^+$) may also be recruited and may be involved in alveolar wall destruction.

all release a variety of inflammatory mediators and proteases, which collectively result in the typical pathology of COPD (Barnes, 2004b).

Mediators

Prominent mediators are those that amplify inflammation, such as TNF-α, interleukin(IL)-1β (IL-1β) and IL-6, and chemokines which attract inflammatory cells such as CXCL8 (IL-8), CXCL1 (GROα), CXCL10 (IP-10), CCL1 (MCP) and CCL5 (RANTES) (Donnelly and Barnes, 2006). Elastolytic enzymes account for the tissue destruction of emphysema and include neutrophil elastase and matrix metalloproteinase-9 (MMP-9). There is an imbalance between increased production of elastases and a deficiency of endogenous antiproteases, such as α_1-antritrypin, secretory leukoprotease inhibitor and tissue inhibitors of MMPs. MMP-9 may be the predominantly elastolytic enzyme causing emphysema and also activates TGF-β, a cytokine that is expressed particularly in small airways that may result in the characteristic peribronchiolar fibrosis.

Oxidative stress is a prominent feature of COPD and is due to exogenous oxidants in cigarette smoke and endogenous oxidants release from activated inflammatory cells, such as neutrophils and macrophages (Bowler et al., 2004). Endogenous antioxidants may also be defective. Oxidative stress enhances inflammation and may lead to corticosteroid resistance. There is also increase production of nitric oxide (NO) in peripheral lung of COPD patients, with increased formation of peroxynitrite (Brindicci et al., 2005; Ricciardolo et al., 2005).

Differences from Asthma

Although both COPD and asthma involve chronic inflammation of the respiratory tract, there are marked differences in the inflammatory process between these diseases, which are summarized in Table 47.3 (Barnes, 2000b). While there are striking differences between the inflammation in mild asthma and COPD, patients with severe asthma become much more similar to patients with COPD, with involvement of neutrophils, macrophages, TNF-α, CXCL8, oxidative stress and a poor response to corticosteroids (Barnes, 2006a). This has suggested that there may be similarities in genetic predisposition to COPD in smokers and severe asthma. Several novel susceptibility genes, including DPP10, GPRA, PHF11 and ADAM33, that have been identified in severe asthma have now also been identified in COPD patients (van Diemen et al., 2005).

Gene Regulation

Proinflammatory mediators, such as TNF-α and IL-1β, activate the transcription factor nuclear factor-κB (NF-κB), which is activated in the airways and lung parenchyma of COPD patients, particularly in epithelial cells and macrophages (Di Stefano et al., 2002). There is further activation of NF-κB during exacerbations (Caramori et al., 2003). NF-κB switches on many of the inflammatory genes that are activated in COPD lungs, including chemokines, adhesion molecules such as ICAM-1 and E-selectin, inflammatory enzymes such as cyclo-oxygenase-2 and inducible nitric oxide synthase, elastolytic enzymes such as MMP-9 and

TABLE 47.3 Differences between inflammation in COPD and asthma

Inflammation	COPD	Asthma
Inflammatory cells	Neutrophils	Eosinophils
	CD8+ T cells+++	Mast cells
	CD4+ T cells+	CD4+ T cells
	Macrophages+++	Macrophages+
Inflammatory mediators	LTB_4	LTD_4, histamine
	TNF-α	IL-4, IL-5, IL-13
	CXCL1, CXCL8	CCL11
	Oxidative stress+++	Oxidative stress+
Inflammatory effects	Epithelial metaplasia	Epithelial shedding
	Fibrosis++	Fibrosis+

	Parenchymal destruction	
Response to corticosteroids	±	+++

LT, leukotriene; TNF, tumor necrosis factor; IL, interleukin; GRO, growth-related oncogene; AHR, airway hyperresponsiveness.

proinflammatory mediators such as TNF-α and IL-1β which themselves activate NF-κB. NF-κB-activated genes result in acetylation of core histones (particularly histone-4), which is necessary for activation of inflammatory genes and this is reversed by histone deacetylase-2 (HDAC2) (Barnes et al., 2005). There is a marked reduction in HDAC2 activity and expression in lung parenchyma, airways and alveolar macrophages of COPD patients (Ito et al., 2005). This is a mechanism that can account for the amplified pulmonary inflammation seen in COPD compared to smokers with normal lung function and also explains why COPD patients are not responsive to corticosteroids, since HDAC2 is the mechanism whereby corticosteroids switch off activated inflammatory genes (Barnes, 2006b) (Figure 47.4). The reduction in HDAC2 expression in COPD appears to be secondary to increased oxidative and nitrative stress and the formation of peroxynitrite, which nitrates tyrosine residues on HDAC2.

Genomics

Better knowledge of the complex underlying pathophysiology has identified many candidate genes that appear to be involved in the molecular mechanisms of COPD, and polymorphisms of several of these have been investigated for association with COPD. With gene microarrays it is now possible to study the global expression of all human genes in cells and tissues (transcriptomics). Few studies of global gene expression have been conducted in COPD, but several laboratories are now looking at the differences in gene expression between COPD patients and smokers exposed to similar numbers of cigarettes who have normal lung function. These studies are using alveolar macrophages, circulating monocytes, airway epithelial cells and peripheral lung. Serial analysis of gene expression and microarray analysis in peripheral lung from mild to moderate COPD patients versus normal smokers has demonstrated that a total of 261 genes showed differential expression (Ning et al., 2004). Many of these genes encode inflammatory transcription factors and growth factors. The transcription factor Egr-1 was notably upregulated and shown to increase the activity of mitogen-activated protein kinase pathways (MAPK), which regulate multiple inflammatory genes. A microarray study of human bronchial epithelial cells exposed to nicotine has identified upregulation of several genes in the MAPK pathway (Tsai et al., 2006). Gene expression profiling of alveolar macrophages has demonstrated 40 genes upregulated and 35 downregulated in smokers compared to nonsmokers. Most of these genes belong to the functional categories of immune/inflammatory response, cell adhesion and extracellular matrix, proteases/antiproteases, antioxidants, signal transduction and regulation of transcription (Heguy et al., 2006). The amplification of inflammation in COPD patients compared to equivalent smokers with normal lung function may be genetically determined, through amplification of inflammatory genes or defective expression of anti-inflammatory or protective mechanisms. Studies looking at susceptibility to the effects of cigarette smoke in different strains of mice may also be informative. For example, the susceptible strain AKR/J shows increased expression of cytokines linked to T helper 1 cells after exposure to tobacco smoke compared to non-susceptible strains (C57BL/6/J and NZWlac/J) (Guerassimov et al., 2004). Molecular genomics may identify markers of risk, but may also reveal novel molecular targets for the development of treatments of the future.

A whole genome-wide linkage scan in relatives of patients with familial early-onset COPD found evidence for linkage of airway obstruction with chromosome 2 (LOD 2.60 at 216 cM). In a smokers-only analysis, evidence for linkage was also observed with chromosome 12 (LOD 5.03 at 35 cM) and chromosome 2 (LOD 4.13 at 229 cM), but the specific genes involved have not been identified (Demeo et al., 2004).

Proteomics

While gene microarray analysis gives considerable information about proteins that are transcriptionally regulated it is

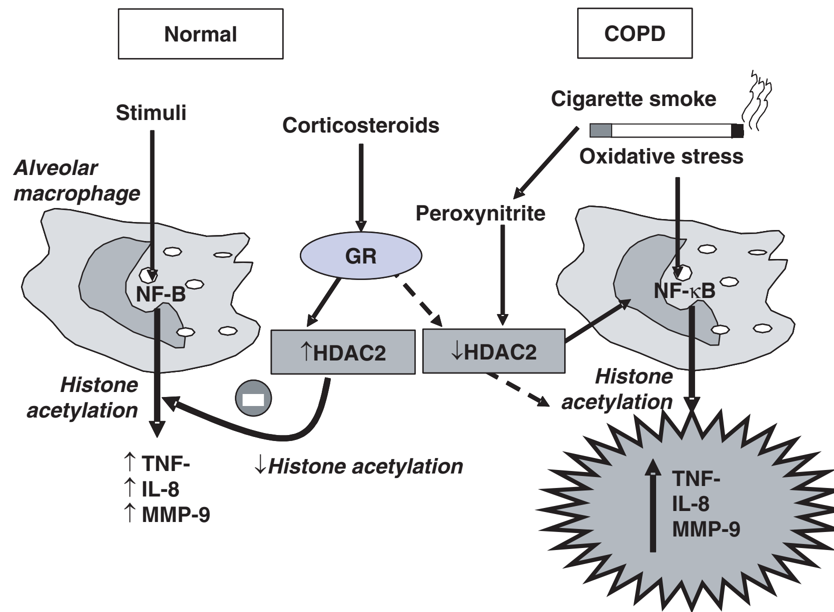

Figure 47.4 Proposed mechanism of corticosteroid resistance in COPD patients. Stimulation of normal alveolar macrophages activates nuclear factor-κB (NF-κB) and other transcription factors to switch on histone acetyltransferase leading to histone acetylation and subsequently to transcription of genes encoding inflammatory proteins, such as TNF-α and IL-8. Corticosteroids reverse this by binding to glucocorticoid receptors (GR) and recruiting histone deacetylase-2 (HDAC2). This reverses the histone acetylation induced by NF-κB and switches off the activated inflammatory genes. In COPD patients cigarette smoke activates macrophages, as in normal subjects, but oxidative stress (acting through the formation of peroxynitrite) impairs the activity of HDAC2. This amplifies the inflammatory response to NF-κB activation, but also reduces the anti-inflammatory effect of corticosteroids as HDAC2 is now unable to reverse histone acetylation.

now recognized that many genes involved in inflammation are regulated post-transcriptionally and that it is necessary to measure protein expression using proteomic approaches (Bowler et al., 2006). A recent study used a proteomic approach to investigate the plasma concentrations of multiple inflammatory and immune proteins during COPD exacerbations compared to baseline measurements (Hurst et al., 2006). CRP was found to be the most discriminant marker and was linked to various proteins associated with monocytic and lymphocytic inflammatory pathways. In another study 143 plasma proteins were assayed in COPD patients compared to control subjects and 25 found to show some correlation with clinical parameters in the COPD patients (Pinto-Plata et al., 2006). Proteomic analysis may also be applied to cells, lung tissue or sputum (Barnes et al., 2006).

DIAGNOSIS AND SCREENING

Diagnosis

Diagnosis is commonly made from the history of progressive dyspnea in a chronic smoker and is confirmed by spirometry, which shows an FEV_1/VC ratio of <70% and FEV_1<80% predicted. Staging of severity is made on the basis of FEV_1, but exercise capacity and the presence of systemic features may be more important determinants of clinical outcome (Celli et al., 2004). Measurement of lung volumes by body plethysmography shows an increase in total lung capacity, residual volume and functional residual capacity, with consequent reduction in inspiratory capacity, representing hyperinflation as a result of small airway closure. This results in dyspnea which may be measured by dyspnea scales and reduced exercise tolerance, which may be measured by a 6 min or shuttle walking test (Figure 47.5). Carbon monoxide diffusion is reduced in proportion to the extent of emphysema.

A chest X-ray is rarely useful but may show hyperinflation of the lungs and the presence of bullae. High resolution computerized tomography demonstrates emphysema, but is not used as a routing diagnostic test. Blood tests are rarely useful; a normocytic normochromic anemia is more commonly seen in patients with severe disease than polycythemia due to chronic hypoxia. Arterial blood gases demonstrate hypoxia and in some patients hypercapnia.

Screening

COPD is grossly underdiagnosed, as symptoms present late in the progression of disease (Chapman et al., 2006). Population screening with measurement of FEV_1 and FEV_1/VC ratio would pick up early COPD in smokers over 40 years. However, this would not identify COPD due to nonsmoking causes, which constitute 10–20% of the total. This would require

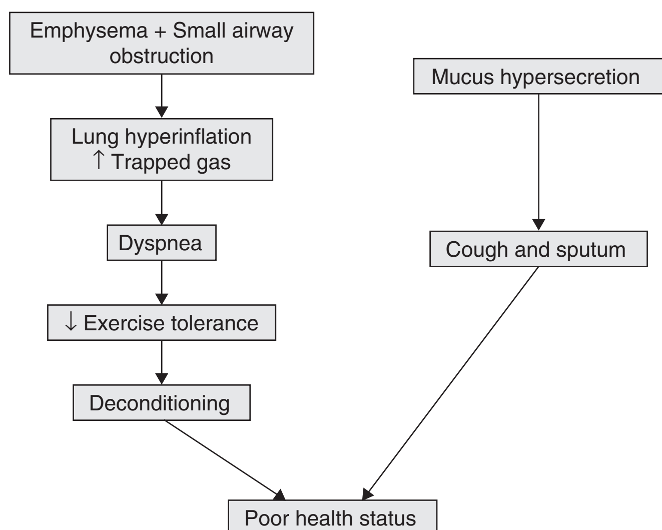

Figure 47.5 Symptoms of COPD. The most prominent symptom of COPD is dyspnea, which is largely due to hyperinflation of the lungs as a result of small airways collapse due to emphysema and narrowing due to fibrosis, so that the alveoli are not able to empty. Hyperinflation induces an uncomfortable sensation and reduces exercise tolerance. This leads to immobility and deconditioning and results in poor health status. Other common symptoms of COPD are cough and sputum production as a result of mucus hypersecretion, but not all patients have these symptoms and many smokers with these symptoms do not have airflow obstruction (simple chronic bronchitis).

screening spirometry of all individuals over 40 years in addition to the 20–40% of the population who smoke. It is hoped that gene expression studies might result in a biomarker that is correlated with COPD susceptibility, but this is unlikely as so many genes are likely to be involved (Barnes et al., 2006).

PROGNOSIS

COPD is slowly progressive with an accelerated decline in FEV_1, leading to slowly increasing symptoms, fall in lung function and eventually to respiratory failure (Figure 47.1). The only strategy to reduce disease progression is smoking cessation, although this is relatively ineffective once FEV_1 has fallen below 50% predicted and the patient is symptomatic. Patients with more severe exacerbations develop acute exacerbations, which have a prolonged effect on quality of life for many months. There is still debate about the role of acute exacerbations on disease progression, but the decline in lung function may be accelerated further following an acute exacerbation (Donaldson et al., 2002). Factors other than FEV_1 are important in the prognosis of the disease, including exercise performance and muscle weakness, which signal a greater mortality (Celli et al., 2004). Patients who develop right heart failure (*cor pulmonale*) also have poor survival, although this may be improved by long-term oxygen therapy. It is hoped in the future that genetic approaches will help to improve the prediction of prognosis and identify what the most effective management strategies may be.

MANAGEMENT

COPD is managed according to the severity of the disease, with a progressive escalation of therapy as the disease progresses (Barnes and Stockley, 2005; Rennard, 2004).

Anti-Smoking Measures

Smoking cessation is the only measure so far shown to slow the progression of COPD, but in advanced disease stopping smoking has little effect and the chronic inflammation persists. Nicotine replacement therapy (gum, transdermal patch, inhaler) helps in quitting smoking, but bupropion, a noradrenergic antidepressant, is more effective. More effective anti-smoking therapies, including partial nicotinic agonists and cannabinoid receptor antagonists are currently being evaluated. As discussed above, there may be genetic determinants of smoking cessation that make it very difficult for some patients to quit.

Bronchodilators

Bronchodilators are the mainstay of current drug therapy for COPD. The bronchodilator response measured by an increase in FEV_1 is limited in COPD, but bronchodilators may improve symptoms by reducing hyperinflation and therefore dyspnea, and may improve exercise tolerance, despite the fact that there is little improvement in spirometric measurements. Previously short-acting bronchodilators, including β_2-agonists and anticholinergics, were most widely used, but more recently long-acting bronchodilators have been introduced. These include the inhaled long-acting β_2-agonists (LABA) salmeterol and formoterol and the once daily inhaled anticholinergic tiotropium bromide. In patients with more severe disease, these therapies appear to be additive. Theophylline is also used as an add-on bronchodilator in patients with very severe disease, but systemic side effects may limit its value.

Antibiotics

Acute exacerbations of COPD are commonly assumed to be due to bacterial infections, since they may be associated with increased volume and purulence of the sputum. However, it is increasingly recognized that exacerbations may be due to upper respiratory tract viral infections or may be non-infective, questioning the place of antibiotic treatment in many patients. Controlled trials of antibiotics in COPD show a relatively minor benefit of antibiotics in terms of clinical outcomes and lung function. Although antibiotics are still widely used in exacerbations of COPD, methods that can reliably diagnose bacterial infection in the respiratory tract are needed so that antibiotics are not used inappropriately. There is no evidence that prophylactic antibiotics prevent acute exacerbations.

Oxygen

Home oxygen accounts for a large proportion (over 30% in the United States) of health care spending on COPD. Long-term oxygen therapy was justified by two large trials showing reduced mortality and improvement in quality of life in patients with severe COPD and chronic hypoxemia ($PaO_2 < 55$ mmHg). More recent studies have demonstrated that patients with less severe hypoxemia do not appear to benefit in terms of increased survival, so that selection of patients is important in prescribing this expensive therapy. Similarly, nocturnal treatment with oxygen does not appear to be beneficial in terms of survival or delaying the prescription of long-term oxygen therapy in patients with COPD who have nocturnal hypoxemia.

Corticosteroids

Inhaled corticosteroids are now the mainstay of chronic asthma therapy and the recognition that chronic inflammation is also present in COPD provided a rationale for their use in COPD. Indeed, inhaled corticosteroids are now widely prescribed in the treatment of COPD. However, the inflammation in COPD shows little or no suppression even by high doses of inhaled or oral corticosteroids. This may reflect the fact that neutrophilic inflammation is not suppressible by corticosteroids as neutrophil survival is prolonged by steroids. There is also evidence for an active cellular resistance to corticosteroids, with no evidence that even high doses of corticosteroids suppress the synthesis of inflammatory mediators or enzymes. This is related to a decreased activity and expression of HDAC2 (Barnes, 2006b). Approximately 10% of patients with stable COPD show some symptomatic and objective improvement with oral corticosteroids, and it is likely that these patients have concomitant asthma, as both diseases are very common. Furthermore, these patients have elevated sputum eosinophils and exhaled NO, which are features of asthmatic inflammation. Long-term treatment with high doses of inhaled corticosteroids fails to reduce disease progression, even at the early stages of the disease. However, there is a small protective effect against acute exacerbations (approximately 20% reduction) in patients with severe disease. In view of the risk of systemic side effects in this susceptible population, inhaled corticosteroid are only recommended in patients with $FEV_1 < 50\%$ predicted who have two or more severe exacerbations a year.

There is a small beneficial effect of systemic corticosteroids in treating acute exacerbations of COPD, with improved clinical outcome and reduced length of hospital admission. The reasons for this discrepancy between steroid responses in acute versus chronic COPD may relate to differences in the inflammatory response (increased eosinophils) or airway edema in exacerbations.

Other Drug Therapies

Systematic reviews show that mucolytic therapies reduce exacerbation by about 20%, but most of the benefit appears to derive from *N*-acetylcysteine which is also an antioxidant. A controlled trial, however, did not show any overall benefit in reducing exacerbations or disease progression (Decramer et al., 2005).

Pulmonary Rehabilitation

Pulmonary rehabilitation consists of a structured program of education, exercises and physiotherapy and has been shown in controlled trials to improve the exercise capacity and quality of life of patients with severe COPD, with a reduction in health care utilization. Pulmonary rehabilitation is now an important part of the management plan in patients with severe COPD. There is debate about the duration and frequency of pulmonary rehabilitation (Troosters et al., 2005). Most of the benefits appear to relate to exercise so that modified simplified programs are now often used.

Lung Volume Reduction

Surgical removal of emphysematous lung improves ventilatory function in carefully selected patients (Wouters, 2004). The reduction in hyperinflation improves the mechanical efficiency of the inspiratory muscles. Careful patient selection after a period of pulmonary rehabilitation is essential. Patients with localized upper lobe emphysema with poor exercise capacity do best, but there is a relatively high operative mortality, particularly with patients who have a low diffusing capac ity. Significant functional improvements include increased FEV_1, reduced total lung capacity and functional residual capacity, improved function of respiratory muscles, improved exercise capacity and improved quality of life. Benefits persist for at least a year in most patients, but careful long-term follow-up is needed in order to evaluate the long-term benefits of this therapy. More recently nonsurgical bronchoscopic lung volume reduction has been achieved by insertion of one-way valves by fiberoptic bronchoscopy. This gives significant improvement in some patients and appears to be safe, but collateral ventilation reduces the efficacy of this treatment so that significant deflation of affected lung may not be achieved.

Management of Acute Exacerbations

Acute exacerbations of COPD should be managed by supplementary oxygen therapy, initially 24% oxygen and checking that there is no depression of ventilation. Antibiotics should be given if the sputum is purulent or there are other signs of bacterial infection, High doses of corticosteroids reduce hospital stay and are routinely given. Chest physiotherapy is usually given, but there is little objective evidence for benefit. Noninvasive ventilation is indicated for incipient respiratory failure and reduces the need for intubation.

Pharmacogenomics

There is no information about the impact of pharmacogenomics on COPD therapy. Polymorphism of the β_2-receptor affect the bronchodilator response to short- and long-acting β_2-agonists in asthma, with reduce responses seen in patients with the Arg–Arg[16] polymorphism (Liggett, 2002). However this is not a large effect and is unlikely to have a major clinical impact. It is possible that polymorphism in corticosteroids signaling pathways may contribute to the corticosteroids resistance in COPD

but this has not yet been investigated. Using genomics to better define the clinical phenotypes may lead to a more rational use of specific therapies in the future.

Impacts of Genomics on Therapy

As indicated above, molecular genetics and genomics may identify novel targets for the development of new therapies. Pharmacogenomics might have an impact on choice of therapy in the future. It is unlikely that gene-based therapies will be useful, but silencing of inflammatory genes by inhaled interfering RNAs and antisense oligonucleotides might be a feasible approach in the future (Ulanova et al., 2006). Micro-RNAs (miRNA) are small regulatory RNAs that inhibit the translation of several activated genes and may have application to the suppression of multiple inflammatory genes in the future (Ying et al., 2006).

2009 UPDATE

Gene Polymorphism Studies

Several new associations between COPD and SNPs in candidate genes have recently been described. Stratified linkage analysis in early onset COPD patients with emphysema identified an association with an intronic SNP of transforming growth factor receptor-3 (TGFR3, betaglycan), and this was confirmed in an independent COPD population (Hersh et al., 2009). Studies in mice and microarray studies in COPD have also identified this target, consistent with the previously demonstrated SNP of TGFβ1, indicating an abnormality in the TGF signaling pathway that may be relevant to the small airway fibrosis that is a key component of COPD. The association between SNPs of TGFβ in emphysema patients has also been confirmed in a Japanese population (Ito et al., 2008).

One of the problems in the genetics of COPD is the clinical heterogeneity of the disease. There is now an effort to link different aspects of the disease to specific genetic associations in order to classify disease subtypes that might be useful in selecting patients for different types of therapy in the future. Several SNPs were reported to be associated with severe COPD in almost 400 patients who participated in the National Emphysema Treatment Trial (NETT). Two of these genes – microsomal epoxide hydrolase (EPHX1) and SERPINE2 – were found to be significantly associated with hypoxema. In a separate population of early onset COPD patients, the same SNPs were associated with the requirement of domiciliary oxygen (Castaldi et al., 2008). Another SNP in the surfactant protein B (SFTPB) gene was associated with pulmonary hypertension. The same research group has also linked bronchodilator responsiveness to the inhaled β_2-agonist albuterol with SNPs in the SERPINE2 and EPHX1 genes, as well as in the β_2-adrenergic receptor (ADRB2) gene (Kim et al., 2008). Extracellular superoxide dismutase (SOD3) is an important antioxidant enzyme in the lungs, and two novel SNPs of SOD3 have been linked to reduced FEV_1 values in a Danish population study and these polymorphisms were associated with hospitalization and mortality from COPD (Dahl et al., 2008).

Matrix metalloproteinases appear to play an important role in the remodeling of COPD lungs and MMP-9 is the predominant elastolytic enzyme in the lung periphery. There is a significant association between a genetic variant of MMP-9, Gln279Arg, which is associated with the increased substrate binding that is increased in COPD patients (Tesfaigzi et al., 2006).

Genome-Wide Association Studies

Although genome-wide association studies (GWAS) are now widely applied to complex diseases, this approach has not yet been applied successfully in COPD patients. The GWAS approach has been applied to over 70,000 samples from the Framingham Heart Study, and reduced lung function (lower FEV_1 and FEV_1/FVC ratio) was significantly associated with SNPs in the IL-6 receptor and glutathione *S*-transferase omega-2 genes, as well as SOD3 (Wilk et al., 2007). Several GWAS in COPD are currently underway.

Biomarker Studies

There is continued search for novel biomarkers in COPD that might predict disease progression and response to therapy. Desmosine and isodesmosine are amino acids that are unique to elastin fibers and may therefore have potential as markers of elastin degradation in COPD lungs. However, they have previously proved to be of little value because of the high background levels. Novel separation methods and more sensitive detection methods are now being applied and indicate that these biomarkers are increased in urine, plasma and sputum of COPD patients (Luisetti et al., 2008).

Gene Expression Studies

There is increasing use of microarrays to study abnormal patterns of gene expression in cells from COPD patients. Airway epithelial cells from COPD patients show downregulation of the Notch signaling pathway, which is involved in epithelial regeneration (Tilley et al., 2009). Microarray analysis of peripheral lung from COPD patients also shows abnormal expression of genes involved in epithelial repair and matrix synthesis and degradation (Wang et al., 2008). However, there appears to be enormous variability in the expression of cytokine

and chemokine genes in small airway epithelial cells and macrophages in response to cigarette smokers, which is greater in COPD patients than in normal smokers and nonsmokers (Ammous et al., 2008; Howrylak and Choi, 2008). This variability means that large numbers of samples are likely to be needed to characterize the COPD transcriptome (Zeskind et al., 2008).

Disease Mechanisms

Increased oxidative stress is important in the pathophysiology of COPD and may be an important driver of chronic inflammation and corticosteroid resistance. As well as an increase in oxidants from cigarette smoke and other inhaled particles and from activated inflammatory cells, there may also be a defect in antioxidant defenses in the lung, which may be genetically determined. The transcription factor nuclear erythroid- 2 related factor 2 (Nrf2) is important in regulating the transcription of many antioxidant and detoxifying genes. A recent study has demonstrated that Nrf2 activity is reduced in the lungs and epithelial cells of COPD patients and that this is associated with reduced expression of several antioxidant genes (Malhotra et al., 2008). Nrf2 activity has also been found to be reduced in alveolar macrophages from COPD patients (Suzuki et al., 2008) This defect is related to reduced nuclear translocation of Nrf2 in response to oxidative stress as a result of defect in the protein DJ1, which normally stabilizes Nrf2 in the cytoplasm. There is no obvious association between SNPs of Nrf2 and COPD, but other genes in the pathway such as DJ1 have not yet been studied. This defect in Nrf2 may be reversed using drugs, such as sulforaphane, which occurs naturally in broccoli (Barnes, 2008). A more potent and selective Nrf2 activator triterpenoid CDDO-imidazolide prevents cigarette smoke-induced emphysema in mice (Sussan et al., 2009).

CHAPTER

Genetics and Genomics of Interstitial Lung Disease

Paul W. Noble and Mark P. Steele

INTRODUCTION

Interstitial lung diseases (ILDs), also referred to as diffuse parenchymal lung diseases (DPLDs), are a diverse group of lung diseases that can be classified according to clinical, radiologic, physiologic, or pathologic criteria that result in fibrosis of the alveolar interstitium and impairment of gas exchange. The term DPLD more accurately describes these entities, since among the ILDs there is substantial variation in the degree of involvement of lung structures other than the alveolar interstitium, including capillaries, terminal and respiratory bronchioles, and lymphatics along the bronchovascular bundle and interlobular septae. A general classification scheme of ILD/DPLD categorizes DPLD related to connective tissue diseases, drug-induced diseases, occupational and environmental exposures, granulomatous diseases, inherited conditions such as familial interstitial pneumonia (FIP) and Hermansky-Pudlak syndrome, unique conditions such as eosinophilic granuloma and amyloidosis, and the idiopathic interstitial pneumonias (IIPs). While the pathogenic mechanisms are known or inferred in some of the DPLDs such as those related to environmental exposure, drug exposure, or autoimmune mechanisms, the pathogenesis of most of these entities is poorly understood. Furthermore, it is well recognized that there is considerable individual variation in the natural history of DPLD, particularly regarding the susceptibility to agents known to cause pulmonary fibrosis, such as radiation or asbestos. Since the lung responds to these injuries in a limited fashion, when using standard radiologic and pathologic evaluation, there is significant overlap and diagnostic uncertainty with DPLD. Consequently, there is considerable interest in the study of the genetics, genomics, and proteomics of ILD/DPLD to better understand the pathogenesis of these diseases and individual disease susceptibility, to discover biomarkers for disease diagnosis and prognosis, as well as to develop effective treatment interventions.

Four lines of evidence suggest that the development of pulmonary fibrosis is, at least in part, determined by genetic factors. First, clustering of pulmonary fibrosis, an uncommon disease, has been reported in monozygotic twins raised in different environments (Bonanni et al., 1965; Javaheri et al., 1980; Solliday et al., 1973), in genetically related members of several families (Bitterman et al., 1986; Bonanni et al., 1965; Hughes, 1964; Swaye et al., 1969), in consecutive generations of the same families (Bonanni et al., 1965; Hodgson et al., 2002; Lee et al., 2005), and in family members separated at an early age (Swaye et al., 1969). While a single report suggests that FIP is inherited as an autosomal recessive trait (Tsukahara and Kajii, 1983), other pedigrees demonstrate an autosomal dominant pattern of inheritance (Adelman et al., 1966; McKusick and Fisher, 1958; Swaye et al., 1969), perhaps with reduced penetrance (Adelman et al., 1966; Bitterman et al., 1986; Hughes, 1964; Javaheri et al., 1980; Marshall et al., 2000; Musk et al., 1986a, b;

Essentials of Genomic and Personalized Medicine

Solliday et al., 1973; Swaye et al., 1969). Second, pulmonary fibrosis is observed in genetic disorders with pleiotropic presentation, including Hermansky-Pudlak syndrome (Depinho and Kaplan, 1985), neurofibromatosis (Riccardi, 1981), tuberous sclerosis (Harris et al., 1969; Makle et al., 1970), Neimann-Pick disease (Terry et al., 1954), Gaucher disease (Schneider et al., 1977), familial hypocalciuric hypercalcemia (Auwerx et al., 1985), and familial surfactant protein C mutation (Thomas et al., 2002). Third, considerable variability exists in the development of pulmonary fibrosis among workers exposed to similar concentrations of fibrogenic dusts or organic antigens. For instance, following exposure to asbestos, similarly exposed individuals may experience very different outcomes (Polakoff et al., 1979; Selikoff et al., 1979). Fourth, inbred strains of mice differ in their susceptibility to fibrogenic agents. In comparison to BALB/c or 129 mice, C57BL/6 mice develop more lung fibrosis when challenged with either bleomycin (Ortiz et al., 1998; Rossi et al., 1987) or asbestos (Corsini et al., 1994; Warshamana et al., 2002).

This review will focus on the genetic, genomic, and proteomic approaches to identify disease susceptibility genes that predispose to DPLD or to aid in the diagnostic classification of DPLD. To better understand the pathogenesis of pulmonary sarcoidosis, both candidate gene and genome-wide linkage strategies have been utilized, as well as proteomic approaches to identify pathogenic antigens causing granulomatous inflammation. Surfactant protein C deficiency has been linked to familial cases of pediatric and adult interstitial pneumonia and represents the most successful candidate gene approach to studying genetic susceptibility to DPLD. Microarray-based expression profiling is being successfully utilized to aid in the classification of DPLDs and to identify novel disease-susceptibility genes. Recombinant inbred and congenic mouse strains have been successfully used to map susceptibility loci related to radiation-, bleomycin-, and asbestos-induced pulmonary fibrosis. Finally, genome-wide scans are being utilized to identify susceptibility loci that predispose to the development of IIPs.

GENETIC DETERMINANTS OF SARCOIDOSIS

Evidence for Genetic Basis

Sarcoidosis represents a complex disease with racial and ethnic differences in disease prevalence, an association with environmental exposures, and a genetic predisposition. A genetic basis for pulmonary sarcoidosis is suggested by familial clustering of sarcoidosis (Buck and Mc, 1961; Harrington et al., 1994; Headings et al., 1976; Moura et al., 1990; Wiman, 1972) and racial differences in disease prevalence (Rybicki et al., 2001a, b). A large multicenter case control study investigating the familial aggregation of sarcoidosis in the United States demonstrated a 5.8-fold increase in the relative risk of developing sarcoidosis among first degree relatives (Rybicki et al., 2001a, 2005a).

Candidate Gene Studies

Sarcoidosis demonstrates characteristic granulomatous inflammation with morphologic features of the granuloma having a concentration of CD4 positive T cells at the central core, CD8 positive T cells at the periphery, and a host of associated immunologic abnormalities (Statement on sarcoidosis, 1999). Immunologic abnormalities observed in patients with sarcoidosis include expansion of T cells bearing restricted T cell receptor suggesting oligoclonality; increased expression of members of the TNF-ligand and TNF-receptor superfamilies by T cells; B cell hyperactivity and spontaneous *in situ* production of immunoglobulin; and accumulation of monocytes/macrophages with antigen presenting capacity associated with increased release of macrophage-derived cytokines (IL-1, IL-6, IL-8, IL-15, TNF-α, IFN-γ, GM-CSF), chemokines (RANTES, MIP-1α, IL-16), and fibrogenic cytokines (TGF-β, PDGF). Genes involved in these pathways are plausible biologic candidate genes.

Given the known racial and ethnic differences in disease prevalence, the characteristic immunologic features of the disease, attention has been directed to HLA region genes that predispose to the development of sarcoidosis. HLA class II alleles have been most frequently reported to be associated with the risk of developing sarcoidosis. Studies performed in different populations have produced conflicting results demonstrating either increased risk or protection from various HLA alleles. There is a consistent association with HLA-DR3 haplotypes and a more favorable prognosis in Czech, German, Italian, Japanese, Polish, and Scandinavian populations (Berlin et al., 1997; Bogunia-Kubik et al., 2001; Foley et al., 2001; Gardner et al., 1984; Ina et al., 1989; Ishihara et al., 1994; Martinetti et al., 1995; Swider et al., 1999). The HLA-DRB1 and HLA-DQB1 alleles have been associated with milder forms of the disease (erythema nodosum, Löfgren's syndrome, stage 0/1 CXR findings) in patients from Scandinavia, UK, and the Netherlands (Berlin et al., 1997; Sato et al., 2002). Of note, HLA-DQB1 is in linkage disequilibrium (LD) with HLA-DRB1, which is in close proximity to non-HLA-related genes such as TNF that may be similarly influencing outcomes in sarcoidosis (Mrazek et al., 2005). The favorable outcome associated with increased TNF-α production based on the A2 promoter allele may be related to a common haplotype shared by HLA-DR3 (Seitzer et al., 2002). Other HLA loci that confer disease susceptibility include HLA-A1, -B8, -B22, -B13, -DR15, and -DR16, whereas protection from disease or milder forms of the disease have been associated with HLA-DR17 and -DRw52 (Berlin et al., 1997; Grunewald et al., 2004; Maliarik et al., 1998a; Martinetti et al., 1995; Rossman et al., 2003).

A number of non-HLA genes have been investigated for an association with sarcoidosis. The most heavily investigated is an insertion/deletion located in intron 16 of the gene for angiotensin converting enzyme (ACE), which is known to affect serum ACE levels. While this mutation affects serum ACE levels, there appears to be no relationship to disease susceptibility (Alia et al., 2005; Maliarik et al., 1998b; McGrath et al., 2001). Other non-HLA candidate genes studied in sarcoidosis and their associations are summarized in Table 48.1. In interpreting these data,

it is important to look closely at the method of choosing control populations to avoid spurious associations due to population stratification, as well as statistical genetic methods such as verification that genetic markers are in Hardy–Weinberg equilibrium, and correction for multiple comparisons. It is also important to look for evidence of linkage disequilibrium (LD) flanking putative disease susceptibility single nucleotide polymorphisms (SNPs) since unknown mutations in LD with the putative disease susceptibility SNP may be responsible for the apparent association. In general, replication studies in multiple populations are necessary before a candidate gene SNP is unequivocally linked as a sarcoidosis susceptibility gene. Currently, utilizing mutation screening in candidate genes, only HLA alleles have been validated unequivocally as susceptibility genes for sarcoidosis.

Genetic Epidemiology

Evidence that sarcoidosis aggregates in some families, and the ability to accurately identify and phenotype these families, is critical to the successful completion of family-based linkage studies. The most comprehensive study of the familial aggregation of sarcoidosis comes from A Case Control Etiologic Study of Sarcoidosis (ACCESS) (Rybicki et al., 2001a). The study population was drawn from 10,862 first-degree and 17,047 second-degree relatives identified by 706 sarcoidosis case-control pairs. Controls were matched to cases on race, sex, age, and three-digit phone numbers. The familial relative risk of sarcoidosis was 5.8 (OR = 5.8, [2.1, 15.9]) for sibs, and 3.8 (OR = 3.8, [1.2, 11.3]) for parents.

Linkage Analysis

The first published genome-wide linkage study in sarcoidosis was from 63 German families consisting mostly of affected sibling pairs having 138 affected siblings and 95 first-degree relatives (Schurmann et al., 2001). This genome-wide scan utilized 225 microsatellite markers, and was analyzed using the NPL score (Genehunter 2.0), a nonparametric, model-free approach where modes of inheritance and penetrance values are not required. The highest NPL score was 2.99, $p=0.001$, obtained with marker D6S1666, which resides in the MHC class II gene. The genome-wide significant NPL score is approximately 3.6, $p<0.001$. Therefore, the NPL score of 2.99 is very suggestive but not conclusive evidence for linkage to the MHC class II gene. Other chromosome regions showing minor peaks ($p<0.05$) include NPL scores of 2.39 on chromosome 3p21, 1.87 on chromosome 1p22, 1.82 for chromosome 9q33, 1.64 on chromosome X, and 1.92 on chromosomes 7q22 and 7q36. The second linkage study in sarcoidosis is from the Sarcoidosis Genetic Analysis Consortium (SAGA) reporting linkage analysis of sibling pairs from 229 African American families utilizing 380 microsatellite markers. These investigators reported *p*-values based on Haseman-Elston regression. The smallest *p*-value was 0.0005 on chromosome 5 at marker D5S2500. Interestingly, despite using a higher density of markers in the MHC class II region, the SAGA investigators did not find evidence for linkage in the MHC class II region. The different linkage results in the German and African American populations would be consistent with ethnicity-related locus heterogeneity. Also, the sample sizes in these two studies are relatively small for a complex disease, and may account for the different results. Nevertheless, these studies indicate that genome-wide linkage studies can be utilized to identify disease susceptibility genes in sarcoidosis.

Based on the initial linkage analysis of the 63 German families demonstrating linkage to chromosome 6p21, SNP-based fine mapping of the region was performed using extended families and trios to conduct transmission disequilibrium test (TDT), and case-control association analysis (Valentonyte et al., 2005). The results demonstrated an association with SNP rs2076530 ($P_{\mathrm{TDT}} = 3 \times 10^{-6}$, $P_{\mathrm{case-control}} = 1.1 \times 10^{-8}$) located in the butyrophilin-like2 gene (BTNL2) located adjacent to HLA-DR1. Additional analysis demonstrated G to A transition in BTNL2 that leads to the use of a cryptic slice site resulting in a 4bp

TABLE 48.1 Non-HLA candidate gene polymorphisms in sarcoidosis

Candidate gene	Polymorphism	Result	Reference
ACE	Intron 16 in/del	Population specific	Berlin et al. (1997); McGrath et al. (2001)
Vitamin D receptor	BsmI RFLP	Increased risk	Niimi et al. (2000b)
IL-1 cluster	IL-α-889	Increase risk 2X	Niimi et al. (2000a)

TGFβ	4875A	Fibrotic sarcoid	Takada et al. (2001)

deletion that generates a premature stop codon, and the resulting protein lacks the C-terminal immunoglobulin-like constant domain and transmembrane domain. The authors demonstrate that the disease allele encodes for a protein that is located in the cytoplasm rather than on the plasma membrane. The odds ratio (OR) for developing sarcoidosis when heterozygous for the susceptibility allele is 1.6, and 2.75 in homozygotes. The authors did not comment on the overall frequency of the susceptibility allele in their population. Given the complexity of sarcoidosis, and the modest OR in the range of 1.6–2.75, one would expect that BTNL2 is one of the several sarcoid susceptibility genes, and further investigations of BTNL2 in other non-German populations will be important. Additional studies of the role of the BTNL2 gene in sarcoidosis may identify novel mechanisms predisposing individuals to sarcoidosis, or other granulomatous inflammation.

Genomic Medicine and Sarcoidosis

The identification of BTNL2 mutations, or mutations in other genes that lead to the susceptibility of sarcoidosis, will likely aid several aspects of the clinical approach to patients with sarcoidosis. A very clinically relevant application of sarcoid susceptibility alleles would be the development of a diagnostic test that distinguishes chronic progressive forms of sarcoidosis from spontaneous remitting disease. Another useful risk allele would be one that identifies risk for extra-pulmonary sarcoidosis such as cardiac or central nervous system involvement since involvement of these organs results in substantial morbidity and mortality. The identification of risk alleles that distinguish progressive forms of the disease, or forms of the disease associated with higher morbidity would identify a group of patients needing aggressive anti-inflammatory therapy while sparing those with milder, self-limited disease the toxicity of these therapies. In addition, the identification of sarcoid susceptibility genes might provide insight into development of new pharmacologic therapies.

Proteomics in Sarcoidosis

Sarcoidosis is characterized by granulomatous inflammation with expansion of T cells bearing restricted T cell receptor suggesting oligoclonality, and polyclonal antibody production. The intradermal injection of the Kveim reagent, homogenates of diseased sarcoid tissue obtained from spleen, or lymph nodes, induces characteristic granulomatous inflammation known as the Kveim reaction (Siltzbach, 1961). The biochemical features of the Kveim reagent include neutral detergent insolubility; heat, acid, and protease resistance; and sensitivity to potent denaturants, suggesting a poorly soluble protein or protein aggregate (Chase and Siltzbach, 1967; Lyons et al., 1992). Proteomic approaches have been applied to better characterize the inflammatory response of sarcoidosis, and to identify potential antigenic proteins present in the Kveim reagent.

Several studies have analyzed sarcoid bronchoalveolar lavage fluid (BALF) protein by 2-D gel electrophoresis and mass spectroscopy. These studies demonstrate increased concentrations of many plasma proteins in sarcoid BALF (Magi et al., 2002; Rottoli et al., 2005; Sabounchi-Schutt et al., 2003). The largest study to date compared alveolar proteins in patients with acute forms of sarcoidosis with chest radiographs having only bilateral hilar adenopathy to those with more chronic forms of sarcoidosis (Kriegova et al., 2006). Forty differentially expressed proteins were seen and some were identified as albumin, alpha-1-antitrypsin, and protocadherin-2 precursor. These data demonstrate that BALF analyzed by SELDI-TOF or MALDI-TOF mass spectroscopy can identify unique disease-related protein profiles, and that these protein profiles may change with the stage of the disease or disease progression.

Epidemiologic studies suggest an association between infective agents and sarcoidosis based on seasonal variations and case clustering (Baughman et al., 2003). Several lines of evidence suggest mycobacteria as a candidate organism. First, while mycobacteria in general cannot be isolated from sarcoid tissue using conventional microbiologic techniques, cell wall deficient L forms persisting as an intracellular organism can be identified. Second, several PCR-based studies have identified mycobacterium DNA in sarcoid tissue homogenates (Song et al., 2005). Utilizing biochemical techniques similar to that used to isolate the Kveim reagent and immunoblotting using immunoglobulin obtained from the serum of sarcoid patients, investigators identified immunoreactive proteins unique to sarcoid tissue homogenates. These antigenic bands were excised from gels, subjected to trypsin digestion, and analyzed by MALDI-TOF mass spectroscopy. The peptide fingerprints were identified as mycobacterium tuberculosis catalase–peroxidase. These authors hypothesize that insoluble aggregates of mycobacteria-derived catalase–peroxidase drive the sarcoid immune response in genetically predisposed individuals.

SURFACTANT PROTEINS AND DPLD

Pulmonary surfactant

Pulmonary surfactant is a complex mixture of phospholipids and proteins that functions to reduce surface tension at the alveolar air interface preventing atelectasis. Deficiency of pulmonary surfactant is the principal cause of respiratory distress syndrome in premature infants (Whitsett and Weaver, 2002). Four surfactant-associated proteins, surfactant proteins A, B, C, and D, have been described, and two have been associated with DPLD. Surfactant protein C (SP-C) is a highly hydrophobic protein that enhances the surface tension lowering properties of pulmonary surfactant. Familial cases of neonatal respiratory distress have been associated with surfactant protein B deficiency, but respiratory distress of neonates is not considered a form of DPLD/ILD (Nogee et al., 2000). Genetic variants of SP-A have been associated with increased risk of idiopathic pulmonary fibrosis (IPF; Lawson et al., 2004).

Family Studies with SP-C

Nogee et al. (2001) reported a full-term baby girl born to a woman who had desquamative interstitial pneumonia, a type of IIP, at 1-year of age. The infant's maternal grandfather died of an

unknown lung disease. The infant developed respiratory distress at the age of 6 weeks, and surgical lung biopsy demonstrated non-specific interstitial pneumonia (NSIP). Both the infant and the mother had minimal SP-C by either immunohistochemical staining, or immunoblotting of lung tissue. DNA sequence analysis of the SP-C gene demonstrated a heterozygous substitution of A to G at the first base of intron 4 that abolished the normal donor splice site resulting in a truncated mRNA. Subsequently, there have been several other similar families with SP-C mutations and interstitial pneumonia (Chibbar et al., 2004; Thomas et al., 2002). In the largest kindred, a heterozygous T to A substitution was identified in exon 5 causing glutamine for threonine substitution. In this pedigree, there was both adult-onset interstitial pneumonia of the usual interstitial pneumonia (UIP) histology and children with the cellular NSIP (Thomas et al., 2002). Immunohistochemical analysis of these patients demonstrated intracellular aggregates of SP-C and *in vitro* expression studies demonstrated abnormal intracellular processing of SP-C in alveolar type II cells.

SP-B and SP-C Genetic Variants Associated with IPF

In a single study by Selman and colleagues, the SP-A1 $6A^4$ haplotype is associated with a substitution of 3 amino acids at positions 19, 50, and 219, with the 219 variant being a tryptophan for arginine substitution (Lawson et al., 2004; Selman et al., 2003). The amino acid 219 variant is associated with IPF in smokers and nonsmokers (OR = 3.67 [1.34, 10.07], $p = 0.01$).

GENETIC DETERMINANTS OF PULMONARY FIBROSIS IDENTIFIED IN RARE INHERITED DISORDERS

Pulmonary fibrosis is observed in genetic disorders with pleiotropic presentation, including Hermansky-Pudlak syndrome, neurofibromatosis, tuberous sclerosis, Neimann-Pick disease, Gaucher disease, familial hypocalciuric hypercalcemia, familial SP-C mutation, and most recently in dyskeratosis congenital. Recently, mutations associated with the dyskeratosis congenita syndrome have been in a small percentage of FIP (Armanios et al., 2007). Specifically, 8% of 73 families with more than one case of IIP were found to have heterozygous mutations in telomerase reverse transcriptase, resulting in shortening of telomeres. These authors suggest that telomere shortening may cause apoptosis of the alveolar epithelium.

Emerging Concepts from Genomic Studies of Associated DPLD

An interesting feature of these studies is the variable histopathologic features among family members sharing the identical SP-C mutation, suggesting modification of disease phenotype by other unknown factors. Mutations in SP-C and telomerase reverse transcriptase also suggest that abnormalities of the alveolar epithelium, particularly alveolar type II epithelial cells, the major source of pulmonary surfactant and also the progenitor cell for alveolar type I epithelial cell, are critical for the development of pulmonary fibrosis and interstitial pneumonia. In the instance of SP-C mutations, intracellular aggregates of abnormally processed SP-C may induce functional abnormalities of alveolar epithelial cells. These studies have resulted in a paradigm shift in the mechanism and the pathogenesis of IIP, away from an inflammatory hypothesis, toward one of abnormal injury and repair of the alveolar epithelium and the fibroproliferative response. These data support the lack of efficacy of glucocorticoid and cytotoxic treatments of IPF.

GENETIC DETERMINANTS OF FIP

Clinical Features

The interstitial pneumonias can be classified as sporadic or idiopathic (IIP), in which no positive family history can be identified, or FIP. There are no data on the relative proportion of interstitial pneumonias that are familial, but estimates are in the range of 5%. Familial aggregation has been reported in a variety of studies in twins, siblings raised apart, and multigenerational families. Steele et al. (2005) reported the largest collection of families, identifying 111 families from the United States, and 20 multigenerational pedigrees were consistent with autosomal dominant inheritance. Forty-five percent of the families demonstrated phenotypic heterogeneity with some families having bronchiolitis obliterans or NSIP and UIP within the same pedigree. Cigarette smoking was associated with affection status among siblings (OR = 3.6, [1.3, 9.8], $p = 0.01$). The histopathologic heterogeneity in these families has been confirmed in a subsequent study with multiple independent pathologists. UIP is found in 40% of these families, but the predominant histopathologic pattern (60%) for the FIP cohort was difficult to classify pattern characterized by advanced fibrosis with a high incidence of microscopic honeycombing, smooth muscle proliferation and fibrosis, and variable diffuse alveolar septal and airway-centered scarring. Similar to the findings with SP-C mutations, these data suggest that histologically distinct forms of pulmonary fibrosis may have common pathogenic mechanisms, and that cigarette smoking may contribute to the development of pulmonary fibrosis in individuals who are genetically prone to this disease.

Candidate Genes Identified by Microarray Analysis in Familial Pulmonary Fibrosis

Yang and colleagues performed microarray analysis of 16 cases of sporadic IIP (14 UIP, 2 NSIP), and 10 cases of familial IIP (6 UIP, 4 NSIP), compared to 9 normal lung controls. RNA was extracted from diseased lung tissue (specimens from surgical lung biopsy, autopsy, or explanted lung at the time of lung transplant), or normal controls (9 lung samples taken from donor lung at the time of lung transplant). cRNA was synthesized and hybridized

onto whole human genome arrays modified with an additional 657 probes for genes/ESTs that would be potentially informative based on preliminary linkage data (Yang et al., 2005). Expression profiling was performed using standard protocols (co-hybridized with human universal cell line reference RNA; replicates with the two dyes swapped; Lowess-normalized intensities; analysis using the TGR MIDAS and MeV software), and differentially expressed genes were identified using significance analysis of microarrays (SAM) with 100 permutations. 558 differentially expressed transcripts between cases compared to controls were identified, with 135 genes being up- or down-regulated greater than 1.8-fold. When hierarchical clustering was applied to the set of 135 genes, all but two samples clustered according to disease versus no disease, and familial disease segregated from sporadic disease (Figure 48.1). Sixty-nine differentially expressed genes were identified that distinguish sporadic and familial IP, and these

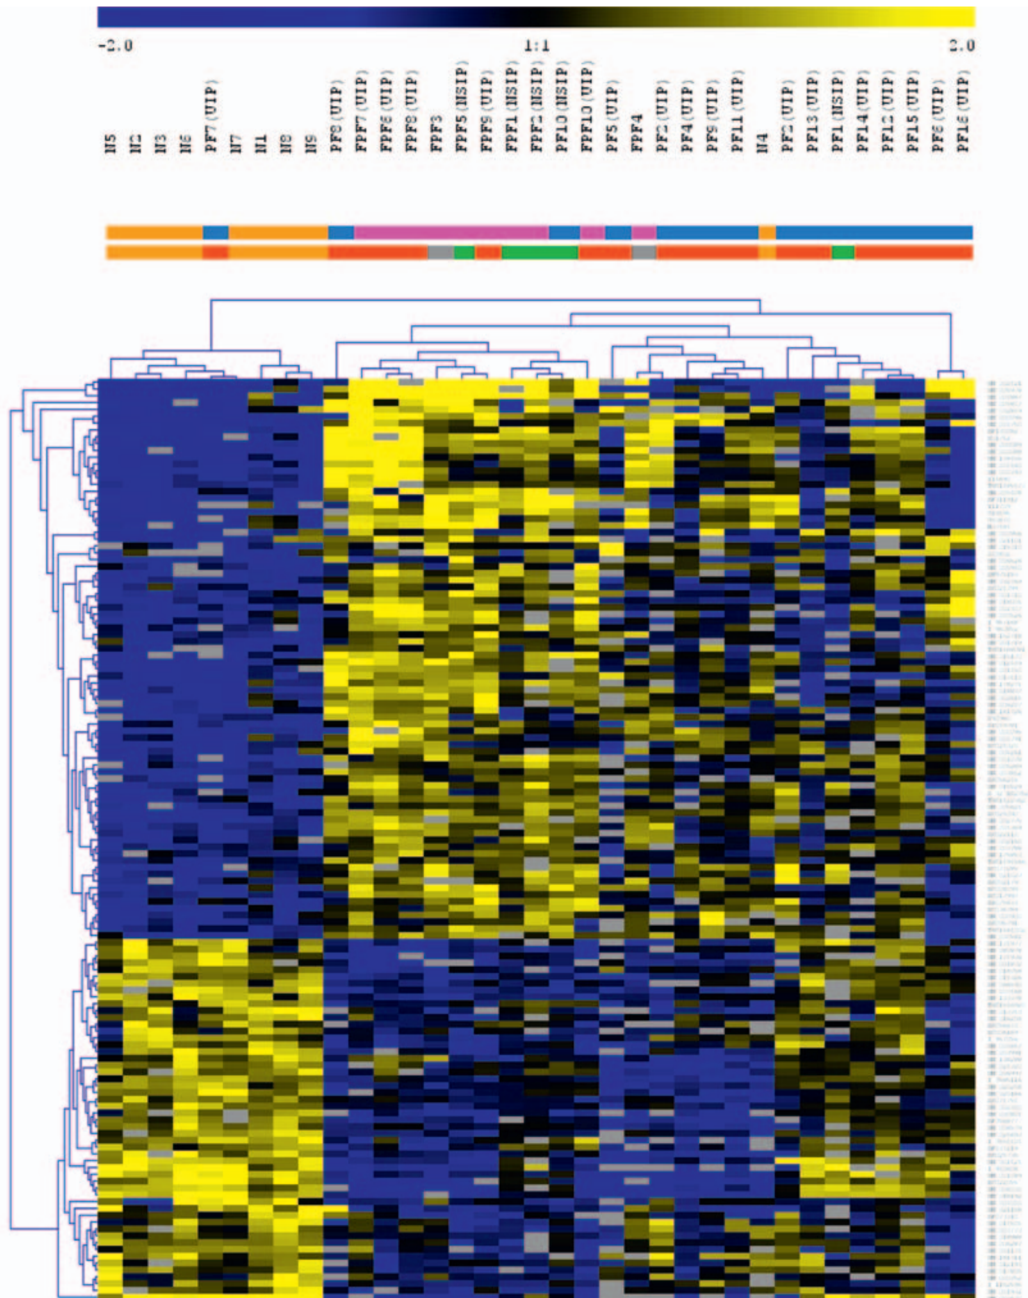

Figure 48.1 Hierarchical clustering of 35 cases and 16 controls. Hierarchical clustering of 35 samples based on 135 transcripts that best differentiate patients with pulmonary fibrosis from normal controls. Samples are color-coded according to the disease inheritance status (orange – normal, blue – sporadic IIP, magenta – familial IIP) or histological features (orange – normal, green – NSIP, red – UIP, gray – no histological evaluation). Average linkage clustering with Euclidian distance metric was used.

are broadly grouped into functional classes (Figure 48.2), with a wide variety of chemokines, extracellular matrix, and growth-related genes that are differentially expressed. These data indicate that familial and sporadic IIP are transcriptionally distinct and also suggest many similarities between the histologic subtypes of UIP and NSIP. This study indicates that additional candidate genes that may be important in the pathogenesis of IIP, or that might be useful as biomarkers of disease activity, can be identified using whole-genome microarray analysis.

Relevance of Genomics and Microarray Studies to DPLD/ILD

A number of clinical challenges exist that impede better understanding of disease mechanisms in DPLD and are potentially addressed using expression profiling, proteomic, and genomic approaches. First, even in the hands of expert clinicians, radiologists, and pathologists specializing in DPLD, a definitive consensus diagnosis is achievable in about 85% of patients due to the clinical, radiologic, and pathologic overlap of these

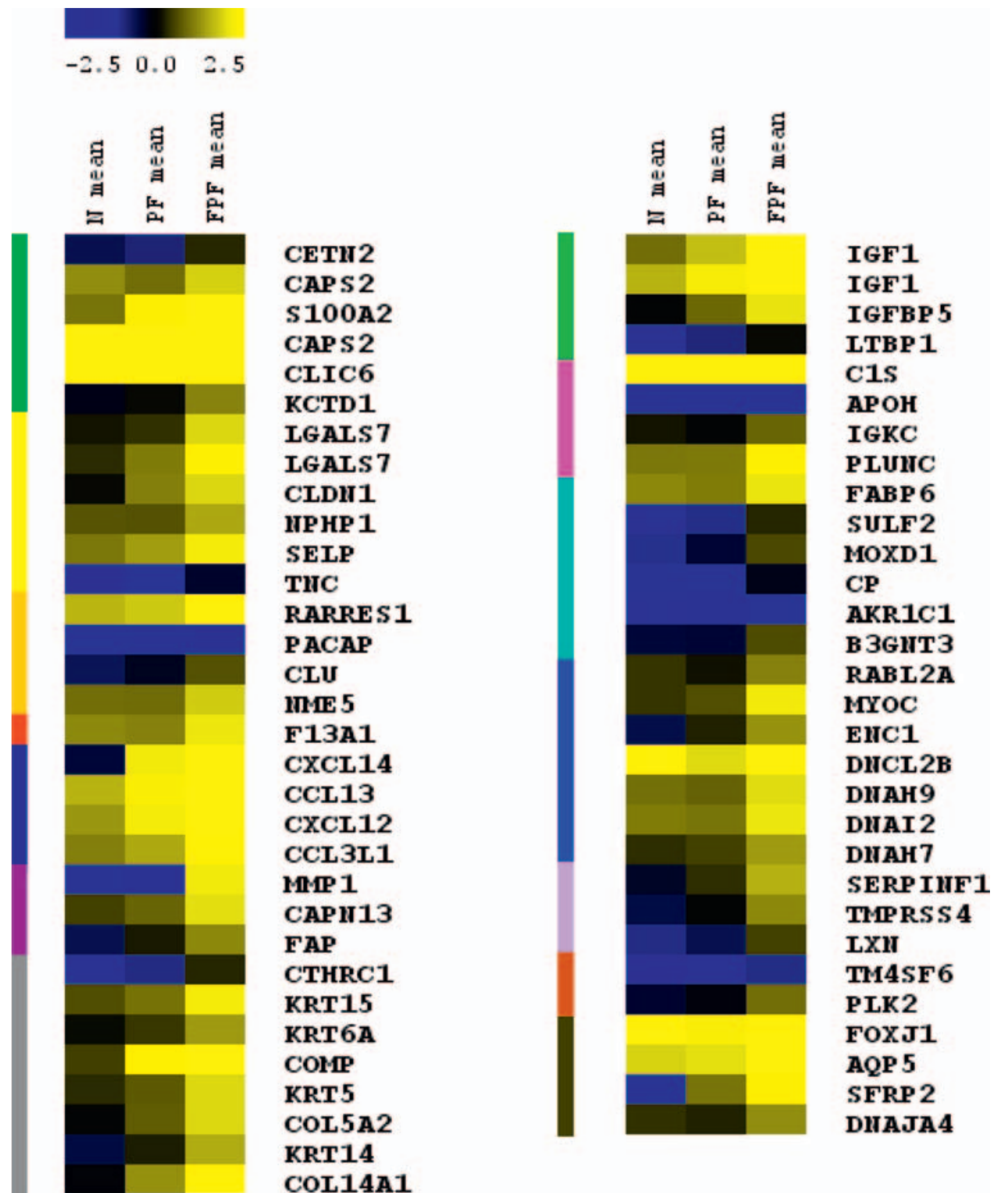

Figure 48.2 Mean Expression Ratios in normal, sporadic IIP, and familial IIP. Groups of 69 genes with known function that best differentiate familial IIP from sporadic IIP. Genes are arranged and color-coded according to their function: dark green – calcium/potassium ion binding and transport; yellow – cell adhesion; orange – cell proliferation and death; red – coagulation cascade; blue – cytokines, chemokines, and their receptors; purple – ECM degradation; gray – ECM structural component; bright green – growth factors and their receptors; magenta – immune response; turquoise – metabolism; navy – motor activity; lavender – proteases and inhibitors; brown – regulation of I-kappaB/NF-kappaB cascade; and black – other.

entities. Microarray-based expression profiling has the capability to improve diagnostic accuracy. A recent study by Selman and colleagues demonstrates that a distinct microarray expression signature exists for hypersensitivity pneumonitis, a clinical entity with well-recognized radiologic and pathologic overlap with IIP, when compared to IPF (Selman et al., 2006).

Linkage Studies in Pulmonary Fibrosis

The only published study performing genome-wide linkage analysis in FIP comes from Finland (Hodgson et al., 2006). Using 6 pedigrees, NPL scores of 1.7 on chromosome 3 (marker D3S1278) and chromosome 4 (marker D4S424), and NPL score of 1.6 on chromosome 13 (D13S265) were obtained. On chromosome 4, a shared haplotype was identified among 8 of 24 multiplex families. A candidate gene located in the region of interest, ELMOD2, was further investigated by resequencing of exons and exon/intron boundaries. No mutations in ELMOD2 in these locations were identified. RT-PCR and *in situ* hybridization demonstrated decreased levels of ELMOD2 mRNA in six cases of sporadic IPF compared to controls. Genome-wide linkage analysis of the 111 US families is in progress, and preliminary results indicate linkage (LOD score >3.0) on chromosome 11p15 not identified in the Finland study (unpublished data).

2009 UPDATE

IPF is the most common of the IIPs and continues to be a devastating and poorly understood disease. While IIPs most often occur as sporadic cases, familial forms represent about 5–10% of IPF cases. Genetic studies of both familial and sporadic IPF are providing new insights into potential disease mechanisms. Recently, both sporadic and familial IPF have been associated with telomere shortening and mutations in telomerase genes.

Two groups independently reported an association with mutations in TERT, the reverse transcriptase component of telomerase, in both familial and sporadic IPF (Armanios et al., 2007; Tsakiri et al., 2007). Variants in TERTC, the gene encoding the RNA component of telomerase, have also been identified. These studies were from a relatively small number of cases in the United States. Recently, abnormalities in TERT have been associated with sporadic IPF from a genome-wide association study (GWAS) in larger cohort of patients from Japan. A GWAS using 159 patients with IPF and 934 controls tested 214,508 tagged SNPs and showed that SNP rs2736100, located in intron 2 of TERT, had a p value of 2.8×10^{-6}. In a replication set of 83 IPF patients and 535 controls, a p value of 3.6×10^{-3} was obtained (Mushiroda et al, 2008). This TERT intron 2 SNP is located within a LD block (D' and $r^2 > 0.8$) within TERT, suggesting that rs2736100 may be associated with some other unidentified variation within TERT in this population of IPF patients from Japan.

Novel missense mutations were identified in TERT in patients from the United States with dyskeratosis congenita who had pulmonary fibrosis (Armanios et al., 2007). These investigators also sequenced TERT in 73 kindreds with familial IPF and identified 8% of probands heterozygous for TERT mutations and one proband heterozygous for a mutation in TERTC. Telomere length in these affected individuals was reduced to below the 10th percentile in lymphocytes. Whole-genome linkage analysis was performed in two large families with pulmonary fibrosis that showed evidence for linkage to chromosome 5 in a region containing TERT, and variants in TERT were found in these families as well (Taskiri et al., 2007).

Recently, the possible role of telomere shortening has been generalized to sporadic and familial IPF patients without identified mutations in TERT/TERTC (Cronkhite et al., 2008). Using a modified Southern blot technique, restriction fragment length methods and a quantitative polymerase chain reaction method to measure telomere length of genomic DNA, these investigators found telomere length less than the 10th percentile ($p = 2.6 \times 10^{-8}$) in a significantly higher proportion of probands with familial pulmonary fibrosis (24%) and sporadic cases (23%) in which no coding mutations in TERT or TERTC had been found. Pulmonary affected status was significantly associated with telomerase restriction fragment lengths even after controlling for age, sex and ethnicity ($p = 6.1 \times 10^{-11}$). Overall, 25% of sporadic IPF and 37% of familial IPF had telomere lengths below the 10th percentile. These studies were performed in circulating lymphocytes, and it will be important to replicate these results in future studies in lung cells, particularly in the alveolar epithelium.

To date, studies of the genetics of pulmonary fibrosis have identified mutations in surfactant proteins and more recently in telomerase, as susceptibility alleles for the development of pulmonary fibrosis. Multiple lines of evidence – including GWAS in sporadic IPF, family linkage studies and measurements of telomere length in sporadic IPF – all suggest a role for telomere shortening and susceptibility to pulmonary fibrosis. The association of the risk of developing pulmonary fibrosis and telomere shortening may explain in part the late onset of these diseases. In addition, there are environmental influences in pulmonary fibrosis, such as cigarette smoking, that are known to cause telomere shortening, thus providing a potential gene–environment connection. These data also provide additional support for the hypothesis that apoptosis of the alveolar epithelium predisposes to the development of pulmonary fibrosis.

CHAPTER

Peptic Ulcer Disease

John Holton

INTRODUCTION

Peptic ulcer disease (PUD) comprises both duodenal ulcer (DU) and gastric ulcer (GU). Duodenal ulcers occur most often in the first part of the duodenum or in the pre-pyloric region of the stomach (antrum). Gastric ulcers are most frequently seen on the lesser curve of the stomach at the junction of the body and antrum (angularis) (Figure 49.1). Acute stress ulcers involve the body of the stomach and are often multifocal and transient. Histologically, the ulcer is a break in the mucosa with loss of epithelial cells, exposure of the basement membrane and involvement of the muscularis mucosae.

Ulcers develop because of an imbalance between the normal protective attributes of the stomach and the potentially damaging secretions in the lumen of the stomach. This imbalance may be caused by a number of factors, the principal one being colonization by *Helicobacter pylori* (Figure 49.2). Ulceration may also occur associated with a number of other conditions such as Crohns disease, vascular insufficiency, hypersecretory states such as gastrinoma (Zollinger Ellison syndrome), antral G cell hyperplasia, mastocytosis and multiple endocrine neoplasms (MEN-1). Acute stress ulcers are caused by excess alcohol use, non-steroidal anti-inflammatory agents (NSAIDS), burns, trauma to the central nervous system, cirrhosis, chronic pulmonary disease, renal failure, radiation and chemotherapy.

Pre-*Helicobacter* Management of PUD

Prior to the isolation of *H. pylori*, ulceration was thought to be caused by psychological stress and excess spicy foods. It was recognized that smoking was a contributory factor and that excess acid in the stomach was the primary pathology. The treatment was mainly surgical. The first operation was carried out in 1882 with antral resection and duodenogastrostomy (Billroth I) followed a few years later by antral resection and gastrojejunostomy (Billroth II). The aim of these surgical procedures was to reduce the antral phase of acid production. In 1943, Dragstedt introduced truncal vagotomy to reduce the cephalic phase of acid production. However, vagotomy also reduced the drainage from the stomach and had to be combined with a pyloroplasty in order to allow free drainage from the stomach. Frequently both these procedures (antral resection, either Billroth I or II; vagotomy with pyloroplasty) were combined. In the 1970s highly selective vagotomy was introduced, which specifically reduced acid secretion. Side effects of these surgical procedures included diarrhea, a dumping syndrome and anemia. In addition to surgical procedures, in 1976 long-term pharmacological acid suppression with H_2-receptor antagonists was introduced to ameliorate symptoms and allow ulcer healing. However, if the medication was stopped, the ulcer frequently recurred.

Isolation of *H. pylori* and Post-*Helicobacter* Management

Curved or spiral shaped bacteria had been seen in the stomach of various animals and humans as far back as 1888 and had been thought of as commensals and of no significance. Since this period, however, two technical advances set the ground for the subsequent isolation of *H. pylori*: in the 1970s the development of endoscopes allow stomach biopsies to be taken, and the

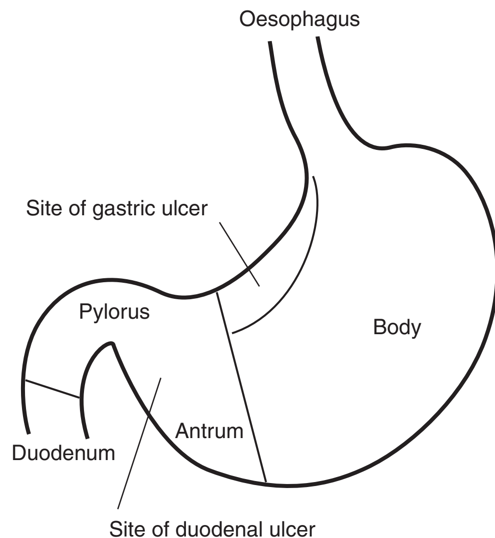

Figure 49.1 This diagram shows the usual location of gastric and duodenal ulcers. Duodenal ulcers are found in the antrum of the stomach or the first part of the duodenum. Gastric ulcers are located at the junction of the antrum and fundus or body of the stomach.

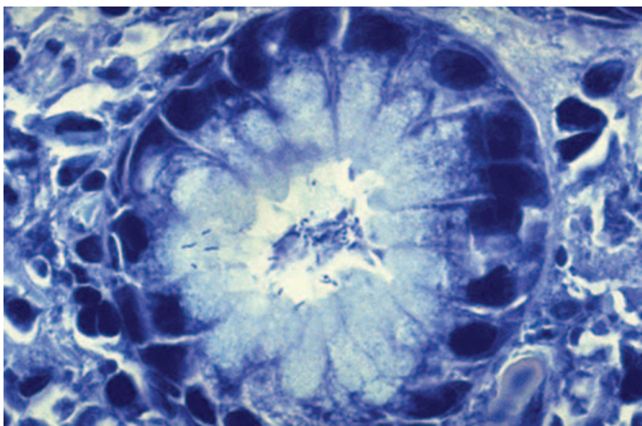

Figure 49.2 This is a Giemsa stained section of stomach showing *Helicobacter pylori* located within a gastric gland, Some of the bacteria are located on the surface of the epithelial cells.

recognition of cultural conditions necessary for the isolation of microaerophilic bacteria. In 1982–1983, Warren, a histopathologist from Perth, Australia, had noted an association between the presence of these organisms and gastritis. He and his colleague Marshall, a gastroenterologist, studied a large series of endoscopic biopsies demonstrating the almost perfect association between gastritis and the presence of this curved bacterium (Warren and Marshall, 1983) that was initially called a campylobacter-like organism. Additionally, they were successful in isolating the organism on artificial media by culturing it under microaerobic conditions similar to that used to isolate the gastrointestinal pathogen *Campylobacter jejuni*. The organism was initially called *Campylobacter pylori* but in 1989 was transferred to a separate Genus called *Helicobacter* (Goodwin, 1994). The initial suggestion that gastritis and ulceration may be caused by this organism was met with scepticism, leading both Marshall and Morris to separately swallow a culture of the organism in order to fulfill Koch's Postulates. Both individuals developed gastritis, which resolved on eradication of the organism. In 1997 the genome sequence of one strain of the organism was determined (Tomb et al., 1997). Eventually, the causal nature of at least 90% of cases of PUD as being *H. pylori* was widely accepted, and both Warren and Marshall received the Nobel Prize for Medicine and Physiology in 2005 (Megraud, 2005).

The recognition that *H. pylori* is the principal cause of PUD has led to a dramatic change in the management of disease: from surgery or lifelong H_2-receptor antagonists to a short course of an acid suppressive (usually a proton pump inhibitor, PPI) combined with two antibiotics – usually amoxycillin and clarithromycin or amoxicillin and metronidazole (European Helicobacter Study Group, 2005).

PATHOPHYSIOLOGY OF ULCER FORMATION

The two most common causes of PUD are infection with *H. pylori* and taking NSAIDS.

Helicobacter-Induced Ulcers

H. pylori causes damage to the host by five principal mechanisms:

1. *H. pylori* causes direct damage to the protective mucus barrier and the epithelial cell layer by inhibiting mucus secretion, secreting phospholipase A (which disrupts the micellar structure of the mucus) and generating ammonium which, in addition to disrupting the protective mucus layer, is also directly cytotoxic for the gastric epithelial cells. *H. pylori* also secretes a vacuolating cytotoxin which is directly cytotoxic (Harris et al., 1996; Kubota et al., 2004) and injects the cagA protein (see later) into the epithelial cell by means of a type IV secretion apparatus. This latter protein disrupts intracellular signaling pathways in the epithelial cell which in part leads to secretion of the chemokine (IL-8).
2. *H. pylori* induces a Th-1 mediated acute inflammatory response by stimulating IL-8 secretion from the epithelial cells and recruiting granulocytes into the lamina propria. Products from *H. pylori* induce the release of free oxygen radicals from the granulocytes, thus causing bystander damage to the epithelial cells (Brisslert et al., 2005).
3. *H. pylori* inhibits the negative feedback loop in the control of acid regulation by means of its lipopolysaccharide inhibiting the production of somatostatin. This leads to continuous production of gastrin (and thus acid) and a characteristic hypergastrinaemia (Moss et al., 1992).

4. *H. pylori* affects the balance of cell division/apoptosis, thus affecting ulcer development and healing as well as having pathological implications for the long-term complication of colonization by *H. pylori* – gastric adenocarcinoma (Cai et al., 2005).
5. During infection with *Helicobacter pylori* auto-antibodies are produced, which target the acid secreting mechanism of the parietal cells and eventually may lead to loss of parietal cells and thus loss of the ability to produce acid (Lo et al., 2005).

NSAIDS-Induced Ulcers

Non-steroidal anti-inflammatory agents damage the stomach by two mechanisms, a local mechanism and a systemic effect on mucus production.

1. NSAIDS are both weak acids and lipophilic, and as such the hydrophobic surfactant layer on the apical surface of the epithelial cells and in the mucus does not present such a barrier to penetration. Once they have penetrated the protective mucus, NSAIDs cause direct damage to the epithelial cell by altering cell permeability and damaging mitochondria, leading to apoptosis (Nagano et al., 2005).
2. When absorbed into the blood, NSAIDS inhibit the enzyme cyclo-oxygenase 1 (COX-1), which produces prostaglandins from arachidonic acid metabolism. The effect of prostaglandins is to increase blood flow in the stomach, increase mucus and bicarbonate production and inhibit acid production. Reduction in prostaglandin secretion diminishes three of the major defense mechanisms of the stomach: bicarbonate and mucus production and blood flow (Gambero et al., 2005).

Ulcer Formation

The net effect of these various insults is the loss of protective mucus and death of the epithelial barrier, resulting in exposure of the damaged epithelium and underlying lamina propria to the effects of acid and proteolytic enzymes resulting in an ulcer (Figures 49.3 and 49.4). If *Helicobacter* spreads from the antrum to give a pan-gastritis, the acid-producing cells suffer damage, and eventually an atrophic gastritis develops with a decrease in acid production and an increase in intraluminal *p*H. Atrophic gastritis and the subsequent intestinal metaplasia that develops are premalignant risk factors that in a percentage of individuals will lead onto the development of gastric adenocarcinoma. Similar damage results from NSAID usage but by a different mechanism.

THE HELICOBACTER GENOME

Genome Structure and Diversity

In 1997, the genome sequence of *H. pylori* 26695 was sequenced by The Institute for Genomic Research (TIGR) (Tomb et al., 1997) and 2 years later that of another strain, J99, was sequenced by AstraZeneca in collaboration with Genome Therapeutics Corporation, United States of America.

Strain 26695 has 1667867 base pairs (bp) an average GC content of 39% and 1590 predicted coding sequences, of which 1091 were annotated. Well developed systems for motility, iron scavenging, restriction and modification and outer membrane proteins (OMPs)/adhesions were noted with a relatively restricted repertoire of metabolic and biosynthetic systems or regulatory networks. An abundance of homopolymeric tracts was found, underscoring the potential for antigenic variation by slipped strand mispairing. In this strain there were five areas with a different GC ratio, one of which has been identified as a pathogenicity island (PAI), and two others in relation to the presence of insertion sequences (IS). Two ISs were identified with 13 copies of one (IS605) and 4 copies of the other (IS606). In all 95 paralogous gene families (16% of the total genome) are present, the largest family with 32 members related to porins/OMP. Three secretion pathways are present: the SecA-dependent one found in many bacteria, a Type IV secretion system associated with the PAI and related to that of *Agrobacterium* and a flagellar export pathway. The large number of homopolymeric tracts, dinucleotide repeats and paralogous families explains the potential for the high degree of variation known to occur in the *H. pylori* genome, reflecting its ability to survive and evolve in its restricted ecological niche. Although placed in the gamma Proteobacteria it also carries genes more closely related to non-Proteobacteria testifying to lateral gene transfer at some point in the organism's evolutionary history.

The second *H. pylori* isolate to be sequenced allowed a comparison of both J99 and 26695 (Alm et al., 1999). *H. pylori* J99 has 1643831 bp, which is smaller than that of 26695 by 24036 bp. The number of predicted coding sequences in J99 is 1495, which is fewer than the revised number of predicted coding sequences in 26695 (now estimated to be 1552 rather than the original 1590). Each strain has unique genes not found in the other strain. J99 has 89 unique genes, of which 56 are of unknown function whilst 26695 has 117 unique genes with 91 of unknown function. There are a predicted 1406 genes common to both strains. J99 has fewer complete ISs. Like 26695, J99 carries a complete PAI and also like strain 26695 has a large number of paralogous gene families. One region of both genomes carries 46–48% of the strain-specific genes and has been termed the plasticity zone (PZ). In J99 this PZ is continuous but in strain 26695 it is split into two sections separated by about 600 kb. Allelic variation occurs in both strains with differences found mainly at the third codon position. Moderate macrogenome diversity also exists between the strains, with about 85% of orthologs having the same neighbor at both sides, 10% with the same neighbor on one side and a strain-specific gene on the other and about 3% flanked by strain-specific genes. Despite these genomic variations the proteome of both strains are very similar. Following the sequencing of the second *H. pylori* genome (J99), it was necessary to re-annotate both genomes to a common classification (Boneca et al., 2003).

H. pylori has one of the highest allelic diversity of any organism, and comparison of both sequenced genomes indicates a high degree of size variation between orthologs due to a variety of

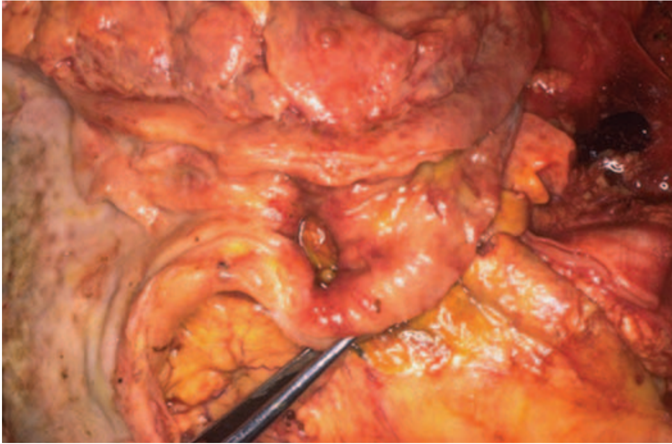

Figure 49.3 This is a photograph of the macroscopic appearance of a duodenal ulcer in the antrum of the stomach.

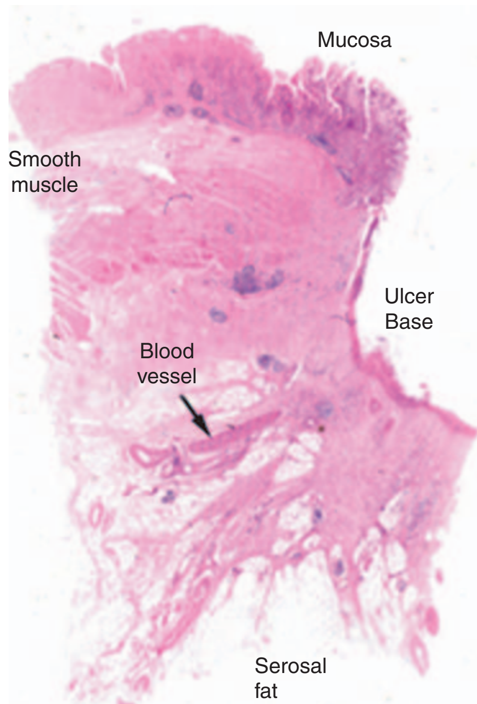

Figure 49.4 This is a photomicrograph of a hematoxylin and eosin stained section of stomach illustrating an ulcer that has eroded the epithelium exposing the underlying tissues.

mechanisms. The diversity is generated by frequent recombination, a high mutation rate, slipped strand mispairing, frame shifts and the presence of pseudogenes (Tomb et al., 1997; Suerbaum et al., 1998; Wang et al., 1999). Much of the diversity is localized within the PAI or PZ. On a macrogenomic scale, however, the sequences of the two genomes indicate a similar organization.

The population genomic structure of *H. pylori* is regarded as panmictic rather than clonal (Go et al., 1996) although isolates from an individual or family group are clonal (Han et al., 2000). A study of 23 isolates using electrophoresis of 16 enzymes indicated an allelic diversity ranging from 2–11 alleles with no obvious clustering of disease-related strains (Hazell et al., 1997). A whole-genome microarray analysis of 15 strains utilizing 1660 unique sequences derived from the strains J99 and 26695 showed a high degree of genetic diversity between the strains (Salama et al., 2000). One thousand two hundred and eighty one sequences were common to all the strains and 362 were missing from at least one of the isolates. At a conservative estimate, about 12–18% of the genes of an individual isolate were strain-specific. This genetic diversity is probably a reason for the ability of *H. pylori* to become a chronic pathogen in the stomach despite a vigorous local and systemic immune response. In part, it explains the different clinical outcomes of infection with *H. pylori*, and it also reflects the continuing evolution of the organism over decades within the human stomach of an individual. Several studies (Han et al., 2000; Israel et al., 2001; Lundin et al., 2005) have demonstrated the presence of related sub-strains of *H. pylori* within the stomach of a single individual. In one study the person who was infected with the original sequenced isolate, J99, remained infected despite appropriate therapy, and after 6 years additional cultures were isolated from the same patient. The new isolates were subjected to random amplified polymorphic DNA-PCR (RAPD-PCR), sequencing of unlinked genes and micro-array analysis. The results demonstrated that all the isolates were related to the original strain, although the isolates varied in genetic content from the original strain and co-isolates by about 3%. Current isolates did not hybridize with some open reading frames (ORFs) from the original strain with a loss of 0.28–1.52% ORFs and yet some ORF sequences from current isolates hybridized with specific sequences from the other strain, *H. pylori* 26695, of which the whole genome sequence is known. A second study confirmed the presence of closely related sub-clones isolated from a single individual (Bjorkholm et al., 2001) and additionally went on to demonstrate the genetic and phenotypic stability of these two clones in an experimental system using transgenic mice expressing human Lewis b, the ligand for the BabA adhesion on the organism. Of the two original isolates, one had lost the PAI and, although this isolate could colonize germ-free transgenic mice along with the PAI positive isolate, only the PAI positive isolate could colonize conventional mice harboring a normal flora. Over a 3- or 10-month period of study, no nucleotide substitutions or deletions were detected in either strain indicating that in this model system either there was insufficient selective pressure or time for divergence to occur.

Allelic Diversity and Disease

H. pylori colonizes over half the population of the world. In some countries the colonization rate is as high as 90% even by the age of 10 years. In others it is about 30% overall, with only 5% being colonized within the first decade. This geographical difference in prevalence is caused principally by variation in availability of a good public health infrastructure and prevailing social conditions. Of those colonized, the vast majority are

without symptoms although they do have gastritis. A small proportion, about 5–20%, will develop PUD and an even smaller percentage, about 1%, which develop gastric cancer. The difference in clinical outcome is the results of the interaction of three factors: environmental, host susceptibility and strain variation.

Strain Variation and Virulence

As mentioned, *H. pylori* possesses a number of virulence characteristics that are not present or not expressed in all strains. Some strains have acquired a PAI that carries 31 different genes, some of which relate to the synthesis of a Type IV secretion system, and a gene (*cagA*) coding for a protein that the Type IV secretion system transfers to gastric epithelial cells – the cytotoxin associated gene product (CagA). Nearly all strains carry another locus *vacA*, separate from the PAI, that secretes a vacuolating cytotoxin (VacA). This latter product, however, is secreted in varying amounts depending on the presence of allelic diversity within the *vacA* gene and possibly the presence of the cagA PAI. Strains can thus be broadly divided into two main types: Type I that co-express *cagA* and *vacA* and Type II that do not (Xiang et al., 1995). The clinical significance of this is that Type I strains are more often isolated from patients with serious gastroduodenal disease such as PUD and gastric cancer.

Vacuolating Cytotoxin

About 50% of isolates produce a vacuolating cytotoxin. The *vacA* gene encodes a 139–140 kDa protein which is cleaved into a 33 amino acid signal sequence and a 90 kDa toxin. The *C*-terminal domain of the toxin comprises 14–16 β strands that inserts into the bacterial membrane and acts as an autotransporter (Type V secretion system) for the toxin (Fischer et al., 2001) that is secreted. After secretion, the toxin is further cleaved into a 34 kDa *N*-terminal region and a 58 kDa *C*-terminal region that nevertheless remain associated. The toxin monomer is activated by acid, undergoing a conformational change and then oligomerizes to form a 900 kDa protein, as it associates with lipid rafts in the cytoplasmic membrane of epithelial cells (Lupetti et al., 1996). In the cytoplasm of the epithelial cell, its mode of action is to disrupt the endocytic pathway leading to enlargement of late endosomes. The toxin forms anion-selective channels in membranes allowing the accumulation of weak bases, stimulated by the acidification of the vacuole by V-ATPase. Additionally, transfection experiments show that the p34 peptide becomes associated with the mitochondria releasing cytochrome C from the mitochondria and thus activating the caspase cascade (Galmich et al., 2000). When given directly onto gastric epithelium, the cytotoxin induces damage causing necrosis and ulceration. A further consequence of the action of the toxin is the inhibition of processing of antigens in antigen-presenting cells, thus affecting T-cell responses.

Although most strains carry the *vacA* gene, there is a large diversity in the sequence of the mid region (MR) and the leader sequence (LS). This diversity has consequences in relation to secretion of toxin, binding to cell types and geographical distribution of strains. The general structure of the VacA protein is illustrated in Figure 49.5. There are four variations of the LS designated S1a,S1b,S1c and S2 and several variations of the MR designated m1a, m1b, m1T, m2a m2b and chimeric types, for example, m1b-m2 (Atherton et al., 1995; Pan et al., 1998; Strobel et al., 1998; van Doorn et al., 1998; van Doorn et al., 1999; Wang et al., 1998). The primers used to detect these variations are given in Table 49.1.

Strains with an S1 LS have a different cleavage site from that of S2, and these strains are more often found associated with PUD than S2-containing strains. They produce high levels of cytotoxin and are more frequently found in cagA positive strains (Atherton, 1997). The MR is also an independent marker for cytotoxin activity *in vitro* with m1 stains being more cytotoxic than m2 strains. The MRs are responsible for binding to cells and depending upon the cell type m2 strains are just as toxic as m1 strains (Ji et al., 2000; Pagliaccia et al., 1998). Various combinations of the LS and MR alleles have been isolated from patients, giving strains with different phenotypes of cytotoxin activity. Strains with the S1/m1 alleles appear to produce more cytotoxin compared to S2/m2 strains, which apparently do not produce detectable cytotoxin activity, although the gene is transcribed. This lack of association between *H. pylori* S1/m2 strains in countries with high levels of PUD and gastric cancer is explicable by the lack of binding of m2 strains to cell types used in testing cytotoxic activity. However, there may also be a modulation of toxin production based on levels of transcription of the vacA gene (Forsyth et al., 1998), which could affect the phenotype of the strain and clinical outcomes.

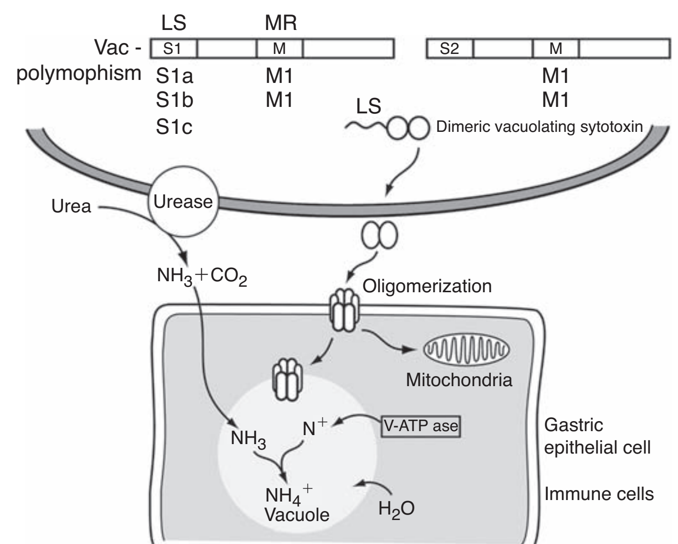

Figure 49.5 This diagram illustrates the polymorphisms found in the *vac A* gene in the LS and mid region (MR) of the gene. It also illustrates the secretion and oligomerization of the vacA protein and its action on the epithelial/immune cell to disrupt normal endosomal trafficking leading to the production of large vacuoles and its effect on the mitochondria leading to apoptosis.

Cag PAI and the CagA Gene Product

CagA is a marker for the cag PAI: a 40 Kb DNA fragment containing 31 genes, of which 6 encode a Type IV secretion system, by which the CagA protein is injected into host cells. Once inside the gastric epithelial cell, it is phosphorylated at a tyrosine residue, present in EPIYA motifs, by Src-family kinases and binds to the SH2 domain of SHP-2 phosphatase, thus deregulating its activity (Hatakeyama, 2003). The immediate result of this is the alteration of cell morphology, with the prolonged activation of Erk signaling and the production of the 'humming bird' phenotype. The cell cycle is also interfered with, caused by an increasing expression of cyclin D3, the phosphorylation of the tumor suppressor Rb and the expression of the transcription factor c-jun, leading to the increase in cell proliferation of gastric epithelial cells, probably caused by a deregulation of the G1/S checkpoint of the cell cycle (De Luca et al., 2003). These effects may have long-term consequences in relation to gastric carcinogenesis. Additionally, CagA recruits both scaffolding protein ZO-1 and the junctional adhesion protein to its site of attachment (inducing loss of villi and pedestal formation) and affects epithelial barrier functions (Amieva et al., 2003). Finally, engagement of the Type IV secretion apparatus leads to secretion of IL-8 from the epithelial cell with consequent recruitment of granulocytes (Fischer et al., 2001).

The presence of the cag PAI is not an "all or none" phenomenon. Several studies have shown that the PAI can exist as a single contiguous entity or can be divided by an insertion element (IS 605) or chromosomal DNA into two parts; cag I and cag II. Various deletions of the cag PAI have also been recognized (Censini et al., 1996; Covacci et al., 1997). The insertion

element is an additional variable as it may be completely absent or it may be present in variable numbers located in different parts of the genome (Figure 49.6).

The cagA protein is also variable in size (120–140 kDa) due to a different number of repeats of sequences present in the 3′-end of the gene. Analysis of this region of the cagA gene revealed four types designated A-D based on the nucleotide sequence and organization of the locus (Yamaoka et al., 1999). These repeats are illustrated in Figure 49.6. Geographic differences can also be found in the 3′ region of the genome. Studies of European strains compared to East Asian strains have identified nucleotide differences leading to two amino acid sequences denoted as (1) Western cagA specific Sequence (WSS) and (2) East Asian cagA specific sequence (EASS) (Azuma et al., 2002; Yamaoka et al., 1999), namely:

1. FPLKRHDKVDDLSKVGRSVSPEPIYATIDDLG
2. ESSAINRKIDRINKIASAGKGVGGFSGAGRSASPEPIY ATIDFDEANQAG

Differences of nucleotide sequence also exist in the less variable, 5′ end, of the *cagA* gene. Two types have been identified, cagA1 and cagA2, the former found in Europe, America and Australia whilst the latter was found in isolates from East Asia. Isolates with the cagA2 strains were principally vacA S1c, and cagA1 was more commonly linked to vacA m1 strains (van Doorn et al., 1999b). Potential additional complexity is provided by the presence of EPIYA motifs in the cagA protein, whose number and phosphorylation status may vary.

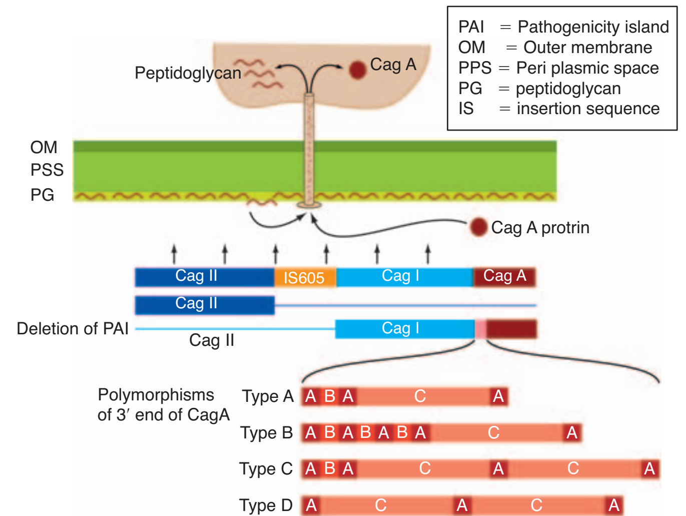

Figure 49.6 This diagram illustrates the PAI and its deletions and the polymorphisms found with in the *cagA* gene based upon the variation in the number of repeats of sequences A, B and C. The diagram also illustrates the inoculation of both bacterial peptidoglycan from the cell wall of *Helicobacter pylori* and the cagA protein into a gastric cell leading to disruption of intercellular signaling. The materials are transferred into the eukaryotic cell by a Type IV secretion system which is coded for by genes on the pathogenicity island.

Other Virulence Markers

Several other virulence characteristics have also been identified. Some of these characteristics, such as the urease enzyme and the flagella, are important for establishing colonization. Urease also acts as a toxin by hydrolyzing urea to produce ammonia, which is cytotoxic, and by diminishing the viscous nature of the mucus layer, which is protective.

Several adhesins have been identified, the best characterized one being BabA, which binds the Lewis b blood group antigen expressed on gastric epithelial cells. Some strains have a non-functional pseudogene (BabA1) whilst other strains only have one functional gene, BabA2, and others have a separate functional allele, BabB. BabA has several polymorphisms located in the MR of the protein leading to variation in degree of binding to Lewis b. Strains expressing a chimeric protein BabA2/BabA1 have also been identified that show phase variation of expression of the protein, and this reported heterogeneity may have clinical implications (Backstrom et al., 2004; Hennig et al., 2004). Other adhesins are SabA (which binds sialyl Lewis x and which is found in inflamed tissue), AlpA and AlpB, HpA and HopZ. Less information is available concerning the other adhesions. The ligands for AlpA/B are unknown. HpA is the coding sequence for an hemaglutinin that binds *N*-acetylneuraminyl-lactose and HopZ exists as two alleles and its expression is possible regulated by slipped strand mispairing.

Other virulence factors that have been identified are: an OMP HopQ that is present as two alleles Type I and Type II, an outer inflammatory protein OipA associated with increased expression of IL-8, and a locus called *ice*A (*i*nduced by *c*ontact with *e*pithelium), which has two alleles *ice*A1 and *ice*A2, the former encoding a putative restriction endonuclease (Peek et al., 1998; Yamaoka et al., 2000).

Whole Genome Expression Studies

In order to understand the changes in genome expression following infection, analysis of genome expression by microarrays have been performed. In one study, the effects of *in vitro* acid stress were investigated (Ang et al., 2001). A microarray containing 1534 ORFs from strain 26695 was prepared and the genome expression at *pH* 7.2 and 5.5 analyzed. Four hundred and forty five ORFs were expressed under both *pH* conditions, 80 had increased expression under acid conditions and 4 had reduced expression. Of those that had increased expression, one group coded for proteins recognized to be involved in the acid-stress response, one group had no obvious connection to acid stress and one group was of unknown function.

A second study (Graham et al., 2002) investigated the *in vivo* whole genome expression from the human stomach. In order to overcome the instability of RNA isolated from tissue and the comparatively low numbers of bacteria found in the stomach, the method of selective capture of transcribed sequences (SCOTS)

combined with microarray analysis was used. In all, 14 genes were differentially expressed *in vivo* compared to *in vitro* grown bacteria, including the VirB4 homolog (part of the Type IV secretion apparatus). The majority of the genes expressed in the human stomach encoded *H. pylori*-specific proteins of unknown function.

This approach of analyzing *in vivo* gene expression is likely to be valuable in identifying disease-related genes, and these results encourage further studies in this area.

Geographic Distribution and PUD

Studies of the genome sequence of the hypervariable regions of the *H. pylori* genome isolated in different geographical locations show that different strains have geographical predominance. These differences can be used to analyze population migrations and also suggest that *H. pylori* may have been transmitted to the New World from European invaders. In Northern and Eastern Europe S1a alleles predominate; in France and North America S1a and S1b are equal in number; in Iberia and South America S1b predominate; and in East Asia S1c is the major strain type. The MR alleles are equally distributed in these regions except for South America where m1 predominates. These studies also confirm that East Asian strains are quite distinct from European isolates (Kersulyte et al., 2000; van der Ende et al., 1998; Yamaoka et al., 2000b).

Markers for PUD

Genome Analysis

The high level of genetic variation within the genome of *H. pylori* explains, in part, the variation in clinical outcome of infection and why the majority of individuals colonized by the organism remain asymptomatic whilst other will develop serious gastroduodenal disease including PUD. Type I strains (presence of S1 *vacA* alleles and production of the vacuolating cytotoxin and presence of the cag PAI) are more often isolated from patients with PUD compared to Type II strains, which do not have the cag PAI and are not phenotypically cytotoxic but possess the vacA S2 allele. Similarly the presence of BabA2, oipA, iceA1 and Type I HopQ alleles have all been linked to PUD in some studies.

In Europe and North America, S1a/m1, cagA positive strains are more common in patients with PUD compared to non-ulcer dyspepsia (NUD), but in China nearly all strains are vacA and cagA positive and are equally distributed between PUD and NUD (Pan et al., 1998). In Korea, S1c strains are more common in PUD (Choe et al., 2002), and in a Japanese study the S1a/m1a WSS 3′ cag region was significantly associated with PUD whereas the S1c/m1b ESS 3′ cag region were not (Yamazaki et al., 2005). The Far East genotype, however, was correlated with gastric atrophy in a study in Japan (Azuma et al., 2004). In Brazil, cagA was correlated with DU but the subtypes of the 3′ cagA region were not correlated with disease groups (Rota et al., 2001). On the other hand, in Malaysia in a study of the three different ethnic groups (Malay, Chinese, Indian) no correlation could be found between cagA, or vacA and PUD (Tan et al., 2005).

In Europe, the association of VacA (s1), cagA, BabA2 or Lewis expression by Hp (Thoreson et al., 2000) is correlated with PUD. The association is more so in strains that are positive for all three alleles (Olfat et al., 2005), but in Brazil a study could not show any correlation between BabA2 and PUD although the locus was more common in chronic gastritis (Gatti et al., 2005). A large study of 827 strains from four countries, however, found that of the three loci, only BabA2 could be considered as a marker for separating PUD from gastritis although none were particularly valuable as predictive markers (Yamaoka et al., 1999; Yamaoka et al., 2002). A further locus identified as a marker for PUD is iceA (van Doorn et al., 1998), although once again a study from Japan could not confirm this (Ito et al., 2000). These conflicting results demonstrate that other bacterial markers may be important and that interaction with host factors are also important in disease outcome.

A study of two strains (both caA^{+}vacAs1, iceA1) isolated from either DU (G1.1) or GU (B128) were investigated by microarray and for the induction of inflammation in a gerbil model (Israel et al., 2001). The GU isolate induced more inflammation, IL-8 secretion and apoptosis compared to the DU isolate. The microarray analysis demonstrated that the DU-inducing strain had a large deletion covering cag6-cag23 (which includes cagE). This study emphasizes both the importance of the cag PAI in pathogenesis of serious disease and also the utility of microarray analysis in identifying potential markers for specific clinical outcomes.

A study of three genes in the PZ (JHP940; JHP947; HP986) from 200 Brazilian patients identified JHP947 as being associated more strongly with DU and gastric carcinoma (99%) as opposed to gastritis (44%) (Santos et al., 2003), but again, as with other studies, it was not specific for PUD.

Proteome Analysis

An immunoproteomic approach using the strain 26695 and sera from 24 *H. pylori* positive patients (Haas et al., 2002) yielded 310 antigenic protein spots, of which some were differentially recognized in patients with gastritis or PUD. Further work by this group (Krah et al., 2003) identified peptides within a subset of spots using MALDI-TOF. The protein GroEL was identified as a component in 15 of the spots and was recognized antigenically.

A proteome analysis of *H. pylori* isolates from two patients (Pereira et al., 2006), one with gastritis and the other with DU showed that four spots were uniquely associated with each condition and six spots had variable expression. Further work is required to confirm this study and to identify the proteins.

Serological Markers of PUD

A number of serological studies have identified low molecular weight proteins as possible markers of PUD. A study of 108 patients with gastric cancer, PUD or NUD showed that antibodies to a 26 kDa protein were more common in PUD and that when combined with sero-prevalence to the cagA protein the sensitivity and specificity was 76% and 62% respectively (Kuo et al., 2003). A similar study of 156 patients from Thailand

(Vilaichone et al., 2003) showed that antibodies to a 35 kDa protein were associated with GU. A study of 80 Japanese patients with different clinical conditions showed the 35 kDa antigen was more common (97%) in GU or DU compared to gastritis (70%) (Yamaoka et al., 1998).

HUMAN POLYMORPHISM AND PUD

The first demonstration that polymorphisms in the human genome could affect the clinical outcome of *Helicobacter* infection was provided by the increases risk of developing gastric adenocarcinoma in patients who had certain polymorphisms in IL-1 (El-Omar et al., 2000). It was subsequently shown that a synergistic effect was seen between bacterial and human polymorphisms (Rad et al., 2003). Thus, the VacA s1 genotype was linked to a greater risk of developing severe gastroduodenal disease, especially if in combination with other 'high risk' host markers such as the host IL-1β genotype IL-1β–511T/-31C and the genotype of its receptor IL-1RN*2.

When examined singly, in relation to the development of DU in 278 individuals, the alleles IL-1B + 3954 and IL-RN*2 were not associated with the development of DU; however, there was a strong allelic link between the two loci in patients with DU (Garcia-Gonzales et al., 2001). On the other hand, a study of 315 individuals showed that the presence of IL-1RN*2 was a risk factor, with an odds ratio (OR) of 22.6 in the presence of colonization by *Helicobacter* (Hsu et al., 2004). A smaller study of 215 individuals could not confirm that any polymorphisms in IL-1B, IL-1RN, TNF-A TNF-B were related to the development of DU (Garcia-Gonzales et al., 2005). However, when looked at in combination: IL-1RN*2; IL-1B-31; IL-1B-511C; IL-1B + 3954C; TNF-haplotypeE was found with a slight (non-significant) increase in the patients with DU. An earlier study by the same group showed that genotype LTA (lymphotoxin, TNF-B) NcoI 2.2 and TNF-I were both more common in GU than DU (Lanas et al., 2001). Further confirmation of tumor necrosis factor (TNF) polymorphisms associated with PUD was provided (Lu et al., 2005), showing that the alleles TNF-A-1031C and TNF-A -863A have an OR of 2.4 for the loci individually and 6.0 in combination.

A significant association between IL-8 A/T heterozygote and duodenal ulceration (Gyulai et al., 2004) or gastric ulceration (Ohyauchi et al., 2005) has been identified compared to the wild type T/T allele. Studies of polymorphisms in IL-6, IL-12 and CD14 have not shown any association (Garcia-Gonzales et al., 2005; Gyulai et al., 2004; Lobo Gatti et al., 2005). Finally, associations between CD11c exon 15 and intron 31 G/A in combination show an OR of 2.4 for GU disease (Hellmig et al., 2005) and polymorphisms in the myloperoxidase (−468 A/A) locus show an OR of 8.7 for DU when infected with *H. pylori* (Hsu et al., 2005). An inability to mount an effective immune response may be more likely to lead to chronic infection and thus indirectly to PUD. A study of microsatellite polymorphisms in the T-cell receptor V β6 locus has identified a genotype (TCRBV6S1B/B) that is not able to eliminate *Helicobacter* and thus is more susceptible to chronic infection although in the cohort studied this genotype did not correlate with clinical outcome (Kunstmann et al., 2000). A study of 20 single nucleotide polymorphisms (SNPs) in the genes for matrix metalloproteases 1, 3, 7 and 9 in 599 isolates from infected patients showed a strong association between GU and a promoter variants of MMP 7 and 9 (Hellmig et al., 2006).

Polymorphisms in genes related to the action of NSAIDS have been identified although relationships to clinical outcome and ulcer formation have not been so far linked. Cyclo-oxygenase 1 (COX-1) converts arachidonic acid to prostaglandin H2, and heterozygosity for the polymorphisms A-842G/C50T are more likely to show a greater inhibition of prostaglandin synthesis by aspirin than is the homozygous (Halushka et al., 2003).

GENOMICS IN THE MANAGEMENT OF DISEASE

Cytochrome P450 (CYP) represents a group of enzymes involved in metabolism of drugs, which are found principally in the liver. The enzymes are coded for by at least 50 genes with a number of pseudogenes identified. In one study it was found that nearly 60% of over 300 drugs were metabolized by CYP (Bertz and Granneman, 1997). Polymorphisms in these enzymes are recognized to be important in treatment of diseases, as some polymorphisms may metabolize different drugs at different rates thus having different clinical outcomes, that is, success or failure. *H. pylori* is treated with PPI, for example, omeprazole, and a combination of clarithromycin and metronidazole (or amoxicillin). CYP2C19 is important in metabolism of PPIs and CYP3A4 in metabolism of clarithromycin. In one study (Sapone et al., 2003) of 143 patients with *H. pylori* infection, lack of eradication was correlated with homozygous extensive metabolizers (HomEM) (CYP2C19*1/*1) or heterozygous extensive metabolizers (HetEM) (CYP2C19*1/*2 or *1/*3). All patients with CYP2C19*2/*2 had their organism successfully eradicated. Those individuals who were HetEM in CYP2C19 and carried the polymorphisms CYP3A4*1B and CYP3A4*2 were more likely to have *Helicobacter* eradicated compared to the wild type CYP3A4, suggesting some synergistic action between the two cytochrome P450s. A cost analysis of genotyping patients for CYP2C19 polymorphisms prior to commencing eradication therapy in the United States showed a savings ranging from $495–$2125 for every ulcer prevented (Lehmann et al., 2003).

Interleukin-1beta is also an important determinant of successful eradication of *Helicobacter* using triple therapy (Furtura et al., 2004; Take et al., 2003). In a study of 336 patients, IL-1B-511T/T had the highest eradication rate (94.7%) compared to IL-1B-511C/C with 77.3%, with the heterozygote C/T having an intermediate eradication rate. This is mediated by the intragastric *p*H (related to the IL-1 polymorphism) as this affects the activity of particularly clarithromycin in the stomach.

An additional *Helicobacter*-associated factor that affects the eradication rate is resistance to clarithromycin. Resistance is related to polymorphisms within the 23S ribosome subunit to which clarithromycin binds. Resistant isolates have A2124G or A2143G polymorphisms, and, if present, the eradication rate is only 48% compared to 87% in the absence of these polymorphisms (Furtura et al., 2005).

Results of a study including 684 subjects showed a reduced risk of developing DU if they carried the TGFb + 869C/C polymorphism and that the T/C polymorphism was involved in susceptibility to developing DU (Garcia-Gonzalez et al., 2006). A correlation between susceptibility to developing DU and NOD1 A796A was present in 20% of patients with DU compared to 6% in controls (Hofner et al., 2007). In children with DU, the G238A of the TNFα gene was present in 31% of cases also carrying the strain marker iceA1, compared to 1.6% in controls (Wilschanski et al., 2007). In adults, iceA1 compared to iceA2 was also more frequent in DU cases (Caner et al., 2007). In rats, real-time PCR and RT-PCR were used to show that of 8000 genes studied in relation to cysteamine-induced ulceration, 40 genes had marked changes in expression, suggesting the interaction of many genes in the development of ulceration (Deng et al., 2007).

The effect of host polymorphisms on eradication of *H. pylori* showed that MDR1 T3435T polymorphism had an eradication rate of 67% when given lansoprazole + amoxicillin + clarithromycin, compared to C/C or C/T which had eradication rates of 81–82% (Furtura et al., 2007).

The effects of host polymorphisms in the cytochrome P450 2C9 (CYP2C9) locus on ulceration and bleeding in association with NSAID use were shown in a study of 26 patients compared to 52 controls, all of the study population being *H. pylori* negative. Higher frequencies of bleeding were found in patients with CYP2C9*1/*3 (34/5.8%) and CYP2C9*1/*2 (27/15.4%) compared to controls (Pilotto et al., 2007).

Genomics in Relation to Diagnosis

A number of molecular techniques have been applied to the detection, typing and assessment of eradication of *H. pylori*. Detection of markers of virulence and antibiotic resistance has been achieved largely by the polymerase chain reaction (PCR) with appropriate primers. The use of real-time PCR allows direct detection and quantification of the target of interest and the development of robotic workstations can increase throughput of analytes. Specimens used for the detection and genotyping of *Helicobacter* has largely been gastric biopsies although stool specimens have also been used. A number of different methods of typing *H. pylori* have been used such as ribotyping, RAPD-PCR, PCR-RFLP and pulse field gel electrophoresis (PFGE) (Ge and Taylor, 1998) in both coding and non-coding areas (Bereswell et al., 2000).

2009 UPDATE

Host–pathogen interaction in *Helicobacter pylori*-related disease continues to be investigated by genomic techniques for polymorphisms in both bacterial and host loci that may act as biomarkers for specific clinical outcomes. Ongoing studies using proteomic analysis of host–pathogen interactions (Wu et al., 2008) and sequence analysis of *H. pylori* isolates (Mcclain et al., 2009) are likely to lead to the identification of disease-related biomarkers.

Microbial Polymorphisms

The role of the *VacA* locus continues to be investigated in various geographical locations. In Italy, the incidence of the VacA s1m1 genotype is increasing despite the falling incidence of PUD, raising questions of the relevance of s1m1 as a biomarker for PUD (De Francesco et al., 2009). In Iran, VacA s1m2 is predominant in PUD (Selehi et al., 2008), although another study from Iran could find no correlation between VacA genotypes and clinical outcome (Hussein et al., 2008). In Iraq, the vacA i1 locus and the dupA locus were both correlated with PUD, but this was not the case in Iran (Hussein et al., 2008). Similarly, in Italy the vacA i1 locus was associated with PUD (Basso et al., 2008). In Iran and Iraq (Selehi et al., 2008), Egypt (Said Essa et al., 2008), and Italy (Basso et al., 2008), the cagA locus was correlated with PUD. In Brazil, a study of restriction fragment length polymorphism in the *ureC* and *ureB* loci in *H. pylori* could demonstrate no differences in the patterns between PUD or gastritis (Roesler et al., 2008). In a Chinese population, the *dupA* locus was positively associated with DU and inversely with GU and gastric cancer (Zhang et al., 2008).

Host Polymorphisms

Various studies of polymorphisms in genes associated with gastric physiology, antigen processing and inflammation have been reported. A study from India has demonstrated that a certain Cox-2 polymorphism is positively associated with PUD (and gastric cancer) (Saxena et al., 2008) and a subsequent study has confirmed this and that other Cox-2 polymorphisms are associated with gastritis or with a lower risk of gastric atrophy (Achyut et al., 2009). A study from the same group on PPARγ demonstrated that carriage of the G allele was associated with PUD and gastric cancer compared to NUD (Prasad et al., 2008). In Brazil, polymorphisms with TLR2, 4 and 5 were not found to be associated with DU in children, although a TLR4 polymorphism was associated with higher levels of IL-8 and IL-10 and colonization by cagA strains (Moura et al., 2008). A study from Korea of polymorphisms in IL-10, IL-8 and IL-6 demonstrated they were significantly associated with GU (and gastric cancer) and that a synergistic effect on the development of either

of these conditions occurred with some of the polymorphisms and others were less frequent than controls in patients with DU (Kang et al., 2008b). A study from Mexico demonstrated that a TLR4 polymorphism was found more often in patients with DU compared to gastritis and expressed lower levels of IL-1β, IL-6, IL-8 and Groα, yet higher levels of TNFα, IL-10, MCP-1 and MIP-1α (Trejo-de la et al., 2008). In Turkey, the role of polymorphisms in IL-1β and IL-1RN was investigated showing as association with PUD and gastric cancer or NUD depending on the polymorphism (Erzin et al., 2008). A study from Japan (Tahara et al., 2008) on the role of a polymorphism in NADPH oxidase did not show any relationship between PUD and controls, although it was associated with less intestinal metaplasia. In Chinese patients, a study of a polymorphism of histamine *N*-methyltransferase did not show any significant difference in allele frequency between DU patients and controls (Hailong et al., 2008). A study of the multidrug resistant transporter (MDR1) polymorphism in patients with PUD or gastric cancer compared to controls could not demonstrate any association (Sugimoto et al., 2008). In patients with PUD, the role of the SHP-2 gene in relation to gastric atrophy was investigated. Previous studies in Japanese subjects demonstrated that the AA genotype was associated with a lower risk of gastric atrophy, whereas in the current study in Uzbekistan, the GG genotype was linked to a lower risk of atrophy (Hamijima et al., 2008).

Management of *H. pylori*

Polymorphisms within CYP2C19 affect the plasma levels of PPIs being lower in normal homozygotes and heterozygotes (fast metabolizer) compared to mutant homozygotes (slow metabolizer) (Chaudry et al., 2008). The role of MDR1 C3435T and CYP2C19 genotypes on the eradication of *H. pylori* was investigated in Korean patients treated with pantoprazole + clarithromycin + amoxycillin (Oh et al., 2008). No effect on the eradication rates was noted. In a further study from Korea, however, the eradication rates were higher in the slow metabolizer groups compared to the fast metabolizer group (Kang et al., 2008a). A new oligonucleotide array was reported for the investigation of clarithromycin resistance in *H. pylori*. The technique was reported to be both rapid and accurate compared to conventional methods (Chen et al., 2008).

PUD and NSAIDS

The role of polymorphisms in CYP2C9 and NSAID-induced gastropathy has been investigated, but could not show that CYP2C9*2 and CYP2C9*3 are involved (Ma et al., 2008). Polymorphisms of endothelial nitric oxide synthase have been investigated in relation to gastric bleeding in persons taking low-dose aspirin. The results demonstrate that persons with a lower frequency of GPIIIa A2 have a reduced risk of bleeding (Piazuelo et al., 2008).

RECOMMENDED RESOURCES

Websites

http://www.tigr.org/tigr-scripts/CMR2gene_table.spl?db=ghp

As given on the website: The Comprehensive Microbial Resource (CMR) is a free website used to display information on all of the publicly available, complete prokaryotic genomes.

http://www.helicobacter.org

The website of the European Helicobacter Study Group

http://genolist.pasteur.fr/PyloriGene

As given on the website: The purpose is to collate and integrate various aspects of the genomic information from *H. pylori*. PyloriGene provides a complete dataset of DNA and protein sequences derived from two different strains: 26695 and J99, linked to the relevant annotations and functional assignments.

http://ecocyc.org:1555/HPY/organism-summary?object=HPY

As given on the website: EcoCyc is a bioinformatics database that describes the genome and the biochemical machinery of *E. coli* K-12 MG1655. The long-term goal of the project is to describe the molecular catalog of the *E. coli* cell, as well as the functions of each of its molecular parts, to facilitate a system-level understanding of *E. coli*. EcoCyc is an electronic reference source for *E. coli* biologists, and for biologists who work with related microorganisms.

http://www.histopathology-india.net/PepUlc.htm

The gastroenterology website of Prof Sampurna Roy.

Book

Axon, A. (ed). *Best Practice & Research: Clinical gastroenterology*. vol. 21(2) *Helicobacter pylori*, Elsevier.

Description from the Elsevier website: In practical paperback format, each 200 page topic-based issue of *Best Practice & Research Clinical Gastroenterology* will provide a comprehensive review of current clinical practice and thinking within the specialty of gastroenterology.

INTRODUCTION

The liver has been called the "the custodian of the milieu interieur." Consistent with its many varied metabolic functions, the liver has a complex transcriptome and proteome. The normal liver has many diverse functions including synthesis of vitamins and proteins, bile production, immune defense, as well as metabolism of carbohydrates, lipids and toxins. Despite being only 2.5% of body weight, the liver receives 25% of the cardiac output that is essential for maintaining its metabolic and synthetic functions. The functional unit of the liver is the hepatic lobule, which is arranged in an organized repeating fashion around a central venule to form the intact organ. Liver injury is characterized by progressive fibrosis tissue deposition within the lobule, leading to eventual disruption of normal lobular architecture that is characteristic of cirrhosis (Figure 50.1) (Friedman, 2000). In the genomic era, the molecular classification of fibrosis and cirrhosis development is predominantly characterized by morphological changes.

Cirrhosis is the pathogenic hallmark of advanced liver injury. Cirrhosis is morphologically defined by distortion of hepatic architecture by dense bands of fibrosis "scar" leading to "islands" or nodules of hepatocytes (Friedman, 2000). The causes of cirrhosis are varied with many etiologies (Table 50.1). The development of cirrhosis is a premalignant condition, with virtually all cases of liver cancer (also known as hepatocellular carcinoma [HCC]) developing in individuals with prior cirrhosis. Various intrahepatic cell populations are essential in understanding the development of cirrhosis. The pivotal cell involved in fibrosis leading to cirrhosis is the hepatic stellate cell (HSC). However, the functional unit of the liver is the hepatocyte, which is the cell type from which HCC develops. The mechanisms of fibrosis leading to cirrhosis will be discussed in the context of understanding the pathogenic mechanisms by which this process evolves. Genomic medicine promises new insights into the pathogenesis of fibrosis and the promise of individualized predictive medicine aiming to prevent cirrhosis and the sequelae of liver failure and HCC.

FIBROSIS AND CIRRHOSIS

Despite the adoption of genomic medicine approaches in recent years, the hallmark of liver injury remain the morphological changes. In end-stage fibrosis there is "encapsulation" of islands of hepatocytes by bands of fibrosis, known as cirrhosis (Figure 50.1). The hepatic fibrotic response represents a wound healing response with morphological features of matrix remodeling, contraction and "scaring" (Eng and Friedman, 2000). The HSC is central to this fibrogenic process (Figure 50.1). The fibrogenic process can be regarded in stages based on morphology or on molecular pathogenic events (Friedman, 2000). Fibrosis of the liver has classically been regarded as an irreversible disease process. However, it is now clear that advanced fibrosis, possibly even cirrhosis, can significantly improve and possibly resolve completely in some cases (Benyon and Iredale, 2000; Corbett et al., 1993; Dufour et al., 1998; Tsushima, et al., 1999). Molecular studies of intrahepatic fibrogenesis in progressive injury indicated that this process is dynamic and characterized by distinct events associated with initiation, perpetuation and regression (Bataller

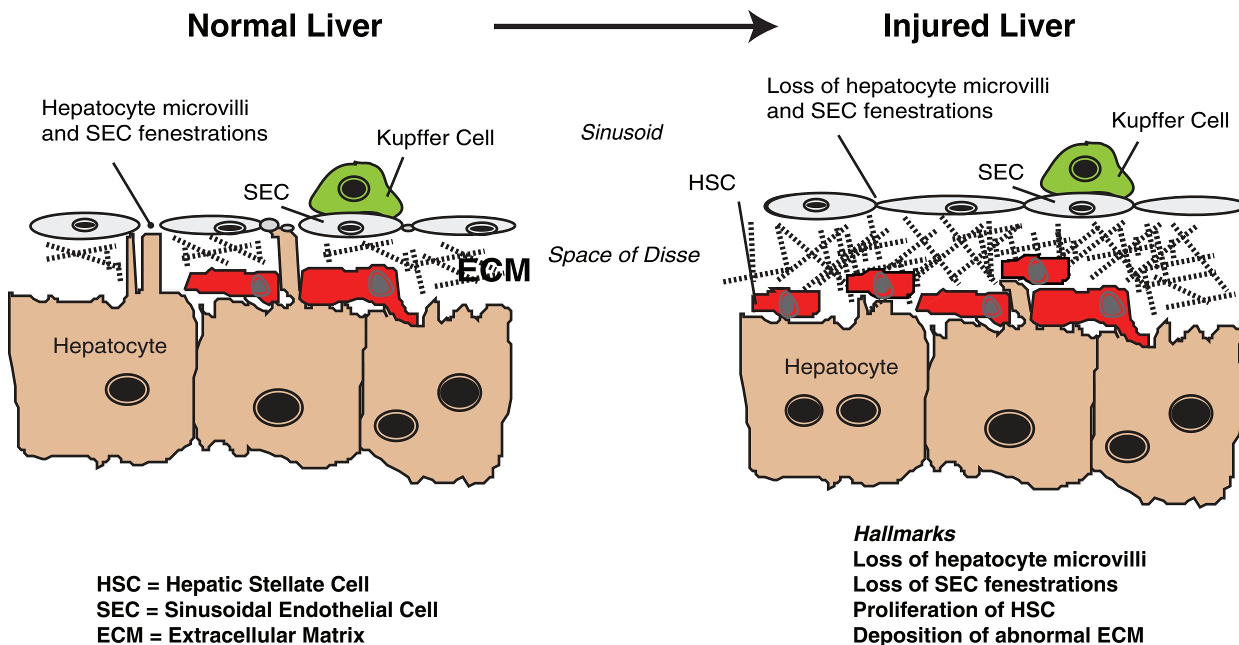

Figure 50.1 Liver fibrogenesis. In liver fibrosis development the quiescent stellate cell is transformed into an activated phenotype with ECM changes characterized by the deposition of a scar-like matrix within the space of Disse. This change is accompanied by a loss of hepatocyte microvilli and endothelial fenestration.

and Brenner, 2005). The remodeling of the ECM in fibrogenesis is clearly a dynamic process, and an improved understanding of the molecular pathways involved in this process will help in developing future targeted therapeutic agents.

Liver injury characterized by fibrosis is extremely rare in the absence of intrahepatic inflammatory changes. The evolution of both innate and adaptive immune response in chronic liver injury is an essential factor perpetuating and driving intrahepatic injury resulting in liver fibrogenesis. Therefore, the separate study of fibrogenic pathways characterized by ECM remodeling and intrahepatic inflammatory response is often completely arbitrary.

DIAGNOSIS OF CIRRHOSIS

An accurate assessment of cirrhosis and the preceding evolution of intrahepatic fibrosis is a frequent diagnostic challenge. Routine biochemical analysis, as well as clinical signs, are at best suggestive but not diagnostic of the grade of fibrosis or the development of cirrhosis. To-date, liver biopsy has been the principal approach to the assessment of fibrosis. However, liver biopsy is an invasive procedure that is prone to sampling error, significant observer variability and may be associated with morbidity and mortality (Siegel et al., 2005). This has led to the development of non-invasive measures of fibrosis including the appraisal of panels of profibrogenic serum markers and assessment of intrahepatic elasticity or 'stiffness' changes using modified ultrasonography (elastometry). Other imaging techniques of the liver with ultrasound, computer tomography or magnetic resonance imaging can provide indicators of cirrhosis, but interpretation is often operator-dependent and lacks sensitivity for accurate staging of advanced disease. However, imaging and biochemistry may be useful in providing indicators of worsening hepatic function from cirrhosis, such as ascites or the development of HCC. To-date there are no established molecular markers of fibrosis progression or cirrhosis.

GENETICS OF CIRRHOSIS

Cirrhosis pathogenesis is characterized by many conserved as well as divergent pathways involved in the development of progressive fibrosis. There are clearly a number of important host genetic factors that influence the development of fibrosis, rate of progression and the subsequent development of complications (Bataller et al., 2003). Older individuals and males are known to have significantly greater rates of liver fibrogenesis and subsequent development of cirrhosis (Poynard et al., 2005). Multiple candidate genes thought to be central to cirrhosis development have been identified using rodent models, and many human gene polymorphisms are likewise associated with fibrosis development (Table 50.2) (Bataller et al., 2003). Genetic polymorphisms have been implicated at all stages of fibrosis development including disease susceptibility (i.e., HCV and haptoglogin), injury (i.e., LPS interaction with CD14), immune responses (i.e., HLA-II alleles), activation of HSC (i.e., angiotensinogen) and increase in fibrogenic ECM (i.e., plasminogen and TGF-β) (Bataller et al., 2003). The single most comprehensive analysis of genetic polymorphisms

Non-alcoholic steatohepatitis (NASH)
Primary biliary cirrhosis
Primary sclerosing cholangitis
Sarcoidosis
Causes of non-cirrhotic hepatic fibrosis
Idiopathic portal hypertension (Non-cirrhotic portal fibrosis, Banti's syndrome); three variants: Intrahepatic phlebosclerosis and fibrosis; Portal and splenic vein sclerosis and Portal and splenic vein thrombosis
Schistosomiasis ("*pipe-stem*" fibrosis with pre-sinusoidal portal hypertension)
Congenital hepatic fibrosis (may be associated with polycystic disease of liver and kidneys)

in fibrosis analyzed 24,832 putative functional, single nucleotide polymorphisms (SNPs) in 916 individuals with HCV infection. This study identified a missense mutation in the DEAD box polypeptide 5 (DDX5) gene associated with two POLG2 SNPs that are linked with an increased risk of advanced fibrosis (Huang et al., 2006). The same study identified another missense SNP in carnitine palmitoyltransferase 1A (CPT1A) associated with a decreased risk of fibrosis. The fibrosis association of these polymorphisms was validated in a separate cohort of 483 individuals (Huang et al., 2006). However, it is unclear what the function of these genes is in HCV induced liver injury. Further, it is unclear if the identified polymorphisms are important only in HCV liver injury or more generally in other types of liver injury.

Table 50.2 Candidate gene and polymorphisms involved in cirrhosis

Gene	Candidate gene	Gene polymorphism	Effect of protein on fibrosis
ADH		√	Unknown
ALDH		√	Unknown
Angiotensinogen		√	Increases
ApoE		√	Increases
CD14		√	Increases
CPT1A	√		Decreases
CTLA-4		√	Increases

TGF-β1	√	√	Increases
TIMP-1	√		Increases
TNF	√		Unknown

The identification of candidate genes and polymorphisms has seen a number of novel molecular approaches adopted in an attempt to treat liver disease (Prosser et al., 2006). These have included the use of caspase inhibitors, TGF-β blockade, TNF blockade, PDGF blockade and inhibition of Kupffer cell activity (Prosser et al., 2006). Further approaches have attempted to change the ECM composition in fibrosis via the administration of matrix metalloproteinases and plasminogen activator (Prosser et al., 2006). Although modern molecular approaches have identified multiple genes involved in the pathogenesis of cirrhosis, most of these findings have yet to lead to therapeutic agents in the clinical trial setting.

The identification of genetic loci associated with the development of progressive liver injury has focused on the underlying disease rather than the common pathway leading to the development of fibrosis and eventual cirrhosis (Table 50.3). The immunogenetics of autoimmune liver disease and viral hepatitis are partially characterized with a number of genetic loci being associated with disease severity and/or progression (Donaldson, 2004). However, the immunogenetics of other forms of liver injury is poorly characterized. To-date the precise association of many of these markers with liver disease severity remains to be determined. However, in the future the determination of the genetic haplotypes conferring susceptibility to fibrosis or predicting the progression of liver disease is likely to be incorporated into routine clinical practice.

THE LIVER TRANSCRIPTOME

Evolving genomic medicine approaches to liver disease require an understanding of the complexity of genome expression within the normal and diseased liver. There are estimated to be approximately 20–25,000 protein-encoding genes in the human genome. Further, there are an unknown number of functionally significant alternately spliced transcripts arising from these genes that may exceed 100,000 in number. How many of these mRNA transcripts are expressed in the liver is unknown. Methods of identifying and comparing organ transcriptomes are also uncommon. One method of inferring complexity is to examine GenBank human UniGene clusters of non-redundant gene sets (Yuan et al., 2001). These UniGene clusters are compiled from annotated and uncharacterized mRNA sequences and as a group represent a species' transcriptome (Yuan et al., 2001). Currently the human UniGene assembly of clusters (Build 196) has approximately 7 million sequences representing 83,896 non-redundant transcripts. Parsing key word searches[1], approximately 20% of transcripts (representing 16,950 clusters) were identified in liver tissue; this compares to brain (37%), lung (31%), kidney (25%), colon (22%) and heart (16%). Coulouarn et al. (2004) used a similar approach and identified 12,638 non-redundant clusters from liver tissue (UniGene Build 129). An alternate approach in which Serial Analysis of Gene Expression (SAGE) libraries were examined can also provide insights into the complexity of the liver transcriptome (Yamashita et al., 2000, 2004a, b). Two normal human liver SAGE libraries identified 15,496 and 18,081 unique transcripts from a total number of 66,308 and 125,700 tags, respectively (Yamashita et al., 2000, 2004a, b). However, in a SAGE comparison of multiple organs, 32,131 unique tags were identified (from a total of 455,325 tags) of which 56% were expressed in the liver compared to brain (75%), breast (81%) and colon (91%) (Yamashita et al., 2004a, b). Therefore, it is clear that the normal liver has a complex transcriptome expressing many thousands of mRNA transcripts.

Normal liver transcriptome expression varies to account for phenotype differences such as sex and age variation (Cao et al., 2001; Tadic et al., 2002; Yang et al., 2006). Microarray analysis of normal human liver by Yano et al. (2001) highlights the variability of the non-diseased liver transcriptome. A total of 2418 genes were examined in five normal patients, with only half of these transcripts being detected in four out of five patients. Further, only 27% of genes had co-ordinate expression in these non-diseased, apparently normal patients. Therefore, in addition to the liver having a complex transcriptome, there appears to be significant individual variability in transcript expression. This is further highlighted by the observation of Enard et al. (2002) that duplicate liver samples from the same individual differed by 12% (technical variation) but that intraspecies variation was as pronounced as interspecies variation in hepatic mRNA transcript expression when comparing chimpanzees and humans. Focused specialized arrays such as the Liverpool nylon array targeting the liver transcriptome have now been synthesized and include in excess of 10,000 target genes (Coulouarn et al., 2004). However, such approaches fail to detect differential gene expression for transcripts not expressed in normal liver that are subsequently

TABLE 50.3 Immunogenetics of liver disease

Disease	Dominant haplotype
Autoimmune liver disease	
AIH	DRB1*0301, DRB1*0401, DRB1*1501, DRB1*0405, DRB1*1301
PSC	MICA*008, DRB1*0301, DBQ1*0603, DBQ1*0602, DBQ1*0302, DBQ1*0303, MICA*002
PBC	DRB1*0803, DRB1*0801
Viral hepatitis

HCV	DRB1*0101, DRB1*0301

AIH: auto-immune hepatitis; PSC: primary sclerosing cholangitis; PBC: primary biliary cirrhosis; HAV: hepatitis A virus; HBV: hepatitis B virus; HCV: hepatitis C virus.

[1]Parsing string used ("liver" or "hepatic") and "human" for UniGene Build 180.

expressed with the development of liver pathobiology. This is a particularly important consideration in genomic medicine, as transcriptomes in disease can markedly increase in complexity, especially in the presence of neoplastic transformation and inflammation (Feezor et al., 2005; Scriver, 2004).

THE LIVER PROTEOME

The human proteome is complex and variable depending on the organ or cell population being studied. Proteins can be subject to in excess of 100 different types of post-translational modifications (Cantin and Yates, 2004). Therefore, the estimated 25,000 genes in the human genome may give rise to greater than a million distinct proteins (Neverova et al., 2005; Righetti et al., 2005). Utilizing an approach of parsing GenBank with key words, we can gain insight into human organ proteome complexity[2]. Proteomes from human brain, liver, lung, kidney, bowel/colon, heart and serum express 40%, 13%, 10%, 18%, 6%, 7% and 6% respectively, of the proteins found in all of these organs. The number of GenBank human protein entries for each organ was: brain (53,091), liver (17,610), lung (12,770), kidney (23,283), bowel/colon (7749), heart (8961) and serum (8122). This highlights the complexity of the proteome within the liver and other solid organs.

Contained within a cell, approximately 90% of the cellular protein mass is due to the 100 most abundant proteins and a further 1200 proteins account for another 7% of the protein mass (Lefkovits et al., 2000, 2001). However, the remaining 3% of the protein mass includes 2800 proteins (over 50% of the different protein species) and frequently is below the detection limit of most proteomic detection methods (Lefkovits et al., 2000, 2001). Therefore, it is important to consider the frequency of protein expression within a homogeneous cellular sample (i.e., cell lines) compared to heterogeneous cellular sample (i.e., organs). This is an especially important consideration in genomic medicine, as the non-parenchymal cell subpopulation abundance in biopsy specimens is low and sample representation of the whole organ is often inaccurate, a problem known to occur in upward of 15% of liver biopsy samples (Ratziu et al., 2005; Regev et al., 2002).

Genomic medicine approaches often assume that changes in gene/mRNA expression reflect changes in corresponding protein expression. However, there are multiple examples where protein expression or function is not controlled by mRNA expression. Indeed, in the intact non-diseased liver tissue, approximately 25% of the changes in the mRNA transcript expression are not accompanied by changes in protein expression (Anderson and Seilhamer, 1997). Studies comparing mRNA and protein expression are rare in all organs, including the liver. Anderson et al showed a poor correlation of the liver tissue abundance of 19 proteins and corresponding mRNA transcripts (correlation coefficient of only 0.48) (Anderson and Seilhamer, 1997). Additionally, they isolated 50 abundant mRNA transcripts, of which 29 encoded secreted proteins (Anderson and Seilhamer, 1997). However, this result contrasted with the 50 most abundant proteins they isolated, as none were secreted (Anderson and Seilhamer, 1997). Overall, within mRNA transcriptomes compared to the corresponding proteomes, there is a bias in expression toward an over-representation of mRNA transcripts encoding secreted proteins, and high abundance mRNA transcripts such as G3PDH have been repeatedly demonstrated (Anderson and Seilhamer, 1997; Jansen and Gerstein, 2000; Miklos and Maleszka, 2001a, b; ter Kuile and Westerhoff, 2001). However, it is salient to remember that the protein expression in every cell is controlled by the transcriptome, although the relationship between individual gene transcripts and the corresponding protein expression may not at first be apparent.

[2]In November 2006, the GenBank protein entries were parsed with the key word *human* and one of the following: *brain, liver, lung, kidney, bowel or colon, heart, kidney and serum*. A total of 131,586 protein entries across all of these organs were identified. The percentage for each organ was then calculated to give an estimate of relative protein abundance.

DEVELOPMENT OF LIVER FIBROSIS

Liver fibrosis is characterized by activation of the HSC. Invariably, there is associated inflammation and an intrahepatic immune response driving the perpetuation of the pro-fibrogenic phenotype of the HSC. Therefore, fibrosis development can be examined by focusing on the pro-fibrogenic HSC or alternatively by studying the various types of liver injury, associated inflammatory response and the pathways of HSC activation.

Hepatic Stellate Cell

The HSC is the principal cell type mediating the matrix remodeling and degradation of fibrosis (Figure 50.2). The HSC normally constitutes approximately 5% of the intrahepatic cell mass in the non-diseased liver and increases to 10–15% in the diseased liver (Friedman, 2000; Mehal et al., 2001). The HSC is likely to have evolved from the neural crest origin in contrast to the endoderm origin of hepatic parenchymal cells, as suggested by the presence of markers such as glial fibrillary acidic protein, nestin and N-CAM (Levy et al., 1999; Nakatani et al., 1996; Niki et al., 1999; Vogel et al., 2000). The use of gene array analysis has led to the identification of a number of additional neural markers in cirrhosis including BDNF, GDNF and neuromodoluin, which are now thought to be previously unrecognized markers of HSC (Shackel et al., 2002). However, heterogeneity in the intrahepatic HSC population suggests that the intrahepatic stellate cells may not derive from a single embryonic source (Levy et al., 1999; Nakatani et al., 1996; Sell, 2001). The normal stellate cell exists in a quiescent state, and with injury it is transformed into a proliferative, fibrogenic and contractile myofibroblast,

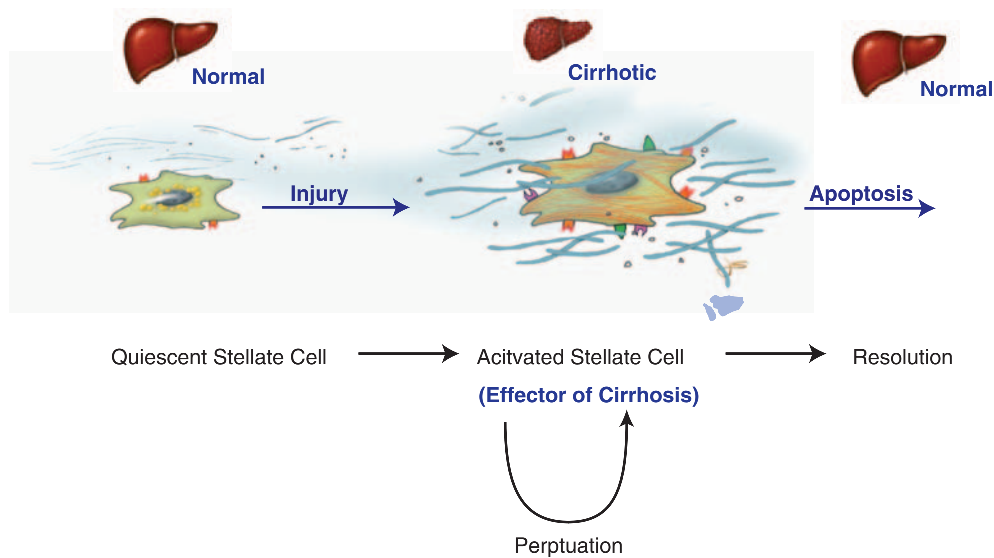

Figure 50.2 HSC activation. Intrahepatic injury is accompanied by activation of the HSC. This transformation sees the quiescent stellate cell, which stores retinoid, transformed into a profibrogenic cell that actively remodels the ECM leading to cirrhosis. Activation of the stellate cell leads to state in which the activated cell phenotype is perpetuated by both the initial injurious insult and also by autocrine cell activation. Resolution of fibrosis is due to removal of the activated stellate cell through the process of apoptosis.

a response known as stellate cell activation (Friedman, 2000). The activation of the HSC involves both an initiation and perpetuation of the activated cell phenotype. Additionally, the activated phenotype can resolve in the liver with cessation of injury. It is now clear that distinct molecular pathways are involved in the process of initiation, perpetuation and resolution of the activated HSC (Friedman, 2000).

Overall, fibrosis is characterized by a three- to six-fold increase in collagen and non-collagenous components of the ECM (Gressner, 1998). Activated stellate cells produce hyaluronan, fibronectin, entactin, tenescin, undulin, elastin and laminin (Gressner, 1998). The quiescent stellate cell produces predominantly type IV collagen, whereas the activated myofibroblast produces predominantly collagen type I as well as collagen type IV and III (Friedman, 2000; Gressner, 1998). Additionally, myofibroblasts produce proteoglycan, with chondroitin sulfate being the predominant proteoglycan, as well as LTBP sulfate and heparin sulfate (Gressner, 1998).

The phenotypic changes associated with HSC activation include matrix remodeling, proliferation and contractility. Upon activation the morphology of the HSC changes with a loss of intracellular vitamin A stores, development of more pronounced cytoplasmic processes and flattening of the cell (Friedman, 2000; Gressner, 1998). This is accompanied by increased HSC contractility, especially due to the production of NO and endothelin-1, which is an important determinant of the increased portal venous pressure during liver injury (Rockey, 1997). Proliferation of the activated HSC occurs in response to a number of growth factors, most of which signal through receptor tyrosine kinases (Ankoma Sey et al., 1998; Friedman, 2000). Growth factors such as PDGF, TGF-β and EGF are initially secreted from adjacent Kupffer cells, hepatocytes and cells of the inflammatory infiltrate (Callahan et al., 1985; Marra et al., 1994; Pinzani et al., 1996). Subsequently, an autocrine loop is established by the activated HSC that produces these growth factors, especially PDGF and TGF-β (Friedman, 2000; Callahan et al., 1985; Marra et al., 1994).

The dynamic nature of the fibrotic response is apparent given the documented resolution seen in many animal models of fibrosis and the improvement seen with treatment of some causes of human liver disease. The resolution of the activated HSC is unlikely to involve the "retrodifferentiation" or transition back to the quiescent phenotype but appears to involve activated HSC elimination by apoptosis (Benyon and Iredale, 2000). In animal models of fibrosis, there is a significant increase in the rate of activated HSC apoptosis. Activated HSC are more sensitive to Fas-ligand-induced apoptosis compared to quiescent HSC. Intrahepatic natural killer (NK) cells in response to liver injury upregulate Fas-ligand (FasL) expression (Benyon and Iredale, 2000; Moroda et al., 1997; Tsutsui et al., 1996). Persistence of the activated HSC despite increased Fas-ligand and Fas-ligand sensitivity seems to be due to the concurrent increase in proliferative factors, especially PDGF, that are anti-apoptotic (Benyon and Iredale, 2000; Simakajornboon et al., 2001; Staiger and Loffler, 1998). Similarly other autocrine factors may act to enhance activated HSC apoptosis including expression of IL-10 and members of the Bcl-2 family (Galle, 1997; Kanzler and Galle, 2000; Ockner, 2001). This pro- and anti-apoptotic response seen with HSC activation may be a means of autocrine regulation limiting "scar" formation.

Genomic Studies of HSCs

Genomic studies of HSC have led to the development of *ex vivo* cell culture systems and a better understanding of *in vivo* injury attributable to HSC. Microarray analysis has been utilized to identify differential gene expression in activated HSCs from *in vitro* culture models (Lee et al., 2004; Liu et al., 2004). In one study, a number of novel and previously recognized genes were identified, including MAPK pathway genes, osteopontin and ERK-1 (Lee et al., 2004; Qiang et al., 2006). Further, ERK-1 was subsequently shown in RNA interference experiments to be necessary for HSC proliferation as well as being anti-apoptotic with expression maintaining the activated cell phenotype (Qiang et al., 2006). Differentially expressed genes in murine-activated HSC included those involved in protein synthesis (RP16), cell-cycle regulation (Cdc7), apoptosis (Nip3) and DNA damage response (MAT1) (Liu et al., 2004). Further, genomic studies addressing the perpetuation of the activated HSC phenotype identified expression of the telomerase catalytic subunit (human telomerase reverse transcriptase [hTERT]) in human activated HSCs, which immortalizes these cells and maintains an activated HSC phenotype (Schnabl et al., 2002). Senescent HSCs expressed reduced levels of ECM proteins, including collagens, tenascin and fibronectin. Furthermore, maintenance of telomere length represents an important survival factor for activated human HSCs (Schnabl et al., 2003). Therefore, an immortalized human HSC line has been generated by infecting primary human HSCs with a retrovirus over-expressing hTERT (Schnabl et al., 2002). The hTERT positive HSCs do not undergo oncogenic transformation and exhibit morphologic and functional characteristics of *in vivo* activated HSCs. Subsequent Genechip™ and RT-PCR analysis showed that mRNA expression patterns in telomerase-positive HSCs are similar to those in primary *in vivo* activated human HSCs (Schnabl et al., 2002). Similarly, another two immortalized HSC lines LX-1 and LX-2 were characterized by microarray analysis and determined to have a gene expression profile similar to that of *in vivo* activated human primary HSC (Xu et al., 2005). These newly developed cell lines are proving to be valuable tools to study the biology of human HSCs. Importantly, although microarray and Genechip™ studies have demonstrated that these *ex vivo* HSC are similar to *in vivo* activated HSC with a greater than 70% similarity in transcript expression, a number of differences have been identified. Therefore, *ex vivo* cell culture of stable HSC may not be completely representative of *in vivo* injury highlighting the importance of intracellular interactions within the liver in determining transcriptome expression.

TRANSCRIPTOME ANALYSIS OF LIVER DISEASE

Presently there are hundreds of published gene array studies of human liver disease or studies that utilize human liver tissue. Most of these studies attempt to understand liver by examining mRNA transcript expression. There are few publications in human liver disease where gene expression is correlated with clinical outcome. Two of the most common causes of liver injury globally, viral hepatitis B and C, are discussed in more detail in Chapter 112. Unfortunately, many forms of liver injury cannot be studied in commonly used laboratory animal models and most animal studies focus on the pathways of fibrosis development.

Hepatitis B Virus Infection

Functional genomics studies of acute hepatitis B virus (HBV) infection in the chimpanzees has led to unique insights into how this virus evades the immune response and causes injury (Wieland et al., 2004). Initially, there is no apparent significant immune/inflammation-associated differential gene expression during the early phase of HBV infection and viral replication. Therefore, HBV infection acts in the initial phase as a "stealth virus" failing to induce a significant innate immune response (Wieland and Chisari, 2005; Wieland et al., 2004). Intrahepatic gene induction is first seen during the phase of attempted viral clearance. Gene expression during the early phase of infection was associated with T cell receptor and antigen presentation. Following this T cell effector function (granzymes), T cell recruitment (chemokines) and monocyte activation-associated gene expression has been demonstrated. A later phase of clearance was associated with the expression of B cell-related genes. Chronic HBV infection is characterized by gene expression profiles consistent with active inflammatory response (increased IRF-6 and CCL16), cell proliferation (increased cyclin-H and p53) and cellular apoptosis (14-3-3 interacting gene increased) (Honda et al., 2001, 2006).

Hepatitis C Virus Infection

Acute and chronic hepatitis C virus (HCV) infection has been studied using functional genomics techniques. These experiments have examined acute HCV infection in primates, as well as the sequelae of chronic infection. The results from microarray studies of acute HCV infection in the chimpanzee are intriguing. Acute HCV infection is characterized by a rapid (within 2 weeks) as well as a delayed induction (up to 6 weeks) of genes involved associated with the innate immune response (Bigger et al., 2001). Most of these genes are associated with interferon gene expression and are known as interferon response genes (IRG's; including ISG15, ISG16, CXCL9, CXCL10, Mx-1, stat-1, 2′5′-oligoadenylate synthetase and p27). Viral clearance appears to be associated with rapid induction of these IRG's. Overall HCV persistence appears to be associated with comparatively less induction of IRG's compared to viral clearance. Further, chronic HCV-related liver injury appears to be characterized by an IRG-associated chronic Th1 immune response, which is insufficient to clear the virus but is chronic and responsible for ongoing liver injury. The situation with interferon treatment of HCV infected individuals, which is aimed at viral eradication, is similar to acute infection as an immune response, characterized by a significant increase in IRG expression following treatment, is associated with a greater likelihood of a sustained long-term therapy response. Clearly, the immune response to HCV drives fibrogenesis,

as interferon administration is associated with a reduction intrahepatic inflammation and fibrosis even in the absence of a long-term virological clearance following treatment.

Alcoholic Liver Disease

Globally, alcohol is a leading cause of progressive liver fibrosis leading to cirrhosis. Intrahepatic gene profiling using microarrays in ethanol-fed baboons has identified increased expression of multiple annexin-related genes (including A1 and A2) that were not previously implicated in the progression of fibrosis in alcoholic liver disease (ALD; Seth et al., 2003). Further, the intrahepatic transcriptome profile in alcohol-associated liver injury is significantly different from other forms of liver disease (Deaciuc et al., 2004; Seth et al., 2003). Transcriptome profiling has allowed differentiation of alcoholic hepatitis from alcoholic steatosis. Genes known to be involved in alcohol injury such as alcohol dehydrogenases, acetaldehyde dehydrogenases, interleukin-8, *S*-adenosyl methionine synthetase, phosphatidylethanolamine *N*-transferase and several solute carriers have been shown to be differentially expressed in alcoholic hepatitis versus alcoholic steatosis. In alcoholic hepatitis, many novel differentially expressed genes have been identified, including claudins, osteopontin, CD209, selenoprotein, annexin A2 and genes related to bile duct proliferation (Seth et al., 2003). Differentially expressed genes involved cell adhesion, ECM proteins, oxidative stress and coagulation that were common to alcoholic hepatitis and end-stage ALD. Importantly, genes associated with fibrosis, cell adhesion, ECM remodeling are increased in human advanced ALD, consistent with the fibrotic nature of ALD. However, many of these genes are not specific to alcohol-induced liver injury and have been reported in other forms of liver cirrhosis such as primary biliary cirrhosis (PBC) (Shackel et al., 2001, 2002).

Non-Alcoholic Fatty Liver Disease

Non-alcoholic fatty liver disease (NAFLD) is the "western" liver disease related to obesity and form part of the metabolic syndrome characterized by increased BMI, hypertension and insulin resistance. Non-alcoholic steatohepatitis (NASH) is the clinicopathological syndrome in NAFLD in which lipid deposition within the liver is accompanied by inflammation and is widely studied using gene array analysis of mRNA transcript expression. The inflammation in NAFLD that results in NASH is of considerable importance as NASH, not NAFLD, is characterized by progressive injury and eventual cirrhosis. Studies have identified differentially expressed genes in end-stage NASH cirrhosis compared to other disease states (Sreekumar et al., 2003; Younossi et al., 2005a, b). Decreased expression of genes associated with mitochondrial function and increased expression of genes associated with the acute phase response are observed (Sreekumar et al., 2003). The latter increases were speculated to be associated with insulin resistance, a feature of NAFLD (Sreekumar et al., 2003). Further differential expression of genes involved in lipid metabolism, ECM remodeling, regeneration, apoptosis and detoxicification have all been observed in NASH following microarray analysis (Younossi, et al., 2005a, b).

Autoimmune Hepatitis

Autoimmune hepatitis (AIH) is an uncommon autoimmune disease affecting the hepatic lobule with a number of morphological similarities to the injury caused by HBV and HCV. The only available data on AIH are a comparison between HCV- and AIH-associated cirrhosis (Shackel et al., 2002). One of the key findings in this study was the observation that three inhibitors of apoptosis (IAP) genes were selectively differentially expressed in AIH. This is an intriguing finding. If this gene expression was identified to be in the intrahepatic lymphocyte population, then lack of apoptosis of such cells may be an important pathogenic pathway in the perpetuation of AIH. In this comparison to HCV, AIH was associated with an inflammatory gene pathway that consisted of a mix of Th1- and Th2-associated genes. Therefore, an intrahepatic Th1 immune response appears to be more fibrogenic, as evident from this work, HCV liver injury and animal models of liver injury (Shi et al., 1997).

Biliary Liver Injury

Viral hepatitis and alcoholic liver injury typically affect the hepatic lobule within the liver and are referred to classically "hepatitic" or "lobular" liver injury. However, a number of other types of liver injury are characterized by insults primarily to the bile ducts and are commonly referred to a "biliary" disease. Classically, biliary diseases include autoimmune-mediated bile duct injury of PBC and the poorly understood condition of bile ducts known as primary sclerosing cholangitis (PSC) in which inflammation, infection and fibrosis initially affects the bile ducts and then the liver parenchyma.

One of the major findings in a gene array examination of PBC end-stage liver disease was the identification of a subset of genes associated with the Wnt pathway (Shackel et al., 2001). In particular, Wnt13, Wnt5A and Wnt12 were shown to be differentially expressed. Other genes particularly upregulated in PBC included transcription initiation factor 250 kDa subunit (TAFII 250), PAX3/forkhead transcription factor and patched homolog (PTC). A consistent feature of the gene array analysis of PBC was the repeated identification of *Drosophila* genes homologs that were differentially expressed (Wnt genes, hedgehog pathway, notch pathway) (Shackel et al., 2001).

The only available data on PSC come in a comparison with PBC (Shackel et al., 2001). Compared with PBC, there were a far greater number of genes showing differential expression in PSC versus non-diseased liver (compared with PBC, and non-diseased liver). These include genes associated with epithelial biology (amphiregulin, bullous pemphigoid antigen), inflammation (T cell Secreted Protein P I-309, CTLA4), apoptosis-related genes (Bcl-2 interacting killer, Bcl-x, Death associated protein 3) and intracellular kinases such as CDK7 and JAK1.

A disease in which bile ducts are absent, biliary atresia (BA), has been studied comparing gene expression in embryonic versus perinatal forms of the disease (Zhang et al., 2004). Gene profiling clearly separated these two conditions. The most remarkable difference was in the expression of so-called regulatory genes.

In embryonic BA, 45% of differentially expressed genes were in this category versus 15% in the perinatal form. Included in these genes were imprinting genes, genes associated with RNA processing and cell cycle regulation that were not present in the perinatal form of BA. Overall, the results from genomic studies of biliary liver disease are consistent with distinct patterns of injury each associated with unique gene signatures.

The first clinically adopted genomic medicine approach in liver disease arose from the development of a gene array resquencing chip capable of diagnosis of a number of rare inherited inborn errors of metabolism resulting in neonatal hyperbilirubinemia (Liu et al., 2007; Watchko et al., 2002).

Hepatocellular Carcinoma

Liver injury characterized by cirrhosis is a premalignant condition. Despite the many diverse causes of liver injury, the development of HCC invariably occurs in the setting of cirrhosis. Indeed, the development of HCC without cirrhosis is extremely rare. Functional genomics methodologies are advancing the understanding of how fibrosis progression to cirrhosis is required for malignancy development. However, this sequence of events is still poorly understood.

Neoplastic proliferation in HCV-associated HCCs has been studied by microarray analysis. A plethora of potential novel tumor markers have been identified. These include the serine/threonine kinase 15 (STK15) and phospholipase A2 (PLA2G13 and PLA2G7) that were found to be increased in over half of the tumors identified (Smith et al., 2003). However, different studies identify different gene groups in HCV-associated HCC such as: cytoplasmic dynein light chain, hepatoma derived growth factor, ribosomal protein L6, TR3 orphan receptor and c-myc (Shirota et al., 2001). The clustering analysis in this study showed that the expression of 22 genes in HCC related to differentiation of the malignancy, with over half of these genes being transcription factors or related to cell development or differentiation (Shirota et al., 2001). Although many of these genes can be implicated in HCC development, they are often identified in gene sets obtained from end-stage diseased tissue. Therefore, whether these genes represent cause or effect is unknown. HBV-associated HCC has been studied by several groups (Iizuka et al., 2002, 2004; Kim et al., 2004a, b). Genes associated with cell proliferation, cell cycle, apoptosis and angiogenesis were dysregulated in HCC tissues. Increased expression of cyclin-dependent kinases was seen whilst several cell cycle negative regulators were decreased. Metastatic development has also been studied using gene arrays (Pan et al., 2003; Qin and Tang, 2004; Tang et al., 2004; Ye et al., 2003). Genes identified with metastatic development include osteopontin, and *in vivo* neutralizing antibodies to osteopontin block tumor invasion (Ye et al., 2003). A study of unsupervised gene profiling of patients with HCC revealed a set of genes associated with decreased survival including RhoC (Wang et al., 2004). These genes include a subset of pro-proliferative, anti-apoptotic genes as well as genes involved in ubiquitination and histone modification. Gene profiles in HCC have also demonstrated patterns of gene expression associated with tumor differentiation, vascular invasion as well as recurrence after surgery (Tang et al., 2004).

PROTEOMIC STUDIES OF LIVER DISEASE

Proteomic studies of liver disease have fallen into the following four groups: (1) discovery of previously unrecognized proteins in a cell population or disease state (Eng and Friedman, 2000; Kawada et al., 2001; Kristensen et al., 2000), (2) biomarker discovery (Schwegler et al., 2005; Seow et al., 2001), (3) hepatic toxicological prediction/profiling (Fella et al., 2005; Fountoulakis and Suter, 2002; Gao et al., 2004; Guzey and Spigset, 2002; Kaplowitz, 2004; Low et al., 2004; Meneses-Lorente et al., 2004; Merrick and Bruno, 2004; Nordvarg et al., 2004; Roelofsen et al., 2004) and (4) studies of known proteins or classes proteins (Greenbaum et al., 2002; Joyce et al., 2004) (see Tables 50.1 and 50.2). Proteomics has successfully been used in biodiscovery of proteins in hepatocytes, HSCs (Eng and Friedman, 2000; Kawada et al., 2001; Kristensen et al., 2000), HCC (Seow et al., 2001) and viral hepatitis (Comunale et al., 2004; Garry and Dash, 2003; Kim et al., 2003; Lu et al., 2004; Rosenberg, 2001; Scholle et al., 2004). In these studies tens to hundreds of proteins were identified. However, these studies are limited as they sample rather than profile the proteome. Further observed changes in protein expression may reflect weak associations rather than a direct role in the development of pathobiology. The biodiscovery approach has been successfully used in toxicological models and used to develop characteristic profiles of protein expression that may predict intrahepatic toxicology responses (Fella et al.,2005; Fountoulakis and Suter, 2002; Gao et al., 2004; Guzey and Spigset, 2002; Kaplowitz, 2004; Low et al., 2004; Merrick and Bruno, 2004; Meneses-Lorente et al., 2004; Nordvarg et al., 2004; Roelofsen et al., 2004).

This is an area of intense research focus for pharmaceutical companies as they strive to reduce development cost and aim to predict drug toxicity earlier in the drug development cycle. Biomarker discovery is another area receiving attention using proteomic methods. However, for years there has not been a newly FDA-approved serum marker as this is an immense research challenge. Biological sample protein concentrations vary by 12–15 orders of magnitude, and specific serum markers are likely to be expressed at nanomolar or lower concentrations. One approach to overcome these limitations is to use a combination of potential markers that are easier to detect but with each protein marker alone having a lower specificity but high sensitivity. This is an approach currently used in serum tests of hepatic fibrosis, and proteomic methods are being used to try and identify new serum markers of hepatic fibrogenesis (Henkel et al., 2005; Poon et al., 2005; Xu et al., 2004). One of the most promising approaches is the use of accurate mass tags (AMT) or suicide substrates that selectively and reproducibly target a sub-proteome (Bogdanov

and Smith, 2005; Greenbaum et al., 2002; Joyce et al., 2004; Pasa-Tolic et al., 2004). This has the added advantage of aiding prefractionation and increasing resolution of proteins as the tag can be captured on an affinity surface (Greenbaum et al., 2002; Joyce et al., 2004).

Hepatitis B Virus Infection

In contrast to gene array experiments, there are a number of studies that use proteomics on sera to examine different stages of chronic HBV infection. In one study, altered proteomic profiles were identified for haptoglobin beta and alpha 2 chain, apolipoprotein A-1 and A-1V, alpha-1 antitrypsin, transthyretin and DNA topisomerase 11 beta (He et al., 2003). Some of these proteins are amongst the most abundant serum proteins secreted by the liver and are generally associated with acute phase inflammatory responses. What was apparent in this study was that different isoforms of some of these proteins showed distinct changes in HBV infection itself and differed at times between patients with low inflammatory scores versus high inflammatory scores. Some examples include a decrease in cleaved haptoglobin beta peptides and ApoA-1 fragments in patients with higher inflammatory scores. In comparison, some alpha-1-antitrypsin fragments were increased in patients with higher inflammatory scores. An alternate approach studied serum protein profiles and correlated this with disease severity using a SELDI Protein Chip analysis and artificial neural network (ANN) models (Poon et al., 2005). They found 6 fragments with a positive and 24 with a negative prediction of fibrosis stage and subsequently developed a fibrosis index with excellent precise values for significant fibrosis and cirrhosis based on the Ishak fibrosis score. The inclusion of clinical biochemical parameters such as ALT, bilirubin, total protein, hemoglobin and INR strengthened the accuracy of their predictive model (see Chapter 112).

Hepatitis C Virus Infection

Proteomic methodologies have been applied to a number of aspects of HCV-related liver injury. These include the study of HCV-related HCC development in which overexpression of alpha enolase was identified and correlated with poorly differentiated HCC (Kuramitsu and Nakamura, 2005; Takashima et al., 2005). The response of hepatocyte cell lines to IFN gamma treatment has uncovered over 54 IFN response genes including many novel targets, an approach that may pave the way for novel therapies. Examination of protein extracts that bind to the HCV IRES has identified a number of novel protein targets such as Ewing Sarcoma breakpoint 1 region protein EWS and TRAF-3. The final aspect of HCV liver injury receiving attention is the study of potential biomarkers such as heat shock protein HSP-70 associated with HCV infection progression to HCC (Takashima et al., 2003) (see Chapter 112).

AIH, PBC and PSC Associated Liver Disease

There are few published proteomic studies addressing the pathophysiology of these diseases. Cholangiocarcinoma that is associated with PSC has been studied using proteomics techniques (Koopmann et al., 2004). Using tandem mass spectroscopy, Koopman and colleagues identified Mac-2-binding protein (Mac-2BP) as a diagnostic marker in biliary carcinoma. The diagnostic accuracy of serum Mac-2BP expression in biliary carcinoma was superior to the established marker CA19-9. This study highlights the progression of proteomic research in liver disease; a focus initially on malignancy and biomarker discovery is followed by studies of pathophysiology.

ALD and NAFLD

Proteomic studies of alcoholism have, like the gene array studies, been an eclectic mix of research examining HCC development associated with alcohol, studies of hepatocyte alcohol-related biology and neural aspects of alcohol addiction. Studies of the intrahepatic toxic effects using proteomics have helped outline toxicology profiles that can be used for screening as well as trying to understand the alcohol-associated liver injury. Mitochondrial ethanol hepatoxicity is thought to involve modification of protein thiol redox state. Using 2D gel proteomic studies, Venkatraman et al. (2004) were able to demonstrate a decrease in the reduced thiols on aldehyde dehydrogenase and glucose regulated protein 78 (Venkatraman et al., 2004). The change in aldehyde dehydrogenase-reduced thiols was accompanied by a reduction in specific activity of the enzyme. The term "alcoholomics" has been coined to refer to the study of those proteins (i.e., the sub-proteome) that are directly or indirectly affected by alcohol.

There has been to date only a single study evaluating proteomic profiling in NAFLD (Younossi et al., 2005a, b). This study used SELDI-TOF MS to profile serum samples from 91 patients with NAFLD and 7 obese controls. Twelve unique protein peaks were identified that associated with NALFD (4 associated with steatosis, 4 with steatosis with non-specific inflammation and 4 with NASH). Unfortunately, although the peak mass was shown, SELDI-TOF MS lacks the accuracy required to give mass determination enabling equivocal protein identification.

Hepatocellular Carcinoma

To date, biomarker profiling has predominantly focused on studies of malignant tissue (Liu et al., 2005; Wiesner, 2004; Wong et al., 2004). In one study, HCC development in chronic HBV infection was characterized by a significant decrease in a fragment of complement-3 and an isoform of apolipoprotein A-1 (Steel et al., 2003). In tissue studies, expression of variants of aldehyde dehydrogenase and tissue ferritin light chain has been identified in HCC, but not surrounding tissues. Similar studies have also identified fructose-bisphosphatase arginosuccinate synthetase and cathepsin B pre-protein as downregulated in HCC tissues. In an extensive study using laser capture microscopy, Li et al. (2004) identified 261 proteins differentially expressed between HCC and non-HCC hepatocytes. Kinases in the Eph family were identified along the Ras-like family of Rho proteins. In addition a DEAD box polypeptide was downregulated whilst three members of the spliceosome and heterogeneous

nuclear ribonucleoprotein K were upregulated. Also SELDI-TOF MS has examined the sera of 82 patients with cirrhosis (38 without and 44 with HCC). An algorithm including the six highest scoring peaks allow the prediction of HCC in over 90% of cases (Paradis et al., 2005). The highest discriminating peak was a C terminal peptide of vitronectin.

Proteomic Analysis of Blood As a Marker of Liver Disease: "Next Generation" Liver Function Tests?

Several studies have evaluated proteomic analysis of serum protein as a diagnostic test to assess the severity of liver disease and in particular for non-invasive assessment of liver fibrosis. These studies are in their infancy, with basic methodologies still unresolved. However, the early studies show the technique has promise. In a pilot study of 46 patients with chronic hepatitis B, an ANN model was derived from the proteomic fingerprint and used to derive a fibrosis index (Poon et al., 2005). The ANN fibrosis index strongly correlated with Ishak scores and stages of fibrosis. The area under the ROC curve for significant fibrosis (Ishak score >2) and cirrhosis (Ishak score >4) were both >0.90. Inclusion of International Normalized Ratio (INR), total protein, bilirubin, alanine aminotransferase and hemoglobin in the ANN model improved the predictive power, giving accuracies >90% for the prediction of fibrosis and cirrhosis. Another study found that pre-treatment of serum proteins to remove *N*-glycosylation enhanced the resolution of serum polypeptide profiles (Comunale et al., 2004). This technique has the potential to improve diagnostic serum proteomics.

Chen et al. (2004) developed a method of glycoproteomic analysis in an attempt to discover serum markers that can assist in the early detection of HBV-induced liver cancer. The authors showed that woodchucks diagnosed with HCC have dramatically higher levels of serum-associated core alpha-1,6-linked fucose. One glycoprotein, Golgi Protein 73 (GP73), was found to be elevated and hyper-fucosylated in the serum of animals and humans with a diagnosis of HCC. Serum profiling was used to distinguish HCC from earlier stages of HCV-related liver disease (Schwegler et al., 2005). The proteomic model distinguished chronic HCV from HCV to HCC with moderate sensitivity and specificity. Inclusion of known serum markers alpha feto-protein, des-gamma carboxyprothrombin, along with GP73, significantly improved the diagnostic accuracy of detecting HCC.

PROTEOMICS IN OTHER LIVER DISEASE

The metalloproteome is defined as the set of proteins that have metal-binding capacity by being metalloproteins or having metal-binding sites. The copper and zinc metalloproteomes were defined in human hepatoma lines (She et al., 2003). Although the gene for Wilson disease has been identified, the mechanisms by which excess copper leads to oxidative stress, acute liver failure or cirrhosis are not fully understood. Using an *in vitro* model of copper loading, novel copper-binding proteins were isolated using proteomic techniques (Roelofsen et al., 2004).

Although there has been limited proteomic analysis of liver tissue in models of disease, liver-associated pathobiological processes have been examined. One study of the liver aging process identified 85 differentially expressed proteins comprised of antioxidation glucose/amino acid metabolism signal transduction and cell cycle systems (Cho et al., 2003). In aging, the antioxidation system showed a large increase in glutathione peroxidase and a decrease in glutathione-*S*-transferase. Similarly, levels of t-glycludic enzymes were decreased in the aging animal. Furthermore, levels of proteins associated in signal transduction/apoptosis, for example, cathepsin B, were decreased in the aging process. However, it is unclear if the identified genes explain the increased rate of fibrosis progression seen with increasing age.

Proteomics has been used to also identify genes associated with LPS-induced liver injury. Proteins such as TRAIL receptor 2 were downregulated in the liver of LPS treated mice, whilst TNFAIP1 was significantly upregulated. Four different proteins were novel in the fatty liver proteome (aconitase succinate dehydrogenase, propanol Co-A carboxylase alpha chain and 3-hydroxyanthrilate 3-4-dioxygenase). LPS is thought to be an important mediator of injury in a number of conditions such as alcohol-related liver injury.

2009 UPDATE

Recent advances in high-throughput genotyping technology have led to an increasing number of genome-wide association studies to assess disease progression and determine risks for development of HCC in chronic liver disease. The importance of selection of adequate samples and controls for functional genomic studies was highlighted by a study that noted differential gene expression patterns in inflammatory response pathways among 28 histologically normal liver tissue samples obtained by either percutaenous or surgical techniques (Asselah et al., 2008). Emerging data indicate that changes in hepatic miRNA expression may occur during fibrosis progression and development of cirrhosis, and miRNAs that represent targets of cell division, mitosis, and G_1-S transition may determine outcomes in HCC (Jiang et al., 2008). Liver tumors appear to have distinct miRNA expression profiles dependent on malignancy, risk factors, and oncogene/tumor suppressor gene alterations (Ladeiro et al., 2008). Emerging tools for large-scale epigenetic analysis have also been applied in relation to development of HCC. A study using methylated CpG island amplification microarray techniques identified 719 prominent genes of hypermethylation

in HCC tissue, with distinct patterns of gene methylation noted in progression from adjacent normal liver tissue to HCC (Gao et al., 2008). Another study using real-time PCR for quantitative DNA methylation in 77 matched HCC and noncancerous liver tissues noted higher levels of methylation in HCC corresponding noncancerous liver tissues compared to 22 normal liver tissue samples. Methylation causes disruption of a variety of genes and pathways during hepatocarcinogenesis, such as RB-related (*p16*, *RIZ1*), p53-related (*HIC-1*, *Reprimo*), WNT/APC (*APC*, *SFRP2*, *CDH1*), receptor-tyrosine kinase-associated (*RASSF1A*, *RASSF2*, *SOCS-1*), transforming growth factor beta signaling (*RUNX3*), and apoptosis-related pathways (*CASP8*). This study indicates that chronic HCV infection may act as a powerful epimutagen based on findings of significant association with the progression of age-related methylation compared to HBV infection (Nishida et al., 2008). At this stage, there are no epigenomic data available in relation to fibrosis or responses to antiviral therapy.

A DNA-mediated annealing, selection, extension, and ligation (DASL) 6000-gene expression profiling method applied to paraffin-embedded tissue from patients with HCC has been shown to yield high quality data, even in tissue stored for up to 24 years. A 186-gene expression signature from adjacent noncancerous tissue was noted to correlate with increased survival in a validation cohort. In this study, the poor-prognosis gene signature included inflammatory pathway genes related to IFN signaling and activation of nuclear factor-κB and tumor necrosis factor-α (Hoshida et al., 2008).

Proteomic profiling using 2D-gel electrophoresis or SELDI-TOF has been evaluated in relation to developing biomarkers of fibrosis in HCV infection, and demonstrate differential protein expression for advanced stage fibrosis (White et al., 2007), with only minimal incremental diagnostic benefit compared to validated serum marker panels of fibrosis (Morra et al., 2007). Quantitative proteomic profiling using iTRAQ in liver tissues from HCC patients indicated differential expression of newly identified proteins in this disease state, including fibroleukin, interferon induced 56 kDa protein, milk fat globule-EGF factor 8, and myeloid-associated differentiation marker (Chaerkady et al., 2008). Serum protein peaks identified using SELDI-TOF MS may also accurately detect HCC compared to established tumor markers such as α-fetoprotein (AFP), AFP-L3, and prothrombin induced by vitamin K absence-II (PIVKA-II) (Zinkin et al., 2008).

There is minimal, reproducible data using "omics" platforms in nonviral mediated chronic liver disease such as nonalcoholic fatty liver disease. Advances in high-throughput functional genomic and quantitative proteomic techniques will likely result in enhanced biomarker and target discovery efforts in other chronic liver disease.

CHAPTER

Genomic Medicine and Obesity

J. Alfredo Martínez

INTRODUCTION

Genetics of obesity have only achieved quantitative standards in the last decades (Marti et al., 2008). However, the first attempts to link the genetic inheritance to body composition were reported in the early 1920s by Davenport, in "Body built and its heritance", which were pursued by Vague and coworkers in the 1940s when they hypothesized about the occurrence of different obesity subtypes associated to sexual dimorphisms. Also, the "thrifty gene" theory raised in the paper by Neel (1962), outlining the fact that genes that predispose to diabetes and obesity would have relative advantage in populations that often experienced starvations, contributed to establish a relationships between genetics and body weight control (Bell et al., 2005). However, the classic books published in the 1970s about *Energy Balance and Obesity in Man* by Garrow (1974) and *The Obese Patient* by Bray (1976) only made minor references concerning monogenic forms of obesity. In 1977, the Nutritional Heart, Lung and Blood Twins Study first indicated the possibility that the observed aggregation for obesity was due to genetic factors rather than environment (Feinleib et al., 1977). Indeed, only in the International Congress of Obesity held at Jerusalem in 1986, the pioneering works by Bouchard et al. concerning the role of genetic predisposition on obesity onset were debated, which was continued with the recognized study concerning weight gain in overfed twins (Bouchard and Tremblay, 1997). Later, other classic textbooks about obesity by Bjorntorp (2001), as well as by Bouchard, Bray, and James (1998 and 2004), reinforced the fundamentals to characterize the role of inheritance, contributions and gene–lifestyle interactions on obesity. More recently the impact of Biomics, particularly genomics and transcriptomics, on obesity research is producing new and challenging breakthroughs by using specific tools and methodologies such a microarrays (Ommen, 2004). Up to 2006, 12 editions of the human obesity map have been published showing the continuous advances in the field (Rankinen et al., 2006).

OBESITY: CAUSES AND GENETIC PREDISPOSITION

Obesity is a multifactorial disorder characterized by disproportionately high adipose tissue content in the body, accompanying a disequilibrium in the energy balance equation: energy intake $>$ energy expenditure (Bray, 2003). A fat content higher than 25% of the body weight in men and 33% in women are often arbitrarily considered as cut-off points to identify a subject as obese (Seidell and Flegal, 1998), which is commonly associated with excessive weight-for-height. However, very muscular individuals or pregnant women may have a greater weight than expected for height according to the standards, without showing an increased adiposity (Kasper et al., 2005). Another aspect to be ascertained is the regional distribution of the weight as fat, since the abdominal fat deposition or "android obesity" is an increased risk factor for disease as compared to "gynoid obesity", in which fat is more evenly and peripherally distributed around the body and upper regions of the legs (Lean, 1998).

A positive energy balance between the amounts of energy consumed over the energy spent in everyday life underlies weight gain. Indeed, the excessive fat accumulation in adipose tissue leading to obesity is the result of a chronic overconsumption of foods and drinks over the energy expenditure requirements, in which dietary and lifestyle habits, sociological factors, metabolic and neuroendocrine alterations as well as hereditary components are involved (Martínez, 2000). Actually, environmental and lifestyle influences promoting excessive caloric intake and sedentary patterns are known to induce a positive energy balance leading to weight gain (Marti et al., 2004). Indeed, the availability of energy-dense meals, and sedentary patterns facilitated by motorized transport and other common physically inactive pursuits (TV viewing, computer work, etc.) have markedly risen in the last decades (Martínez et al., 1999). On the other hand, cross-sectional data show a strong association between unhealthy eating habits and physical inactivity, which have contributed to explain the observed obesity pandemic (OMS Report, 2000). In this context, a high intake of non-starch polysaccharides/fiber has been considered as a protective factor against obesity, while a high consumption of fast food and sweetened sugar drinks or fruit juices is viewed as a obesity risk factor (Bes-Rastrollo et al., 2006). Furthermore, prospective studies provide additional evidence suggesting that an increase in physical activity and small changes in dietary behavior may help to prevent a disproportionate weight gain (Hill et al., 2003).

Body weight stability and the associated regulatory processes depend upon nutrient intake and physical activity patterns, but are also influenced by compensatory genetic-dependent metabolic and neuroendocrine mechanisms (Martinez and Frühbeck, 1996). Thus, despite the daily fluctuations in both components of the energy balance equation (energy intake versus energy expenditure), body weight and adiposity remain in a dynamic steady state for long periods of time (often within ± 1% variation over many years), which has been attributed to the participation of a powerful control system to fine tune the dietary macronutrient supply to body fuel oxidation demands (Jequier and Tappy, 1999). The control of the maintenance of body composition has been the subject of a number of theories or hypotheses such as the occurrence of a physiological set point for body weight, glucostatic or glycogen drives for feeding, metabolic/nutrient partitioning approaches, the participation of the nervous system, an adipostat mediated by signals from the adipose tissue, all of which might be under genetic control and explain individual variability (Martínez, 2000). In this context, it has been hypothesized that the stability of body weight and composition depends upon an axis with three inter-related and self-controlled components: (1) food intake, (2) nutrient turnover and thermogenesis and (3) body fat stores (Figure 51.1). All three elements underlie complex inter-related feedback mechanisms, which are affected by the individual's genetic background. Indeed, obesity is caused by perturbations of the balance between food intake and energy expenditure, which is regulated by a complex physiological system that requires the integration of several peripheral signals and controls coordination in the brain, (Solomon and Martínez, 2006) basically through hypothalamic nuclei and different orexigenic or anorexigenic neuropeptides (NPY, AGRP, orexins, leptin, POMC, etc).

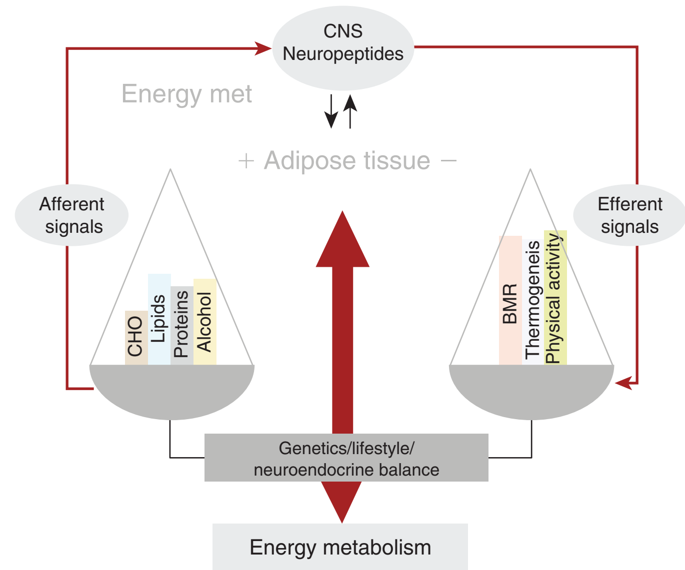

Figure 51.1 Body weight regulation.

Genes may determine afferent and efferent signals, as well as central mechanisms involved in body weight regulation (Bell et al., 2005). Thus, the transferable genetic information involved in short- and long-term stable body weight regulation and composition maintenance is acting via: (1) different peptides and monoamines involved in the regulation of the appetite, (2) variations in energy and nutrient utilization, resting metabolic rate or response to physical activity and (3) individual differences in adipocyte metabolism (Palou et al., 2003). The possible mechanisms through which the genetic susceptibility (Figure 51.2) could be acting include reduced rates of basal metabolism and macronutrients oxidation, alterations of adipogenesis and quantitative and qualitative deviations of food intake (Moreno et al., 2005).

Obesity, similar to other chronic diseases with a recognized monogenic or polygenic origin, is associated with a number of pathological dysfunctions and disturbances with important implications for the individual's and community health (hyperinsulinaemia, diabetes, hypertension, immunological alterations, certain cancer types, etc.), which is further worsened by the growing rates of obesity prevalence (20–40% of the EU population are overweight or obese and more than 50% of US subjects have problems of excessive weight gain) (OMS Report, 2000). Indeed, the health consequences of obesity are serious and diverse, ranging from premature death to different morbidities affecting quality of life (Kasper et al., 2005). Despite that relative risk estimations of the health problems associated with obesity are founded on a limited number of countries, some studies have reflected that the risk of suffering from NIDDM, gallbladder disease, dyslipemia, insulin resistance and sleep apnea are increased at least three times in the obese, while the risk of cardiovascular diseases and hypertension is moderately increased in the obese, and the risks of certain cancer and hormonal

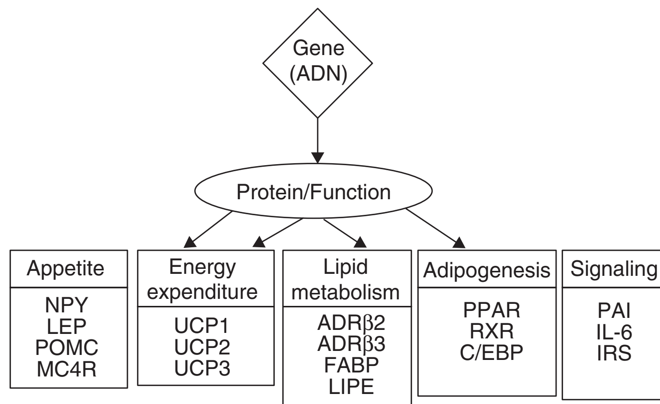

Figure 51.2 Some genes involved in body weight homeostasis categorized by processes.

disturbances as well as back pain associated with obesity show relative risks ranging between 1 and 2 (OMS Report, 2000). Also, severe obesity has been found to produce a 12-fold increase in mortality in 25–35 years old obese individuals when compared to lean subjects.

The rapid increase in obesity incidence over recent years suggests that environmental and lifestyle influences in addition to other psychopathological or genetic determinants are independently affecting the energy balance equation adjustment (Bray and Bouchard, 2004). Actually, the growing prevalence of obesity around the world is mainly attributed to changes in lifestyle (increase of the consumption of high-energy-yielding foods enriched with carbohydrates and fats or reductions of the physical activity, etc.) that specifically may impact genetic susceptibility. Also, from an evolutionary point of view, the individuals with thrifty genes are more resistant to malnutrition, explaining why large proportions of diverse populations are susceptible to become obese (Bell et al., 2005). The mutual interactions between the genetic make-up and the environment undoubtedly complicate the understanding of the specific roles of genes and external influences in obesity (Schuldiner and Munir, 2003).

SEARCH FOR GENES INVOLVED IN OBESITY

The interaction of genetic, environmental, physiological and psychosocial factors is involved in body weight homeostasis (Tremblay et al., 2004). Thus, the specific distribution of energy expenditure requirements and individual substrate partitioning are known to influence the energy balance equation depending on the genetic make-up (Moreno-Aliaga et al., 2005). In this context, the risk of excessive weight gain in children of some families with obese parents is increased two- to three-fold for moderate obesity and up to eight times for severe obesity (Marti et al., 2004). Moreover, twin and adoption studies substantiate a role for genetics in obesity (Bray and Bouchard, 2004). The discovery of populations such as Pima Indians with shared alterations in basal metabolism rates or in fat oxidation after food intake corroborates such hypothesis, as well as the fact that genetic factors can modulate the effects of physical activity and diet on weight and body composition (Bray et al., 1998). Furthermore, several studies carried out in large numbers of families encompassing members of different degrees of relatedness have allowed the quantification of the statistical association regarding objective indicators of obesity (body mass index (BMI) or percentage of fat) depending on the degree of the familial relationship (Bell et al., 2005; Marti et al., 2004). The heritability of BMI is lower between husband and wife (0.10–0.19) and between uncle/aunt and nephews (0.08–0.14), and increases between parents and children (0.15–0.23) and among siblings (0.24–0.34). The concordance for BMI is higher in monozygotic (0.70–0.88) than in dizygotic twins (0.15–0.42). Also, studies of dietary intervention, based on positive and negative energy balances in identical twins, convincingly pointed out that the differences in the susceptibility to overfeeding or periods of semi-starvation seem to be partially explained by genetic factors (Bouchard and Tremblay, 1997). Family studies have largely revealed that the heritability of the Quetelet index is about 25–50%, while twin studies have mostly estimated the contribution of genetic factors at 70–80% (Bell et al., 2005; Comuzzie and Allison, 1998). However, this information is not enough to prove unequivocally the genetic origin of obesity, since the families share, besides genes, other factors implied in obesity such as lifestyle, dietary habits and environmental factors. In this context, genetic association studies search for statistical relationships among a gene polymorphism with a given phenotype, generally among non-related individuals (Rosmond, 2003). This research strategy can consider the comparison between cases and controls, analysis of the variability for specific loci or the discrimination between mutation carriers and non-carriers regarding a given character. On the other hand, genetic linkage studies imply the persistence or co-segregation of a genetic marker or locus and a phenotypical character within a family (Bouchard, 1997). Furthermore, quantitative genetics allow assessing the influence of environmental factors on the hereditary variability, which can be based on diverse genes (polygenic interaction). The studies of gene expression as affected by dietary and activity patterns constitute another approach to relate the specific participation, both quantitative and qualitative, of different genes in energy homeostasis processes (Viguerie et al., 2005a). A salient feature of a study concerning the role of the lipid/carbohydrate content or the calorie restriction in affecting the mRNA levels is that the energy intake is more important than the macronutrient distribution (Viguerie et al., 2005b). Additionally, animal models have been able to characterize the impact of fat intake on gene expression (Lopez et al., 2005), which have evidenced that a number of genes controlling many different metabolic pathways such as lipogenesis, thermogenesis, lipolysis, adipogenesis, differentiation, oxidative stress, inflammation, etc. are affected by lipid consumption, which may help in the future to define molecular phenotypes or subsets of obesity.

Obesity as a complex syndrome with a multiple etiology may be explained in some circumstances by monogenic mutations, but in most cases appears as a polygenic condition, which may be additionally affected by a myriad of environmental influences (Guy-Grand, 2003). A widely accepted hypothesis assumes that complex diseases such as obesity are likely to be based on a limited number of predisposing alleles, each conferring a small increase in the risk to the individual. Heterogeneity in complex phenotypes implies that the genetic predisposition may also result from any one of several rare variants in a number of genes (Marti et al., 2004).

The role of a genetic predisposition in obesity has long been assumed to affect both sides (intake/expenditure) of the energy equation (Figure 51.2). In this context, evidence from human single-gene mutations (leptin: LEP; leptin receptor: LEPR; pro-opiomelanocortin: POMC; melanocortin 4 receptor: MCR4; protein convertase 1: PC1; etc) has solely implicated energy intake (Rankinen et al., 2006). However, Mendelian syndromes with obesity as a clinical feature (e.g., Prader–Willi syndrome) have also revealed reductions in energy expenditure as a contributing factor to obesity (Lyon and Hirschhorn 2005).

In this context, evidence from single-gene mutation obesity cases, Mendelian disorders exhibiting obesity as a clinical feature, transgenic and knockout murine models relevant to obesity, quantitative trait loci (QTL) screening from animal cross-breeding experiments, association studies with candidate genes, and linkage studies from genome scans have been reported (Table 51.1). So far, at least, 176 human obesity cases due to single-gene mutations in 11 different genes have been reported, 50 loci related to Mendelian syndromes relevant to human obesity have been mapped to a genomic region, and causal genes or strong candidates have been identified for most of these syndromes. There are about 250 genes that, when mutated or expressed as transgenes in the mouse, result in phenotypes that affect body weight and adiposity. The number of QTLs reported from animal models currently reaches more than 450 markers. The description of human obesity QTLs derived from genome scans continues to grow, and at least 250 QTLs for obesity-related phenotypes from genome-wide scans have been reported. More than 50 genomic regions harbor QTLs supported by two or more investigations. The number of studies reporting associations between DNA sequence variation in specific genes and obesity phenotypes has also increased considerably, with more than 400 findings of positive associations with 127 candidate genes. A promising observation is that 22 genes are each supported by at least five positive studies (Tables 51.2 and 51.3). The obesity gene map shows putative loci on all chromosomes except Y. The latest electronic version of the map with links to useful publications and relevant sites can be found at http://obesitygene.pbrc.edu. Overall more than 600 genes, markers or chromosomal regions have been associated with human obesity phenotypes (Rankinen et al., 2006).

In this context, genetic epidemiology of obesity aims to screen and assess the phenotype traits associated to the genetic make-up and their relationships with lifestyle factors (Hill et al., 2003). The research strategies to identify the genetic determinants of obesity are multiple (Table 51.1). Indeed, the process of ascribing a gene to a phenotype is complex due to the low density of coded DNA (<5%), the potential interactions of genes with environmental factors and the diversity of methods and tools to assess body fat and energy metabolism phenotypes, which have hampered the advances in this area (Marti et al., 2004). The identification of genes may follow ascending strategies from the genotype to the phenotype, in which a gene or genes are investigated to find out a relation with a given obesity marker, but also descending strategies in which from a clinical feature of excessive fat accumulation, the genetic determinant is searched concerning the heritability of BMI, skinfolds and waist circumference (Bray et al., 1998). In Caucasian families, an estimate of 0.45–0.60 for measures of fat men such as BMI and 0.29–0.48 for measures of fat distribution has been calculated, which fit in well with the estimate from twin studies, where a minimum 0.40 for fatness or obesity was reported (Bell et al., 2005). The co-existence of obesity manifestations on various members of a family corroborates that the genetic make-up can play a role in obesity, which is reinforced by the fact that impairments in the thermogenesis, basal metabolic rate and sympathetic activity as well as specific effects on hyperphagia or physical activity performances are genetically controlled (Palou et al., 2003). However, these investigations do not discard a role for the shared environment conditioning dietary habits and physical activity patterns. Another aspect is that genetic predisposition may influence the android/gynecoid fat distribution (central or gluteo–femoral phenotypes), as has been proven in familial obesity risks studies (Katzmarzyk et al., 1999), which may be mediated in some cases by sexual gene-dependent differentiation of the adipose tissue muscle ratio (Vague et al., 1989).

DIAGNOSIS AND CHARACTERIZATION OF GENES ASSOCIATED WITH OBESITY

Genetic diseases are usually categorized as chromosomal alteration, monogenic or mendelian and multifactorial syndromes

TABLE 51.2 Selected list of genes that have been associated with obesity phenotypes

Gene	Name/Function	Associated phenotype
ACE	Angiotensin 1-converting enzyme	BMI, waist circumference, body fat
ADIPOQ	Adiponectin, C1Q and collagen containing domain	BMI, waist circumference
ADRB2	Adrenergic, beta 2 receptor	BMI, waist-to-hip ratio, body fat, skinfolds, lipolysis
ADBR3	Adrenergic, beta 3 receptor	BMI, abdominal visceral fat, waist-to-hip ratio
DRD2	Dopamine receptor D2	Body weight, reduced energy expenditure, skinfolds
GNB3	Guanine nucleotide-binding protein 3(G-protein)	BMI, reduced lypolysis, body fat
HTR2C	5-Hydroxtryptamine (serotonin) receptor 2C	BMI, weight change
IL-6	Interleukin 6	BMI (in men) waist circumference (in men) reduced, fasting energy expenditure
INS	Insulin	BMI, body weight, leptin
LDLR	Low-density lipoprotein receptor	BMI
LEP	Leptin	BMI, body weight
LEPR	Leptin receptor	BMI, fat-free mass, fat-free mass, body fat (%), leptin, abdominal total fat
LIPE	Lipase	BMI, body fat, skinfolds, waist-to-hip ratio, reduced lipolysis
MC4R	Melanocortin 4 receptor	BMI, body fat (%), resting energy expenditure
NR3CI	Nuclear receptor 3C 1 (glucocorticoid receptor)	BMI, waist-to-hip ratio (in men), leptin, skinfolds
PPARG	Peroxisome proliferative-activated receptor gamma	BMI, leptin, waist circumference, body fat (%), leptin, lipid oxidation
RETN	Resistin	BMI, waist circumference
TNFA	Tumor necrosis factor alfa	BMI, body fat (%), waist circumference
UCP1	Uncoupling protein 1	BMI, waist-to-hip ratio, body fat (%)
UCP2	Uncoupling protein 2	BMI, energy expenditure, macronutrient oxidation, body fat, skinfolds
UCP3	Uncoupling protein 3	BMI, waist-to-hip ratio, body fat (%), resting energy expenditure, leptin, skinfolds
VDR	Vitamin D (1,2,5-dihydroxyvitamin D3) receptor	Fat mass

(Kasper et al., 2005). The chromosome alterations involve absence, duplication or abnormal distribution of one of several chromosomes related to excessive or faulty material, which may affect body fat content as occurs in Down Syndrome (trisomy 21) or Turner syndrome (X monosomy), which are often accompanied by obesity and other abnormal anatomical manifestations.

Obesity-related Mendelian disorders can be classified as autosomal dominant, autosomal recessive or X-linked (Table 51.4). Thus, a search (July 2006) in the obesity heading of the OMIM database produced 75 entries concerning autosomal dominant transmission, 74 entries concerning autosomal recessive transmission and 40 X-linked. Most of these syndromes have been already assigned to a specific locus. The clinical features of some of these metabolic disorders include, in addition to obesity, mental retardation and some craniofacial/ anatomical deformations as well as insulin resistance, hypertension, etc. Interestingly, 11 single-gene mutations with a specific obesity phenotype have been identified so far (CRH1, CRH2, GPR24, LEP, LEPR, MC3R, MC4R, NRTK2, POMC, PCSK1 and SIM1). The majority of the monogenic obesity cases reported in the literature remain those with a genetic defect in the MC4R gene (Hebebrand et al., 2003).

The fundamental requirements for the candidate gene approach are the identification of a gene that is involved in

the disease phenotype, a polymorphic maker within that gene and a suitable set of subjects to genotype for that marker (Bray et al., 1998). Association studies seek to establish statistical relations between a genetic polymorphism and a given phenotype. The statistical approach may search the comparison between cases and controls, the analysis of variations between cases and controls, the analysis of variations between specific loci and discrimination study between carriers and non-carriers for a trait (Rosmond, 2003). The association studies provide information in order to identify genes with low involvement, but they require establishing high statistical cut-offs (usually $p < 0.001$) to avoid random or biased findings. Evidence for association between markers of candidate genes with obesity-related phenotypes (BMI, skinfolds, waist circumference, LEP, etc.) has been reported for at least 125 genes (Perusse et al., 2005). Thus, statistical relationships with $p < 0.0001$ have been found for the following genes: ADA, ADBR2 and ADBR3, ATP1A2, ENPP1, GNB3, MRT2C, IL6R, INS, LEPR, MC3R, NR3C1, PPARG, PYY, RETN, UCP1, UCP2 and UCP3. (Tables 51.2 and 51.3).

Linkage studies are designed to investigate the persistence or co-segregation during generations of a genetic marker or locus within a family (Bray et al., 1998). This approach can be applied with candidate genes or genetic markers concerning specific polymorphisms. This protocol is commonly used on nuclear families or pedigrees in order to investigate the role of new genes through genome-wide scans (Bosse et al., 2004; Rankinen and Tiwari, 2004). Linkage studies with obesity phenotypes have been able to identify more than 200 QTLs related to excessive weight gain (Rankinen et al., 2006). Thus, linkage with obesity-related phenotypes (LOD > 2.0) has been reported for different genes or markers including the following: LEPR, AMPD1, ACP1, ISL1, NR3C1, BF, NPY, LEP, KEL, IGF1, MC5R, LDLR y ADA (Table 51.3). Genome-wide linkage scans involve the typing of family using polymorphic markers that are positioned across the whole genome followed by calculating the degree of linkage of the marker to a disease trait (Rankinen and Tiwari, 2004). In obesity, the sample sets are families representative of the general population and families that include at least an obese proband.

The 2005 update of the human obesity gene map revealed that the number of genes or markers that have been directly and indirectly linked with human obesity are increasing rapidly and now are higher than 625 (Figure 51.3). Some of these genes or chromosomal regions, such as the uncoupling proteins (UCPs), LEP, LEPR, adrenergic receptors (ADRB2, ADRB3), peroxisome proliferator-activated receptors (PPARs), fatty acid binding protein (FABP), etc. have been related to energy metabolism control and may be specifically affected by dietary intake and composition, and also by physical activity. Other genes are specifically involved in control of food intake (NPY, POMC, CCK, MCH, etc.), while some others influence different metabolic and signaling pathways, adipogenesis, etc. (PPAR, FABP, PKA, c/EBP, etc.), affecting the energy equation and, consequently, body weights of those individuals who are carriers of specific defective gene mutations/polymorphisms with an influence on fat deposition (Rankinen et al., 2006).

The studies of interactions of the genotype with environmental factors constitute a new challenge to establish the role of diet and physical activity in the genetics of obesity as well as those investigations devoted to evaluate the impact of lifestyle on gene expression (Cheung and Spielman, 2002). Indeed, genes predisposing to obesity potentially have an impact on dietary intake as well as on physical activity performance, while gender and age have been also reported as effect modifiers on

TABLE 51.4 Some Mendelian syndromes with obesity manifestations

	Prader Willi	Bardet-Biedel	Alstrom	Borjesson Forssman Lenhman	Simpson Golabi Behmel
Inheritance	Dominant 15q11.2	Recessive (> 8 loci)	Recessive 2p13.1	X-linked Xq26.3	X-linked (2 loci)
Craniofacies abnormalities	Frequent	No distinctive	No distinctive	Frequent	Frequent

Other common features	Hypogonadism Muscular hypotonia Depigmentation	Hypertension diabetes mellitus Hypogonadism Renal abnormalities Retina dystrophy	Diabetes blindness deafness	Hypometabolism epilepsy	Cardiac arrhythmias

obesity risk in subjects carrying different gene polymorphisms, respectively (Marti et al., 2004). Several association studies have described interactions between macronutrient intake and different polymorphisms in candidate genes affecting the obesity trait in predisposed subjects (Martínez et al., 2003; Moreno-Aliaga et al., 2005; Nieters et al., 2002).

Genes Involved in Appetite Regulation

A number of genes and chromosomal regions have involved in the regulation of the food intake through association or linkage studies such as leptin, neuropeptide Y, ghrelin, AGRP, orexins, CART, etc. (Riccardi et al., 2004). In this context, a monogenic form of obesity in humans occurs as a consequence of very rare mutations of the leptin gene, which lead to undetectable levels of serum leptin (Clement, 2005). Also, members of a consanguineous family with a rare LEPR deficiency were identified, exhibiting severe early-onset obesity with several metabolic disturbances. Affected individuals were homozygous for a mutation that truncates the receptor before the transmembrane domain, and the mutated receptor circulates bound to leptin. Additionally, several more common mutations at the LEPR gene have been described, but only some of the studies have been able to show an association with overweight and fat mass excess (Perusse et al., 2005).

Much attention has been focused on the role of the hypothalamic LEP–melanocortin system in body weight regulation and obesity (Hebebrand et al., 2003). The importance of the melanocortin signaling pathway in humans has been suggested by a number of monogenic polymorphisms identified in genes involved in the synthesis or processing of the glycoprotein POMC or in mutations leading to defects in POMC signaling via melanocortin receptors. All mutations result in profound obesity; however, specific gene mutations in the LEP/POMC pathway account for 5% of cases of obesity. In this context, dominant inheritance of obesity conferred by different missense, nonsense and frame-shift mutations in the MC4R gene has been extensively reported in many populations including European and American individuals (Hebebrand et al., 2003). Genetic variation in serotonin receptors, NPY, orexins and other neuropeptides, has also been widely studied in obesity given its potential involvement on food intake and body weight gain (Solomon and Martínez, 2006).

Genes Involved in Energy Expenditure Regulation

There are a number of studies that have evaluated the role of specific polymorphisms in relation to the control of the energy expenditure (Bastarrachea et al., 2004). Thus, adrenergic receptor genes mediate the rate of lipolysis in response to endogenous and exogenous catecholamines. The Trp64Arg variant of the β_3-adrenergic receptor have been associated in some studies to lipid accumulation in the adipose tissue and also there are studies concerning the β_2 and α_2 adrenoceptors in the same direction concerning different polymorphisms (Bray and Bouchard, 2004). Also genes controlling the expression of the inner mitochondrial uncoupling proteins (UCP1, UCP2 and UCP3) have been related to obesity phenotypes (Moreno et al., 2005). A number of human's studies have found relationships between UCP polymorphisms and exercise efficiency resting energy expenditure, substrate oxidation, energy metabolism, BMI, fat accumulation and body weight changes (Macho et al., 2000).

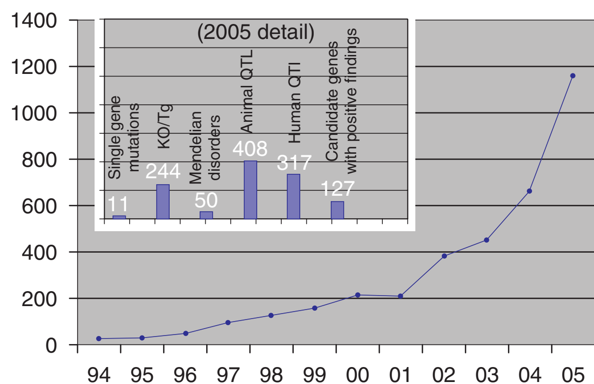

Figure 51.3 Evolution of the genes and chromosomal regions related to obesity between 1994–2005.

Genes Involved in Adipocyte Metabolism

Some genes involved in the regulation of adipocyte growth and differentiation have been associated with regulation of metabolism and body weight control (Bray and Bouchard, 2004). Thus, PPARγ particularly the adipose specific isoform (PPARγ2) is a key transcription factor implicated in adipogenesis as well as glucose and lipid homeostasis. A higher BMI for Ala carriers was also observed compared to non-carriers in 3-year and 10-year follow-up studies (Moreno-Aliaga et al., 2005). Another example is adiponectin, which is an adipocyte expressed protein that participates in the homeostatic control of glucose, lipid, and energy metabolism. Adiponectin gene polymorphisms have been associated with obesity, insulin sensitivity and type 2 diabetes in some cross-sectional studies (Rubio, 2006). Also, PGC1 is a cofactor regulating the expression of UCPs, the mitochondrial biogenesis, and other processes related to adipocyte energy homeostasis, whose variants are being related to excessive weight gain (Bray and Bouchard, 2004). Furthermore, the renin-angiotensin system is involved in adipocyte growth and differentiation.

Other Genes Related to Obesity

Common allelic variants of genes related to the insulin signaling pathway have been evaluated in relation to energy metabolism control such as the insulin gene, insulin-like growth factor 1 receptor (IGF-1R), plasma cell membrane glycoprotein 1, insulin receptor substrates 1 and 2 (IRS-1 and IRS-2), and the phosphatidylinositol 3-kinase p85 gene. Also, resistin, PAI, and different genes involved in lipid metabolism have been shown to potentially play a role in energy homeostasis and obesity such those codifying hepatic lipase (HL), lipoprotein lipase (LPL) and several lipoproteins (Rubio, 2006). Polymorphism of angiotensin converting enzyme (ACE) gene has been associated with overweight and abdominal adiposity, insulin resistance and hypertension in humans. Moreover, heterotrimeric guanine nucleotide-binding proteins (G proteins) mediate many pathways including the β-adrenergic signaling pathway. The C825T polymorphism in the gene coding for the β_3 subunit of G proteins (GNB3) has been shown to be associated with several phenotypes such as hypertension, obesity, and diabetes mellitus comprising the metabolic syndrome, although the conclusions have been inconsistent (Moreno et al., 2005). The fat mass and obesity gene (FTO) has also shown to contribute to common forms of human obesity (Loos and Bouchard, 2008).

SCREENING AND DIAGNOSIS

Epidemiologic, genetic and molecular studies suggest that there are people who are most susceptible than other to becoming overweight or obese (Bray and Bouchard, 1998). The degree of excess of fat, its distribution within the body and the associated health consequences depends on the genetic background (Moreno et al., 2005). Therefore, it is important to adequately assess the obesity phenotype not only for diagnosis, but also for therapeutic purposes. Thus, the graded classification of overweight and obesity aims for meaningful comparison of weight status among populations and identification of individuals/groups at risk, which helps to set up the intervention. Body weight for height and BMI (Kg/m^2) are common measures to define the obesity situation, which are suitable for general population samples, despite being relatively crude (OMS Report, 2000). In this context, other anthropometric or body composition determinations can be used such as the waist–hip ratio, percentage body fat, circulating leptin levels, etc. Other tools to characterize the obesity phenotype are based on the application of methods to assess food intake such as 72-h recall, food frequency questionnaires, dietary records, etc. Additional screening/diagnostic protocols aiming to identify the etiology of excessive weight gain are focused to estimate the energy expenditure (macronutrient oxidation and BMR) on the energy devoted to physical activity, through pedometers or calorimetry techniques, heart rate monitoring, sedentarism questionnaires, etc. (Table 51.5). Indeed, both appetite and physical activity patterns are potentially involved in obesity onset and complications, which must be adequately assessed.

Genomic medicine, aiming to improve the quality of medical care, is benefitting from the use of genotypic testing (DNA analysis) to identify genetic predisposition markers of obesity and to design individualized medical therapy based on the genotype (Challis and Yeo, 2002). Also, clinically oriented transcriptomics, focusing on the analysis of RNA by measuring the level of all or selected subset of genes based on the amount of mRNA in a given sample, are helping to understand and screen the causes of obesity (Moreno-Aliaga et al., 2001).

DNA sequence analysis is increasingly used as a diagnostic tool for determining carrier status and prenatal testing in monogenic disorders (Kasper et al., 2005). A number of techniques described in this textbook are available for the detection of mutations in monogenic disorders, which include cytogenetics, fluorescence in situ hybridization (FISH), Southern blotting, polymerase chain reaction based methods (PCR and RT-PCR),

Table 51.5 Methods to phenotypically characterize obesity

- *Body composition*: BMI, waist/hip circumferences, isotope dilution, bioelectrical impendence, skinfolds, etc.
- *Anatomical distribution of fat*: Imaging techniques (CT, NMR, DEXA, etc.)
- *Energy expenditure*: Stable isotopes, indirect/direct calorimetry, respiratory quotient, physical activity questionnaires, pedometers, heart rate, etc.
- *Energy intake*: Dietary records and recall, diaries, food frequency questionnaires, etc.
- *Molecular phenotypes*: Hormone levels, DNA, mRNA, and protein measurements

DNA sequencing and restriction fragment length polymorphisms (RFLP). Other approaches that have been used to identify mutations related to obesity are simple-strand conformational polymorphism (SSCP), gradient gel electrophoresis (DGGE) RNAse cleavage and protein truncated test (PTT). Novel technologies for the analysis of mutations, genetic mapping and mRNA expression profiles are rapidly developing (Ross, 1998; Ommen, 2004). Thus, microarray-based methods allowing the hybridization of thousands of genes simultaneous are being clinically used for mutational analysis and, characterizations of gene expression patterns in both obesity screens/diagnosis and research in humans and animals models (Kasper et al., 2005; Moreno-Aliaga et al., 2001).

The application of complex analytical techniques to encompass all the types of studies has led to the conclusion that the heritability estimate for BMI in large sample sizes was likely to be from 25 to 40%, while the amount of abdominal fat was influenced by a genetic component attaining about 50% of the individual differences (Bell et al., 2005; Comuzzie and Allison, 1998). Also, it should be stressed that the current epidemic of obesity is not really a consequence of the sudden appearance of mutations in genes regulating weight homeostasis, but the lack of adaptation in gene expression to environmental factors, such as the consumption of high-energy-yielding foods and sedentary habits.

Possible mechanisms through which a genetic susceptibility may be operating is the low body metabolism rate, low levels of macronutrient oxidation rates, low fat-free mass, low appetite control or low RQ post-prandial adjustments to intake or low oxidative process associated to physical activity (OMS Report, 2000). Other factors involved in the development of obesity thought to be genetically modulated are associated to impairments on adipose tissue, lipid metabolism, adipogenesis, on nutrient partitioning as well as endocrine/neural disturbances related to energy homeostasis such as insulin sensitivity, GH status, leptin action, hypothalamic neuropeptides, etc. (Martinez et al., 2002). Indeed, it is envisaged that genetic analyses, specifically in high-risk individuals, may be used for gene-based diagnosis and more interestingly for gene-founded therapies concerning genotypes affecting food intake, thermogenesis, adipogenesis, etc. In this context, gene polymorphism analysis could orient clinical recommendations to high-risk patients, since physical activity programs may be more suitable for some genotypes (Corbalan et al., 2002) or changes in carbohydrate or lipid intake may be more convenient for some specific gene variants (Luan et al., 2001; Martínez et al., 2003).

PROGNOSIS AND GENE-BASED TREATMENTS

The health consequences of obesity are diverse and serious, ranging from an increased risk of premature death to higher associated risks of suffering for diabetes, hypertension, inflammatory disturbances, cancer, etc. (Bray and Bouchard, 2004). The obesity prognosis depends upon a number of anatomical-linked phenotypical characteristics, such as the number of fat cells and fat distribution as well the causal factors, such a neuroendocrine disorders, drug-induced, weight gain sedentary lifestyles, psychological misbehaviors, which may be genetically dependent (Bray, 2003). Indeed, the prognosis and the treatments are affected by the genetic make-up, since genetic predisposition may influence the associated clinical manifestations and complications commonly found in obese subjects (Lean, 1998). This situation envisages that genetically based diagnosis and therapeutical approaches will be routinely applied in the obesity area as is occurring in some others diseases such as inborn errors of metabolism or diseases related to lipid metabolism (Basse et al., 2004; Kasper et al., 2005). Actually, it is of current interest to identify the involvement of some genetic polymorphism in relation to the ability of losing weight induced by different types of interventions commonly prescribed to obese patients such as diet therapy, pharmacotherapy and surgical approaches. Indeed, on the horizon is the possibility to individually treat obesity subjects depending on the genotype (Table 51.6) as reviewed by Moreno-Aliaga et al. (2005); a role for pharmacogenomics is not immediately clear since not many specific drugs to fight against obesity are currently in the market (Moreno et al., 2005).

In this context, congenital leptin deficiency is an extreme case of genetic obesity, whose deleterious effects can be restored by the administration of exogenous recombinant human leptin. In this special situation, the success of the pharmacological treatment with leptin would completely depend on the genetic make-up of the patient (O'Rahilly et al., 2003). By contrast, initial trials in obese patients with no leptin deficiency showed no significant benefits in terms of weight reduction unless substantially high doses were given. Using patients with polygenic (common) obesity, the response to low-calorie diet in relation with genetic polymorphisms in the promoter region of the LEP gene was studied (Mammes et al., 1998). At position C-2549A of the LEP gene, a weaker BMI reduction was found for −2549A allele carriers than the observed for homozygotes for the −2549C allele.

Some attention has been paid to the potential effects of Trp64Arg polymorphism in the ADBR3 gene in weight reduction programs (Table 51.6). Initially, resistance to lose weight

TABLE 51.6 Candidate genes and prognosis of weight loss response to dietary programs

Gene	Polymorphism*	Comments
Genes related to appetite control		
Leptin	C-2549 A (5-region)	Potential influence of BMI reduction
POMC	R236G	Weight loss is apparently unaffected
HTR2C	759C/T	Lower resistance to weight loss
Genes related to energy expenditure		
ADB3R	Trp64Arg	Potential influence in weight and fat distribution losses
ADB2R	Gln27Glu	Participation in rebound weight gain
UCP1	A-3826G	Potential impact on the magnitude of weight loss
UCP3	−55C⟶T (promoter)	Potential role on body fat distribution loss
Adipogenesis		
PPARG2	Pro12Ala	Potential involvement in maintenance after weight loss
Genes related to insulin resistance insulin signaling pathway		
IRS-1	Gly972Arg	No apparent role
IRS-2	G1057D	No apparent role
IGF-1R	GAA1013GAA	No apparent role
Genes related to lipid metabolism		
LIPC	G-250G (Promoter)	Weight loss dependent on the genotype
LPL	Hind III polymorphism	Weight loss dependent on the genotype
Apolipoproteins	ApoE e4	Possible relation with responsiveness to diet
	ApoB/VNTR	Possible relation with responsiveness to diet
	ApoA-IV-1/2	Potential involvement in food intake
Other genes potentially related to obesity		
PAI-1	4G/5G (promoter)	Genotype dependent reduction in BMI
IL6	−174 G > C	Potential involvement in maintenance after weight loss

*Modified from Moreno-Aliaga et al. (2005) and Martinez et al. (2008). Polymorphism nomenclature is shown as reported by the authors.

in homozygotes for the Arg64 allele compared with higher reductions either in heterozygotes or Trp64 homozygotes have been reported. On the contrary, other investigations did not find differences in weight loss by Trp64Arg genotypes in women submitted to a low-calorie diet. It is worth mentioning the differences on design in these studies according to the selection of participants (obese versus non-obese, diabetic versus non-diabetic) or the characteristics of the weight loss protocol (Moreno-Aliaga et al., 2005). Additionally, a lower ratio of visceral to subcutaneous fat has been reported in Arg64 carriers compared to non-carriers, especially in pre-menopausal women after a 3-month reduction period. Interestingly, a loss of visceral tissue has been found in Arg64 carriers compared with non-carriers after the intervention, but no differences in either body composition or energy expenditure by genotype groups were found. The response to exercise as a weight-lowering strategy appears to be affected by polymorphisms in the β_2-adrenergic receptor gene (Macho-Azcarate et al., 2003). A high initial degree of body fat mass determined by the Gly16 allele for the β_2-adrenoceptor polymorphisms predict those individuals who will have a rebound weight gain after their initial successful weight loss (Masuo et al., 2005).

The effect of uncoupling proteins on weight loss has been assessed in different studies (Riccardi et al., 2004). Thus, a relevant

role for the A-3826G polymorphism of the UCP1 gene in the magnitude of weight loss has been suggested (Table 51.6). In opposition to these results, no differences by genotype in weight loss of obese patients submitted to a gastroplasty were found. On the other hand, comparing proton leak and UCP2 and UCP3 expression in skeletal muscle of diet-resistant and diet-responsive overweight women, it was found that weight loss, mitochondrial proton leak-dependent respiration, and expression of UCP3 mRNA was greater in diet-responsive than in diet-resistant subjects, while no changes were found in UCP2 mRNA levels. Also, some UCP3 polymorphisms were associated with the changes in mRNA levels and body weight loss (Cha et al., 2006).

Other studies have reported a possible synergistic effect of UCP1 and ADBR3 gene polymorphisms on obesity and body weight changes (Sivenius et al., 2000). Thus, subjects with mutations in ADBR3 and UCP1 genes lost less weight than either those with the Trp64Arg variant alone (ADRB3) or the GG genotype of the UCP1 gene. Other researchers found a lower weight reduction in subjects with both mutations compared with subjects with no mutations, and a faster weight gain after the ending of the very-low-calorie diet intervention, while similar weight reductions after a clinical intervention for the four defined genetic categories concerning the Trp64Arg polymorphism (ADRB3 gene) and a promoter polymorphism (−55C→T) of the UCP3 gene in overweight-obese subjects with coronary artery disease or metabolic syndrome. However, a beneficial effect of the wild-type genotype for both variants was suggested for body fat distribution and glycemic control (Table 51.6).

Also, some genotype-dependent food intake control related cases have been studied. A recent trial to compensate for the genetic lack of hypothalamic melanocortin function was conducted by the administration of adrenocorticotropic hormone 4–10 (ACTH4-10), a melanocortin fragment with anorexic effect. However, after 3 months of treatment with increasing doses of ACTH4-10, no change of body weight or metabolic rate was observed. On the other hand, it has been reported that the individual ability to lose weight was not hampered in three children heterozygous for the R236G variant of the POMC gene that underwent a weight reduction program during 11 months (Santoro et al., 2004). Also, the serotonin receptor HTR2C genotype (−759C/T polymorphism) on weight loss program, was involved in the resistance to weight loss in the heterozygous genotype compared with either CC or TT homozygous genotypes and attributed such observation to a heterosis effect.

Moreover, several intervention studies were aimed to explore the relationship between PPARγ2 genotypes and weight loss (Nieters et al., 2002). Thus a 3-year study showed that subjects with the Ala12 allele lost more weight than subjects with the other genotypes, although a significant higher weight regain was achieved during subsequent follow-up (12 months) in carriers of the Ala12 allele in comparison with the Pro12 homozygotes (Lindi et al., 2002).

These observations suggest that a general distinction should be made between genetic factors affecting weight loss *per se* and weight loss maintenance. Thus, also, it has been shown that a IL-6 polymorphism (−174 G > C) may influence weight regain after a weight-lowering program based on a energy-restricted diet, which may interact the Pro12Ala polymorphism of the PPARγ gene (Goyenechea et al., 2006). On the other hand, no significant differences in weight reductions linked to the genotype were detected, in the subjects carrying risk genotypes in the IGF-1R, IRS-1 and IRS-2 genes after lifestyle interventions (Moreno-Aliaga et al., 2005). However, a reinforced effect on weight loss with the presence of both the Gly972Arg polymorphism of the IRS-1 gene and Trp64Arg polymorphism in the ADRB3 gene in women who underwent a formal weight-loss program was described (Benecke et al., 2000).

In the Finnish DPS, it was found that subjects with the G-250G promoter polymorphism of the HL gene (LIPC) tended to loss less weight than subjects with the −250A allele both in the control and in the intervention group (Todorova et al., 2004). In addition, having the G-250G genotype predicted the conversion from impaired glucose tolerance to Type 2 diabetes independently of weight at baseline and weight change. Furthermore, numerous polymorphisms of the apolipoprotein B gene have been described, which have been accompanied by alterations in lipid metabolism (Bosse et al., 2004). A meta-analysis indicated that the apoB EcoRI and MspI polymorphisms are associated with responsiveness to diet. A study investigating the effects of apoA-IV genotype during weight loss found that subjects with apoA-IV-1/2 lost more weight than apoA-IV-1/1 subjects. On the contrary, it was found by others no significant differences in weight loss between both genotypes, although subjects with the apoA-IV-1/1 genotype showed a higher increase in HDL-C after in response to weight loss compared to the apoA-IV-1/2 subjects. Also the potential relationship between the PAI-1 promoter 4G/5G genotype and weight loss on the fibrinolytic system and lipid parameters in obese children was assessed and after a 3-month period of treatment (nutritional counseling and physical activity). A decrease in PAI-1 levels was observed in obese children, who have reduced their BMI in comparison with those obese children who did not decrease their BMI (Estelles et al., 2001). On the other hand, a behavioral interventional activity in obese carriers of the Trp64Arg polymorphism of the ADBR3 gene demonstrated difficulties in losing weight (Shiwaku et al., 2003).

Additionally, a large scale European intervention trial (NUGENOB) concerning the comparison of the impact of more than 40 genetic polymorphisms on weight loss revealed that much work is required to be performed in this area (Sorensen et al., 2006). Other studies have been reported, by using microarrays, that mRNA levels (gene expression) could be affected by the energy restriction, but not apparently by the composition of the hypocaloric diet (low versus moderate fat content), suggesting that more research is needed in this field (Viguerie et al., 2005b).

2009 UPDATE

Obesity is nowadays considered as the result of a dysregulation of energy homestasis inducing excesive weight gain and fat deposition, which is explained in most cases by the interactions of the genetic background with inadequate dietary habits, physical inactivity, especific diseases, drug-side effects, etc (Ichihara and Yamada, 2008; Marti et al., 2008).

Current ongoing genome-wide association scans are yielding new loci and chromosomical regions related with measures of obesity (Thorleifsson et al., 2009). Such studies are also facilitating the detection and interpretation of the role of single nucleotide polymorphisms and common copy number variations, as well as epigenomic phenomena such as DNA methylation, histone modifications leading to chromatin remodelling and regulation of gene expression patterns that underlie the developmental programming of obesity and metabolic syndrome features (Campion et al., 2009b; Herbert, 2008; Junien and Nathanielsz, 2007). All such variations have a potential impact on genomic medicine.

In this context, new candidate genes and novel variants involved in obesity physiopathology such as FTO (Qi et al., 2008), MC4R (Krakoff et al., 2008), interleukin-15 (Nielsen et al., 2008), adiponectin (Goyenechea et al., 2009a), etc., have been described.

Further, the developments and advances in high-throughput genomics tools and –omics technologies such as proteomics, metabolomics, epigenomics, transcriptomics and integrative system biology approaches are having an impact on predicting obesity related outcomes (Mutch et al., 2008) and providing new views concerning the role of the adipose tissue and adipokines (Dahlman and Arner, 2009; Herbert, 2008), inflamation and oxidative stress factors (Crujeiras et al., 2008a; Goyenechea et al., 2008), mitocondrial functions (Højlund et al., 2008) and metabolic efficiency (Sorensen., 2008) among others, which will contribute to "personalize" medicine and nutrition (Goyenechea et al., 2009b).

Upcoming new molecular procedures devised to transfer specific genetic material (Cordero et al., 2008) as well as the development of powerful mRNA profiling protocols (Capel et al., 2008; Crujeiras et al., 2008b; Goyenechea et al., 2009b), microRNA analyses (Lovis et al., 2008) and methylated DNA measurements (Campion et al., 2009a) are enabling us to assess and characterize different cell functions and mechanisms under genetic or epigenetic regulation concerning genes such as PPAR, sirtuins, TNF-alfa, etc., which are contributing to identify new pharmacogenetic and nutrigenomic targets (Crujeiras et al., 2008b; Goyenechea et al., 2009b) based on the genotype and, therefore, to a more "individualized" and genomic style of medicine.

CHAPTER

Diabetes

Maggie Ng and Nancy J. Cox

INTRODUCTION

Diabetes mellitus is a group of metabolic disorders characterized by high blood glucose levels resulting from defects in insulin secretion, insulin action or both. Chronic high blood glucose levels are associated with long-term tissue damage, dysfunction and failure of various organs especially the eyes, kidneys, nerves, heart and blood vessels. The most common forms of diabetes are type 1 diabetes, in which autoimmune destruction of the insulin-secreting pancreatic β-cells leads to an absolute insulin deficiency (or complete absence of endogenous insulin), and type 2 diabetes, which is characterized by a relative deficiency of insulin attributable to defects leading to insulin resistance, defects in insulin secretion, or both. Type 1 diabetes commonly arises in childhood or adolescence, and the lifetime risk of type 1 diabetes in US populations of European descent is about one in 250 (0.004), but lower in US populations of recent Asian, African or Native American ancestry. Type 2 diabetes is more frequently diagnosed in late adulthood and is far more common, with 8–10% of Americans of European descent diagnosed with type 2 diabetes by age 60. Age-specific rates of type 2 diabetes are even higher in some US populations, including African Americans, Mexican Americans and Native Americans, and there are alarming increases in the incidence of type 2 diabetes in younger Americans, due at least in part to increasing levels of obesity in the United States coupled with increasingly sedentary lifestyles (Narayan et al., 2003).

Some 1.6 million Americans have been diagnosed with type 1 diabetes and more than 16 million Americans with type 2 diabetes. And for many of these individuals, their family members are at a substantially increased risk relative to the population average; for example, sibs of a patient with type 1 diabetes have a 15-fold increased risk of disease (i.e., $\lambda_s = 15$), while sibs of a patient with type 2 diabetes have a 1.8–2.8-fold increased risk of disease (i.e., $\lambda_s = 1.8–2.8$) (Rich, 1990). Thus, because it is easy and inexpensive to diagnose, common and familial, diabetes has long been a model for exploring the genetic basis of complex disorders – those that cluster in families but do not have simple patterns of transmission (Florez et al., 2003). In addition, given especially the incidence of type 2 diabetes in the general adult population and the expectation that one or more genetic variants could alter individual risk of disease, it has become an attractive candidate for early thinking about the introduction of genetic and genomic concepts into medical practice.

Despite the efforts of many investigators over many years, though, association studies at candidate genes and genome-wide linkage studies have, until very recently, yielded only a small number of loci having genetic variation reproducibly shown to affect risk of either type 1 or type 2 diabetes. Prior to recent GWAS (see Chapter 4), susceptibility loci for type 1 diabetes with broad support over multiple studies included the HLA region, with primary determinants thought to be variation at the *HLA-DRB1*, *-DQA1* and *-DQB1* loci (Davies et al., 1994), the insulin gene (*INS*) (Bell et al., 1984), the gene for cytotoxic T-lymphocyte associated protein 4 (*CTLA4*) (Ueda et al., 2003) and the protein tyrosine phosphatase-22 gene (*PTPN22*) (Bottini et al., 2004). All of these were originally identified through candidate gene studies. With respect to linkage, in a large type 1 diabetes

consortium dataset with 1435 multiplex families (Concannon et al., 2005), the significance of the evidence for linkage at the HLA region was quite dramatic, at $p < 2 \times 10^{-52}$, with the next best region located near *CTLA4*, with $p < 9 \times 10^{-5}$. Two other regions with notable evidence for linkage were 10p14-q11 with $p < 1.2 \times 10^{-4}$, and 16q22-q24 with $p < 4.9 \times 10^{-4}$. In contrast, there was only modest evidence for linkage at *INS*, and loci with relatively modest sibling risk ratios could be excluded from much of the rest of the genome ($\lambda_s > 1.3$ excluded from 82% of the genome; $\lambda_s > 1.5$ excluded from 95% of the genome).

Results of early candidate gene association studies as well as linkage and positional cloning studies in type 2 diabetes had yielded a similar paucity of genes and regions with widely reproducible linkage or association (for a recent review, see Permutt et al., 2005). Although a number of candidate genes, including candidates derived on the basis of effective treatments for type 2 diabetes such as *KCNJ11* and *PPARG*, had been validated through large-scale meta-analysis (Altshuler et al., 2000; Gloyn et al., 2003), the vast majority of candidate gene studies in type 2 diabetes had not yielded reproducible associations. Similarly, while a few linkage studies yielded positionally cloned genes with at least some support from other studies, including *CAPN10* (Horikawa et al., 2000) and *HNF4A* (Love-Gregory et al., 2004; Silander et al., 2004), only *TCF7L2* (identified by investigators at deCode in Iceland in positional cloning studies based on one of their best conditional linkage signals [Grant et al., 2006]) has been widely replicated in multiple populations (Cauchi et al., 2006; Groves et al., 2006).

As predicted by Risch and Merikangas (1997), GWAS have allowed identification of genetic risk factors with relatively modest effects while preserving the utility of the genome-wide context. The first of the GWAS in diabetes were published in 2007, and to date, some 10 such studies have been published for type 2 diabetes (Diabetes Genetics Initiative, 2007; Florez et al., 2007; Hanson et al., 2007; Hayes et al., 2007; Rampersaud et al., 2007; Salonen et al., 2007; Scott et al., 2007; Sladek et al., 2007; Steinthorsdottir et al., 2007; Zeggini et al., 2007), while three GWAS (Hakonarson et al., 2007; Smyth et al., 2007; WTCCC, 2007) and a follow-up study (Todd et al., 2007) have been published for type 1 diabetes.

These studies have enabled the identification of new genetic risk factors for both disorders and have provided valuable additional context for understanding the relative importance of some of the previously identified risk factors. For example, *TCF7L2*, identified originally through positional cloning studies in an Icelandic sample (Grant et al., 2006), is clearly the largest individual genetic risk factor for type 2 diabetes, at least in type 2 diabetes cases from northern Europe. Similarly, HLA remains the undisputed major genetic risk factor for type 1 diabetes (WTCCC, 2007); as with the linkage studies, no other association comes close to the magnitude of effect detected at HLA. For both disorders, outside the locus with the largest individual effect, the remaining genetic risk factors have quite modest odds ratios (OR), with a few for type 1 diabetes being near 2.0, but most in the range of 1.1–1.2. Moreover, there are clearly many additional genetic risk factors to be identified, as the established genetic risk factors account for only a small proportion (2.3%) of the inter-individual variation in genetic risk for type 2 diabetes and just over half of the variation in genetic risk for type 1 diabetes (due mostly to the large effects in the HLA region). Given that the genetic risk factors yet to be identified are unlikely to have much larger effects than those already identified, but rather are likely to be of similar magnitude or smaller, it is clear that more studies, larger studies, or more sophisticated or novel approaches will be needed to identify additional loci and allow us to achieve a more comprehensive understanding of the genetic risk factors for diabetes.

Indeed, it could be argued that the loci identified to date have added little to our fundamental understanding of the genetic component to either type 1 or type 2 diabetes. That is, type 1 diabetes was already known to be an autoimmune disease, and genetic risk factors identified to date merely confirm the importance of genes involved in T-lymphocyte development, regulation of the immune system and tolerance. Similarly, genetic risk factors identified to date for type 2 diabetes have provided no more insight than we have ever had toward a comprehensive understanding of its fundamental biological basis. Indeed, the more pessimistic viewer might reasonably argue that the modest effect sizes observed to date are the "big" ones – that whatever additional genetic risk factors are identified will have such modest effects as to be nearly indistinguishable from background loci and thus of limited scientific or clinical value.

So, is the glass already half full and filling fast with diabetes susceptibility genes that will provide us that elusive and comprehensive understanding of the genetic component to diabetes? Or is the glass, at best, half empty, with little likelihood of filling no matter how much money we spend at the tap? As with almost all of the earlier genetic research in complex disorders, including candidate gene and linkage mapping studies, the GWAS in diabetes have been among the first, and are certainly among the most numerous with large sample sizes, to be conducted on complex traits; thus, the answers to these questions have implications not only for type 1 and type 2 diabetes, but for other complex disorders as well. In order to address these questions, it is important to examine critically the studies that have been conducted to date and to review what we have learned from them.

GWAS IN TYPE 2 DIABETES

The GWAS for type 2 diabetes have been conducted in a variety of populations, using a variety of study designs and high-throughput platforms. Studies on type 2 diabetes using the first generation GWAS platforms (e.g., the Affymetrix 100K single nucleotide polymorphism [SNP] platform) were quite expensive and consequently included relatively modest numbers of samples. The low sample sizes coupled with the low density and high redundancy of the 100K platform precluded any of the studies on the 100K platform from identifying loci with genome-wide significant associations (Florez et al., 2007; Hanson et al., 2007; Hayes et al., 2007; Rampersaud et al., 2007).

TABLE 52.1 Samples, study designs and SNP genotyping platforms used in dense GWAS for type 2 diabetes published in 2007

Study	Samples	Design	Platform	Follow-up
Sladek et al. (2007)	French 690 cases 660 controls	Case/control Lean cases	Illumina 300K + 100K	57 SNPs 2617 cases 2894 controls
Steinthorsdottir et al. (2007)	Icelandic 1399 cases 5275 controls	Case/control	Illumina 300K	47 SNPs 1110 cases 2272 controls
Scott et al. (2007)	Finns 1161 cases 1174 controls	Case/control	Illumina 300K	80 SNPs 1215 cases 1258 controls
Diabetes Genetics Initiative (2007)	Finns 1464 cases 1467 controls	Case/control and family BMI matched	Affymetrix 500K	107 SNPs 5065 cases 5785 controls
WTCCC (2007)	English 1924 cases 2934 controls	Case/control	Affymetrix 500K	21 + 56 SNPs 2022 cases 2037 controls
Salonen et al. (2007)	European 500 cases 497 controls	Case/control	Illumina 300K	10 SNPs 2573 cases 2776 controls

This situation changed dramatically with the availability of higher density SNP platforms, and Table 52.1 summarizes population, sample size and study design information for the studies published in 2007 and conducted using the denser SNP genotyping platforms on type 2 diabetes. The scans conducted using sufficiently dense platforms to be considered truly genome-wide have been focused exclusively on populations of recent European descent, primarily northern European populations, and it is only in these dense scans on very large samples that loci meeting genome-wide criteria for significance have been identified and confirmed (Table 52.2). Some studies utilized only lean cases (Sladek et al., 2007), matched cases to controls on the basis of body mass index (BMI) (Diabetes Genetics Initiative, 2007), or conducted analyses separately in lean and obese cases (Steinthorsdottir et al., 2007). Many of the studies enhanced power by utilizing cases with a family history of disease in their primary screen, their follow-up studies, or both.

The varying designs have led to intriguing differences in results that help to extend the observed associations. For example, although most studies have reported the OR for *TCF7L2* to be in the range of 1.35–1.4 even within studies in which cases were chosen to have a positive family history of type 2 diabetes, Sladek et al. (2007) estimated the OR for *TCFL2* to be 1.65. This higher estimate may be attributable to the use of lean cases, as the allele at *TCF7L2* increasing risk of type 2 diabetes is associated with lower BMI in both cases and controls; thus lean cases are likely to be particularly enriched for individuals carrying the high-risk allele for type 2 diabetes at *TCF7L2*. Similarly, while the *FTO* locus was easily detected in the WTCCC study and was also apparent in the FUSION study, it had little signal in the DGI study, largely because the DGI study matched cases and controls on BMI. As *FTO* appears to affect risk of type 2 diabetes primarily through its effects on obesity and BMI, the failure to detect the effects of *FTO* in the DGI sample is easily understood; conditioning on BMI similarly reduced the *FTO* effects in the WTCCC samples (Frayling et al., 2007).

The confirmed loci for type 2 diabetes listed in Table 52.2 have little in common with respect to known function, although the risk allele at several of the susceptibility loci (*TCF7L2*, *CDKAL1*, *SLC30A8*) has been shown to be associated with reduced insulin secretion. Clearly, however, considerable additional research into the physiological basis of the risk imparted by the genetic variation at these loci is necessary. Moreover, it is clear we have barely begun to identify genetic risk factors for type 2 diabetes. The WTCCC group noted that the combined effects of all of the risk factors identified in the combined samples of the DGI, FUSION and WTCCC studies together would yield an estimate of λ_s of 1.07 (WTCCC, 2007), which contrasts substantially with the overall λ_s value for type 2 diabetes estimated to be in the range of 1.8–2.8. Investigators from the DGI study noted that the eight loci identified in the combined DGI, FUSION and WTCCC studies account for only about 2.3% of the overall variance in type 2 diabetes risk among individuals (Diabetes Genetics Initiative, 2007). In addition, OR are modest overall and can be quite low within any individual study. As indicated in Table 52.2, the maximum OR for most loci is less than 1.2 and most of these loci have sufficiently low OR in at least one study that the locus did not meet the study's threshold for reporting the result.

TABLE 52.2 Confirmed susceptibility loci/regions for type 2 diabetes

Locus	Chromosome	Odds ratio (range across studies)	Risk allele frequency (controls)
TCF7L2	10	1.34–1.71	0.30
SLC30A8	8	1.01[a]–1.18	0.70
CDKAL1	6	1.16[a]–1.20	0.32
HHEX	10	1.15[a]–1.13	0.58
PPARG	3	1.02[a]–1.20	0.86
CDKN2A/B	9	1.12[a]–1.17	0.83
KCNJ11	11	1.14[a]–1.15	0.45
IGF2BP2	3	1.12[a]–1.18	0.32
FTO	16	1.03[a]–1.23	0.40

[a]Lowest value found, but the lowest OR could not be determined because some studies did not report all results, and the locus indicated did not have OR greater than the threshold for reporting in at least one study.

As has been found in GWAS for other complex traits, most of the alleles associated with increased risk of type 2 diabetes are located in non-coding sequence without obvious function (sometimes between genes, sometimes within introns), a notable exception being an amino acid polymorphism in *SLC30A8*. Even when the associated allele is within an intron of a gene, however, we should be cautious about ascribing risk to the gene in which the SNP resides, and it is clearly premature to ascribe the function of a SNP between genes to the closest gene based only on physical proximity. It is possible that at least some of the risk alleles affect expression of genes outside the one in which they are located or near and may well exert their effects through a gene or genes on other chromosomes. Thus, it may be prudent to continue to refer to these as susceptibility loci rather than as susceptibility genes.

It is also notable that many of the loci with confirmed associations have very common risk alleles (i.e., the frequency of the risk allele is greater than 0.5). While no one has claimed that the polymorphisms identified to date are the actual causal alleles driving the observed associations, it is unlikely that the true susceptibility alleles will be very different in frequency from those already identified. Even with D' of 1.0 between the tag SNP and the causal variant, differences in allele frequencies of the causal and associated alleles would reduce the r^2 value between them sufficiently to degrade the power to detect the association.

The observation that the risk allele is the more common allele for several of the confirmed associations raises the possibility that it is the ancestral allele (i.e., the allele fixed in other primate species) at the causal site that increases risk of disease, with a more recent mutation at that site (i.e., the derived allele) reducing risk relative to the ancestral state. As noted by Di Rienzo and Hudson (2005), quite a number of the polymorphisms confirmed to affect risk to common disorders have ancestral susceptibility alleles. For any biallelic polymorphism there is always one allele that increases and one allele that decreases risk relative to the other, and thus characterization of a susceptibility locus as a "risk" locus or a "protective" locus is often made in arbitrary ways. Considering risk versus protection in the context of ancestral versus derived alleles can substantially improve our understanding of associations. Patterns of variation in the vicinity of susceptibility loci with ancestral susceptibility alleles can be quite different from expectations shaped by the more familiar Mendelian paradigm in which alleles increasing risk of disease are the rare, recent mutations. Accordingly, geneticists may need to revamp their thinking to correctly interpret results of association studies involving such loci.

While it is undeniably exciting to have identified so many susceptibility loci for type 2 diabetes, what we have is still far from the comprehensive understanding of the genetic component to type 2 diabetes that we seek. Given the sample sizes (on the order of 40,000 cases and 40,000 controls for all dense-platform studies combined) and total resources necessary to make the discoveries summarized in Table 52.2, it is daunting to consider what it might take to identify additional susceptibility loci.

FUTURE RESEARCH IN TYPE 2 DIABETES GENETICS

There would clearly be value in combining results across all of the dense GWAS carried out to date. Fortunately, the long-standing collegiality of the diabetes genetics community continues to flourish, with the early collaboration of the DGI, FUSION and WTCCC groups providing an outstanding example of the value of collaborative science in the GWAS era, and it is likely that combined results from all available GWAS in type 2 diabetes will be completed in the near future. In addition to those that have been published, dense GWAS have been conducted in the Framingham cohort (>9000 samples), and in smaller Chinese and Korean samples, and are underway in Pima Indian, Mexican American and African American samples, as well as a variety of additional populations of European descent. If combined analyses can be conducted with even the GWAS that will be available in 2008, it is likely that additional susceptibility loci for type 2 diabetes can be identified.

Notably, studies completed by mid-2008 will provide additional context for the susceptibility loci that have been identified largely in northern European populations, as GWAS in many other populations will be available. Among these additional populations are some in which cases are likely to be leaner than those in northern European populations (e.g., Chinese, Korean), as well as some in which cases are likely to be more obese and insulin resistant than those in northern European populations (e.g., Mexican Americans, African Americans, Pima Indians). The similarities and differences in susceptibility loci detected in these populations may provide more insight into the genetic component of diabetes by highlighting different pathways or parts of pathways in different populations. For example, it is unlikely that *TCF7L2* will be the most significantly associated susceptibility locus in the Chinese, Korean, Pima or Mexican Americans populations, because the allele increasing risk at *TCF7L2* has much

lower frequency in Asian and Native American populations. In addition, as summarized in Table 52.2, only very modest numbers of SNPs have been included in follow-up studies conducted in GWAS on type 2 diabetes to date. Deeper follow-up may well lead to the identification of additional susceptibility loci as well.

But it should not be necessary to rely solely on more studies in more samples to identify additional susceptibility loci for type 2 diabetes. It may be possible to use various types of "enrichment" analyses to determine whether the top signals are enriched for SNPs within genes in certain pathways or within genes associated with particular biological processes. Such analyses are challenging for a number of reasons. While our signals come as SNPs, these bioinformatics analyses require gene lists. As noted above, it may be perilous to annotate SNPs to genes without knowing what the causal polymorphisms actually are. Moreover, even if causal SNPs have been identified, those SNPs may lie outside genes and/or may affect the expression of genes outside the gene in which they are located. Additional studies on the association of genetic variation to expression phenotypes in tissues relevant to type 2 diabetes may help to annotate SNPs to genes for downstream bioinformatics studies. Regardless, enrichment analyses should be conducted in a way that explicitly allows for the uneven interrogation of genes that inevitably occurs even with dense SNP genotyping platforms. For example, genes might be weighted for bioinformatics enrichment studies according to the proportion of known variation that is interrogated on the platform used for analysis.

Potential Clinical Utility

Ideally, the accumulation of additional dense GWAS and the thoughtful application of bioinformatics approaches to these data will enable the identification of a sufficient number of type 2 diabetes susceptibility loci to obtain a better understanding of the nature of the genetic component to type 2 diabetes in all populations. What will the clinical utility of this information be? Type 2 diabetes is one of the few disorders in which there are confirmed associations in genes relevant to the mechanism of drug action for some of the drug therapies used to treat diabetes. This certainly raises the possibility that the identification of additional susceptibility loci will lead to discovery of new drug therapies for this disorder. It has also been argued that if we identify enough of the genetic risk factors, we may be able to develop sufficiently accurate predictive models to permit risk reduction (through behavior modification or even drug therapies) in those with the highest risk of disease.

The problem with that idea is that we already have good models for predicting the risk of type 2 diabetes, and it is unclear that the inclusion of genetic risk factors will improve risk prediction any time soon, if at all (Wilson et al., 2007). These models use a variety of inexpensively measured complex traits (lipid levels, BMI, family history) that are likely to share some of both their genetic and their non-genetic determinants with type 2 diabetes. Thus, knowing the *overall* genetic risk is not really necessary to develop accurate predictions of risk for type 2 diabetes. Nonetheless, it is certainly possible that knowing *specific* genetic risk factors that an individual carries may help determine the most appropriate therapy for that individual. Thus, clinical trials of diabetes therapies should be incorporating information on genetic risk factors as quickly as associations become replicated. It is also possible that knowledge of the specific genetic risk factors will allow us to conduct more targeted epidemiological studies to identify non-genetic risk factors more specific than "Western diet and lifestyle" that increase risk of type 2 diabetes. These more specific non-genetic risk factors may be cost-effective targets for interventions that could prevent, or at least delay onset of disease.

GWAS IN TYPE 1 DIABETES

The first GWAS to be published for type 1 diabetes was a survey of 6500 non-synonymous SNPs conducted in 2029 cases and 1755 controls (Smyth et al., 2006). In addition to confirming the previously known association at *PTPN22*, a SNP at the gene *interferon induced with helicase C domain 1*, *IFIH1,* was found to be strongly associated with type 1 diabetes in both the original and the replication samples of 2471 cases, 4593 controls and 2134 parent–child trios. Subsequent GWAS used dense SNP genotyping platforms to assess the entire genome for type 1 diabetes susceptibility loci. Hakonarson et al. (2007) reported results of a GWAS for type 1 diabetes conducted using the Illumina 550K SNP set on 563 cases, 1163 controls and 483 complete trios for primary analysis and 939 families including at least a trio for follow-up studies. Their studies confirmed associations at HLA, *INS* and *PTPN22*, and identified variation at KIAA0350 as contributing risk to type 1 diabetes.

The initial genome-wide screen in the WTCCC (2007) included ~2000 cases with type 1 diabetes and ~3000 controls unphenotyped with respect to type 1 diabetes. These studies also confirmed the previous associations at HLA and *PTPN22*, and provided independent support for recent reports implicating variation at *CD25*. Subsequent studies reported on both follow-up to the findings in the WTCCC studies and follow-up to a study of 13,378 non-synonymous SNPs in 3400 cases and 3300 controls, with the follow-up being conducted in 4000 cases, 5000 controls and 2997 trios (Todd et al., 2007). Based on the initial WTCCC genome-wide studies, 11 SNPs from regions with $p < 1.64 \times 10^{-5}$ and not previously implicated in type 1 diabetes were genotyped in all of the follow-up samples. Four of these regions yielded compelling replication of association: a region on 18p11 in which *PTPN2* was the only gene, a region on 12q24 in which a single non-synonymous SNP in *SH2B3* was sufficient to model the observed association, the 16p13 region containing KIAA0350, and the 12q13 region, in which a SNP near *ERBB3* was the most strongly associated SNP. They also followed up 14 SNPs from the non-synonymous screen, which provided replication for a SNP in the T-lymphocyte co-stimulation gene *CD226* as well as for SNPs in *CAPSL, C20orf168*, *IL7R* and *CFTR*.

The results of genetic studies in type 1 diabetes provide a more cohesive picture of the genetic risk factors for this autoimmune disease. Genes involved in T-cell development, immune regulation and recognition of pancreatic autoantigens all appear to play a role in the development of type 1 diabetes. As with type 2 diabetes, very large samples were required to identify and confirm these

susceptibility loci. OR for HLA approach 7, and for *INS* and *PTPN22* are around 2.0, but are between 1.2 and 1.3 for many of the other loci that have been identified. Thus, the initial screens were only modestly powered to detect effects at these loci.

FUTURE STUDIES IN TYPE 1 DIABETES

The clinical utility of genetic risk factors identified for type 1 diabetes rises considerably if it becomes possible to reduce the likelihood that individuals with high risk of developing type 1 diabetes actually develop the disease. Good predictive models for type 1 diabetes risk remain elusive, however, and we still lack understanding of the non-genetic triggers for type 1 diabetes. Thus, one may also harness genetic risk factors to improve epidemiological studies targeting identification of specific non-genetic risk factors for type 1 diabetes. While gene–environment interaction complicates the identification of genetic risk factors, it can be an ally for clinical studies, as only one element of the interaction need be disrupted to reduce the entire risk due to the interaction. Thus, prevention strategies might also focus on non-genetic risk factors that interact with genetic risk factors.

CLINICAL UTILITY OF GENETIC RESEARCH IN DIABETES

The most immediate clinical utility of the genetic research in diabetes relates to the ability to use genetic information to improve the quality of diagnosis with respect to the particular subtype of diabetes, which in turn can have profound implications for how patients should be treated. The most dramatic examples of altered diagnosis and treatment regimens relate to the subset of individuals who have been diagnosed with type 1 diabetes at a very early age (usually before 6 months of age), and therefore treated with insulin. Individuals diagnosed with diabetes at this early age are more likely to have a rare Mendelian form of diabetes called permanent neonatal diabetes (PND). The most common cause for PND is mutation at *KCNJ11* within Kir6.2, the inwardly rectifying ATP-sensitive potassium channel. These patients can be safely and more effectively treated with sulfonylureas (taken orally) than with insulin (Pearson et al., 2006), and this change in treatment regimen dramatically alters the lifestyle of patients for the better.

As with the rare monogenic forms of diabetes, we expect that better understanding of the genetic risk factors for diabetes will ultimately lead to new drugs targeting the new genes and pathways that are identified, ultimately leading to more individualized therapies based on primary etiology of disease. Pharmacogenetic studies are providing insights into other ways of individualizing therapies. For example, recent studies (Shu et al., 2006) indicate that genetic variation at *OCT1* may contribute to interindividual variation in response to metformin, a commonly used agent for treatment of diabetes. *OCT1* (organic cation transporter 1) has a role in hepatic uptake of metformin and thus was a candidate gene for generating such effects. The coming years are likely to see more direct investigation of pharmacogenetic effects for drugs used to treat diabetes, and translation of these findings will also personalize diabetes treatment.

2009 UPDATE

The past year has seen continuing advances in efforts to identify and better understand the genes and variants that contribute to the development of diabetes.

Genetics of Type I Diabetes

On the basis of linkage studies and candidate gene studies, at least two dozen genes have now been implicated in type I diabetes (Concannon et al., 2009). Overwhelming evidence supports a clear role for genes in the HLA region on chromosome 6 (notably *HLA-DR* and *–DQ*, but also the gene for insulin, *INS*), with only modest effects on individual risk reported for genes elsewhere in the genome. While the odds ratio reported for HLA is nearly 7 and variants at *INS* and *PNPN22* have odds ratios near 2, the rest of the variants implicated in type I diabetes have reported only modest odds ratios in the range of 1.1–1.3. Nonetheless, most of the implicated genes have reported functions in immunity, suggesting potential pathways for further functional analysis (Concannon et al., 2009).

A large genome-wide association study involving over 7500 cases and 9000 controls raised the estimate to some 41 genetic loci with evidence for association (Barrett et al., 2009). In addition to confirming known susceptibility loci, 18 regions were newly replicated in a further study of 4200 cases and 4500 controls. Among the new candidate genes implicated by this study were *IL10, IL19, LGIS3, CD69* and *IL27*. As in previous studies, odds ratios were reported to be modest.

In a landmark study for identifying causal variants, Todd and colleagues took a candidate gene resequencing approach to search for sequence variants that are rare in the general population, but that reside close to SNP variants implicated by association studies (Nejentsev et al., 2009). They resequenced exons and splice sites from 10 candidate genes in DNA from nearly 500 patients with type 1 diabetes. They reported four rare variants in the *IFIH1* gene, a gene located in a genomic region previously implicated by genome-wide association studies.

Genetics of Type 2 Diabetes

As compiled by Florez (2008), at least 17 genetic loci have now been implicated in type 2 diabetes on the basis of genome-wide association studies involving more than 10,000 individuals. While the associated SNPs are relatively common in those of European ancestry, the reported contributions to risk are, as in type 1 diabetes, quite modest, in the range of ~1.1–1.2 (Florez, 2008; Zeggini et al., 2008). The one confirmed exception to this is variation in the *TCF7L2* gene, with a reported odds ratio of ~1.5. Several other useful reviews of genome-wide association studies have also appeared in the last year (Prokopenko et al., 2008; Ridderstrale and Groop, 2009).

Several large cohort studies have explored the ability of such variants to predict diabetes in a clinical setting. To examine the combined effect of multiple variants, Cornelis et al. (2009) carried out a nested case-control study of over 2800 patients and 3500 healthy controls, all of European ancestry, studying a total of 10 polymorphisms in 9 loci known to be associated with type 2 diabetes. The combined "genetic risk score" resulted in odds ratios ranging from ~0.5 to ~2.0 for different groups of patients, but such scores improved individual risk prediction only slightly beyond conventional risk factors such as BMI, family history, smoking and physical (in)activity. Nonetheless, for the 20% of the population with the highest genetic risk score, the authors conclude this score may be useful for identifying those at highest risk (Cornelis et al., 2009).

In addition, Lyssenko et al. (2008) studied 16 SNPs associated with type 2 diabetes risk, together with clinical factors, in a prospective cohort of over 16,000 Swedish and 2779 Finnish subjects. Over 2200 subjects developed diabetes over a follow-up period of about two decades. Variants in 11 genes were associated with risk of progression to diabetes, with 8 of the genes known to be involved in beta-cell function. Again, however, the addition of specific SNP information only modestly improved the prediction of future diabetes over conventional clinical risk factors (Lyssenko et al., 2008).

All of these variants are likely to contribute to our understanding of the biological underpinnings of this complex disease and may even help to stratify populations into different subtypes beyond simply "type 1" and "type 2". However, it still remains unclear how these variants will contribute to the clinical evaluation and treatment of patients who are at risk. The clinical utility of genetic variation that predisposes to (or protects from) diabetes remains to be fully established. (*Update prepared by editors*)

CHAPTER

Genetics and Genomics of Dementia

Robert L. Nussbaum

INTRODUCTION

Dementia is a serious and growing problem as the average age of the population increases. As one example, the over-65 population of Canada has more than doubled over the past 70 years, from 5% to 12% of the population, while the fraction of the population over age 85 has quadrupled, from 0.2% to 0.8% (Hogan and Hogan, 2003); a similarly aging population is found throughout the developed world. The number of dementia patients is rising proportionately to the aging of the population, placing a tremendous economic and emotional burden on their families and society. Dementia is a serious problem in younger individuals as well, with an estimated half-million individuals under age 65 afflicted in the United States alone (Maslow, 2006). There is a clear need to understand the causes of dementia, to determine their pathogenetic pathways, and to develop methods to intervene to prevent or delay the onset.

Dementia is a clinical syndrome, defined as a progressive impairment of cognitive function, particularly in the areas of memory, judgment, decision-making, attentiveness when communicating with others, orientation to familiar surroundings, and language (Dugue et al., 2003). Many different diseases with different pathological processes cause dementia. In 30% of cases, the dementia is secondary to systemic disease such as hypertension or atherosclerosis, leading to vascular-occlusive dementia with multiple small infarcts (Barker et al., 2002). Other secondary causes include paraneoplastic syndromes, alcoholism, and AIDS (Dugue et al., 2003). The majority of cases, however, reflect primary dementia; among these, the different forms can be roughly divided into two general categories based on pathological appearance of the postmortem brain: those with neurodegeneration and aggregates of protein, and those with vascular-occlusive disease and infarction. Many elderly individuals who die with dementia, however, have both vascular pathology and protein aggregation findings at autopsy.

More than half of all primary dementia is due to Alzheimer disease (AD). Another 10% of dementia is due to diffuse Lewy body disease (DLBD), which presents as a dementia clinically similar to AD but is associated with the characteristic intracellular protein aggregates referred to as Lewy bodies (Lippa et al., 2007). Finally, there are a number of early-onset, autosomal dominant hereditary dementias, ranging from the relatively common, such as frontotemporal dementia (FTD), to the rare, such as CADASIL and the prion diseases (Figure 53.1).

Minimal cognitive impairment (MCI) is a term used to describe individuals with mild difficulty with one component of cognition, such as short-term memory ("amnestic MCI") (Dugue et al., 2003). Between 10% and 15% of amnestic MCI patients progress each year to true dementia, usually of the AD-type, which is five- to seven-times greater than the rate at which dementia occurs in a group of age-matched elderly without MCI (Petersen et al., 1995).

Essentials of Genomic and Personalized Medicine

In this chapter, we focus on the various forms of primary dementia. We will describe the clinical features, incidence, and what is known about the underlying genetic bases for these diseases. The underlying pathophysiology leading to neuronal cell death is not completely understood for any of the primary dementias, but protein aggregation in or around neurons is a striking feature that is in common among nearly all the primary dementias (CADASIL being the exception, where protein aggregates occur in blood vessels, leading to micro-infarcts).

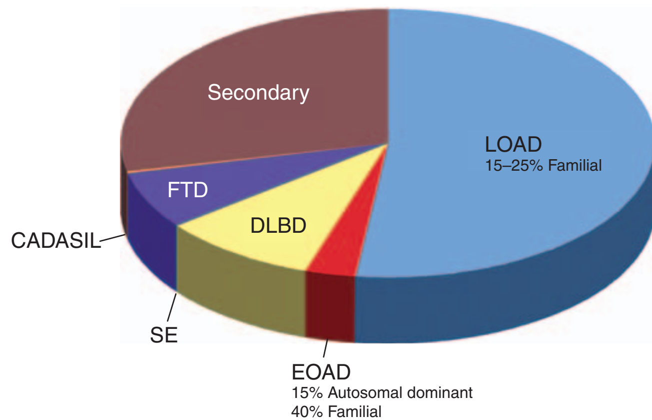

Figure 53.1 Relative contributions of various causes of dementia to the overall population burden of disease. LOAD: late-onset Alzheimer disease; EOAD: early-onset Alzheimer disease; FTD: frontotemporal dementia; DLBD: diffuse Lewy body disease; SE: spongy encephalopathy (prion disease); CADASIL: cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy. Figures are approximate.

INCIDENCE OF DEMENTIA

Over 95–98% of all dementias occur after age 65, an age that is often cited as the arbitrary dividing line between early- and late-onset diseases. Early-onset dementias (i.e., those that occur before the age of 65) are rare and have an incidence of approximately 2–5 per 1000 person-years in the age group 55–64 (Knopman et al., 2006; Maslow, 2006), whereas the incidence of dementia over the age of 65 is approximately 20 per 1000 person-years. The incidence of dementia increases steadily with increasing age, from nearly 5 per 1000 in the 65–69-year-old group to over 84 per 1000 person-years in individuals over 90 (Kukull and Ganguli, 2000; Kukull et al., 2002) (Figure 53.2). Over age 65, well over 95% of dementia is primary, caused by one of the neurodegenerations (principally AD) described in this chapter, or is secondary to vascular-occlusive disease of the brain (McMurtray et al., 2006). In contrast, below age 65, only 70% of dementia is either neurodegenerative or vascular in origin.

PRIMARY DEMENTIAS

Alzheimer Disease

AD is a disorder of slowly progressive dementia associated with extracellular aggregates of beta-amyloid ("amyloid plaques") and intracellular aggregates of the cytoskeletal protein tau ("neurofibrillary tangles") (Figure 53.3). At autopsy, AD patients have plaques and tangles throughout the cortex, but most particularly in the entorhinal cortex and hippocampal CA1 layer. Approximately 5–7% of all AD has an early age of onset; among these early-onset cases, approximately one-sixth are inherited in an autosomal dominant manner while another 40% show some familial recurrence without a clear mendelian inheritance pattern (Ertekin-Taner, 2007; Rao et al., 1994). The majority of late-onset AD (LOAD) is sporadic (i.e., a single individual is affected in the family) although 15–25% do have other affected individuals in their families. Even when there are multiple AD patients in a family, however, the disease usually lacks a clear-cut mendelian inheritance pattern (Nussbaum et al., 2007).

Early-Onset AD

The majority of all of the autosomal dominant, early-onset forms of AD are caused by mutations in one of three genes: the amyloid precursor protein gene (*APP*) located on human chromosome 21, the presenilin 1 gene (*PSEN1*), and the presenilin 2 gene (*PSEN2*) (Rogaeva et al., 2006). Mutations in *APP* and *PSEN1* cause a highly penetrant, predominantly early-onset disease. In contrast, *PSEN2* mutations have more variable penetrance and an older age of onset (Rogaeva et al., 2006).

APP, *PSEN1*, and *PSEN2* mutations cause AD through their effect on the processing of the protein encoded by *APP*, the amyloid precursor protein. This protein is a single-pass transmembrane protein located at the cell surface. It can be cleaved by one of two pathways: either via an a-secretase or a b-secretase (Figure 53.4) (Nussbaum and Ellis, 2003). Further cleavage by c-secretase following b-secretase cleavage creates peptide fragments containing 40 or 42 amino acid residues, referred to as the Ab40 and Ab42 peptides. A large body of evidence implicates the Ab42 fragment, a highly amyloidogenic peptide, as a major toxic agent in the pathogenesis of AD (Eckman and Eckman, 2007). First, of the nearly two dozen missense mutations in *APP* that cause autosomal dominant, early-onset AD (EOAD), all result in amino acid substitutions near the a-, b- or c-secretase cleavage sites. Through mechanisms that are not completely understood, these mutations promote cleavage via the b- and c-secretase pathways and generate relatively or absolutely increased amounts of Ab42. Second, copy number mutations of the *APP* gene, ranging in size from a few hundreds of kilobases to the entire chromosome 21 (as in Down syndrome) lead to EOAD and also cause an increased production of the Ab42 peptide (Cabrejo et al., 2006; Lai and Williams, 1989; Rovelet-Lecrux et al., 2006, 2007; Schupf et al., 2007). Finally, elevated production of Ab42 also occurs in association with mutations in the *PSEN1* and *PSEN2* genes in families with autosomal dominant EOAD (Citron et al., 1997). Hundreds of different missense mutations have been found throughout the *PSEN1* gene; in contrast, only a few mutations have been described in the much rarer families with *PSEN2* mutations. How these mutations affect the activity of the various secretases and cause increased Ab42 production is not known.

Late Age of Onset AD

Genetics also contributes substantially to the risk for late age of onset AD, as documented in twin and family epidemiological studies. For example, in a large Swedish twin registry with long-term follow-up, a typical concordance rate for AD was 59% for monozygotic twins (Gatz et al., 2005). In contrast, concordance for dizygotic twins was typically between 24%, for unlike-sexed, and 32%, for like-sexed twins. Such twin studies suggest that about half of the liability to develop AD is genetic in origin (Pedersen et al., 2004).

Comparing the frequency of AD in the family members of AD patients versus the relatives of unaffected controls is a complementary approach to estimating the genetic contribution to LOAD. Among first-degree relatives of patients affected with AD, the average lifetime risk for AD is 40% up to age 96, with a somewhat higher risk applying to women, as compared to a lifetime risk of 15–20% in individuals without affected relatives (Lautenschlager et al., 1996; Seshadri et al., 1995). Based on family data, it is estimated that about half of the liability to develop late age of onset AD is genetic in origin (Martinez et al., 1998). A similar heritability was noted when MRI scans were used to detect AD endophenotypes in the relatives of AD patients (Lunetta et al., 2007).

Although twin and family studies clearly support a major genetic contribution to LOAD, only one gene variant has so far been incontrovertibly shown to contribute significantly to AD disease risk, the ε4 allele at the apolipoprotein E (*APOE*) gene.

There are three alleles at *APOE*, ε2, ε3, and ε4, and the risk for AD increases substantially and additively with each ε4 allele an individual carries (Corder et al., 1993; Saunders et al., 1993). Among Caucasians, the risk for AD increases approximately threefold in carriers of one ε4 allele and approximately eightfold in ε4/ε4 homozygotes. The impact of the ε4 allele appears to be predominantly through its effect on the average age of onset: each ε4 allele lowers the average age of onset of AD by approximately 10 years.

The effect of the ε4 alleles at the *APOE* locus appears to be the strongest in populations of European and Japanese origin. The data are much more equivocal for African American populations, with some studies suggesting an association between ε4 alleles and AD and others showing no association (Murrell et al., 2006; Tang et al., 1998). The controversies surrounding the association between *APOE* ε4 and AD in different ethnic or racial groups has been recently reviewed (Ertekin-Taner, 2007).

The mechanism by which the *APOE* ε4 allele increases the risk for AD has not been clearly determined. However, it is clear that the apolipoprotein E is synthesized in neurons in response to injury and undergoes proteolytic cleavage (Mahley et al., 2006). The product of the ε4 allele appears to be cytotoxic through an effect on the cytoskeleton and on mitochondrial function. Further work needs to be done to elucidate the role of APOE, and the ε4 allele in particular, in neurodegeneration.

It should be stressed, however, that the *APOE* genotype alone does not explain the entire genetic contribution to LOAD (Martinez et al., 1998). A large number of linkage and association studies have been performed in an attempt to find additional loci at which variants increase the risk for AD. Studies in many populations in the United States and Europe have identified more than 75 different loci with significant linkage (LOD scores) or statistically significant association (Ertekin-Taner, 2007). Unfortunately, some of these studies used overlapping sample sets and cannot be considered independently confirmed. Others have not been replicated, and there is some persistent skepticism as to whether these loci represent real linkage or association findings or false positive signals (Finckh, 2003). For

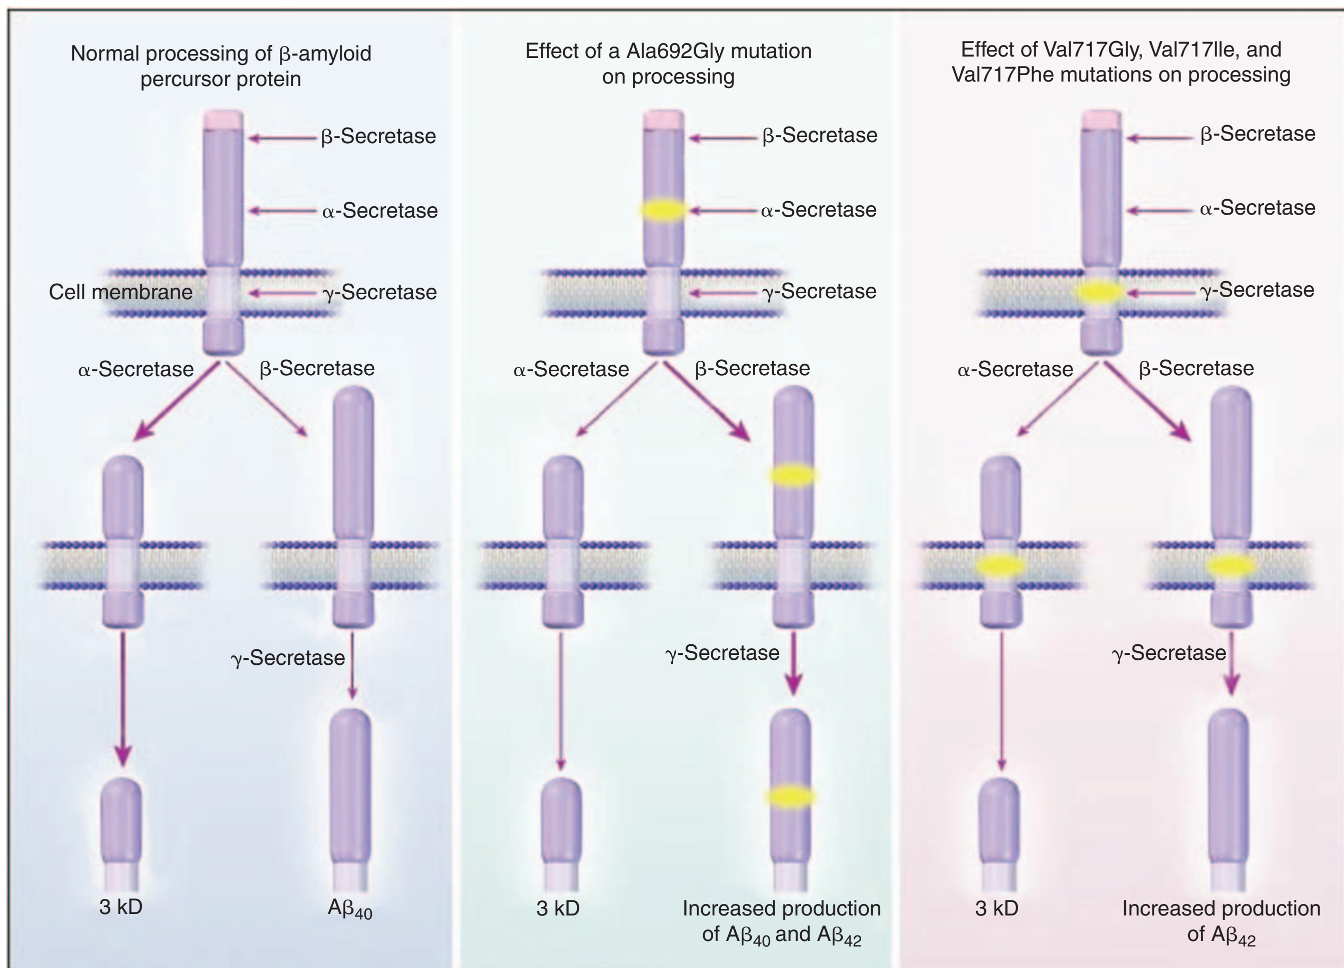

Figure 53.4 Pathways of APP cleavage by the a-, b-, and c-secretases, demonstrating the steps by which the amyloidogenic, toxic Ab42 peptide is generated (Panel A). Panels B and C depict the effect of various missense mutations in the *APP* gene that lead to increased Ab42 production. Reproduced from Nussbaum and Ellis (2003) with permission.

example, one large genome-wide scan using over 500,000 SNP markers in over 1000 autopsy-proven AD patients and controls confirmed that *APOE* itself is contributing to LOAD, but failed to find any other loci in which variants are significantly associated with AD (Coon et al., 2007). Nevertheless, a number of chromosomal regions stand out as possible locations for genes involved in AD risk because they have suggestive LOD scores or demonstrate significant association that appear to have been replicated in multiple, different studies that analyzed independent samples: chromosome 6 (regions 6p21-2 and 6q27), chromosome 10 (region 10q21.3), chromosome 12 (regions 12p11.23 and 12q13.2) and chromosome 9 (regions 9p21.2-p22.2 and 9q22.2) (Ertekin-Taner, 2007). Positional candidate genes within these regions have been analyzed for association to AD, and some genes demonstrate an association with AD that has been replicated in multiple studies. A database of such associations is available at the AlzGene website (Bertram et al., 2007). These genes and regions of the genome are, therefore, attractive candidates for further genetic and functional studies.

Clues from the cell biology of Ab42 production have also been used to identify potential functional candidate genes in which variants might be associated with a risk for AD. Variants in one interesting class of genes, those that encode proteins involved in APP sorting and delivery to the various secretase pathways, have been analyzed for association. The sortilin-related receptor gene *SORL1* has emerged from these studies as a candidate contributor to AD risk (Lee et al., 2007; Rogaeva et al., 2007). In cell culture systems, loss of SORL1 function causes an increase in the amount of APP that is sorted to the b- and c-secretase pathways, thereby increasing the production of Ab42. Variants in the non-coding regions upstream and downstream of the gene constitute two independent haplotypes that show significant association to AD in three independent populations. These same risk haplotypes were associated with a decreased expression of *SORL1* mRNA in white blood cells, thereby providing a functional link to the genetic association.

Despite extensive genetic analysis, much remains to be done to identify the genetic contributors to AD. The field of AD genetics is represented in the current deluge of genome-wide association studies being carried out in many complex diseases (see Chapter 4). One hopes that the pathogenic variants in most of the genes, even those associated with modest increases or decreases in AD risk, will be discovered and confirmed. With these genes in hand, novel therapeutic targets will become evident for the potential development of interventions to combat the disease.

Frontotemporal Dementia

FTD is an early-onset form of dementia that is nearly as common a cause of early-onset dementia as is EOAD (Ratnavalli et al., 2002). The disease may, however, occur even after age 65 and may account for up to 5–10% of dementia in the elderly. The disease is often familial and can be inherited as an autosomal dominant trait with very high, age-dependent penetrance. FTD is clinically heterogeneous, and the dementia seen in FTD differs in some respect from that seen in AD (Haugarvoll et al., 2007). For example, early in the course of FTD, the dementia is often associated with difficulties with social interactions that result from behavioral and personality changes, disinhibition, and neglect of personal hygiene. Disorientation to familiar surroundings and short-term memory loss are less prominent features early in FTD compared to AD. A Parkinsonian movement disorder is very common, as is occasional lower motor neuron dysfunction reminiscent of amyotrophic lateral sclerosis.

FTD results from mutations in four different genes (Haugarvoll et al., 2007). The loci most commonly found mutated in FTD are the progranulin gene (*GRN*) and the gene encoding the microtubular-associated protein tau (*MAPT*), each accounting for an approximately equal number of cases of FTD. Together, they are responsible for just over half of all cases of FTD. At autopsy, FTD brains show loss of large cortical neurons in the prefrontal and anterior temporal lobes. In cases of FTD that are due to mutations in *MAPT*, there are aggregates of the microtubular protein tau associated with gliosis. In other FTD patients, those with mutations in *GRN*, neuronal inclusions contain ubiquitin-positive protein aggregates containing the TAR DNA binding protein-43, seen with microvacuolization of the neuropil and scant gliosis.

The types of mutations causing FTD are very different in the cases due to *GRN* and those due to *MAPT* mutations. The mutations in *GRN* are overwhelmingly loss-of-function mutations, implying that haploinsufficiency is the dominant genetic mechanism (Haugarvoll et al., 2007). The precise biological role of progranulin and the mechanism by which haploinsufficiency of this gene causes highly penetrant FTD are unknown. In contrast, mutations in *MAPT* are toxic gain-of-function mutations (Hutton, 2001). The *MAPT* gene has four exons (exons 9 through 12) that contain copies of a microtubular-binding domain. *MAPT* undergoes extensive alternative splicing that generates at least six isoforms. These six *MAPT* isoforms can be grouped into two classes, those that include exon 10 and have four copies of the repeat and those that skip exon 10 and have only three copies of the repeat (Figure 53.5). Many of the mutations in *MAPT* that cause FTD interfere with the skipping of exon 10 and generate an excess of tau protein containing four microtubular binding domain repeats. Tau with four microtubular binding domains is much more prone to undergo fibrillization and aggregation. There are other *MAPT* mutations that do not affect splicing of exon 10 but alter the properties of the tau protein, rendering it more prone to aggregation and, presumably, lead to FTD that way.

In addition to mutations in *GRN* or *MAPT*, rare missense mutations in the gene for the chromatin-modifying 2B protein (*CHMP2B*) can cause FTD associated with amyotrophic lateral sclerosis; nuclear inclusions are seen at autopsy. Another rare form of FTD results from missense mutations in the valosin-containing protein gene (*VCP*), often in association with an inclusion-body myopathy or Paget disease of bone. The pathogenic mechanism by which missense mutations in *CHMP2B* or *VCP* cause FTD is unknown.

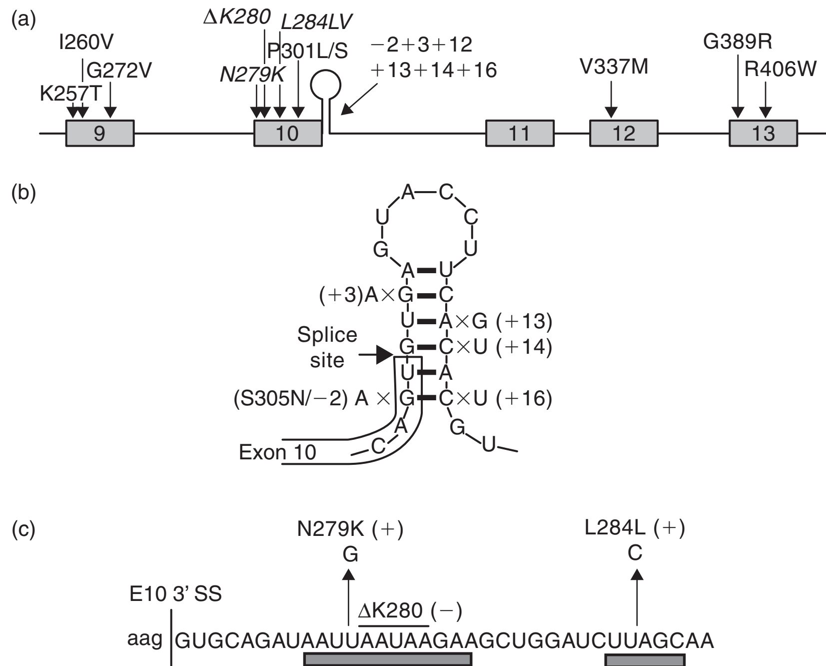

Figure 53.5 *MAPT* mutations in FTD. (a) Schematic diagram of a segment of the gene containing exons 9 through 13. Exonic missense mutations and mutations in intron 10 are shown. (b) Schematic diagram of the stem-loop structure in the 5′ end of intron 10. Mutations that disrupt the stem-loop reduce the inhibitory effect of the stem-loop on splicing that would exclude exon 10, leading to more frequent inclusion of exon 10 and, therefore, increased synthesis of tau protein with four microtubule binding domains. (c) Exonic mutations that strengthen a splice enhancer, lead to more frequent inclusion of exon 10 and, therefore, increased synthesis of tau protein with four microtubule-binding domains. Reproduced from Hutton (2001) with permission.

DLBD and Parkinson Disease with Dementia

DLBD is another form of neurodegeneration, accounting for ~10% of cases of dementia, although some estimates suggest it is nearly as frequent as AD as a cause of dementia in the elderly (Lippa et al., 2007). DLBD is clinically similar to AD but characteristically shows a higher frequency of psychosis with auditory and visual hallucinations and is often accompanied by the symptoms and signs of Parkinsonism (Lippa et al., 2007; McKeith et al., 2005; Walker et al., 2002). At autopsy, brains of DLBD patients have the characteristic a-synuclein aggregates known as Lewy bodies throughout the cerebral cortex as well as in the olfactory bulb/anterior olfactory nucleus and in subcortical regions such as the substantia nigra, locus coeruleus, and dorsal motor nucleus of the vagus (Figure 53.6). The Lewy bodies seen in DLBD are similar to the aggregates found in classic Parkinson disease (PD), although their distribution is more cortical in DLBD, while in PD they are concentrated more in subcortical areas, at least during early stages of the disease (Braak et al., 2003, 2004).

A longstanding controversy exists over the relationship between DLBD and the dementia seen in PD patients (Parkinson disease with dementia or PDD). Dementia develops in 20–40% of patients with PD (Mayeux et al., 1992; Mindham et al., 1993) while clinical or subclinical abnormalities involving the dopaminergic system of the substantia nigra are frequent in patients with DLBD (Walker et al., 2002). An arbitrary distinction used by clinicians to separate PDD from DLBD is the "1-year" rule. If dementia occurs before or up to 1 year following the onset of the Parkinsonian movement disorder, the patient is said to have DLBD. If dementia occurs more than 1 year after the onset of the movement abnormality, the diagnosis of PDD is made instead. Although there are some subtle differences in the dementia seen in PDD and DLBD, both disorders have similar a-synuclein aggregates. Furthermore, the occurrence of PDD and DLBD in different members of the same family carrying a duplication or a triplication of the a-synuclein gene (Chartier-Harlin et al., 2004; Farrer et al., 2004; Singleton et al., 2003) suggest that the underlying pathogenic mechanism is the same in both disorders, even if the clinical features and distribution of the Lewy body pathology is somewhat different.

Mendelian DLBD is rare but does occur in families with autosomal dominant forms of PD. Families with mutations (Kruger et al., 1998; Polymeropoulos et al., 1997; Zarranz et al., 2004) or copy number changes (Chartier-Harlin et al., 2004; Farrer et al., 2004; Singleton et al., 2003) in the a-synuclein gene have early-onset, autosomal dominant disease, presenting clinically as PDD in some family members, but as DLBD in others. Patients with mutations in the *LRRK2* gene, which is responsible

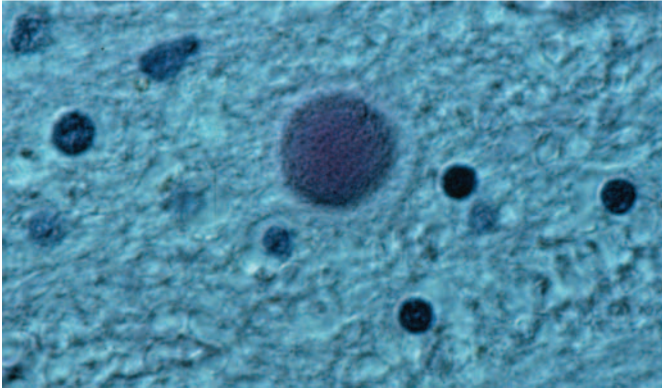

Figure 53.6 Pathology in DLBD. The large circular structure in the center of the field is a Lewy body. (Formalin-fixed human brain section stained with hematoxylin and eosin.)

for a form of autosomal dominant PD with variable penetrance, can also present with DLBD (Ross et al., 2006).

The vast majority of DLBD and PDD cases, however, are sporadic, with a late age at onset. Far less is known about the genetic contributions to Lewy body dementia than is known about AD. There is some suggestive evidence that the *APOE* ε4 allele is increased in individuals with DLBD, as it clearly is in AD, but the evidence is less clear and somewhat contradictory (Jasinska-Myga et al., 2007). One confounding factor is that many patients have a mixed pathological picture at autopsy, with both diffuse cortical Lewy bodies and Alzheimer pathology of amyloid plaques and neurofibrillary tangles. The possible role of the *APOE* ε4 allele in DLBD is difficult to determine when there is mixed pathology and when AD, in which the *APOE* ε4 clearly plays a role, is also present.

Prion Diseases

Prion diseases (spongiform encephalopathies) are a rare cause of dementia, occurring in approximately one in a million individuals (Eggenberger, 2007). About 15% of all spongiform encephalopathy is familial and is referred to as familial Creutzfeldt–Jakob disease (fCJD). In this disorder, patients suffer a general loss of their sense of well being and undergo vague personality changes, confusion, and a form of dementia characterized by difficulties with judgment, memory, and reasoning. Ataxia, myoclonic jerking, and choreo-athetosis appear soon after the initial signs and symptoms. At autopsy, there is widespread neuronal loss with diffuse spongiform change; deposition of amyloid plaques that stain positive with antibodies against the prion protein may also be present. Although classical fCJD has a different clinical presentation and course than early-onset familial AD, there is enough difficulty in making the clinical distinction antemortem that the prion protein gene should be considered for sequencing along with *APPl*, *PSEN1*, and *PSEN2* in all cases of early-onset, familial AD (Finckh et al., 2000).

Other rarer variants of familial prion disease are known that differ in their phenotypic manifestations from fCJD. These disorders, known as fatal familial insomnia (FFI) (Gambetti et al., 1995) and Gerstmann–Sträussler–Scheinker syndrome (GSSs) (Ghetti et al., 1996), occur in patients carrying different missense or frameshift mutations in the prion protein gene. In these disorders, severe autonomic and brainstem dysfunction (in FFI) or cerebellar and basal ganglia dysfunction (in GSSs) are far more prominent than is dementia, although cognition is generally not spared in these familial prion disease variants, especially late in the course.

Prion diseases are caused by aggregation of the prion protein, a naturally occurring neuronal protein that, upon adoption of an abnormal conformation, has a very high propensity to aggregate. This conformational change is induced in normal prion protein molecules by prion molecules that have already adopted the aggregation-prone conformation, thus allowing for propagation of the abnormal conformation and acceleration of the protein aggregation. In familial prion diseases, mutations in the prion gene increase its propensity to adopt an aggregation-prone conformation.

Cerebral Autosomal Dominant Arteriopathy with Subcortical Infarcts and Leukoencephalopathy

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is a rare form of early-onset dementia inherited in an autosomal dominant manner. The disorder has a prevalence of approximately 1 per 50,000 and most commonly presents between age 20 and 60, with a peak in the fifth decade (Opherk et al., 2004; Razvi et al., 2005). Migraine headache is a frequent early symptom of CADASIL patients as are transient ischemic attacks, neuropsychiatric abnormalities, seizures, and, later, a progressive dementia with prominent defects in executive function, judgment, and language (Dichgans et al., 1998; Opherk et al., 2004). Patients generally survive 5–10 years after diagnosis with progressive dementia and neurological disability leading to death.

As opposed to all the other hereditary forms of primary dementia discussed previously in this chapter, CADASIL is not a primary neurodegenerative disorder with protein aggregation in or around neurons. Instead, CADASIL is characterized by an angiopathy in which there is degeneration of vascular smooth muscle cells in association with electron-dense, extracellular particles, visible with the electron microscope, in and around degenerating smooth muscle cells in the media of arterioles. This characteristic finding can be seen in tissue obtained at autopsy or in biopsy material from skin. The angiopathy in CADASIL leads to a progressive, occlusive disease of small blood vessels, resulting in multiple small infarcts, called lacunae, throughout the brain. The neurological defects seen with lacunar infarcts are usually more circumscribed both clinically and pathologically than those seen with the typical large cerebral artery occlusive stroke (Mohr, 1983; van den Boom et al., 2002). Lacunar infarcts in the cortex may result in a clinical

picture of a pure motor stroke, a pure sensory stroke, or a mixed stroke, while the classic syndrome of dysarthria/clumsy hand is seen with deep pontine lacunae. The accumulation of lacunar infarcts throughout the cortex is the likely cause of the progressive dementia seen in three-quarters of patients with CADASIL (Dichgans et al., 1998; Opherk et al., 2004).

The only molecular lesions known to cause CADASIL are mutations in *NOTCH3*, which encodes the cell surface receptor NOTC3 (Dotti et al., 2005; Federico et al., 2005; Joutel and Tournier-Lasserve, 1998). Most *NOTCH3* mutations in CADASIL are missense or splicing mutations that result in an odd number, instead of the normal even number, of cysteine residues in the extracellular epidermal growth factor-like repeats of NOTC3. The abnormal conformation caused by having an odd number of cysteine residues in the NOTC3 extracellular domain leads to the accumulation of misfolded NOTC3 fragments that form the deposits in the arteriolar walls that are visible on electron microscopy (Joutel and Tournier-Lasserve, 1998; Schroder et al., 1995). How these mutations lead to the aggregation of NOTC3 fragments is not understood.

CADASIL is inherited as an autosomal dominant disorder, nearly always from a carrier parent (i.e., new mutations are rare). CADASIL is one of the few human autosomal dominant diseases that is a true dominant rather than a semidominant condition, in that homozygotes and heterozygotes have a very similar clinical phenotype (Tuominen et al., 2001).

CLINICAL APPROACH TO THE DEMENTIAS

The clinical approach to the dementias relies on careful history and neurological examination, neuropsychological testing, family history, brain imaging, and molecular diagnostics when appropriate. The rapidity of disease progression, the presence of neurological signs besides dementia, such as Parkinsonism as seen with DLBD or FTD, or ataxia, dysarthria and myoclonus as in fCJD, the pattern of cognitive losses (language, short-term memory, judgment or executive function), which differ among the FTDs and AD, the degree of atrophy of frontal versus temporal or hippocampal structures seen on brain MRI, the presence of vascular-occlusive lacunae on brain MRI, may all be helpful in making an antemortem diagnosis (Grossman et al., 2007; Mastrianni and Roos, 2000; van den Boom et al., 2002, 2003). Unfortunately, definitive diagnosis of the cause of dementia is not always clear prior to death and requires postmortem examination at autopsy.

When the clinical presentation, family history, neurological examination, and neuropsychological profile are suggestive of one of the dementias in which the gene is known, testing the affected patient by DNA sequencing of the appropriate genes can provide a definitive diagnosis. Physicians who submit DNA for testing should be aware, however, that the test may show a gene variant that has not been seen before and is of unknown pathogenic significance. It is also possible that the sequencing will be normal in a patient with EOAD or FTD because the disease is due to mutations in a yet to be discovered gene.

It is important to distinguish between diagnostic testing in an affected individual and presymptomatic testing of asymptomatic relatives of a patient shown to have a pathogenic mutation in a known gene. At-risk, asymptomatic relatives may choose to have testing to help with decision-making with regard to having more children or for the purposes of career or financial planning. For some of these disorders, such as CADASIL, FTD, or AD due to *APP* or *PSEN1* mutations, penetrance is very high, although age-dependent. A positive test result in these diseases has high predictive value for development of the disease, but not necessarily for when it will develop. In another familial dementia, such as AD due to *PSEN2* mutations or DLBD/PDD due to *LRRK2* mutations, penetrance is much lower and, as a consequence, a positive test has much lower positive predictive value. Because of the risk for serious psychological and potential financial (life or disability insurance) damage from receiving a positive test, pre-test counseling and post-test psychological and social support are mandatory. Most adults who choose such testing and test positive seem able to handle and use the information (Steinbart et al., 2001). Genetic professionals universally recommend against testing children for these disorders.

The role of testing for the ε4 allele at the *APOE* locus in AD is more controversial. In an affected individual in the 65–75 age range with suspected AD, the presence of one or two ε4 *APOE* alleles has a positive predictive value for AD of ~75% and ~98% respectively and, therefore, may help to confirm a diagnosis of AD (Nussbaum et al., 2007). Most physicians, however, would still make sure to rule out one of the rare but treatable causes of dementia, such as depression or endocrine imbalance, regardless of *APOE* genotype. Predictive testing using *APOE* genotype is currently considered to be of little value because no intervention is currently available to prevent or delay the disease process. In the over 65 age group, when ~1 in 50 individuals would be expected to develop dementia each year, the vast majority of people with one ε4 allele and most of those with two ε4 alleles will still not develop AD. However, it should be noted that the utility of identifying individuals at increased risk for AD through *APOE* genotyping would increase dramatically once a preventive intervention becomes available.

2009 UPDATE

Genetic Association Studies

Whole-genome association studies continued apace in an attempt to confirm, narrow, or disprove the association of various regions of the genome with late-onset AD. The results reinforce once more how difficult it can be to pin down real genetic associations in a complex disease. For example, there were four regions that were noted in the original version of this chapter to have support from more than one association study, that is, regions on chromosome 6, 10, 12, and 9. In the interim, no specific gene and gene variant has been identified and confirmed to be associated with the risk for late-onset AD in any of these regions. In the meantime, additional large genome-wide associations have been reported that suggest there may be other loci that will now need further study and replication (Bertram et al., 2008; Li et al., 2008a; Zuchner et al., 2008).

New association analyses with the sortilin-related receptor gene, *SORL1*, have been published as follow-up to the original report of an association between variants at this gene and AD (Rogaeva et al., 2007). Variants at the *SORL1* locus were initially chosen for association analysis with late-onset AD because of the role of *SORL1* in the biology of intracellular trafficking of APP. This association has undergone further evaluation with conflicting results. Meng et al. (2007) mined the large genome-wide association study from Reiman et al. (2007) for any evidence of association with *SORL1*. They reported a positive replication with *SORL1* without applying a multiple testing correction (Bonferroni), arguing it was unnecessary to do so since they used the dataset specifically to ask about this one locus and not to do a genome-wide association. The very same dataset was interpreted differently by Webster et al. (2008), who reported only nominally significant association with some, but not other, SNPs in the linkage disequilibrium block around *SORL1*. In particular, they did not replicate the association with the specific SNPs that showed the initial association reported by Rogaeva et al. (2007). Other studies have either replicated the *SORL1* association (Lee et al., 2007, 2008), found the association to be marginal (Li et al., 2008b), or failed to replicate it (Minster et al., 2008; Shibata et al., 2008).

Reiman et al. (2007) reported a potential gene–gene interaction in their association study of late-onset AD. They performed a genome-wide association using ~500,000 SNPs in a well-designed case-control study consisting of three Caucasian cohorts, one an autopsy-proven group of AD patients serving as "discovery" cohort, a second autopsy-proven group of AD patients serving as "replication" cohort, and a third group of living patients with clinically-diagnosed AD patients serving as a second replication cohort. They reported a highly significant association between SNPs in a 189 kb linkage disequilibrium block containing *GAB2*, which encodes a GRB-binding partner involved in PI3-kinase signaling and late-onset AD based on Bonferroni-corrected p values to correct for multiple testing. Notably, the association was found only in individuals who carried at least one ε4 allele at the *APOE* locus. Among individuals homozygous for *APOE* ε4, being homozygous as well for the *GAB2* risk haplotype increased the risk of developing AD (odds ratio = 4) as compared to those who did not have the *GAB2* risk haplotype. The *GAB2* haplotype had no effect on disease risk in the absence of an ε4 allele. As is often the case with genome-wide association studies, replicating a finding in one ethnic group failed in another ethnic group. A study in Japanese cohorts failed to find any effect of *GAB2* haplotype on the risk for AD in individuals who were ε4ε4 homozygotes (Miyashita et al., 2008). Thus, additional cohorts will need to be studied.

Proteomics in the Diagnosis of Dementia

Although the rapidity of the disease process, the specific neuropsychiatric signs exhibited, and the findings on brain MRI are all very helpful in distinguishing among the various forms of dementia, it still remains difficult to make a definitive diagnosis prior to death and autopsy study of the brain. Attempts to improve the diagnostic capabilities have recently focused on proteomic analysis of serum or CSF to find distinguishing protein markers for the different disorders discussed in this chapter (Aluise et al., 2008; Roche et al., 2008). Methods that rely on two-dimensional protein electrophoresis or surface-enhanced laser desorption and ionization mass time-of-flight mass spectroscopy (SELDI-TOF MS) to separate proteins and look for differences among the different clinical entities have begun to show success, although their wide-spread clinical use awaits further validation. For example, the presence of certain specific protein biomarkers in serum analysis by SELDI-TOF MS can distinguish diffuse Lewy body disease patients from AD patients, with positive predictive values of 91% and negative predictive value of 92% (Wada-Isoe et al., 2007). In another application, CSF analysis by two-dimensional electrophoresis identifies biomarkers that are far more sensitive and specific for Creutzfeldt–Jacob disease than the analysis of 14-3-3 chaperone protein currently used in clinical practice (Cepek et al., 2007).

Another major clinical challenge in the dementias is identifying those patients with MCI who will go on to develop progressive AD. For example, CSF findings such as reduced levels of Aβ42, increased levels of tau, the ratio of Aβ42 to Aβ40, and the ratio of various phosphorylated species of tau to Abeta42 together provide a sensitivity of 90–95% and specificity of 78–87% for the transition from MCI to AD in patients followed from 4–6 years after CSF testing (Hansson et al., 2006, 2007). A number of additional components of CSF and serum have been studied for their predictive value for MCI patients going on to develop AD. However, to date, there is no evidence that there is substantial improvement over currently used biomarkers (reviewed in Frankfort et al., 2008 and Craig-Schapiro et al., 2008).

CHAPTER

Genetics and Genomics of Parkinson's Disease

Shushant Jain and Andrew B. Singleton

INTRODUCTION

Parkinson's disease (PD) is the second most common neurodegenerative disease with at least 5 million people affected globally (Twelves et al., 2003). PD was first described in 1817 by James Parkinson in the *Essay of Shaking Palsy*. Subsequently Brissaud noted lesions within the substantia nigra (SN) and, together with Meynerts previous observation that the basal ganglia is involved in movement, concluded that injury of this region was responsible for the symptoms in PD.

Nearly half a century later, dopamine was identified as a neurotransmitter in the basal ganglia and individuals with PD showed a deficiency in dopamine. This subsequently led to the administration of levodopa (*L*-dopa, metabolic precursor of dopamine) which remains the most effective symptomatic treatment for PD (Birkmayer and Hornykiewicz, 1962).

Although the underlying physiological cause of the major movement symptoms of PD had been exposed, the explanation for specific nigral degeneration remains unclear. For many years it was believed that PD was primarily the effect of environmental insult as studies had recognized that individuals with exposure to certain chemicals such as 1-methyl-4-phenyl-1, 2, 3, 6-tetrahydropyridine (MPTP) could lead to a disease with parkinsonism features. Further studies showed that a PD phenotype could arise from multiple different etiologies including vascular insults, infections (post-encephalitic Parkinsonism caused by the influenza virus) and frontal lobe tumors.

Research into PD was revolutionized when a genetic basis for PD was established with the identification of monogenic forms (Table 54.1). Elucidating the genetics and environmental causes of PD has highlighted biological pathways critical in disease pathogenesis. This in turn could allow the subdivision of the disease based on genetic rather than phenotypic information which could help explain the wide variation in this disease, including differences in clinical course, and response to treatment, and it might help clarify the role of environmental factors in disease cause or susceptibility.

CLINICAL CHARACTERISTICS OF PD

PD belongs to a heterogeneous family of diseases referred to as parkinsonism syndromes. Within this group there are many diseases such as progressive supranuclear palsy (PSP), diffuse Lewy body disease (DLB) and environmentally induced parkinsonism, such as exposure to MPTP or other environmental insults. A clinical diagnosis of PD as opposed to other parkinsonism syndromes requires the presence of tremor, rigidity, and akinesia. In addition, there are inclusion and exclusion criteria which also must be fulfilled: (1) no detectable cause, (2) no cerebella deficits, (3) limited pyramidal signs, (4) no lower motor dysfunction, (5) limited gaze palsy, and (6) minor autonomic deficits. A pathological diagnosis dictates loss of dopaminergic cells in the SN and also the presence of intracytoplasmic eosinophilic inclusions called Lewy bodies (LB) in surviving neurons (Hardy and Lees, 2005).

Essentials of Genomic and Personalized Medicine
by Ginsburg & Willard

Table 54.1 Genetic loci implicated in Parkinson's disease

Locus	Protein name	Inheritance pattern	Phenotype
PARK1 PARK4	α-SYNUCLEIN	AD	AOO~40–50 years Features of dementia with Lewy bodies
PARK2	PARKIN	AR	AOO~35 years Slow disease progression *L*-dopa responsive No Lewy bodies
PARK3	Unknown	AD with reduced penetrance	AOO~50 years Typical PD *L*-dopa responsive No pathology available
PARK5	UCHL-1	AD	AOO~50 years Typical PD *L*-dopa responsive No pathology available
PARK6	PINK1	AR	AOO~35–45 years Slow disease progression *L*-dopa responsive No pathology available
PARK7	DJ-l	AR	AOO~30–40 years Slow disease progression *L*-dopa responsive No pathology available
PARK8	LRRK2	AD	AOO~50 years Typical PD*L*-dopa responsive Variable pathology
PARK9	ATP13A2	AR	AOO~16 years Levodopa-responsive parkinsonism with pyramidal degeneration, supranuclear gaze palsy, and dementia
PARK10	Unknown	Risk factor	AOO~50–60 years Typical PD No pathology available
PARK11	Unknown	Risk factor	AOO~50–60 years Typical PD No pathology available
PARK12	Unknown	Risk factor	AOO~50–60 years Typical PD No pathology available
Chromosome 5 (5q23)	Unknown	Risk factor	AOO~50–60 years Typical PD No pathology available

Abbreviations: AOO: Average age of onset, AD: Autosomal dominant, AR: Autosomal recessive.

PD is a late-onset disease, primarily occurring in the fifth or sixth decades, although some forms, particularly the recessive genetic diseases, can begin in childhood. Disease in individuals where a specific etiology is not known and where there is no clear family history of PD are classified as sporadic PD. The early symptoms of PD are usually non-specific and may be seen in many other neurological syndromes or as a part of normal aging. To begin with, there is a general lethargy with possible

mood and mild cognitive impairment. Subsequently, an intermittent tremor often present only under stress can develop with asymmetrical rigidity moving to the other side of the body within 3–5 years. Within 5 years bradykinesia and postural instability ensue (Hughes et al., 1993).

The average mortality rate in PD is approximately 1.5 above the general population. On average disease duration is 13 years, and the mean age at death has been reported at 73 years. The most common causes of death in PD patients is pneumonia through lack of activity, cardiovascular disease, or severe injury through falling (Hughes et al., 1993).

GENETICS OF PD

Many diseases have a genetic component, whether it is due to inherited mutations or as a result of genetic variation controlling the response to environmental stresses such as viruses or toxins. The identification of the genetic causes of a disease allows one to isolate the primary pathogenic mechanism and/or contributors to a disease. The ultimate goal is to use this information to identify and develop new ways to treat, cure, or even prevent the disease.

A common methodology used in the determination of the relative contribution of genetics to disease is the twin study, this is performed by comparing concordance of disease in monozygotic (MZ) twins (who share all genes) and dizygotic (DZ) twins (who share, on average, 50% of autosomal genes). Recent data from twin studies using the uptake of ^{18}F-dopa and positron emission tomography (PET) imaging have suggested that genetics does play a role in disease (Piccini et al., 1997) but also suggest genetics is not the sole determinant of disease. These data are consistent with the most widely held hypothesis, that the majority of typical PD cases are a result of a complex interplay between genetic variability and environmental exposures.

Many genes have been implicated in PD but the analysis of multiple nuclear families or isolated populations has led to the identification of multiple genes and loci that cause mendelian PD or increase risk for PD (Table 54.1).

SNCA (*PARK1*; *PARK4*; *α-SYNUCLEIN*)

α-synuclein was previously cloned as the non-Abeta (β) component of Alzheimer's disease (AD) amyloid plaques. However, its role in PD became evident in 1997 when a mutation (A53T) within a Greek kindred was shown to cause autosomal dominant PD (Polymeropoulos et al., 1997). Subsequently, a further two additional missense mutations (A30P and E64K) have been identified as rare causes of disease as it has multiplication of the genomic segment containing the gene encoding α-synuclein (*SNCA*) (Singleton et al., 2003).

Soon after the discovery of mutations in the gene encoding α-synuclein as the first genetic cause of PD, this protein was found to be the major component of LB, the pathological hallmark of PD (Spillantini et al., 1997). However, the pathology in individuals with α-synuclein mutations is not typical of idiopathic PD; the pathology is usually more extensive with LB not only in the SN but also throughput the cortex, striatum and locus ceruleus; additionally α-synuclein pathology may also be seen outside of neuronal cells, within glia, somewhat similar to the glial cytoplasmic inclusions noted in multiple system atrophy (Mukaetova-Ladinska and McKeith, 2006). The parkinsonism associated with α-synuclein mutations presents at a relatively early age (30s to 50s) and is rapidly progressive, in many cases the disease in patients with α-synuclein mutations progresses to include a prominent dementia, likely a reflection of the extensive cortical pathology noted in these patients (Kruger et al., 2001).

α-synuclein is part of a gene family including γ and β synuclein. The function of α-synuclein is not well understood but many hypothesizes exist regarding its role in PD pathogenesis. α-synuclein is primarily located at synaptic membranes and therefore may have a role in maintaining synaptic function which in part has been supported by animal modeling; analysis of α-synuclein knockout mice has suggested a role for α-synuclein of long-term regulation and/or maintenance of presynaptic function (Kaplan et al., 2003).

Because *SNCA* was the first gene implicated in PD and because its protein product is the major deposited species in the hallmark lesion of this disease, considerable resources have been used in an attempt to understand the pathophysiological process that results from α-synuclein mutation. Firstly α-synuclein can aggregate under a number of different conditions, the central hydrophobic region, where the missense mutations reside, tends to self-aggregate. The end product of α-synuclein aggregation is the formation of heavily insoluble polymers of protein known as fibrils, which is promoted by both the A53T mutation and overexpression of α-synuclein (Figure 54.1) (Volles and Lansbury, 2003). Conversely, A30P slows the rate of fibril accumulation but increases the rate of α-synuclein protofibril formation. Because of this and other data it is now believed that the protofibril species of α-synuclein are the toxic species (Cookson, 2005). α-synuclein protofibrils have the ability to form pores-like structures (Volles and Lansbury, 2003) which can cause leakage of vesicles. Furthermore, PD associated mutations are able to increase the permeabilizing activity of α-synuclein by increasing protofibril formation. The subsequent binding and formation of pores in the mitochondrial or vesicular membranes (Volles and Lansbury, 2003) or at the cell surface, could lead to disruption of numerous cellular activities and cell death.

Another mechanism of α-synuclein toxicity could be mediated in part by its post-translational modification. α-synuclein is phosphorylated at Ser-129 and it is this form that is primarily deposited in LB. In addition, altering this residue to either prevent or mimic phosphorylation suppresses or enhances α-synuclein toxicity respectively in Drosophila transgenic models (Chen and Feany, 2005). If phosphorylation of α-synuclein is a necessary event in its pathogenesis then inhibiting the kinases responsible would be a good target. Numerous studies are also underway to determine if synuclein levels are a good correlate for disease status and hence a biomarker for pre-symptomatic individuals (Miller et al., 2004).

PRKN (*PARK2*; *PARKIN*)

The gene encoding *PARKIN* (*PRKN*) was the first gene to be identified with mutations that underlie autosomal recessive PD

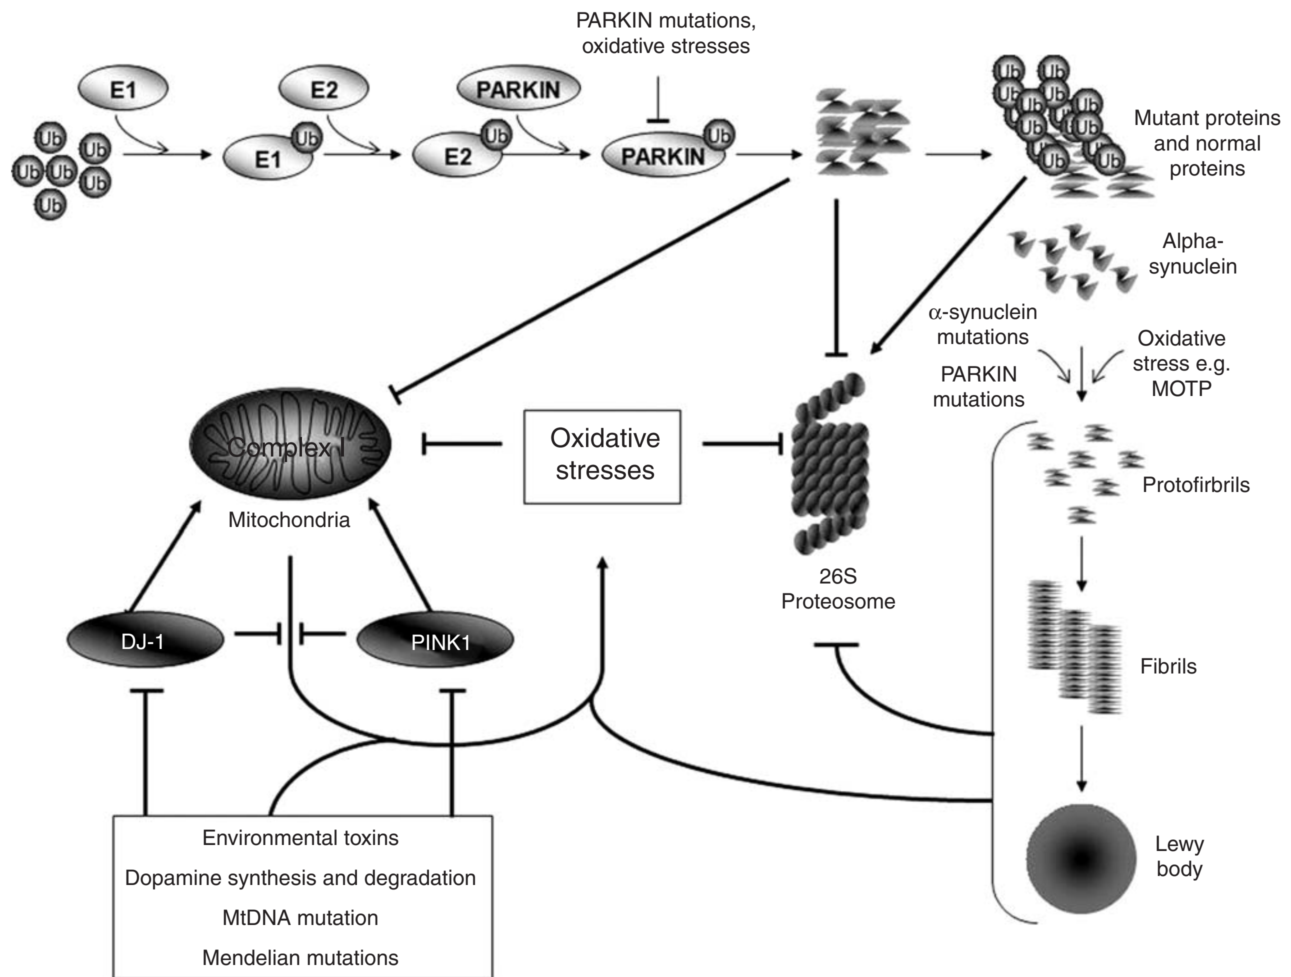

Figure 54.1 A proposed model for mechanisms of cellular toxicity in PD. *PRKN* mutations and oxidative stress can inhibit PARKIN mediated ubiquitination of specific substrates leading to their accumulation. These substrates may inhibit both the proteasome and mitochondria. The formation of α-synuclein protofibrils and aggregates can be toxic to both the mitochondria and proteasome. PINK1 and DJ-1 promote cell survival, either directly or indirectly by protecting mitochondria from oxidative stress.

and represents the most common known cause of early-onset parkinsonism (Kitada et al., 1998). *PRKN* mutations account for nearly 50% familial cases where the age of onset is below 40 years and the probability of a patients having *PRKN*-linked disease increases as age of onset decreases. The clinical picture of *PRKN*-linked disease is not that of typical PD patients commonly present with dystonia, other atypical features include hyperreflexia, slow progression, and early compilations from *L*-dopa treatment. Patients survive an average of 10 to 20 years and have a more symmetrical onset (Lohmann et al., 2003).

Despite the relative abundance of *PRKN*-linked disease there remains a paucity of neuropathological analysis in patients with disease unequivocally caused by *PRKN* mutation. The majority of reports indicate a lack of LB pathology and because the presence of nigral LB is a hallmark pathological feature of PD and a large amount of resources have been invested in an attempt to determine the molecular pathway of disease related to *PRKN* mutation, there has been considerable debate over the relevance of *PRKN*-linked parkinsonism to typical PD (Hardy and Lees, 2005). However, while the nature of LB pathology in this form of parkinsonism is unclear, there is certainly degeneration and dysfunction of the dopaminergic neurons and as such establishing the mechanism of the preferential vulnerability of this neuronal system in *PRKN* disease is likely to be directly relevant to typical PD.

There are multiple types of mutations that cause loss of function mutations within *PRKN*: point mutations to large scale deletions spanning multiple exons, multiplications, frameshift (alters reading frame), truncating, and splice-site mutations. The scale and assortment of mutations within *PRKN* makes genetic diagnosis difficult as extensive screening has to be performed. Furthermore, there are several point mutations where pathogenicity is currently equivocal (von Coelln et al., 2004).

PRKN encodes an E3 ubiquitin ligase which is responsible for the addition of ubiquitin molecules to specific target proteins that are subsequently recognized by the proteasome and degraded (Figure 54.1). As a consequence of the large deletions

and multiple mutations throughout the gene, lack of *PARKIN* may lead to the accumulation of one or more of its substrates and subsequently to cell death. In support of this hypothesis, when suspected substrates of *PARKIN* are overexpressed they can lead to dopaminergic cell loss which can subsequently be rescued by *PARKIN* but not its mutants (Kahle and Haass, 2004). As the accumulation of proteasomal substrates or proteasome inhibition is implicated in PD pathogenesis (McNaught and Olanow, 2006), individuals involved in small molecule proteasome inhibitor clinical trials (e.g. NPI-0052; Chauhan et al., 2006), will have to be carefully monitored to ensure they do not develop parkinsonism features.

Another hypothesis suggests that loss of *PARKIN* may result in mitochondrial damage and apoptosis, as knockout of *PARKIN* homologs from both mice and Drosophila cause decreases in mitochondrial respiratory capacity demonstrated by reduced lifespan, locomotor defects due to apoptotic cell death and male sterility due to spermatid individualization defects; this hypothesis is gaining impetus as the genes mutated in other recessive Mendelian PD cases appear to link mitochondria to neuronal cell loss (Shen and Cookson, 2004).

DJ1 (*PARK7*; *DJ-1*)

DJ-1 mutations are found in young-onset autosomal recessive parkinsonism but are the rarest known genetic cause of parkinsonism (<1–2% of familial PD; Bonifati et al., 2003); however, mutation of *DJ-1* remains the rarest known genetic cause of parkinsonism. Given the rarity of *DJ-1* mutations there is limited clinical data and to date no pathological data available in *DJ-1*-linked patients. Patients with *DJ-1* mutations present with a young-onset disorder (mid-30s) and follows a relatively benign course (Bonifati et al., 2003). Consistent with loss of function, *DJ-1* is recessively inherited and one of the original families possessed a large deletion encompassing the start codon of *DJ-1*. Subsequently, multiple point and splice mutations have been described within *DJ-1*. Although the current function of *DJ-1* is unclear, some mutations (e.g. L166P) destabilize *DJ-1* thus leading to increased degradation by the proteasome. As a consequence there is insufficient *DJ-1* which is hypothesized to increase neuronal vulnerability to toxic insult and apoptosis (Figure 54.1).

Several hypothesis exist as to how *DJ-1* protects cells from toxic insult. *DJ-1* is a 189 amino acid member of the ThiJ/PfpI/DJ1 superfamily, ubiquitously expressed and localizes to the cytosol and mitochondria as well as the nucleus in dividing cells. Under oxidative stress conditions, such as exposure to paraquat or MPTP, *DJ-1* undergoes an acidic shift in pI by modifying the side chain of cysteine 106 to form a sulfinic acid. This is correlated with the protein relocating from the cytosol to the outer mitochondria membrane. Overexpression of *DJ-1* in culture can decrease sensitivity to specific stressors, such as paraquat and MPTP (Canet-Aviles et al., 2004). Conversely, loss of *DJ-1* in mice, cell culture, and Drosophila models leads to increased sensitivity to oxidative stresses (Cookson, 2005; Shen and Cookson, 2004).

DJ-1 only has a weak ability to scavenge free radicals and thus, *DJ-1* is unlikely to primarily function as an anti-oxidant protein. Consequently, a role for *DJ-1* as an oxidative stress sensor has been suggested. *DJ-1* may have an analogous role to the DNA damage sensing enzymes (e.g. ATM, ATR, and RAD proteins) where specific enzymes recognize different types of DNA damage and are able to mediate the appropriate response (e.g. apoptosis, cell cycle arrest, and transcription). As *DJ-1* was cloned as part of a RNA protein-binding complex, it is postulated that *DJ-1* may control transcription and/or translation of particular RNA species in response to oxidative stress (Abou-Sleiman et al., 2003).

Alternatively, *DJ-1* has been shown to bind to numerous proteins such as DAXX, preventing it from activating the apoptotic pathway and decreasing cell sensitivity to oxidative stresses. However, many of these *DJ-1* interactors still require validation *in vivo*, both to confirm the interaction and to establish that they play specific roles in *DJ-1* mediated cell survival (Abou-Sleiman et al., 2003).

PINK1 (*PARK6*; Pten Induced Kinase 1)

Mutations in the gene *PINK1* were identified in four Italian families with recessive early-onset PD (Valente et al., 2004). Initial screens for *PINK1* mutations in early-onset familial cases reveals that *PINK1* mutations are a more common cause of young-onset PD than *DJ-1* mutation, but not as prevalent as *PRKN* mutation. *PINK1* mutations are estimated to cause 4% of familial recessive PD. The clinical course of individuals with *PINK1* mutations resembles that of sporadic PD except the age of onset is earlier (approximately 35–45 years of age) and disease progression is slower. Similar to *PRKN* disease dystonia at onset appears to be more frequent in individuals with *PINK1* mutations. No pathology data is available from any affected individuals (Healy et al., 2004a).

PINK1 is predicted to be a serine-threonine kinase that is targeted to the mitochondria. Once *PINK1* enters the mitochondria, the *N*-terminal mitochondrial targeting motif is cleaved. Although no substrates of *PINK1* have been identified, the recessive nature of the disease and the presence of truncating mutations in *PINK1*-linked cases, suggest loss of kinase activity may result in cell loss. As *PINK1* is a mitochondrial kinase and can protect cells against oxidative stresses such as paraquat and MPTP (Figure 54.1) (Beilina et al., 2005; Valente et al., 2004). PINK1 may phosphorylate multiple proteins to maintain mitochondrial function and inhibit apoptosis. In support of this observation, knockout of Drosophila *PINK1* results in male sterility, apoptotic muscle degeneration, defects in mitochondrial morphology, and increased sensitivity to oxidative stress.

As mutations within *PINK1* were only recently identified in PD, more work is needed to determine what the endogenous function of *PINK1* is and how mutations within *PINK1* can cause selective degeneration of the SN.

LRRK2 (*PARK8*; DARDARIN)

In 2002, autosomal dominant PD within a large Japanese kindred from Sagamihara was linked to the pericentromeric region of chromosome 12 (Funayama et al., 2002). Affected members of this family presented with a clinically typical *L*-dopa responsive PD with an age at onset of approximately

50 years. Neuropathologically, individuals exhibited pure nigral degeneration in the absence of LB. In addition the disease associated haplotype was carried by many unaffected individuals suggesting incomplete penetrance of the mutation (Funayama et al., 2002).

Further linkage of multiple families to the region confirmed the locus and suggested that the gene could be a common cause of PD. However, the pathology of these families was heterogeneous with some individuals presenting with LB pathology while others presented with *TAU* pathology. In 2004, the gene for PARK8-linked PD was identified, *LRRK2* was originally identified as part of the kinome project and the protein (DARDARIN-the Basque word for tremor) is predicted to be a tyrosine kinase (Paisan-Ruiz et al., 2004; Zimprich et al., 2004).

DARDARIN is a very large protein (2527 amino acids) with multiple functional motifs. DARDARIN primarily belongs to a newly identified family of proteins referred to as ROCO that contains two conserved domains (1) a ROC (Ras in complex proteins) domain that belongs to the Ras GTPase superfamily and (2) a COR domain (*C*-terminal of ROC). In addition DARDARIN contains multiple protein interaction motifs such as WD40, armadillo, and a leucine rich repeat (Jain et al., 2005).

The wild-type function of DARDARIN is unknown but from preliminary functional studies it appears that mutations within DARDARIN alter kinase activity and it is required with the formation of intracellular aggregates as well as with toxicity.

In terms of genetic testing, *LRRK2* is arguably the most important gene linked to PD as one single mutation (G2019S) accounts for 1–2% of sporadic PD and 5–6% of familial European PD (Jain et al., 2005). However, there is considerable variability associated with *LRRK2*-linked disease; this includes not only the pathological variability noted above but also variability in clinical presentation, age at onset and penetrance. Initial estimates of penetrance suggested that carrying a G2019S mutation resulted in an 80% chance of having disease; however, the bias of family based recruitment means that this estimate was high and it appears that the penetrance of the G2019S mutation is closer to 30%. This variability in the disease occurrence, presentation, progression, and endpoint suggests that there are other genetic, environmental or stochastic events that modulate the disease process. Unlike mutations in other genes that cause PD, the frequency with which mutations in *LRRK2* occur affords us the opportunity to investigate these specific modulators of the disease, and one would hope these will also be relevant to idiopathic PD (Singleton, 2005).

As common as *LRRK2* mutations may be, one has to question the utility of clinical genetic testing in PD. Multiple mutations within *LRRK2* (Brice, 2005) and several other genes implicated in PD have been described where the pathogenicity of the variants remain in doubt. Furthermore, identification of a mutation does not necessitate an individual will develop disease, or alter its prognosis or clinical treatment. At present, genetic testing in PD should only be used to confirm a clinical diagnosis of PD (McInerney-Leo et al., 2005).

GENETICS OF SPORADIC PD

Mutations in known genes account for less than 10% of all PD thus research has been aimed at identifying genes associated with typical PD and has focused on the role of common genetic variation in modulating lifetime risk for disease. As many of the genes identified in mendelian forms of PD implicate the mitochondria in disease pathogenesis (Shen and Cookson, 2004), numerous studies have questioned if mutation of the mitochondrial genome (mtDNA) or the various components encoded by the nuclear genome, contribute to PD development or progression.

Many lines of evidence support a role of mitochondrial damage in the pathogenesis of PD (Muqit et al., 2006). Mitochondrial complex I activity is systematically decreased in human PD brains and administration of complex I inhibitors (MPTP and rotenone) to rats, mice, and monkeys recapitulates many aspects of PD, including selective neurodegeneration of the SN and formation of LB type pathology (Betarbet et al., 2000). Recently two studies implicated specific mutation of SN mitochondria as causes for impairment of cellular respiration, specific neuronal vulnerability, and age-dependent risk associated with PD (Bender et al., 2006; Kraytsberg et al., 2006). Amplification of mitochondrial DNA revealed more somatic deletions within SN mitochondria than mitochondria from other brain regions and that deletions in SN mitochondria were higher in PD cases than controls, although this difference did not reach statistical significance. By the age 70, nearly all the SN neurons had elevated levels of mtDNA deletions, implying that these types of deletions might contribute to the age-dependent pathogenic processes seen in PD.

It is feasible that mutation and damage of mitochondria contribute to the preferential vulnerability of SN neurons and disease progression, but it remains unclear if accumulation of mitochondrial mutations is the fundamental pathogenic event in the majority of PD. It is probable that genetic variability at different loci contributes and predisposes some individuals to accumulating higher levels of mitochondrial mutations and damage, thus leading to sufficient neuronal loss and clinical manifestation of disease.

More traditional approaches have identified risk factors for PD. This involves a candidate gene association analysis, where typically a gene is chosen based on its function, expression or genomic position, common variants are assayed within the gene, and the frequency of these variants are compared between cases and controls. The ease and low cost of this approach has resulted in hundreds of candidate gene association studies being published in PD. The well-characterized genes in terms of genetic association with typical PD are likely those encoding α-synuclein and *TAU*.

When the *SNCA* triplication was discovered, not only did it validate many overexpression studies but also asked the question if smaller increases in *SNCA* could increase the risk for sporadic disease. Many studies have attempted to address this question but as with most studies looking at risk factors in complex diseases, they have been largely inconclusive. Even though a polymorphic multi-allelic repeat in the promoter of

SNCA (Rep1) can negatively regulate α-synuclein expression, genetic analysis of this marker has not determined if more subtle increases in α-synuclein expression can increase risk for sporadic PD. Examination of common variability in other genes involved in monogenic forms of PD has failed to reveal a consistent association with sporadic PD (Jain et al., 2005).

Perhaps the most robust genetic association with increased risk for PD comes from analysis of the microtubule associated protein *TAU*. Mutations in this gene cause frontotemporal dementia and Parkinsonism linked to chromosome 17 (FTDP-17) (Hutton et al., 1998). *TAU* forms intraneuronal inclusion referred to neurofibrillary tangles (NFTs) in many diseases pathologically referred to as tauopathies such as AD, PSP and corticobasal degeneration (CBD) (Rademakers et al., 2004). Consequently *TAU* was considered as a candidate gene for these diseases and a specific haplotype (referred to as the H1 haplotype) has been consistently associated with increased risk for PSP and CBD. As a common feature of both PSP and CBD is an initial presentation of parkinsonism, a role for *TAU* in PD has been evaluated. Thus far, numerous studies demonstrate that individuals that are homozygous for the H1 haplotype are approximately 1.5 times at greater risk of developing PD (Healy et al., 2004b).

Although *TAU* and *SNCA* have been extensively investigated, the role of common genetic variability in these genes in risk for PD is still arguable. There are many reasons why elucidating the genetics of typical PD has been problematic; some of these lie in study design, many studies are often underpowered, there may be poor selection of control populations and lack of correction for population stratification or multiple testing. All these problems result in the publication of positive association that is usually followed by failure to replicate papers (Botstein and Risch, 2003). Although statistical power will always be a problem, the advent of the HapMap project (www.hapmap.org) and the availability of technology for genome-wide association studies promise a more complete genetic analysis of PD (Maraganore et al., 2005). These data should reveal common genetic variability underlying disease and, in the absence of association, give a reasonable indication of single common genetic variants not underlying disease (Farrall and Morris, 2005).

Therapeutics

Currently the most effective non-surgical treatment for PD is the administration of *L*-dopa. The metabolic precursor to dopamine was first administered in 1960s to a group of individuals affected with post-encephalitic Parkinsonism (Birkmayer and Hornykiewicz, 1962). Within a short period of time individuals improved from a near catatonic state to relatively normal lives. This drug initially offers a remarkable treatment option to most patients with PD; however, as effective as *L*-dopa is in the early stages of PD, with continued use, approximately 60% of patients develop response fluctuations and dyskinesias. The half life of *L*-dopa and therefore the therapeutic benefit can be improved by the co-administration of inhibitors that break down *L*-dopa to non-useful, potentially harmful metabolites such as 3-MT or dopa quinine (COMT and MAO (monoamine oxidase) inhibitors, Figure 54.2).

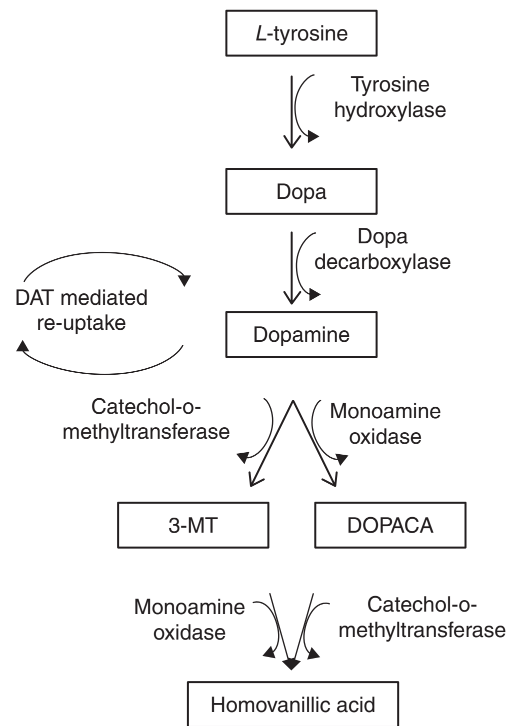

Figure 54.2 Mechanisms of dopamine synthesis and metabolism. 3-MT: 3-methoxytyramine, DOPAC: 3, 4-dihydroxyphenylacetic acid, COMT: Catechol-o-methyltransferase, MAO: Monoamine oxidase.

An alternative to dopamine replacement has been surgical intervention. The loss of dopaminergic cells causes the general deregulation of neurotransmission. The over activation of the subthalamic nucleus (STN) leads to an excessive inhibitory output from the globus pallidus interna (GPi) and SN to the cortex and motor systems (Figure 54.3). As a consequence bradykinesia, tremor, and rigidity arise. The aim of surgical intervention is to disrupt the striatum and other areas to allow increased signaling from the SN. This treatment can be effective at treating *L*-dopa induced dyskinesias, tremor, and rigidity. A more recent advancement in surgical intervention is deep brain stimulation (DBS). This is essentially the same as disrupting the STN and GPi, but as an alternative to ablation, electrodes are implanted to block the signaling via a high-frequency electrical current (Garcia et al., 2005). As a consequence, there is more flexibility in controlling neurotransmission. Current treatments only temporarily manage the symptoms of PD and do not halt or slow down the progression of dopaminergic cell loss.

Since the primary movement disorder associated with PD involves the relative loss of a specific neuronal population, this aspect of the disease represents an excellent target for cell-based therapies. Transplantation of fetal mesencephilic dopaminergic neurons into the STN of PD patients has proven clinical effective with sustained relief from the symptoms (Correia et al., 2005). This therapy has the potential to cure PD if the

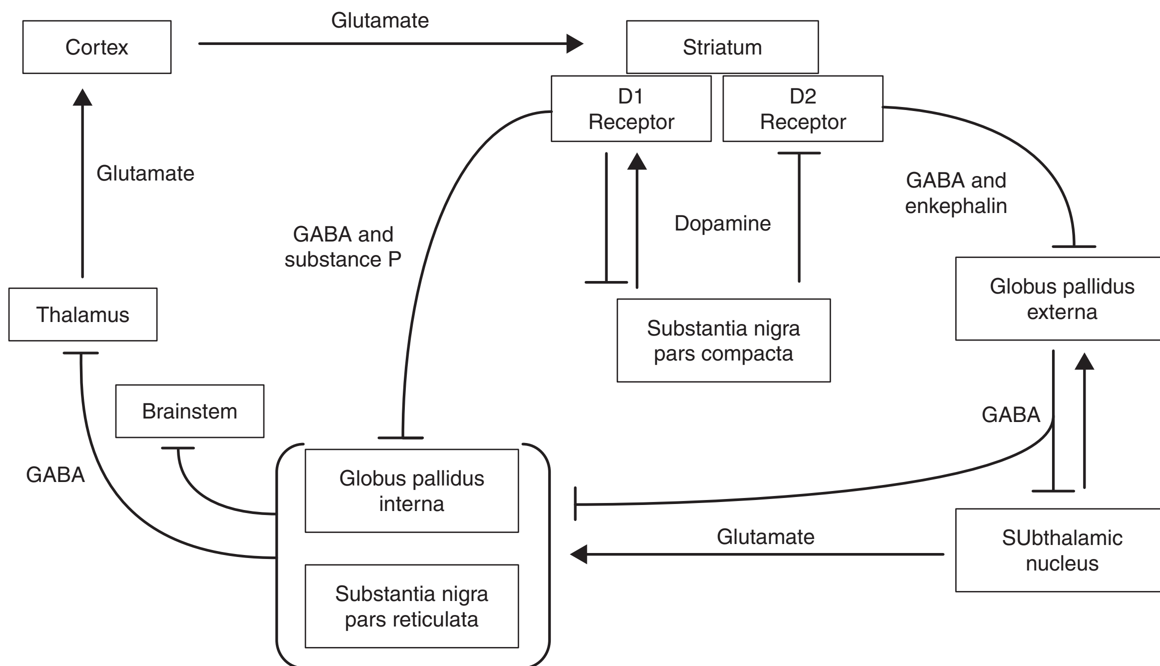

Figure 54.3 Neuronal pathways in the basal ganglia. The overall effect of striatal dopamine release is to reduce basal ganglia output, leading to increased activity of thalamocortical projection neurons. Lack of dopamine results in increased activity of GPi, SN pars reticulata and the STN. This ultimately leads to disruption and inhibition of brain stem motor areas and thalamocortical motor system.

transplanted cells are not afflicted by the same mechanism of neuronal death as the patient's neurons. However, at present a prohibitive number of neurons are required (3–6 fetuses per patient) per patient and current methods of delivery do not lend themselves to treatment of large numbers of patients. Research is underway to grow and differentiate and stem cells into dopamine cells but problems remain. The population of cells produced are not of a pure cell type (i.e. dopaminergic cells) and therefore when implanted into the striatum may actually be detrimental. Studies into creating a pure enriched population of dopamine neurons *ex vivo* and targeting endogenous stem cells for differentiation into dopaminergic neurons are advancing at a significant pace and represent a realistic therapeutic goal for PD.

The Role of Genetics in the Development of Future Therapeutic Strategies

In the near future it will become practical to analyze a person's genome, in a high throughput standardized manner. As a result, identifying genetic variability that alters response to a drug and thus identifying markers that are likely predictors of drug response will gain momentum. Based on this information an individual's drug regime can be tailored to their biological characteristics. This avenue of research should eventually be able to optimize the dose of a drug but also prevent the administration of drugs to individuals who would normally have an adverse potentially lethal reaction. From the opposite side, individuals that respond better to certain drugs may help elucidate biological components of a disease process and identify other potential drug targets. As *L*-dopa is such an effective treatment for PD many of the preliminary pharmacogenomic approaches have aimed to identify biological factors which augment and prolong its result. Accordingly, genes involved in dopamine metabolism have been assessed for their genetic contribution to *L*-dopa efficacy, most notably including analysis of genetic variability within the genes encoding MAO, dopa decarboxylase and COMT among others (Figure 54.2; Maimone et al., 2001). While the initial results of these studies are inconclusive, the application of genome-wide genotyping techniques holds the promise of identifying easily assayable variants that offer predictive value in terms of response to treatment.

The most successful strategies for treating PD will be those that aim to stop or significantly delay the underlying molecular disease processes. Etiology-based treatment will require not only the elucidation of these processes and identification of viable targets but also early diagnosis of the disease. This latter point ensures that protective therapy can be applied before too much irreversible damage has occurred and in the event that the successful therapy is one that slows down but does not halt the pathological process, the therapy can be applied early enough to ensure there is little effect on quality of life for the patient in later years of treatment.

Numerous studies have sought to identify biological or genetic markers that may aid in the pre-symptomatic diagnosis or prognosis of PD sufferer's. As yet no such genetic factors have been identified but ^{18}F-dopa uptake with PET imaging (Khan et al., 2005) and levels of phospho-synuclein have the potential to be used as

pre-symptomatic diagnostic aids (Miller et al., 2004). However, before both can be put into clinical practice, they have to be put to rigorous and extensive testing in large patient cohorts to determine if they are truly diagnostic for disease development and prognosis.

As noted above, it is hoped that highlighting genes involved in the pathogenesis of PD will allow effective modeling of disease in both cell and animal based systems. This in turn will provide a greater understanding of the underlying molecular mechanisms of the disease process and highlight pathways for therapeutic intervention. When these models produce a readily quantifiable endpoint believed to be related to the pathological processes of the disease, they also allow high-throughput screening of molecular libraries of compounds for inhibitors of pathogenic processes. Importantly, the recent discovery of *LRRK2* mutations as a cause of PD has not only provided us with another tool to create model systems of disease, but has also provided clinical researchers with a large patient pool to study disease onset, progression, and response to treatment. Large cohorts of asymptomatic subjects will be relatively easy to identify by assessing siblings and children of patients with G2019S linked disease. This group of subjects affords us the opportunity to not only identify signs and symptoms of disease that may be used as specific early indicators of PD, but also provide a cohort of patients in whom the efficacy of neuroprotective agents can be tested.

2009 UPDATE

Genetic Approaches to PD

A large follow-up study on *LRRK2* (*PARK8*) by the International *LRRK2* Consortium found six pathogenic mutations with frequencies of 1% and 4% in sporadic and hereditary PD, respectively (Healy et al., 2008). This consortium recommended that mutations in *LRRK2* merit testing in patients with hereditary PD.

Genome-wide linkage analysis using a 500K SNP resulted in linkage to chromosome 22 in a large pedigree with Parkinsonian-pyramidal syndrome (PPS). Sequencing of candidate genes revealed a variant (R378G) in *FBX07*, a gene that encodes an F-box protein implicated in protein degradation by the ubitquitin proteosome pathway – a pathway that has been implicated in a variety of neurodegenerative diseases (Shojaee et al., 2008). The role of *FBX07* in neurons is currently not known. Following up on these results, two additional families with early onset, progressive parkinsonism with pyramidal tract signs were assessed for *FBX07*. In one family, a homozygous truncating mutation (A498Stop) was found, whereas in another a variety of compound heterozygous mutations were found. *FBX07* was designated as *PARK15* (Di Fonzo et al., 2009).

Copy number variation (CNV) is becoming a more common finding underlying complex disease. At least two studies reported CNV in α-synuclein (*SCNA*) in sporadic PD (Ahn et al., 2008; Ross et al., 2008). Ross et al. (2008) characterized five families and found that *SCNA* dosage was responsible for the severity of clinical presentation of PD, autonomic dysfunction, and dementia. They screened over 1100 patients and found evidence for *SCNA* multiplication in sporadic PD, suggesting that CNV at this locus should be considered as part of screening for PD.

At least one study investigated the statistical interaction between variants associated with PD. Gao et al. (2008) found a joint effect between polymorphisms in the *FGF20* and *MAOB* genes on PD, suggesting that interactions between *FGF20* and *MAOB* should be considered in investigating PD risk. These genes may interact in regulating dopamine levels in the brain.

The biological interaction of genes may provide another way to define groups of gene variants that may provide greater effect sizes or attributable risk than single gene variants alone. Lesnick et al. (2007) mined large datasets of DNA variations in persons with and without PD and identified SNPs related to axon-guidance pathway genes. The effect sizes and statistical significance for the pathway in predicting disease susceptibility to PD, survival free of PD, and age of onset of PD was greater than any single gene. This approach may have implications not only for studies designed to determine genetic risk for PD but also for the design and analysis of studies of other complex diseases.

Genomic Approaches to PD

An important pilot study was published in 2007 that used gene expression analysis of peripheral blood mononuclear cells to develop "noninvasive" biomarkers of PD (Scherzer et al., 2007). Using a training set of 66 patients and health controls and an independent validation set of 39 patients and controls, a 22 gene model was built that could classify PD (or *de novo* PD) versus a number of other neurodegenerative diseases. A follow-up study of these data showed that a number of neuroimmune signaling pathways were expressed in early PD (Soreq et al., 2008).

Finally, a number of reviews pointed to the potential of neuroproteomics and blood-based proteomic analyses to define novel biomarkers for PD (Goldknopf, 2008; Pienaar et al., 2008). Proteomics provides a "systems approach" that allows for the identification of key proteins and signaling cascades. Examination of disease tissue using this approach can give rise to targets that can be sought in blood that can be used to distinguish PD from other neurodegenerative diseases such as Alzheimers and ALS, provides information that can be used to monitor patients' response to therapy and/or progressive disease, and finally offers the potential to tailor therapies for personalized treatment of PD. CHAPTER

Genomic Considerations in Ophthalmology

Janey L. Wiggs

INTRODUCTION

The function of the eye is to transduce light into an electrical signal and then transmit the electrical signal to the brain. A variety of tissues and specialized cells carry out these complex processes. The ocular globe is divided into two fluid-filled compartments, called the anterior and posterior chambers (Figure 55.1). The anterior chamber is filled with an aqueous fluid called aqueous humor and the posterior chamber is filled with a viscous substance called the vitreous humor. The globe is supported by a tough outer shell, the sclera, that also supports the optic nerve as it exits the eye.

The cornea is a transparent tissue located on the anterior ocular surface that allows light to enter the eye and also helps focus the light on the retina. Inside the eye are a number of structures including the iris and pupil (regulates the amount of light entering the eye), the lens (focuses light on the retina), the ciliary body (makes aqueous humor) and trabecular meshwork (drains aqueous humor). Under normal circumstances the rate of production of aqueous humor equals the rate of removal.

Light traveling through the cornea, pupil and lens is focused on the retina, which carries out the phototransduction of light to produce an electrical signal that is transmitted through the optic nerve to the brain. The retina is a complex tissue made up of 10 distinct layers (Figure 55.2). The most external cell layer is the retinal pigment epithelium, which provides metabolic support and is attached to a basement membrane (Bruch's membrane). Next to the retinal pigment epithelium are the rod and cone photoreceptors, which are the cells where phototransduction occurs. Connected to the photoreceptors are the amacrine, bipolar and horizontal cells that modulate the signal output from the rods (dim light) and cones (bright light). The signal from the photoreceptor goes through the bipolar cells

ROBO3 (Chan et al., 2006) and *HOXA1* (Tischfield et al., 2005). A number of chromosomal syndromes are also associated with strabismus, including Rubenstein–Taybi syndrome (Allanson and Hennekam, 1997), Cornelia de Lange syndrome (Nallasamy et al., 2006) and Down's syndrome (Yurdakul et al., 2006). Screening patients with eye movement disorders for mutations in these genes will help define the diagnosis.

Duane's syndrome is a congenital eye movement disorder characterized by abnormalities of horizontal eye movements, and indicates a problem with cranial nerve VI, the abducens nerve (Bagheri and Repka, 2005). The syndrome can be inherited as an autosomal dominant trait, and using three affected pedigrees a genome-wide scan identified a locus for the syndrome on chromosome 20q13 (Al-Baradie et al., 2002). A novel gene, *LOC57167*, subsequently identified as a new member of the SAL family (*SALL4*) was identified as the causative gene. *SALL4* is a zinc finger protein that shares significant homology with *SALL1* coding for a transcriptional repressor and responsible for a related developmental disorder Towne–Brocke syndrome (Botzenhart et al., 2005). *SALL4* mutations causing Duane's syndrome mainly result in truncated protein products and cause a loss-of-function of the protein (Terhal et al., 2006). The Duane's phenotype suggests that this protein is likely to have an important role in abducens motor neuron development.

A related condition, congenital fibrosis of the extraocular muscles type 1 (CFEOM1) is associated with absence of the superior division of the oculomotor nerve (cranial nerve III) and corresponding midbrain motoneurons and profound atrophy of the two muscles normally innervated by this nerve, the levator palpebrae superioris and superior rectus (Traboulsi, 2004). These two muscles elevate the eyelid and the globe, and their dysfunction accounts for the primary features of the CFEOM1 phenotype. Mutations in KIF21A, a kinesin, have been identified in patients affected with this condition (Yamada et al., 2003). Kinesins are molecular motors responsible for microtubule-dependent transport of cargo; in neurons, they are responsible for anterograde and retrograde axonal transport. CFEOM1 probably results from the inability of mutated KIF21A to successfully deliver a cargo essential to the development of the oculomotor axons, neuromuscular junction or extraocular muscles.

CORNEA

The function of the cornea is dependent on the transparency of the tissue. Any process that causes opacification of the cornea results in a decrease in vision. The cornea can lose its transparency as a consequence of infection (both bacterial and viral), trauma (scar tissue formation) and inherited corneal dystrophies. Genetic causes of corneal disease can be inherited as autosomal dominant and autosomal recessive traits and are caused by mutations in at least nine genes (*ARSC1*, *CHST6*, *COL8A2*, *GLA*, *GSN*, *KRT3*, *KRT12*, *M1S1* and *TGFBI* [*BIGH3*]). Three of these genes (*GSN*, *M1S1*, *TGFBI*) are associated with amyloid deposition in the cornea (review see Klintworth, 2003).

TABLE 55.1 Selected ocular disorders and associated genes discussed in this chapter

Ocular tissue	Specific disorder	Inheritance	Gene – function
Ocular motor (eye movement)	Duane's syndrome	AD	*SALL4* – zinc finger protein; transcriptional regulator
	CFEOM1 (congenital fibrosis of extraocular eye muscles type 1)	AD	*KIF21A* – kinesin; axonal transport
Cornea (dystrophy)	Groenouw's (granular) dystrophy	AD	*TGFB1/BIGH3* – keratoepithelin; extracellular matrix protein
	Lattice type 1 dystrophy	AD	
	Avellino's (combined granular-lattice) dystrophy	AD	
	ReisBückler's dystrophy	AD	
Lens (cataract)	Pulverulent cataract	AD	Alpha3 (C × 46) and Alpha8 (C × 50) – connexins; gap junctions
	Zonular cataract Posterior polar cataract	AD	Alpha A- and alpha B-crystallins – lens proteins
Iris	Abnormal development: Peter's Anomaly Corneal keratitis Aniridia	AD	*PAX6* – transcriptional regulator; gene expression
Trabecular meshwork	Early-onset glaucoma	AD	*MYOC* – Myocilin; extracelluar matrix
Optic nerve	Leber's Hereditary Optic neuropathy	Mitochondrial	Missense mutations in complex I of the respiratory chain (mitochondrial DNA)
	Kjer's optic neuropathy	AD	*OPA1* – dynamin-related GTPase
Retina	Retinitis pigmentosa	AD*	*RHO* – rhodopsin; rod photoreceptor pigment
	Leber's congenital amaurosis	AR	*RPE65* – enzyme responsible for regeneration of 11-cis retinal
	Retinoblastoma	AD	*RB1* – tumor suppressor protein
	Age-related macular degeneration (AMD)	Complex	*CFH* – complement factor H; *LOC387715/HTRA1* – unknown function

*Retinitis pigmentosa may also exhibit autosomal recessive, X-linked and digenic inheritance patterns.

Screening patients with inherited corneal opacities for mutations in this panel of genes will help define the diagnosis and the prognosis. Because some of these disorders are inherited as dominant traits and others as recessive traits, defining the causative gene in an affected individual will also define the disease risk in other family members.

The four most common autosomal dominant corneal dystrophies are: Groenouw's (granular) type 1 (Moller, 1989), lattice type 1 (Klintworth, 1967), Avellino's (combined granular-lattice) (Folberg et al., 1988; Rosenwasser et al., 1993), and Reis–Bückler's (Kuchle et al., 1995). Although all four of these corneal dystrophies affect the anterior stromal layer of the cornea and cause the formation of discrete white localized deposits that progressively obscure vision, the detailed clinical and pathologic features differ. All four dystrophies had been genetically mapped to a common interval on chromosome 5q31 (Eiberg et al., 1994; Gregory et al., 1995; Small et al., 1996; Stone et al., 1994), and mutations in a single gene, *TGFB1/BIGH3*, were subsequently identified in individuals affected with one of the four conditions (Munier et al., 1997). An abnormal protein product of this gene, keratoepithelin, accumulates in patients carrying mutations. The normal protein product is probably an extracellular matrix protein that modulates cell adhesion. Four different missense mutations occurring at two different arginine codons, R124 and R555 have been found. Interestingly, different mutations at the codon R124 cause lattice dystrophy type I or Avellino's dystrophy, the two dystrophies characterized by amyloid deposits (Korvatska et al., 1998). The mutations

that cause Avellino's and lattice dystrophies abolish a putative phosphorylation site that is probably required for the normal structure of keratoepithelin. Destruction of this aspect of the protein structure leads to the formation of the amyloid deposits that cause opacification of the cornea. As a result, the mutant protein is destructive to the normal tissue. Mutations at the R555 appear to result in either granular dystrophy or Reis–Bücklers dystrophy. These phenotype–genotype correlations demonstrate the variable expressivity of mutations in this gene and the significance of alteration of the arginine residues 124 and 555. Of interest, pathologic deposits caused by keratoepithelin accumulation have only been observed in the cornea and not in other tissues or organs (El Kochairi et al., 2006). Because the *TGFB1/BIGH3* gene is expressed in other tissues (Sandgren et al., 1990), these results suggest a cornea-specific mechanism causing the accumulation of mutant keratoepithelin.

LENS

The ocular lens is transparent and focuses the light coming into the eye from the cornea and pupil onto the retina. Cataract is an opacification of the lens that causes a loss of vision and can develop congenitally during childhood and most commonly as an adult (age-related cataract). Congenital cataract is a leading cause of visual disability in children and recently many causative genetic mutations have been identified. Inherited cataract is clinically and genetically heterogeneous with at least 11 different defined phenotypes. Cataracts may be inherited as autosomal dominant, autosomal recessive, or X-linked recessive traits, and at least 12 loci and 15 specific genes are currently identified, with more genes remaining to be discovered (for reviews see Hejtmancik and Kantorow, 2004; Reddy et al., 2004). Two general classes of proteins, the crystallins and the connexins have been associated with early onset cataracts. Screening for mutations in the causative genes will help define the diagnosis in affected individuals. Some forms of early onset cataract severely interfere with vision while others do not. Because of this spectrum of disease severity, in addition to clarification of the diagnosis, genetic screening could help establish a prognosis and also cataract-risk in family members.

Intercellular gap junction channels, consisting of alpha3 (C × 46), alpha8 (C × 50) and alpha6 (C × 43) connexin subunits have been implicated in lens development and maintenance. These channels probably transport metabolites, secondary messages and ions between lens cells (Krutovskikh and Yamasaki, 2000; Xia et al., 2006). Missense changes in these genes have been associated with cataract phenotypes, with changes in the alpha3 (C × 46) and alpha8 (C × 50) associated with a central pulverulent cataract than can have a better prognosis for vision (Berry et al., 1999; Li et al., 2004).

Alpha A- and alpha B-crystallins are the major components of the lens. These proteins are also members of the small heat-shock protein family, and they possess chaperone-like function. Interestingly, mutations in these genes can cause cataract and also various forms of myopathy (Horwitz, 2003). For example, missense and frame-shift mutations in alpha B-crystallin cause autosomal dominant congenital lamellar cataract (Liu et al., 2006), while other missense mutations have been associated with dilated cardiomyopathy (Inagaki et al., 2006). The underlying mechanism appears to be a dominant negative effect that interferes with the normal chaperone-like function of these proteins.

IRIS

The iris contains the pupil, which functions as an aperture regulating the amount of light entering the eye. Disorders causing iris and pupil dysfunction are typically ocular developmental syndromes that lead to abnormal formation of the iris and pupil. These developmental abnormalities can lead to an elevation of intraocular pressure and glaucoma (see below) and also cataract. Most of the genes responsible for these conditions are transcriptional regulatory factors and other proteins that play regulatory roles in ocular developmental processes including *PAX6*, *FOXC1*, *PITX2* and *LMX1B* (for review see Gould et al., 2004; Idrees et al., 2006). Most of the developmental syndromes resulting from mutations in these genes are inherited as autosomal dominant traits. Mutations in these genes are associated with variable expressivity, and there is extensive overlap between the phenotypes associated with the different causative genes. Screening a panel of these genes for mutations in affected patients will define the diagnosis and help identify other family members at risk.

The *PAX6* gene is a transcription factor essential for the development of tissues including the eyes, central nervous system and endocrine glands of vertebrates and invertebrates. It regulates the expression of a broad range of molecules, including other transcription factors, cell adhesion and short-range cell–cell signaling molecules, hormones and structural proteins. It has been implicated in a number of key biological processes including other cell proliferation, migration, adhesion and signaling both in normal development and in oncogenesis (Simpson and Price, 2002). Mutations in *PAX6* are associated with a range of human phenotypes including aniridia (absence of the iris) (Tzoulaki et al., 2005), Peter's anomaly (Singh et al., 1998) and corneal keratitis (Sale et al., 2002). Most mutations cause a truncated polypeptide or disruption of the critical paired box homeodomain (van Heyningen and Williamson, 2002).

TRABECULAR MESHWORK

The trabecular meshwork and related outflow pathways remove aqueous humor from the anterior chamber of the eye. The intraocular pressure is dependent on the rate of fluid removal by the trabecular meshwork which under normal conditions matches the rate of formation. The intraocular pressure can become elevated when the trabecular meshwork no longer

keeps pace with the rate of fluid formation and an elevation of intraocular pressure is a major risk factor for glaucoma (Gordon et al., 2002). Glaucoma is a common blinding disease that results in an irreversible degeneration of the optic nerve (see below). Despite the important function of the trabecular meshwork, very little is known about the molecular pathways involved in fluid removal. A number of genes have been associated with trabecular meshwork dysfunction and elevated intraocular pressure including those that cause abnormal development of the iris and anterior segment (see above and Wiggs, 2005 for review).

The degeneration of the optic nerve associated with high intraocular pressure is an insidious process and significant vision can be irreversibly lost before the patient is aware of the symptoms. Screening for risk factors, including genetic risk factors, is necessary to identify individuals at risk so that pressure-lowering treatment can be initiated before irreversible damage to the optic nerve occurs. Although a major genetic risk factor for glaucoma or elevated intraocular pressure has yet to be discovered, genes that can confer risk in a small number of patients have been described. Missense mutations in the gene coding for myocilin (*MYOC*) are associated with an early onset of elevated intraocular pressure and severe glaucoma (Fingert et al., 2002). Some mutations cause more significant disease than others and probably cause a gain-of-function resulting in retention of the mutant protein in the cell and subsequent cell death (Liu and Vollrath, 2004). Mutations in another gene, *WDR36* are insufficient to cause glaucoma, but patients who have glaucoma and also have changes in this gene have a more severe phenotype (Hauser et al., 2006). The function of the WDR36 protein is not known but may influence immune mechanisms suggesting a possible role for immune response in elevated intraocular pressure (Monemi et al., 2005).

OPTIC NERVE

The optic nerve is the only path for communication between the eye and the brain. When the optic nerve is damaged, irreversible blindness occurs. The optic nerve contains the axons from the retinal ganglion cells that travel through a supporting structure, the lamina cribrosa, before reaching their first synapse in the lateral geniculate body. Inherited disorders of the optic nerve include degenerative processes (primarily glaucoma described above) as well as primary disorders causing optic nerve atrophy (for review see Newman, 2005). Mitochondrial function is a critical element in optic nerve disease: Leber's hereditary optic neuropathy is caused by missense mutations in mitochondrial DNA (Valentino et al., 2004), while Kjer's autosomal dominant optic atrophy is caused by mutations in *OPA1* that also affect mitochondrial function (Olichon et al., 2006). Screening for mutations in genes known to contribute to optic nerve disease can identify individuals at risk, but therapeutic options are currently limited (Johns and Colby, 2002).

RETINA

The phototransduction of light is carried out by the retina. Phototransduction occurs in the rod and cone photoreceptors and is dependent on rhodopsin and the cone opsins. The photoreceptors signal a cascade of retinal neural cells with the terminal axons of the retinal ganglion cells forming the optic nerve. Inherited blinding disorders that affect the structure and physiology of retinal cells participating in this complex process include: retinitis pigmentosa and other retinal degenerations (for review see Kennan et al., 2005); retinoblastoma (for review see Knudson, 2001); and age-related macular degeneration (for review see Tuo et al., 2004; Wiggs, 2006). The role of selected genetic factors in these retinal disorders will be discussed below.

The first gene to be recognized as a cause of retinitis pigmentosa was the gene coding for rhodopsin, the primary pigment in rod photoreceptors. Missense mutations in rhodopsin cause an autosomal dominant form of retinitis pigmentosa (Dryja et al., 1991). In general the rhodopsin mutations associated with retinitis pigmentosa can be placed into two groups: those that affect rhodopsin synthesis, folding, or transport from the rod cell, and those that have detrimental effects on rhodopsin's functions, such as photobleaching, photoactivation and deactivation (Kisselev, 2005). P23H, is the most common mutation associated with autosomal dominant retinitis pigmentosa, and this mutation causes protein misfolding or missorting in the endoplasmic reticulum (Olsson et al., 1992). Missense mutations that affect rhodopsin function, such as K296E cause congenital night blindness in addition to autosomal dominant retinitis pigmentosa (Robinson et al., 1992). Although definitive treatment for these conditions is not currently possible, screening for mutations will help identify individuals at risk.

Leber's congenital amaurosis is a severe blinding condition that leaves infants and children without any useful vision. The most common cause of this condition are mutations in *RPE65* coding for a protein located in the retinal pigment epithelium that is a critical enzyme responsible for regeneration of 11-cis retinal, the chromophore needed for visual pigments (Galvin et al., 2005; Takahashi et al., 2005). Mutations in the gene cause a loss of function of the protein, and restoration of vision has been accomplished in both a canine model and a mouse model of the disease using an rAAV vector containing the normal *RPE65* gene (Acland et al., 2005; Chen et al., 2006). Clinical trials are underway to evaluate the efficacy of injecting *RPE65* viral constructs into human eyes.

Retinoblastoma is the most common primary intraocular malignancy of childhood. Predisposition to the disease can be inherited as an autosomal dominant trait, and the mean age of diagnosis for inherited cases is 12 months of age. Affected children can present with a visible white reflex at the pupil (leukokoria) but tumors can also be located in the retina such that they are not detected by a typical clinical exam. If the tumors are not treated, nearly all patients die of intracranial extension and disseminated disease within 2 years. Careful examination of the retina is

difficult in young children, and usually requires general anesthesia. Children at risk must be examined every 3 months until they have reached an age where tumor development is unlikely (about age 5). The discovery of the *RB1* gene as the causative gene for retinoblastoma made it possible to develop molecular diagnostic tests to detect carriers of mutant forms of the gene (Wiggs et al., 1988). Current methods include the protein truncation test (Tsai et al., 2004) and sequence detection strategies (Houdayer et al., 2004). Individuals identified as carriers of mutant forms of the gene can undergo increased surveillance and timely treatment which involves removal of the eye or treatment of the tumor with proton beam radiation (Abramson and Schefler, 2004).

Age-related macular degeneration (AMD) affects over 10 million Americans and is the leading cause of blindness among the elderly. AMD is a complex disease that results from interactions between genetic and environmental factors. Studies have shown that the risk of macular degeneration increases with age, smoking and excess dietary lipids (Hyman and Neborsky, 2002). Significant genetic contributions have been demonstrated by increased concordance between identical twins, familial clustering and increased risk to first-degree relatives (Stone et al., 2001). Recently variants of two genes, complement factor H (Edwards et al., 2005; Haines et al., 2005; Klein et al., 2005) and a novel gene *LOC387715* (Rivera et al., 2005) have been shown to substantially increase the risk of macular degeneration. These risks are further increased in individuals who smoke (Schmidt et al., 2006). These important results suggest that screening for these genetic factors can identify individuals at risk for the disease and identify individuals who can reduce their risk by behavior modification.

GENETIC TESTING FOR OCULAR DISORDERS

The identification of genes responsible for inherited eye disease and the development of powerful molecular techniques for detecting genetic defects makes it likely that genetic testing for inherited ocular disorders will become commonplace over the next decade. Current genetic tests are available for many ocular disorders, including those discussed in this chapter. A number of CLIA-certified laboratories perform genetic testing for eye diseases in the United States (Stone, 2007), and a group of CLIA laboratories are participating in a genotype/phenotype project sponsored by the National Eye Institute (eyeGENE; http://www.nei.nih.gov). Current tests mainly provide diagnostic information, however, future testing is expected to provide prognostic information. With the additional development of pharmacogenomic tests predicting therapeutic responsiveness, gene-based tests could become an increasingly important component of an individualized treatment plan.

Genetic testing is currently most useful for the numerous rare Mendelian ocular disorders. Recent advances have identified genetic risk factors for two common complex ocular conditions, macular degeneration and one form of glaucoma, pseudoexfoliation syndrome (Edwards et al., 2005; Fan et al., 2007; Haines et al., 2005; Klein et al., 2005; Rivera et al., 2005; Thorleifsson et al., 2007). As more genetic and environmental risk factors for complex diseases are identified, genetic testing will become an important part of establishing risk estimates for these common blinding conditions.

2009 UPDATE

A recent genome-wide association study using Icelandic glaucoma patients and controls demonstrated a very significant association between SNPs in the *LOXL1* gene and pseudoexfoliation glaucoma – one type of age-related, late-onset glaucoma (Thorleifsson et al., 2007). The association in the Icelandic patients has been confirmed in more heterogeneous populations from the United States (Challa et al., 2008; Fan et al., 2008b; Fingert et al., 2007; Yang et al., 2008) and other populations throughout the world, including Australia (Hewitt et al., 2007), Germany (Pasutto et al., 2008), Italy (Pasutto et al., 2008), China (Gong et al., 2008), Japan (Ozaki et al., 2008), and India (Ramprasad et al., 2008). In all the populations studied, the risk genotype at rs3825942 (G153D) accounts for over 90% of the population attributable risk. However, use of this genotype for screening purposes is not yet practical, as the risk genotype is also prevalent in unaffected individuals, significantly lowering the specificity of the test. The high frequency of the risk genotype in controls also suggests that additional factors, both genetic and environmental, are likely to contribute to this disease.

Pseudoexfoliation glaucoma is a specific type of glaucoma characterized by the deposition of microfibrillar material throughout the eye. The composition of the PXFS-related material, although not completely defined, appears to be a complex glycoprotein structure containing elements of basement membranes and the elastic fiber system (Martone et al., 2007). The biological processes that cause this material to accumulate in ocular structures are not known, although recent studies indicate that vascular compromise may be a contributing factor (Parodi et al., 2008). The product of the *LOXL1* gene, *lysyl oxidase like 1*, is a member of the lysyl oxidase family of proteins that catalyze the polymerization of tropoelastin to form the mature elastin polymer. Mice lacking *LOXL1* have abnormal elastic tissues including the basement membranes of blood vessels (Liu et al., 2004). Several studies have suggested that pseudoexfoliation patients have modest elevations of serum homocysteine, which could add further vasculature insult in affected tissues (Altinta et al., 2005; Roedl et al., 2007). Genes coding for proteins that regulate homocysteine

metabolism do not appear to contribute to this syndrome (Fan et al., 2008a), suggesting that the homocysteine elevation seen in these patients may be environmental in origin.

In addition to homocysteine, other candidates for secondary factors influencing the disease have been investigated including *clusterin* (Burdon et al., 2008) and most recently *elastin* (Fan et al., 2009). Variants in these genes were not significantly associated with the disease and did not show any evidence for gene–gene interactions with *LOXL1*, arguing that these genes do not significantly contribute to the condition. Further studies evaluating genes coding for other proteins that interact with *LOXL1* or function in elastic tissues could help identify additional genetic factors contributing to this form of glaucoma.

The *LOXL1* glycine allele specified by rs3825942 is significantly associated with disease in all populations studied; however, it is not yet known if this amino acid substitution is directly responsible for the disease or if it is in linkage disequilibrium with other causal variants. Initial studies have suggested that the condition results from a loss of lyslyl oxidase 1 function, and the glycine at position 153 could affect the catalytic activity of the protein through modifications of propeptide cleavage and binding to substrates such as tropoelastin and fibulin-5 (Schlötzer-Schrehardt et al., 2008).

CHAPTER

Genomics in the Diagnosis and Management of Depression

Brigitta Bondy

INTRODUCTION

Depression is a highly prevalent, potentially life-threatening condition that affects hundreds of millions of people all over the world. It can occur at any age from childhood to late life and exerts a tremendous cost upon society. The psychopathological state involves a triad of symptoms with low or depressed mood, anhedonia and low energy or fatigue. Other symptoms, such as sleep and psychomotor disturbances, feelings of guilt, low self-esteem, suicidal tendencies as well as autonomous and gastrointestinal disturbances are also often present.

Depression is not a homogenous disorder but a complex phenomenon with many subtypes. The differences in symptomatology range from mild symptoms to severe symptoms with or without psychotic features. Interactions with other psychiatric and somatic disorders are quite common. An interaction between depression and cardiovascular disease, with worsened prognosis after myocardial infarction and increased mortality rates, is especially well documented.

The etiology of depression is multi-factorial, including non-genetic and genetic factors. As with most human complex disorders, the relationship between genes and the disorder is not straightforward but the result of complicated interactions between multiple genes and the environment. Similarly, the response to antidepressant medication varies among patients and is also at least partly influenced by genetic variants.

DIAGNOSIS, PREVALENCE AND COURSE OF DEPRESSION

The clinical course of major depression (formerly unipolar depression) is characterized by one or more major depressive episodes without a history of manic, mixed or hypomanic episodes. According to the diagnostic criteria of DSMS-IV (American Psychiatric Association, 1994), five of the following symptoms have to be present for a minimum of two weeks: depressed mood, loss of interest or pleasure, significant alteration in weight and appetite, insomnia or hyposomnia, disturbances in psychomotor activity with either agitation or retardation, fatigue or loss of energy, feelings of worthlessness, diminished ability to think or concentrate and, last but not least, recurrent thoughts of death and suicidal ideation or acts. Recurrent episodes of major depressive disorders may differ in symptomatology and thus show pleomorphic manifestations within one individual (Oquendo et al., 2004).

Essentials of Genomic and Personalized Medicine
by Ginsburg & Willard

The lifetime prevalence of depression is between 10% and 20% in the general population worldwide, with a female to male ratio of about 5:2. Typically, the course of the disease is recurrent and most patients recover from major depressive episodes. However, a substantial proportion of the patients become chronic, and after 5 or 10 years of prospective follow-up, 12% and 7%, respectively, are still depressed (Keller et al., 1997). But patients who recover also have a high rate of recurrence, as approximately 75% of patients experience more than one episode of major depression within 10 years. There is a high level of comorbidity between anxiety and depressive disorders, with co-occurrence rates up to 60% (Gorman, 1996). This suggests that comorbid anxiety and depression are the rule rather than exception. Furthermore, there is high co-occurrence of neuroticism, which is characterized by dysphoria, tension and emotional reactivity and is often a premorbid personality structure and a robust predictor for future onset of depression. It is estimated that both anxiety and neuroticism share about 50% of the genetic factors with depression.

PATHOPHYSIOLOGICAL MECHANISMS

Depressive disorders are complex phenomena in terms of symptomatology and multi-factorial in etiopathogenesis. Although the specific causes have not been elucidated in detail, there is overwhelming evidence that depression is caused by the interaction of multiple genetic risk factors and environmental and neurobiological factors (Mann and Currier, 2006) (Figure 56.1). Cross-influences can be seen between all these pathways, and genes contribute to all of them (Kendler et al., 2006).

The Neurobiological Basis of Depression

Most theories about the neurobiology of depression involve functional deficiencies of the brain monoaminergic transmitters, especially serotonin (5-HT) and norepinephrine (NE). Both neurotransmitters modulate many behavioral symptoms that are disturbed in depression, such as mood, vigilance, motivation, fatigue and psychomotor agitation or retardation. Abnormal function may arise from altered synthesis, storage or release of the neurotransmitters as well as from disturbed sensitivity of their receptors or sub-cellular messenger functions within the synapse (Figure 56.2). Transport proteins play a crucial role in neural transmission, as they reduce the availability of the neurotransmitters in the synaptic cleft and thus terminate their effect on pre- and postsynaptic receptors. It is also noteworthy that most of the available antidepressants have an impact on the 5-HT transporter. On the basis of recent evidence, which showed that the proteins of the postsynapse are involved in long-term adaptive mechanisms in response to altered transmission during disease or when drugs take effect, these proteins are now considered to be the main modulators of neuronal activity and pathophysiology of mental disorders (Manji and Duman, 2001). Newer hypotheses stress the importance of this adaptation or plasticity of neuronal systems and propose that depression could result from an inability to make the appropriate adaptive responses to stress or other aversive stimuli, and that antidepressants may act by correcting this dysfunction or by directly inducing the appropriate adaptive responses (Duman, 2004). Neurotrophic factors (e.g., the brain-derived neurotrophic factor (BDNF), and the BDNF receptor (trkB)) are involved in these processes and promote the function and growth of neurones in the adult brain that contain 5-HT.

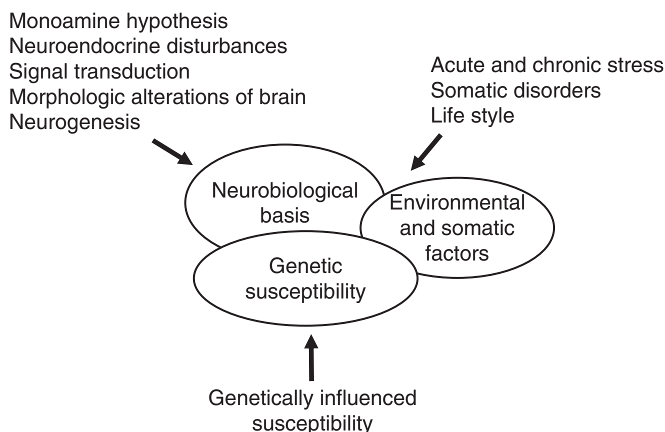

Figure 56.1 Hypothetical model for the etiology of depression.

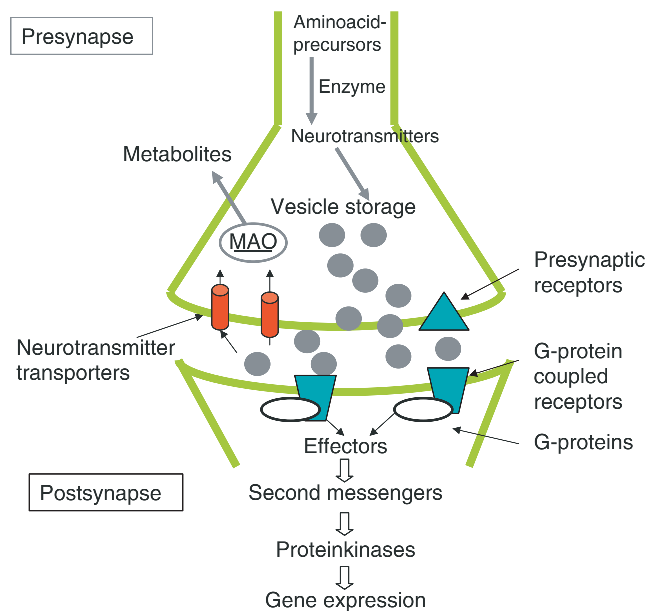

Figure 56.2 The signal transduction cascade in the synapse. All compartments may be disturbed, beginning with neurotransmitter production, storage and release within the presynapse, down to postsynaptic events, mediated via neurotransmitter–receptor coupling and the activation of postsynaptic effectors. According to recent knowledge, the long-term adaptation processes with regulation of gene expression are crucially involved in pathophysiology of disorders and drug response.

Despite these transmission processes within neurones, the stress-response system involving the hypothalamus-pituitary-adrenal (HPA) axis is of paramount importance in the development of depression. One of the consistent findings in psychiatry is that a significant proportion of depressed patients hypersecretes hypothalamic-corticotropin-releasing hormone (CRH), which stimulates adrenocorticotropin (ACTH) secretion from the pituitary and finally leads to increased cortisol levels and inadequate glucocorticoid feedback (Holsboer, 2000). Furthermore, various stress hormones interact with the serotonergic system on several levels, as sustained CRH or cortisol overdrive down-regulate the serotonergic system in terms of turnover, activity of the neurons and alterations on the receptor basis (van Praag, 2005). Thus, a possible conclusion might be that disturbances of the 5-HT and stress hormone systems are of pathophysiological relevance in depression and are not merely an epiphenomenon of the condition.

Genetic Basis of Major Depression

It is well known that depression runs in families. Numerous studies have documented that first-degree relatives of mood disorder patients have an approximately threefold risk of developing depression. There is further evidence that these relatives are also more susceptible to anxiety, substance abuse or social impairment compared to the offspring of non-depressed parents (Weissman et al., 2006). However, the familial loading could also be the result of shared environmental factors, thus suggesting that the vulnerability to depression could be due to nurture rather than nature. A number of studies comparing the prevalence of depression among mono- and dizygotic twins gave sufficient evidence that major depression (as a disease) is moderately heritable, and on the basis of these twin studies, estimated that heritability may be 40–50% (Malhi et al., 2000). Furthermore, there is no doubt that more than one single gene is responsible for the increased vulnerability and that considerable gene–gene and gene–environment interactions complicate the identification of relevant susceptibility genes (Levinson, 2005).

Genetic Linkage Analyses

As heritability of depression does not follow the Mendelian pattern, the available linkage analyses that investigated a major gene effect are less convincing, and genome scan results are not yet available. Nevertheless, in the last decade a number of different results were obtained for depression and related traits. Selected regions on chromosomes 3, 4, 6, 12, 15 and 18 (for review see Levinson, 2005), especially in combination with depression-related personality traits such as neuroticism and harm avoidance, have received support from more than one study. However, as is the case for all linkage analyses for complex disorders, one cannot predict which will be true positives in the long run and thus until now none of these chromosomal regions has really been accepted as a susceptibility gene for depression. As statistical power is one of the fundamental problems of most studies, the full impact of genetic linkage findings on the search for depression susceptibility genes might come from combined analyses of multiple datasets (Levinson, 2005).

As major depression is such a complex disorder, association studies, despite all their well-known pitfalls, appeared to be more suitable than linkage analyses and it was hoped that this method might unravel minor effects of genes. The selection of candidate genes followed the neurobiological hypotheses of depression, which will be summarized briefly here.

Association Studies with Different Candidate Genes

Due to the prominent importance of the serotonergic system, association studies have so far focused on polymorphisms in genes encoding for the rate-limiting synthesizing enzyme tryptophan hydroxylase (TPH), the serotonin transporter (5-HTT), the different 5-HT receptors and the degrading enzyme, monoamine oxidase-A (MAOA).

The majority of studies were carried out with the serotonin transporter, which is a crucial protein within the synapse as it cleaves 5-HT from the synaptic cleft and is the target protein of the selective 5-HT reuptake inhibitors and other antidepressants (see section: Psychopharmacogenetics). A polymorphism within the promoter region of the 5-HTT (5-HTTLPR), comprising a 44-base-pair insertion/deletion resulting in short (S) and long (L) alleles, was shown to affect the transcription and thus the function of the gene (Heils et al., 1995). Many studies followed the first findings that the S-allele is associated with anxiety (Lesch et al., 1996), but the results were discrepant and even meta-analyses yielded inconclusive results as to whether the S-allele confers a risk for depression. Methodological issues might be one explanation for the failure to find such an association, because in most studies the samples were small and clinically heterogeneous. In this respect it is remarkable that a recent study, which investigated a large and clinically well characterized sample, clearly demonstrated that the S-allele of the 5-HTTLPR was significantly more frequent in depressed patients than in controls (Hoefgen et al., 2005). This finding could be independently replicated in a large cohort of the Spanish population (Cervilla et al., 2006). On the basis of these new and methodologically subtle studies, one might be tempted to speculate that the S-allele of the 5-HTTLPR might have a small but independent effect on the vulnerability for depression.

A further interesting and promising gene of the serotonergic pathway is the recently identified, brain-specific TPH2 gene (Walther et al., 2003), which is the limiting enzyme in serotonin synthesis of the central nervous system (CNS). There is now evidence that a region in or around introns 5 of the TPH2 gene might be a susceptibility locus for depression. Zill and colleagues were the first to associate a haplotype in intron 5 with major depression (Zill et al., 2004a) and completed suicide (Zill et al., 2004b). Although the exact location and characterization of the relevant mutations have yet to be established, there are now three independent studies showing that haplotype blocks in regions overlapping with that reported by Zill et al. are associated with major depression, suicidality and bipolar disorder patients of different ethnic groups (Harvey et al., 2004; Van Den et al., 2006; Zhou et al., 2005).

Many other genes of the serotonergic pathway were investigated by several groups, but although some positive results emerged the data were contradictory and even some meta-analyses

TABLE 56.1 Important association studies in major depression

Gene symbol	Gene	Result
BDNF	Brain derived neurotrophic factor	270CT, negative result
CRHR1	CRH receptor	One positive result, not replicated
DRD4	Dopamine receptor D4	48 bp repeat, questionable association
GNB3	G-protein β3	Questionable, partly replicated
5-HT1A	Serotonin receptor 1A	−1019CG polymorphism affect serotonin system Predispose depression
5-HT2A	Serotonin receptor 2A	No association
5-HTTLPR	Serotonin transporter	S-allele associated with anxiety, neuroticism S-allele associated with depression in response to stress
TPH2	Tryptophan hydroxylase, brain specific	SNPs in introns 5 associated with depression

Adapted from Levinson, 2005.

did not give convincing evidence for a significant interaction between any of these investigated genes and the genetic liability for major depression (for review see Leonardo and Hen, 2006; Levinson, 2005). A summary of findings of genetic association studies is listed in Table 56.1. Genome-wide association studies could be very valuable and are currently being carried out, but the results are not yet available.

Evaluating the results of both linkage and association studies it emerges that, besides the established heritability for depression, a susceptibility gene or set of genes could not be identified so far. Beyond the fact that mood disorders are complex in nature, may represent a family of related but distinct conditions and are probably polygenic, the definition of the clinical phenotype of depression is a serious problem in molecular genetic studies. Although the diagnostic criteria seem to be clearly defined by the DSM-IV criteria, the co-occurrence of other psychiatric disorders, such as anxiety or alcohol/drug constitutes a major challenge in genetic studies.

Genetics of Emotional Regulation and the Response to Stress

The identification of biological mechanisms through which genes lead to differences in emotional behavior is paramount to understanding how genes confer risk for psychiatric disorders such as depression (Hariri and Holmes, 2006). As 5-HT is a key modulator of emotional behavior sub-serving anxiety and depression, the effects of gene variations in the serotonin transporter gene were investigated for their influence on temperament, character, and the regulation of emotion. After the first observation almost a decade ago (Lesch et al., 1996) that individuals carrying at least one S-allele of the 5-HTTLPR displayed higher levels of anxiety, neuroticism and harm avoidance, many studies were performed to confirm this observation. Although the results of the various studies were not consistent, meta-analyses have demonstrated a significant association between the S-allele and these personality traits (for review see Hariri and Holmes, 2006; Munafo et al., 2005).

Emerging evidence from human and animal studies indicates that a relative loss in the 5-HTT gene function not only increases anxiety but also exerts a negative influence on the capacity to cope with stress, which further increases the risk for mood disorders. This was underlined by a study by Caspi et al., who investigated a representative cohort in a prospective, longitudinal study (Caspi et al., 2003). They could show that individuals with one or two copies of the S-allele exhibited more depressive symptoms, more diagnosable depression and more suicidality in relation to stressful life events than individuals who were homozygous for the L allele. This finding suggests that genetic variants may act to promote one's resistance to environmental pathogens and that the S-allele moderates the "depressiogenic" influence of stressful life events. Similar studies followed and replicated these findings about an increased vulnerability to stress in S-allele carriers, and were further extended to the impact of the dopamine D4 receptor gene (Ebstein, 2006; Hariri and Holmes, 2006). In addition, the study by Grabe et al. (2005) demonstrated this gene–environment interaction in relation to the 5-HTTLPR genotypes in a cohort with severe mental and physical distress (e.g., myocardial infarction, stroke, diabetes and degenerative diseases). They found an interaction between the 5-HTTLPR S-allele and unemployment or chronic disease, but only in females. This finding goes beyond those of the previous studies, and indicates a higher mental vulnerability to social stressors and chronic disease. All these recent findings demonstrate that the 5-HTTLPR affects not only central 5-HTT function, but as a consequence seems also to be involved in the regulation of bio-behavioral characteristics.

Recent studies have begun to investigate how the 5-HTTLPR S-allele might mediate stress reactivity at the level of the neural pathway regulating emotion. The non-invasive method of neuroimaging was used to determine the effects of 5-HTTLPR

on reactivity of the amygdala, a brain region that is crucial in mediating emotion, to stress. An amygdala hyper-reactivity to stress was shown in S-allele carriers in several ethnically different cohorts (Hariri and Holmes, 2006). Thus, these findings identify a possible neuroanatomical substrate for the negative affect associated with the S-allele in healthy volunteers.

PHARMACOGENOMICS OF ANTIDEPRESSANTS

There is substantial unexplained interindividual variability in the response to treatment with psychoactive drugs, as a proportion of patients who receive a regular dose do not respond adequately or experience limiting side effects. Despite the availability of a vast variety of drugs, about 30–50% of patients are non-responders. The nature of drug response is a highly complex phenomenon involving genetic and non-genetic factors, the latter including age, gender, hepatic and renal status, nutrition, smoking and alcohol intake. Within the last decade, the concept of individualized drug therapy on the basis of genetic investigations has become a major issue in psychopharmacology. After early positive results there was much enthusiasm about the identification of a genetic make-up that would be ideal to optimally tailor drug treatment in psychiatry.

Numerous association studies have been carried out since then, with genes coding for either the pharmacokinetic (i.e., the processes that influence bioavailability) or pharmacodynamic (targets of drug action) pathways. Most pharmacodynamic studies investigated candidate genes that were proposed either by the etiopathology of depression or by the putative pharmacological mechanisms of the drugs (Reynolds et al., 2006). However, despite some advances in various fields, the final goal of an optimally tailored therapy still remains elusive.

Polymorphic Drug Metabolizing Enzymes and Pharmacokinetic Aspects

All antipsychotics are subject to extensive metabolism by various enzymes of the cytochrome P-450 (CYP) family, which play a pivotal role in the elimination of these drugs and therefore influence their efficacy and toxicity. Factors that affect CYP function and expression, such as CYP pharmacogenetics and the processes of inhibition and induction, all influence the *in vivo* rates of drug elimination (Murray, 2006). Genetic variants in CYP enzymes constitute multi-allelic systems that express a variety of phenotypes. Patients with these phenotypes can be distinguished as poor (PM), intermediate (IM), extensive (EM) or ultrafast metabolizers (UM) (Brosen, 2004). The PMs lack an active form of the expressed enzyme due to an inactivating allelic variant, IMs have at least one copy of an active gene and UMs contain duplicated or amplified gene copies, thus leading to either increased, maybe toxic, or decreased, maybe ineffective, concentrations of the drug (Oscarson, 2003). Although many CYP enzymes are known, only a few of them are relevant for metabolism of psychoactive drugs, mainly the CYP1A2, CYP2D6, CYP2C19 and CYP3A4.

Earlier studies focused on the interaction between CYP genotype, the plasma concentration of the drugs and the response to treatment. Although a relation between the CYP genotype and plasma concentration could be shown, a clear effect on drug response is missing. The processes of CYP induction and inhibition may have tremendous effects on drug elimination and thus on the incidence of adverse drug effects. Thus, inhibition of the metabolizing enzyme might convert an EM to a PM type. Since many if not most depressives are on a multidrug regimen, there is a large potential for enzyme inhibitory reactions and an increased rate of adverse drug effects. Especially co-medication with antidepressants, but also with some antibiotics or β-blockers, might considerably increase the plasma concentrations of the main drug (Table 56.2); this interaction is

TABLE 56.2 Major cytochrome P450 isoenyzmes (CYP), their substrates, enzyme inhibitors and inductors

Enzyme	Substrate	Inhibitor	Inducer
CYP1A2	TCAs (e.g., amitriptyline, clomipramine, imipramine), duloxetin, fluvoxamine, mirtazapine	Fluvoxamine, grapefruit juice, antibiotics	Carbamazepine, hyperforin, nicotine
CYP2C19	TCAs (e.g., amitriptyline, clomipramine, doxepin, imipramine, trimipramine); SSRIs (e.g., citalopram, fluoxetine, sertraline), moclobemide, venlafaxin,	Fluoxetine, valproic acid, fluvoxamine	Carbamazepine, phenytoin
CYP2D6	TCAs (e.g., amitriptyline, clomipramine, desipramine, imipramine, nortriptyline); SSRIs (e.g., fluoxetine, fluvoxamine, paroxetine),duloxetin, mianserin, venlafaxine,	Fluoxetine, paroxetine, citalopram, duloxetin, fluvoxamine, fluphenazine, moclobemide, haloperidol, perphenazin, propranolol, antibiotics	No inducer known
CYP3A4	TCAs (e.g., amitriptylin, clomipramin, imipramin), citalopram, reboxetine, venlafaxin,	Fluoxetine, fluvoxamine, olanzapine, grapefruit juice nicotine	Carbamazepine, hyperforin, phenytoin

extremely important in those patients who are already PMs due to genetic variants (Grasmader et al., 2004).

On the other hand, some drugs such as carbamazepine, phenytoin or hyperforin are known to up-regulate CYP expression in the liver; the respective substrates are then eliminated more rapidly via this enzyme induction (Grasmader et al., 2004). Together with environmental factors such as smoking and/or alcohol consumption, both of which are inducers of CYP activity, genetic factors might lead to different metabolism of a given drug.

Pharmacodynamic Aspects: Response to Treatment

The term pharmacodynamics encompasses all processes influencing the resulting effect, such as the interaction with target proteins or with mechanisms that are modulated by this interaction. The primary targets of antidepressants are known and are congruent with the etiological hypotheses. For this reason, mostly candidate genes from the monoaminergic pathway have so far been investigated.

One of the most consistent findings in pharmacogenetics is the involvement of the serotonin transporter (5-HTT), which is not only the initial target of the selective serotonin reuptake inhibitors (SSRIs), but is also affected by most of the other antidepressants. The functional variant in the 5'-regulatory region of this it was repeatedly shown in independent that the S-allele is associated with slower response to SSRIs such as paroxetine, citalopram and fluvoxamine, as demonstrated in more than two independent studies (for review see (Serretti et al., 2005). Interestingly, this polymorphism also seems to be involved in response to drugs beyond the SSRIs, for example lithium ions, which are widely used as a mood stabilizer (review (Binder and Holsboer, 2006). Other possible candidate genes of the serotonergic system were those coding for the different 5-HT receptors, the rate-limiting enzyme for the synthesis of tryptophan hydroxylase (TPH1), or monoamine oxidase (MAO), the degrading enzyme. Further investigated genes were of the norepinephrine and dopamine systems (Serretti and Artioli, 2004; Serretti et al., 2005), however, only a few consistent and replicated studies are available (Lefebvre et al., 2006) (see Table 56.3).

TABLE 56.3 Important genes tested for association with antidepressants drug response

Gene symbol	Gene	Association with response
ACE	Angiotensin converting enzyme	Yes, not independently replicated
COMT	Catechol-O-methyltransferase	Yes, not independently replicated
CYP2D6	Cytochrome P450, family2, subfamily 6	Yes, independently replicated
DRD2	Dopamine receptor D2	No
FKBP5	FK506 binding protein	Yes, independently replicated
GNB3	G-protein β3	Yes, independently replicated
HTR1A	Serotonin receptor 1A	Yes, not independently replicated
HTR2A	Serotonin receptor 2A	Yes, independently replicated
MAOA	Monoamine oxidase A	No
HTT	Serotonin transporter	Yes, independently replicated

GENE AND PROTEIN EXPRESSION STUDIES

New techniques such as proteomics and the cDNA micro-arrays represent prominent expression profiling techniques to investigate multi-factorial and polygenic complex traits. These techniques allow to study the expression of thousands of genes or proteins in one experiment and are thus powerful instruments for the analysis of pathophysiological mechanisms and for the search for new drug targets (Bertilsson et al., 2002). Most of the work currently carried out covered pharmacogenomic aspects and a recent review demonstrated certain novel candidate genes that may underlie the mechanism of action of antidepressants. Among them are genes affecting neurogenesis (via the HPA axis and related neuroendocrine systems, the cAMP messenger system as well as phopshorylation of CREB), neurotransmitter release and neurite outgrowth via cysteine string protein, as well as several neural cell adhesion molecules (for review see (Yamada et al., 2005)). These findings support the hypothesis that plasticity represents the mechanism of action of drugs. Concerning pathophysiological mechanisms of depression alteration of signaling-, oligodendroglial- and GABA-related genes have been observed and opened up new aspects for studying the pathophysiologic mechanisms and the treatment of the disorder (for review (Sequeira and Turecki, 2006).

Proteomic analyses uses two-dimensional electrophoreses and subsequent mass spectrometric sequencing of proteins to investigate protein changes in relation to the disorder or drug treatment. Due to limited accessibility of postmortem brain samples and several technical problems (as e.g., postmortem delay), only few studies have been carried out with this technique, but they may be seen as a non-hypothesis driven screening method for the detection of new candidates genes in neurobiological research (Johnston-Wilson et al., 2000; Schlicht et al., 2006).

FUTURE CONSIDERATIONS

Although the findings described above are important, none of the positive results can fully account for the heterogeneity in depression or in response to antidepressant treatment. Despite the fact

that most of the genetic studies evaluated small samples and only one or a few genetic variants, it appears almost impossible to identify a susceptibility gene for "depression" as a disorder. One of the main reasons for this is the involvement of complex emergent phenomena, including character, temperament and several neurobiological factors, all of which underlie a genetic contribution. The well-known comorbidity between anxiety, depression and neuroticism, with their interacting genetic contributions, further complicates the identification of a disease susceptibility gene as genes influence all levels of cognitive and emotional behaviors and all levels of biology, and thus transcend phenomenological diagnoses (Hariri and Holmes, 2006).

After years of limited success the field is now conceptually evolving from trying to find a gene or genes that confer a risk for the development of depression or are involved in treatment response. Our increasing knowledge of the basic neurobiology and of the complex interactions and functional circuits will have an increasing impact on the search for relevant genes. Newer hypotheses about depression beyond the monoaminergic theory will produce new sets of candidate genes. According to recent hypotheses about the neurobiology of depression these candidates will emerge from the processes of brain development, the long-term response to stress, regulation of the HPA axis and cortisol secretion as well as from neurotrophic, neurotoxic or inflammatory processes, each of which are also genetically influenced.

Similarly, it is still unclear which neurotransmitter systems are the ultimate target via which drugs produce a clinical effect. This means that the majority of genes responsible for drug response are still unknown. The pharmacogenomic approach uses the recent advances in experimental genomics and proteomics, together with the available sequence information of the Human Genome Project. These developments will not only enable genome-wide screens of several millions of SNPs without the use of a candidate gene strategy, but also functional investigations of gene and/or protein expression on the whole genome or proteome level. The goal of pharmacogenomics is to study the mechanisms by which different genetic factors affect the organism's drug response. This will help to find the most efficacious treatment for patients with specific genetic profiles (Paez-Pereda, 2005).

Although there is no doubt that large-scale gene and/or protein expression analyses or whole genome analyses will provide new insight into the pathophysiology of depression and the mechanisms of therapeutic effects and adverse drug reactions, we are presently lacking a serious impact of genomics in daily clinical management. Considering the well-documented increased familial vulnerability for the disorder, an identification of persons at risk is highly warranted. However, as the vulnerability for the disorder might not directly be caused by a mutant gene but by an altered interaction between the mutant gene and other predisposing factors, future research will be directed toward these interactions. To give an example: the serotonin system plays an important mood mediating role, alterations in genes and their functional consequences on the protein might be among the first to be recognized as vulnerability markers. Although this serotonin innate vulnerability, by itself, is not sufficient to cause a depressive episode (Firk and Markus, 2007), it was shown that additional factors, such as environment might trigger the outburst of the disorder. Thus, healthy individuals with a positive family history of depression and a genetic susceptibility that may be due to a polymorphism in the 5-HT transporter which deteriorates stress coping mechanisms, are more prone to develop depression. This example is the beginning of current and future research and thus opens up interesting options in the future management of depression and the identification of high-risk subjects.

2009 UPDATE

Recent advances in genetic and pharmacogenomic studies

A recent meta-analysis summarized about two hundred papers that met the criteria for statistical evaluation (Lopez-Leon et al., 2008). Investigated were the already known candidate genes for depression, but also several new data were available. The authors concluded that six genes might be relevant for the genetic susceptibility for depression. Among them were those previously discussed, including the serotonin transporter (*5-HTTLPR* and the 40 bp VNTR), the G-protein-ß3 subunit GNB3, as well as the DRD4 receptor polymorphisms. But also other alleles, such as the *APOE* ε2 allele and the 677T-allele of the methylenetetrahydrofolate reductase (*MTHFR*) gene, were shown to have some relevance in the susceptibility for major depression.

New pharmacogenomic data are now available that has been obtained with a sample of 4000 patients being treated with selective serotonin reuptake inhibitors (STAR*D study; Sequenced Treatment Alternatives to Relieve Depression). According to these results, some of the previously discussed genes, such as genes for the FK506 binding protein (FKBP5), the 5-HT2A- and the 5-HT1A-receptors as well as the serotonin-transporter, are now confirmed, at least in the treatment with serotonin reuptake inhibitors. But also some other, so far sparsely investigated genes, entered the focus of interest, such as those for the glutamate receptors or the potassium channels (Lekman et al., 2008, Lin and Chen, 2008).

As pharmacogenomics is a rapidly evolving field, some methodological guidelines have recently been proposed in order to reveal more reliable results (Serretti et al., 2008). Specification of sampling source (inpatients versus outpatients, primary versus tertiary settings), standardization of diagnostic systems and treatments, adequate monitoring of compliance through plasma levels, sufficient length of observation (at least 6 weeks for acute antidepressant treatments, though 3-6 months are preferable), the use of a range of response criteria and the inclusion of possible environmental confounding

variables (life events, social support, temperament) are all potentially important issues when planning pharmacogenetic studies.

Epigenetic mechanisms may explain heterogeneity

Considering the diversity of results in genetic studies, heterogeneity of both mechanisms of disease and response to treatment might be a plausible cause. Recently it was recognized that epigenetic mechanisms may be a potential major complication in genetic and pharmacogenomic studies of depression, as they can produce long-lasting changes in protein availability and function. Epigenetic mechanisms, such as DNA methylation, might ultimately abolish gene function, even without a DNA sequence change, and have thus long-lasting effects within mature neurons (Tsankova et al., 2007). Given that these changes may considerably influence gene-environment interactions, epigenetics can explain several aspects of depression, including the high concordance rates among monozygotic twins or the greater prevalence of depression in women (Krishnan and Nestler, 2008).

Although human data in depression are still lacking and most of our knowledge concerning this concept derives from animal studies, the data and the hypotheses are convincing. According to the first studies with animals, significant stress or primary experiences can influence supporting structures of DNA like chromatin in several regions of the brain, being relevant for developing depression, and these changes in DNA might be directly related to behavioral abnormalities.

CHAPTER

Genomic Approaches to the Host Response to Pathogens

M. Frances Shannon

INTRODUCTION

Following a period of relative disinterest in infectious disease research due to the enormous impact of vaccines and antibiotics on the spread of and mortality from these diseases, there is now renewed and growing interest in this area of research. This has been driven by several recent worldwide developments including: (i) the rising incidence of diseases such as Acquired Immune Deficiency Syndrome (AIDS) and antibiotic-resistant tuberculosis; (ii) antibiotic-resistant bacterial strains presenting a severe health threat in hospitals; (iii) the rapid spread of new pathogens such as Severe Acute Respiratory Syndrome (SARS); and (iv) the threat of bioterrorism. Indeed, nearly 25% of annual deaths worldwide are due to infectious disease (Morens et al., 2004). Thus, the need to develop new diagnostic methods, more effective vaccines and better therapeutic strategies is urgent.

In order to effectively deal with infectious disease threats, it is important to understand both the pathogen and the response of the host, since the outcome of infection is determined by complex host–pathogen interactions. Pathogens are initially detected by the surveillance cells of the innate immune system using cell surface receptors known as Toll-like receptors (TLRs) (reviewed in [Cook et al., 2004]). These TLRs recognize specific components of the pathogen, for example, bacterial lipopolysaccharide (LPS) or double-stranded (ds) RNA from viruses. While many cell types express TLRs, cells of the innate immune system such as dendritic cells (DCs) and macrophages play particularly important roles in detecting and responding to pathogens. The response of these cells to a pathogen is determined by the specific pathogen component that interacts with the TLR and the specific TLR family member that is activated. Widespread changes in gene expression are detected following TLR activation and the activated cells produce a plethora of cytokines and chemokines that then activate the adaptive arm of the immune system. The specific cytokines and chemokines produced by the TLR-activated cells tailor the response of the adaptive immune system to deal with the specific pathogen (Cook et al., 2004). Thus, the initial host response to a pathogen through the TLRs determines the outcome of the infection. Host response to infection can be a double-edged sword in that sometimes the response itself can create an adverse outcome for the host. In addition, the aberrant response of the host to self instead of foreign pathogens can create severe pathologies involving chronic inflammatory and autoimmune diseases.

The urgent need to better understand host–pathogen interactions has come at a time when genomics and related technologies are expanding rapidly. The availability of complete genomic sequences of an expanding number of pathogens, the human and mouse genome sequences and the advent of genome-wide genotyping and gene expression profiling has opened up new avenues of investigation in the field.

The genotype of the pathogen plays a major role in the response of the host to infection with more virulent pathogenic

strains often possessing the capability to interfere with the host immune response (Fitzgerald and Musser, 2001; Kato-Maeda et al., 2001; Schoolnik, 2002). In addition, different individuals in a population can have very different responses to a genetically identical pathogen. While there are many complex reasons for this, it is clear that part of the differential response is governed by underlying genetic differences between individuals (Clementi and Di Gianantonio, 2006; Zhang and Zhang, 2006). Studies in mouse models of infection have clearly demonstrated that these genetic differences are complex and may involve more than one genetic locus for a given susceptibility or resistance trait (e.g., [Delahaye et al., 2006]). While there are some classic examples of genetic mutations affecting the response of the host to a pathogen (e.g., malaria and sickle cell mutations) there is much to be learned before the genetics of host susceptibility is fully understood. The advent of genome-wide genotyping using single nucleotide polymorphisms (SNPs) or microsatellite markers, leading to major advances in molecular epidemiology, will revolutionize our ability to determine the complexities of the genetic component of pathogen–host interactions (Weiss and Terwilliger, 2000).

It is well known that the cells of the host immune system are activated upon detection of a pathogen by TLRs as described above. This activation process includes widespread changes in the gene expression profile of the cells with hundreds of genes being either switched on or off in response to signals generated from the pathogen-detecting TLRs. The response of individual genes has been studied in minute detail for a handful of genes and while this has produced an understanding of some aspects of host response to infection it by no means gives us the total picture. Understanding the molecular response of the host to infection has been greatly improved by using microarray-based technologies and these technologies are opening up new diagnostic possibilities as well as presenting new therapeutic options (Aderem and Smith, 2004; Bryant et al., 2004; Feezor et al., 2005; Hedeler et al., 2006; Korth and Katze, 2002; Ng et al., 2006; Ricciardi-Castagnoli, 2005; Ricciardi-Castagnoli and Granucci, 2002; Smith and Bolouri, 2005).

This chapter will focus on two aspects of the host response to pathogens where major advances are being made using genomics approaches and will describe the future impact of these approaches on the development of diagnostics and therapeutics for infectious disease. These are (i) defining the basis of genetic susceptibility to infection and (ii) the definition of the system-wide molecular response to a pathogen.

GENETIC SUSCEPTIBILITY TO PATHOGENS

It is now relatively easy to map genes associated with genetic diseases that show a Mendelian pattern of inheritance. However, these diseases account for only a very small proportion of the human disease burden and many of the more common and fatal diseases have a complex etiology with many genetic and environmental contributions. While it is clear that most complex disease has a genetic component, defining that genetic component has been difficult to date since many complex diseases such as coronary heart disease, diabetes and others are polygenic with different genetic loci contributing in major or minor ways to disease susceptibility. In addition, in different populations or under different environmental conditions, distinct but overlapping sets of genetic loci are likely to contribute. The sequencing of the human genome and the genome-wide genetic and functional mapping that has followed have raised hopes of mapping the genetic component of complex disease and there are many large efforts around the world with this aim.

Studies in both animal models and human populations have shown that infectious disease and the response of the host to a specific infection also has a complex genetic component (Clementi and Di Gianantonio, 2006; Lipoldova and Demant, 2006; Marquet et al., 1996; Mira et al., 2004). Thus, inbred mouse models have been developed that clearly show a genetic component to susceptibility for specific pathogens and in some cases at least part of the underlying genetic reason has been defined (Beck et al., 2000; Mak et al., 2001; Rogner and Avner, 2003). Mapping the genetic components of susceptibility to infection in human populations has been much more difficult due to the large natural variation in humans, the polygenic nature of this trait and the low penetrance of many of the susceptibility alleles. For infectious disease, this is complicated even more by the complex nature of the environmental influences particularly the fact that these diseases, unlike other complex diseases, are transmissible in populations. However, a combination of animal and human population studies, combined with the latest genomic technologies, is beginning to unravel the issues of genetic susceptibility to infection.

The use of inbred and congenic strains of mice are well established systems for identifying susceptibility loci (Beck et al., 2000; Rogner and Avner, 2003). In recent years genetic manipulation of specific loci by deletion or mutation has provided many mouse models for screening (Mak et al., 2001). The use of ethylnitrosourea (ENU) mutagenesis to randomly create point mutations in the mouse genome has opened up a new forward genetics approach to identifying susceptibility loci (Papathanasiou and Goodnow, 2005). This chemical mutagen, when used at appropriate doses and at the correct stage of development, can introduce single point mutations into the mouse genome. By screening libraries of mutant mice for susceptibility to specific pathogens, it should be possible to identify genetic loci that dictate susceptibility or resistance to a range of pathogens on a large scale. It is relatively straightforward to identify a chromosomal region involved in susceptibility in these mouse strains by genotyping with microsatellite markers, but identifying the specific gene that is mutated is still very time-consuming. The speed with which this can be achieved depends on the presence of candidate genes within the chromosomal interval or the ability to resequence large amounts of DNA. The latter is becoming achievable with the advent of new rapid sequencing technologies and is set to revolutionize forward genetic

approaches to disease understanding (Bennett et al., 2005; Serre and Hudson, 2006).

The recent explosion in genetic information for the human genome including the complete genome sequence and detailed genetic and physical maps has increased our ability to find variation in the human genome and correlate it with disease. Family studies, especially twin studies, and population studies have clearly shown a genetic component to susceptibility to infectious disease (Frodsham and Hill, 2004; Lipoldova and Demant, 2006; Strunk and Burgner, 2006). Susceptibility generally follows a complex pattern of inheritance and there are two main methods of mapping and identifying genetic loci involved in such complex heredity. These are either association studies or linkage studies. Association studies involve screening populations for specific mutations in a candidate gene(s) in case–control studies or in family studies. This type of approach identified the link between Human Immunodeficiency Virus (HIV) resistance and the chemokine receptor, CCR5 described below (Dean et al., 1996; Samson et al., 1996). Genome-wide association studies although still quite expensive are now becoming feasible and being used to define linkage between specific markers and susceptibility. These linkage studies depend on the availability of markers and the density of these markers is rapidly increasing with the large scale identification of new SNPs across the human genome. The selection of which SNPs to use and the large numbers of samples needed to generate statistically significant associations for low penetrance alleles are still challenges. The Haplotype MAP (HapMap) project is starting to identify haplotypes within different population groups and together with improvements in large scale genotyping technology and bioinformatics should be useful in studies of complex disease inheritance. Table 57.1 summarizes the best studied genetic susceptibility loci for response to different infectious agents in both mouse models and human studies.

One of the classical examples of genetic susceptibility to infection is the role of the hemaglobinopathies in the outcome of malaria infection (Patrinos et al., 2005). There are also certain chromosomal regions and families of genes that have attracted attention in terms of searching for susceptibility alleles or polymorphisms. Because the TLR family of receptors plays a major role in recognizing pathogens, it was speculated that genetic variation in these receptors or their signaling pathways might be responsible for some susceptibility phenotypes (reviewed in [Schroder and Schumann, 2005]). One of the best examples to date is the occurrence of a single polymorphism in the region of the human TLR4 gene encoding the extracellular domain of the

receptor which confers reduced sensitivity to inhaled *Escherichia coli* (*E. coli*) LPS (Arbour et al., 2000). Interestingly, when septic shock patients were compared with a control group, these lower-responding alleles were found only in the septic shock group and these individuals had a higher incidence of Gram-negative bacterial infection (Feterowski et al., 2003). Such studies need further confirmation since there are also a number of studies that failed to find any linkage between TLR4 mutations and response to various infections (Schroder and Schumann, 2005). There is also enormous variation in the response of individuals to LPS even in the absence of TLR4 mutations implying that variation may occur in other components of the TLR4 signaling system. An example of this is the link between IRAK4 mutations and increased susceptibility to infection with pyogenic bacteria (Picard et al., 2003). Variation in other TLR genes has also been associated with disease susceptibility. For example, a mutation in the extracellular domain of TLR2 is linked to susceptibility to leprosy (Alcais et al., 2005) and a mutation in TLR5 increases susceptibility to *Legionella* (Hawn et al., 2003). Taken together these data support the idea that variation in the innate immune recognition of pathogens play an important part in governing susceptibility to an array of infectious diseases. However, caution needs to be exercised until larger population groups have been studied.

The extensive polymorphism at the chromosomal regions encoding major histocompatibility complex (MHC) proteins is thought to have arisen through natural selection in response to selective pressure from infectious disease. Although human leukocyte antigen (HLA) association with resistance or susceptibility to infectious disease has been difficult to identify because of the complex array of antigenic epitopes involved, a number of studies have implicated this locus in genetic susceptibility to infectious disease (Ghodke et al., 2005; Little and Parham, 1999). MHC molecules fall into two classes, Class I that present foreign antigens to CD8+ cytotoxic T cells and Class II that play a similar role for CD4+ helper T cells. Variation in specific Class I genes has been shown to confer susceptibility to pulmonary tuberculosis and to HIV whereas mutations in other Class I genes confer resistance to HIV and to severe malaria. Class II mutations that confer resistance to hepatitis B or hepatitis C have been identified and susceptibility to typhoid fever and leprosy are also associated with specific Class II mutations. Further molecular analysis of these and other associations may in the future have an impact on the development of new vaccines and immunotherapeutics.

To date the most successful manner of identifying susceptibility genes in human populations has been the candidate gene approach. Candidate genes have emerged from many sources including mouse genetic studies as well as biochemical and function dissection of the immune system. Once a candidate gene is identified, the chromosomal region spanning this gene in the human genome is then scanned for the occurrence of specific mutations or for functional polymorphisms in case–control studies across populations or in linkage studies in family groups. Such studies have identified a number of well described susceptibility loci for infection with various pathogens. One of the most heralded example was the identification of a deletion in the chemokine receptor, CCR5, which was shown to confer resistance to HIV infection (Dean et al., 1996; Samson et al., 1996). Biochemically, this can be explained by the fact that CCR5 is a co-receptor for HIV on the surface of T cells (Dragic et al., 1996). A mutation in another chemokine receptor, CCR2, has also been shown to confer HIV resistance in certain Caucasian populations (O'Brien and Moore, 2000).

Some genes have been associated with susceptibility or resistance to multiple pathogens. For example, variation in the *NRAMP1/Slc11a1* gene is associated with susceptibility to *Leishmania* and to specific intracellular bacteria such as tuberculosis (Barton et al., 1999; Govoni et al., 1996; Lipoldova and Demant, 2006; Sebastiani et al., 1998). Mutations in the tumor necrosis factor (TNF) locus, mainly gene promoter mutations, have been linked with malaria and leprosy susceptibility (Lipoldova and Demant, 2006). Gene promoter or control region mutations have an impact on the level of protein produced from the gene rather than the function of the protein. This is an area of great interest but more difficult to study for several reasons, including the inability to identify control regions simply from sequence information and the complexity and flexibility of transcriptional control. A recent review detailing the genes associated with *Leishmania* susceptibility describes a number of genes that can affect disease outcome including the *interferon-gamma receptor type 1* (*IFNGR1*), the *interleukin-4 (IL-4*) gene and the *NRAMP-1/Slc11a1* gene (Lipoldova and Demant, 2006). These genes and others such as *interleukin-12* (*IL-12*) and its receptor are also linked with *Salmonella* and certain mycobacterial infections (Lipoldova and Demant, 2006). Thus, it is likely that variation in many genes can contribute to disturbing the finely balanced tuning of the immune system and lead to an altered response to a pathogen. It is clear from such studies that the same genes may be involved in susceptibility to an array of pathogens indicating a core immune response critical for any pathogen.

The identification of susceptibility loci for infection with various pathogens will aid in developing new diagnostic screens based on the detection of genetic variants in these loci. It could be envisaged that a person's susceptibility or resistance to a pathogen could be defined by a simple genotyping screen either prior to exposure to any pathogen or upon presentation with an infection. It may also be possible to determine the likely outcome of the infection through a genotyping screen. The definition of susceptibility loci will also contribute to our ability to develop new vaccines and therapeutics.

EXPLORING THE HOST RESPONSE THROUGH EXPRESSION PROFILING

The use of microarray technology to generate expression profiling data is becoming common place in biomedical research (reviewed in [Quackenbush, 2002; Sherlock, 2000]). This

technology allows the documentation of mRNA levels for thousands of genes from total RNA prepared from cells or tissue samples. The data obtained can be compared from sample to sample allowing the changes between samples to be documented and quantified. The "expression profile" for any cell or tissue is simply the list of genes whose expression can be detected using microarrays. The differences in the expression profile from one cell or tissue to the next or in cells treated in a specific manner is a surrogate measure of the cell/tissue phenotype and shows how that phenotype responds to its environment. Expression profiling is most useful when large datasets become available and when the data is combined with other data types and detailed bioinformatics studies. For example, using functional clustering of expression profiling data can help identify pathways that are important for a particular process and co-expression clustering combined with other technologies can help define regulatory networks within the cell.

Over the last 5–6 years, this technology has been applied to identifying the changes in gene expression that occur in response to infection by various pathogens (Aderem and Smith, 2004; Boyce et al., 2004; Bryant et al., 2004; Feezor et al., 2005; Foti et al., 2006; Jenner and Young, 2005; Korth and Katze, 2002; Korth et al., 2005; Ricciardi-Castagnoli and Granucci, 2002). To date there are more than 150 papers in the literature that describe gene expression changes that occur in response to infection with a plethora of pathogens and in many cell types (reviewed in [Jenner and Young, 2005]). Many of these are *in vitro* studies, taking specific cell types and infecting them with specific agents including bacteria, viruses, parasites and yeasts. In addition, cellular responses to bacterial components have also been documented, helping to identify pathogen-specific responses as well as determining the pathogenic component responsible for the major gene expression effects. Virulent or non-virulent strains of specific pathogens as well as mutant organisms have been used to determine the gene expression profile associated with a negative or positive clinical outcome. Few *in vivo* studies have been carried out and have shed light on the more complex responses seen in whole animals and helped to validate the *in vitro* data.

Identifying a Common Host Response to Infection

Several pioneering studies demonstrated that microarrays could be used to determine changes in the gene expression profile of cells in response to virus or bacterial infection (Boldrick et al., 2002; Gao et al., 2002; Huang et al., 2001; Nau et al., 2002). These studies paved the way for the analysis of the host response to a wide variety of infectious agents. The most significant of these studies compared the response of macrophages or DCs to a variety of infectious agents in a single study. In these studies a strong shared response to all infections, be they bacterial, viral or parasitic in nature, was identified. Not only was there commonality from one infectious agent to another but there was also some commonality across cell types. This expression signature has been interpreted as a general "alarm signal" for infection (reviewed in [Jenner and Young, 2005]). Studies of infection with Gram-positive and Gram-negative bacteria also revealed a common expression signature in peripheral blood mononuclear cells. Recently, the Young lab has interrogated all of the publicly available expression profiling data related to the host response to infection (Jenner and Young, 2005). The dataset includes 785 experiments in cells ranging from macrophages and DCs to cells of the adaptive immune response, endothelial and epithelial cells and spanning a wide range of infecting agents. This meta-analysis revealed that a "common host response" can be detected across all of these cell types and infectious agents and show that although cells such as macrophages and DCs specialize in detecting infection, other cells of the body can mount the same "alarm response" as described above (Figure 57.1).

Not surprisingly this expression signature contains many genes associated with the immune system particularly those encoding inflammatory cytokines, chemokines and their receptors. However, some more surprising patterns of expression were also detected. It has been long known that interferon-stimulated genes (ISGs) are regulated by virus infection, but it has only recently been recognized that bacteria and other infecting agents can also illicit the interferon response. This was borne out in these meta-analyses where upregulation of an ISG set is observed across a broad range of infecting agents and cell types.

Not only do these cells change the expression of secreted factors and their receptors during infection but the intracellular milieu is also modified. Once again, there is a common pattern of change observed in all of these studies. The upregulation of signaling and transcription pathways that both augment and attenuate the immune response are observed leading to the interpretation that both positive and negative feedback loops operate within the cell to heighten or dampen the immune

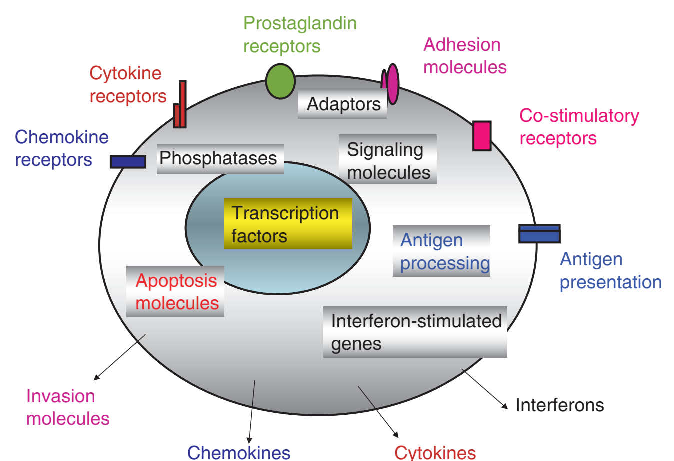

Figure 57.1 Summary of the common host response to infection. This figure is adapted from Jenner and Young (2005) and summarizes their meta-analysis of gene expression changes in response to infection with various pathogens or activation of a variety of cells with agents that mimic infection. Genes are grouped into general functional categories.

response. Temporal profiling can reveal extra layers of complexity and in one study a pro-inflammatory profile followed by an anti-inflammatory profile was identified in macrophages activated with LPS (Wells et al., 2005). Meta-analysis of temporal studies of activation through different TLRs also revealed that the inflammatory chemokines/cytokine signature was an early response while the ISG response was later, presumably reflecting the need for an indirect activation of the ISGs through interferon production (Jenner and Young, 2005). Changes in the expression level of genes involved in both activation and repression of apoptosis also fall under the "common signature" banner and this is interpreted as sending the cells into a state of high alert where apoptosis can be either initiated to eliminate infected cells or terminated if the infection resolves (Jenner and Young, 2005).

Although these *in vitro* studies have provided an overview of the response of isolated cell types to pathogenic infection, *in vivo* studies are needed to validate any of these results before application to clinical medicine. A number of animal models have been used to profile the host response to infection with a variety of agents. These studies are complicated especially if whole tissue samples are used in that changes in gene expression can result not only from genuine changes within the cells of the tissue but also from the recruitment especially of immune cells into the infected or inflamed tissue. Nevertheless, *in vivo* studies have, in some cases, shown good correlation with the expression profiles found from *in vitro* studies. For example, profiling the brains of mice infected with virulent Sindbis virus revealed that ISGs as well as inflammatory chemokines were upregulated (Johnston et al., 2001) and in terms of diagnosis or treatment the exact reason behind these changes in expression signature may be irrelevant. *In vivo* studies also have some advantages in that the gene expression profiles detected in infected tissues will often make more sense when combined with other physiological or cell biology data from studies of the infected host. Thus an "infection signature" would not only describe the altered gene expression of the immune cells that are recruited to the sites of infection but also would include changes in the gene expression of the resident cells of the tissue and may provide a more robust profile of the infection process for use in diagnostic applications.

What can be applied to clinical medicine from these studies? The ability to detect an "infection signature" using focused microarrays could potentially be used as a diagnostic tool. There would be an immediate need to identify a core set of genes with sufficiently robust changes in gene expression to form the basis of a diagnostic array. Arraying technology would need to be priced for diagnostic use and the technology would have to be deemed sufficiently robust to pass all the quality control requirements of a diagnostic laboratory. No doubt progress will be made toward these goals in the near future.

Pathogen-Specific Responses

In addition to the "common host response" described above, microarray studies have revealed that pathogen-specific responses also exist. This is not surprising since it has long been known that different pathogens induce distinct arms of the adaptive immune response. For example, distinct types of helper T cells are activated in response to bacterial and viral infection compared to parasite infection and DC products such as cytokines and chemokines control the differentiation of T helper cell into the correct response type (Mosmann et al., 2005). Thus, the fact that cells of the innate immune system display a pathogen-specific transcriptional response as well as a general alarm signal helps to dictate the subsequent immune response.

Different TLRs are involved in recognizing and responding to different pathogens. For example, TLR2 is responsible for activation in response to Gram-positive bacteria while TLR4 responds to LPS, a component of Gram-negative bacteria (Beutler and Rietschel, 2003; Cook et al., 2004). TLR3 responds to dsRNA and thus dictates the viral immune response for many dsRNA viruses (Beutler and Rietschel, 2003; Cook et al., 2004). Studies using bacterial components such as LPS and flagellin as well as dsRNA have revealed that each TLR induces a specific as well as general transcriptional response. The transcriptional response of macrophages and peripheral blood mononuclear cells is more robust in response to Gram-negative (TLR4) compared with Gram-positive (TLR2) bacteria and the ISG response is considerably reduced for the Gram-positive expression signature (Boldrick et al., 2002; Nau et al., 2002). These differences are further observed when bacterial components are used to activate cells. For example, LPS from Gram-negative bacteria, a specific ligand for TLR4, can activate the ISG profile but TLR2 ligands such as LTA and MDP cannot (Jenner and Young, 2005). Not only the activation of specific gene sets but also the strength of the specific response signature may be important for the immune detection of the type of pathogen involved. *E. coli* infection of DCs strongly upregulates the chemokines/cytokine inflammatory cluster whereas infection with influenza or other single stranded (ss) RNA viruses (through TLR7) has a weaker ability to regulate this cluster but a stronger ability to regulate the ISG signature (Huang et al., 2001; Lund et al., 2004).

These types of results raise the possibility that the diagnosis of the type of pathogen involved in an infection would be helped by the development of customized microarrays that could distinguish the gene expression profiles elicited by particular pathogens. Additionally, arrays that also detect RNAs produced by the pathogen may be even more significant as a diagnostic tool.

Determining the Outcome of the Infection

An infecting agent can either be cleared from the body by the immune system mounting an appropriate response or cause severe or terminal pathology. The outcome depends on a multiplicity of events ranging from the genotype of the host, that is, whether the host displays a resistant or susceptible phenotype, the genotype of the infectious agent, that is, virulent or non-virulent strains and many other less defined environmental factors. Can genomic approaches be used to determine the outcome of infection? Clearly, as discussed above, the technology is developing to define susceptible and resistant host genotypes especially in animal models of infection but the ability to do this routinely in human populations is some way into the future.

Given the smaller genomes of pathogenic organisms, defining virulence genotypes is progressing at a faster rate (Chan, 2003; Dorrell et al., 2005; Fitzgerald and Musser, 2001; Kato-Maeda et al., 2001; MacFarlane et al., 2005; Schoolnik, 2002; Zhang and Zhang, 2006).

Expression profiling studies have been used to investigate the differences in the host response to pathogenic and non-pathogenic strains of specific infectious agents. In one example, mice infected with a pathogenic strain of pneumonia virus upregulated the expected inflammatory chemokines/cytokine profile as well as the ISG profile but an attenuated strain of the same virus could not, although the virus replicated in the lungs of these mice to the same degree (Domachowske et al., 2001). Temporal profiling of the infection process in animals will also help to define the expression signatures associated with the ability of the host to clear specific pathogens.

2009 UPDATE

With the ongoing threat of new or reemerging pathogens, the use of genomic approaches to understand the host response to infectious agents continues to gain momentum. The sequencing of viral pathogens has become routine and there are now more than 800 bacterial genome sequences publicly available (http://www.ncbi.nlm.nih.gov/genomes). This combined with the availability of the human genome and that of an increasing number of model organisms is allowing deeper insight into genomic aspects of host–pathogen interactions.

Genetic susceptibility or resistance to pathogens is still an area of interest with new genetic associations being routinely identified. A number of new studies have again focused on the TLR gene family and their role in susceptibility to infection as well as disease progression. An excellent analysis of all the previous genetic association and functional studies on TLR4 has recently been published (Ferwerda et al., 2008). Some but not all of the association studies indicate a role for TLR4 polymorphisms in pathogen susceptibility (strongest for RSV infection), but many of these studies are small and lack statistical power and the larger studies tend not to find strong associations (Ferwerda et al., 2008). Similarly, functional studies do not always support an important role for TLR4 polymorphisms in controlling cellular responses such as cytokine production (Ferwerda et al., 2008). There are a number of recent association studies that have shown a link between polymorphisms in other TLRs, including TLRs 7, 8 and 9, and HIV susceptibility or disease progression (Bochud et al., 2007; Oh et al., 2007; Soriano-Sarabia et al., 2008). However, these studies will require further verification with larger genetic association studies and more detailed functional studies. Similarly, polymorphisms in the TLR genes continue to emerge as potential players in susceptibility to other pathogens such as TB (Ma et al., 2007). A relatively large association study (1312 individuals) combined with some functional studies revealed a correlation between polymorphisms in the TLR6, TLR1 and TLR10 genes, and the occurrence of TB in certain ethnic populations (Ma et al., 2007). Recent studies of the TLR adaptor protein, TIRAP/MAL, suggest genetic associations between polymorphisms in this protein and TB susceptibility (Hawn et al., 2006; Khor et al., 2007), again implicating the innate immune recognition system in controlling infectious disease responses. For a summary of the literature on genetic association and TB, the reader is referred to a recent review by Berrington and Hawn (Berrington and Hawn, 2007) and for a similar summary of TLR genetic association studies with various pathogens to Misch and Hawn (Misch and Hawn, 2008). It will be very important to clarify the role of the TLR recognition system in pathogen susceptibility and disease progression before any of this information can be applied to clinical screening or drug/vaccine development.

Of particular note, the first whole genome association study to identify the host determinants of HIV-1 infection was recently published (Fellay et al., 2007). Two polymorphisms associated with viral load during the asymptomatic period of infection were located near major histocompatibility allele human leukocyte antigen loci. A second component of the study, examining the time of HIV disease progression, implicated two genes one of which encoded an RNA polymerase I subunit (Fellay et al., 2007). It will be important to follow up these genetic association studies with functional studies of the genes or loci implicated. Given the current availability of genomics resources, we are likely to see many more genome-wide association studies published in this area, a welcome addition to the candidate gene approach.

The recently identified SARS virus has already been the subject of several small scale genetic association studies, especially in relation to the HLA loci. While some associations have been identified, they have not been replicated in different populations and so remain tentative (reviewed in Yang et al., 2008). SNP associations in other genes such as that encoding low serum mannose binding lectin (MBL) and the promoter of the RANTES gene have been replicated in different populations and may stand the test of time (Ng et al., 2007; Zhang et al., 2005).

Expression profiling continues to be a useful tool in the analysis of the host–pathogen interaction. Some examples include a study of *in vivo* human rhinovirus infection (Proud et al., 2008), innate host reponses to Ebola virus and the consequences of a mutation in the virus VP35 protein (Hartman et al., 2008) and Leishmania infection of human macrophages (Guerfali et al., 2008). These and many other studies are leading to the identification of general molecular consequences

of infection as well as the specific consequences of individual pathogens. A recent review outlines the many insights gained into virus–host interaction using functional genomics as well as the use of these approaches in developing and evaluating vaccines (Katze et al., 2008). Studies in model organisms such as *C elegans* support many of the findings in humans (Wong et al., 2007) and provide a useful tool for detailed functional investigation. The "systems biology" approach to study infectious disease is being extended by the use of proteomic profiling. Two recent articles illustrate the usefulness of this approach in examining the response of a human cell line to the avian H9N2 influenza virus (Liu et al., 2008) and of human macrophages to *M tuberculosis* lipids (Shui et al., 2009). Systems biology approaches are moving rapidly in this and other biomedical fields and no doubt the next few years, given the advent of deep sequencing, will see enormous new strides in understanding host–pathogen interactions (for a recent review in relation to virus infection see Tan et al., 2007). Other developments will undoubtedly lead to easier application of these technologies to the clinic in the foreseeable future.

CHAPTER

Host Genomics and Bacterial Infections

Melissa D. Johnson and Mihai Netea

INTRODUCTION

Bacterial pathogens have been known to cause infectious diseases in humans for centuries. Many of these pathogens are commensal organisms that are ubiquitous in the environment or colonize tissues within the host. Despite near constant contact with bacteria, only few of the exposed individuals actually develop clinical signs and symptoms associated with infection. The interplay between host and pathogen is complex, and infection may depend on genetically determined factors such as host immunity or virulence of the pathogen. Despite the long history of infectious diseases, genetic investigations of bacteria and host immunity have only recently been advanced to improve our understanding of the complex host–pathogen relationship. This area of study has experienced great advances since information from the Human Genome Project became available. Recent technologies such as genetic screening and expression analysis may help to better define the role of key features predisposing to infection, transition of a commensal microorganism into a pathogen, or response to infection once the pathogen has invaded normally sterile body tissue. Such advancements have been used to identify new therapeutic modalities, targeting overexpressed or deficient host immune factors, as well as components of pathogens that are critical for the development of resistance or survival. Collectively "omic" approaches to the study of microbial infections have been termed "infectomics" (Huang et al., 2007). Approaches may be centered on the pathogen, the host, or chemical gene or protein targets in an organism for potential therapeutic benefit. In this chapter, we will focus on host genomics, highlighting examples of studies aimed at unraveling the complex nature of immune response to infection. In the future, better understanding of genomics will hopefully enable us to better prevent and/or treat infections.

GENOMICS AND THE STUDY OF BACTERIAL INFECTIONS

Bacterial Genomics

Functional genomics of bacterial pathogens has been the focus of basic science research for some time. Scientists have long wondered what differentiates a commensal organism from an invading one, how some organisms develop resistance to various antibiotic treatments, and how organisms can so rapidly express the Darwinian extreme of "survival of the fittest". At the heart of this is genetic makeup and expression within bacteria or fungi. On recent review, complete genomes have been mapped for more than several hundred species of bacteria, including *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Escherichia coli*, and *Neisseria meningitidis* (Celestino et al., 2004; J. Craig Venter Institute, 2006). These data are valuable in developing new targets for antibiotics, new diagnostic methods, and potential vaccination strategies as well as furthering our understanding of bacterial resistance mechanisms, bacterial pathogenicity and virulence, bacterial niche adaptation, and

contribution of bacteria to certain chronic disease states (Fritz and Raczniak, 2002; Monaghan and Barrett, 2006). A discussion of microbial genomics is outside the scope of this text and will thus not be further considered. Nonetheless, many of the methods and procedures discussed in this text are applicable to the field of microbial genomics.

Host Genomics

The study of the association between the role of genes in susceptibility or outcome of infections is still in its infancy. Recent technological advancements have resulted in a surge of studies in this area. These advances include the availability of a large array of candidate genes that can be studied for association, as well as more affordable and fast technology to perform genome-wide screens to identify new genes that may have a role (Hill, 1998).

Briefly, host defense to infectious pathogens depends upon both innate and acquired immunity (Emonts et al., 2003). Phagocytosis is an important first line of defense for some pathogens, particularly those that enter via mucosal surfaces. Cell types such as neutrophils, macrophages, dendritic cells, and monocytes are important components of response to invading pathogens, and CD4+ expressing T lymphocytes differentiate into TH1, TH2, or TH17 cells that modulate the inflammatory process. Monocytes express a number of molecules that are important for antigen presentation and cell signaling, including FC receptors for IgG, complement receptors, and MHC Class II molecules. Complement is a critical part of the innate immune response. Three pathways are activated by either antibody–antigen and C-reactive protein (classical pathway), the interaction of C3 with factors B and D resulting in C3b (alternative pathway) or mannose-binding lectin (MBL) (innate activation pathway). Proteins important for cellular response to infection are depicted in Figure 58.1 (Jenner and Young, 2005).

Pathogen recognition receptors (PRRs) are cell membrane receptors that recognize structures from pathogenic microorganisms called pathogen-associated molecular patterns (PAMPs). Four major classes of PRRs have been described to date: Toll-like receptors (TLRs), NOD-like receptors (NLRs), C-type lectin receptors (CLRs) and RigI-helicases: PRR members of the first three families are involved in the recognition of bacteria, and are involved in the triggering and activation of the innate host defense (Cambi and Figdor, 2005; Kawai and Akira, 2005; Murray, 2005). MBL is part of the collectin group of C-type lectins, which recognizes sugars, differentiating between foreign

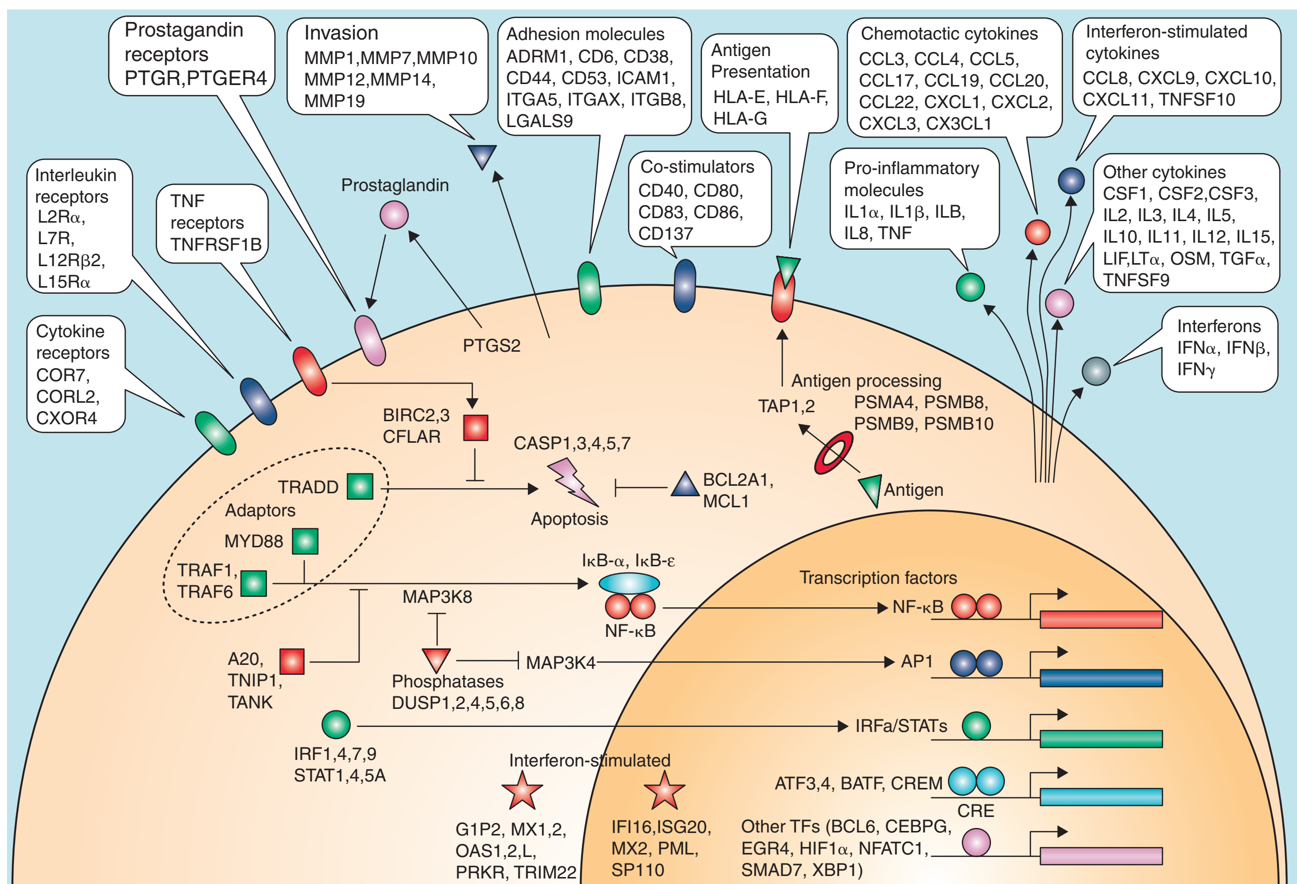

Figure 58.1 Cellular responses to infection (Jenner and Young, 2005). Gene products of the common host response and their functions inside and outside the cell. Arrows represent activatory connections between proteins in signaling pathways; lines ending in bars represent inhibitory connections. This figure does not indicate that these proteins are present in all cells at the same time.

TABLE 58.1 TLR family ligands

TLR	Ligand	Entity commonly bearing ligand
TLR1	Triacyl lipopeptides	Numerous bacteria, mycobacteria
	Soluble factors	*Neisseria* species
TLR2	Lipoprotein/lipopeptides	Numerous pathogens
	Peptidoglycan	Gram-positive bacteria
	Lipoteichoic acid	Gram-positive bacteria
	Lipoarabinomannan	Mycobacteria
	A phenol-soluble modulin	*Staphylococcus* species
	Glycoinositolphospholipids	*Trypanosoma cruzi*
	Glycolipids	*Treponema maltophilum*
	Porins	*Neisseria* spp., *Shigella* spp., *Haemophilus influenzae*
	Zymosan	Fungi
	Atypical LPS	*Leptospira interrogans, Porphyromonas gingivalis*
	HSP70	Host
TLR3	Double-stranded RNA	Viruses
TLR4	LPS	Gram-negative bacteria
	Taxol	Plants
	Fusion protein	Respiratory syncytial virus
	Envelope proteins	MMTV
	HSP60	*Chlamydia pneumoniae*
	F-protein	Cytomegalovirus
	HSP60, HSP70, Type III repeat extra domain A of fibronectin, oligosaccharides of hyaluronic acid, polysaccharide fragments of heparin sulfate, fibrinogen	Host
TLR5	Flagellin	Numerous bacteria (i.e., *Legionella*)
TLR6	Diacyl lipopeptides	*Mycoplasma* species
TLR7	Imidazoquinoline	Synthetic compounds
	Loxoribine	
	Bropirimine	
	Guanine nucleoside analogues	
TLR8	R848/resiquimod	Single-stranded RNA
TLR9	CpG rich motifs of DNA	Bacteria
	Chromatin: IgG complexes	Host
TLR10	Unknown	Unknown
TLR11	Profilin	*T. gondii*
	Not determined	Uropathogenic bacteria
TLR12	Unknown	Unknown
TLR13	Unknown	Unknown

Based on Akira et al., 2006; Brikos and O'Neill, 2008; Dieffenbach and Tramont, 2005.

and self, and subsequently activates complement upon binding to foreign molecules. More than 10 TLRs have been identified, and of these TLR1, TLR2, TLR4, TLR5, TLR6, and TLR9 have proposed roles in recognition of certain bacteria (Table 58.1). Binding of a ligand to a TLR triggers two signaling pathways which differentiate on the basis of MyD88 involvement (Albiger et al., 2007a). MyD88 and another adaptor protein, TIR-associated protein (TIRAP or Mal) lead to induction of a pro-inflammatory cytokine response. With the exception of TLR3, MyD88-dependent pathways are activated by all TLRs. The MyD88-independent pathways are triggered by TLR3 and TLR4; TRIF (TIR domain containing adaptor protein inducing IFN-β) and TRAM (TRIF-related adaptor molecules) activate type I interferons. TRAM is only required in TLR-4 mediated signaling (Turvey and Hawn, 2006). These pathways are depicted in Figure 58.2. NLRs are related molecules that are more specific in their recognition of bacterial organisms in cytoplasm (Elson et al., 2007; Hill, 2006). CLRs are receptors for polysaccharide components such as glucans or mannans, especially in fungi, but they have also been involved in recognition of mycobacteria. CD14 is another pattern recognition receptor and may be important in recognition of both Gram-positive and Gram-negative bacteria. Additional mediators that aid in recruitment, activation or suppression of immune cells include cytokines such as IL-10, IL-6, interferon gamma, TNF, IL-12, and IL-4. Alterations in production or expression of these components

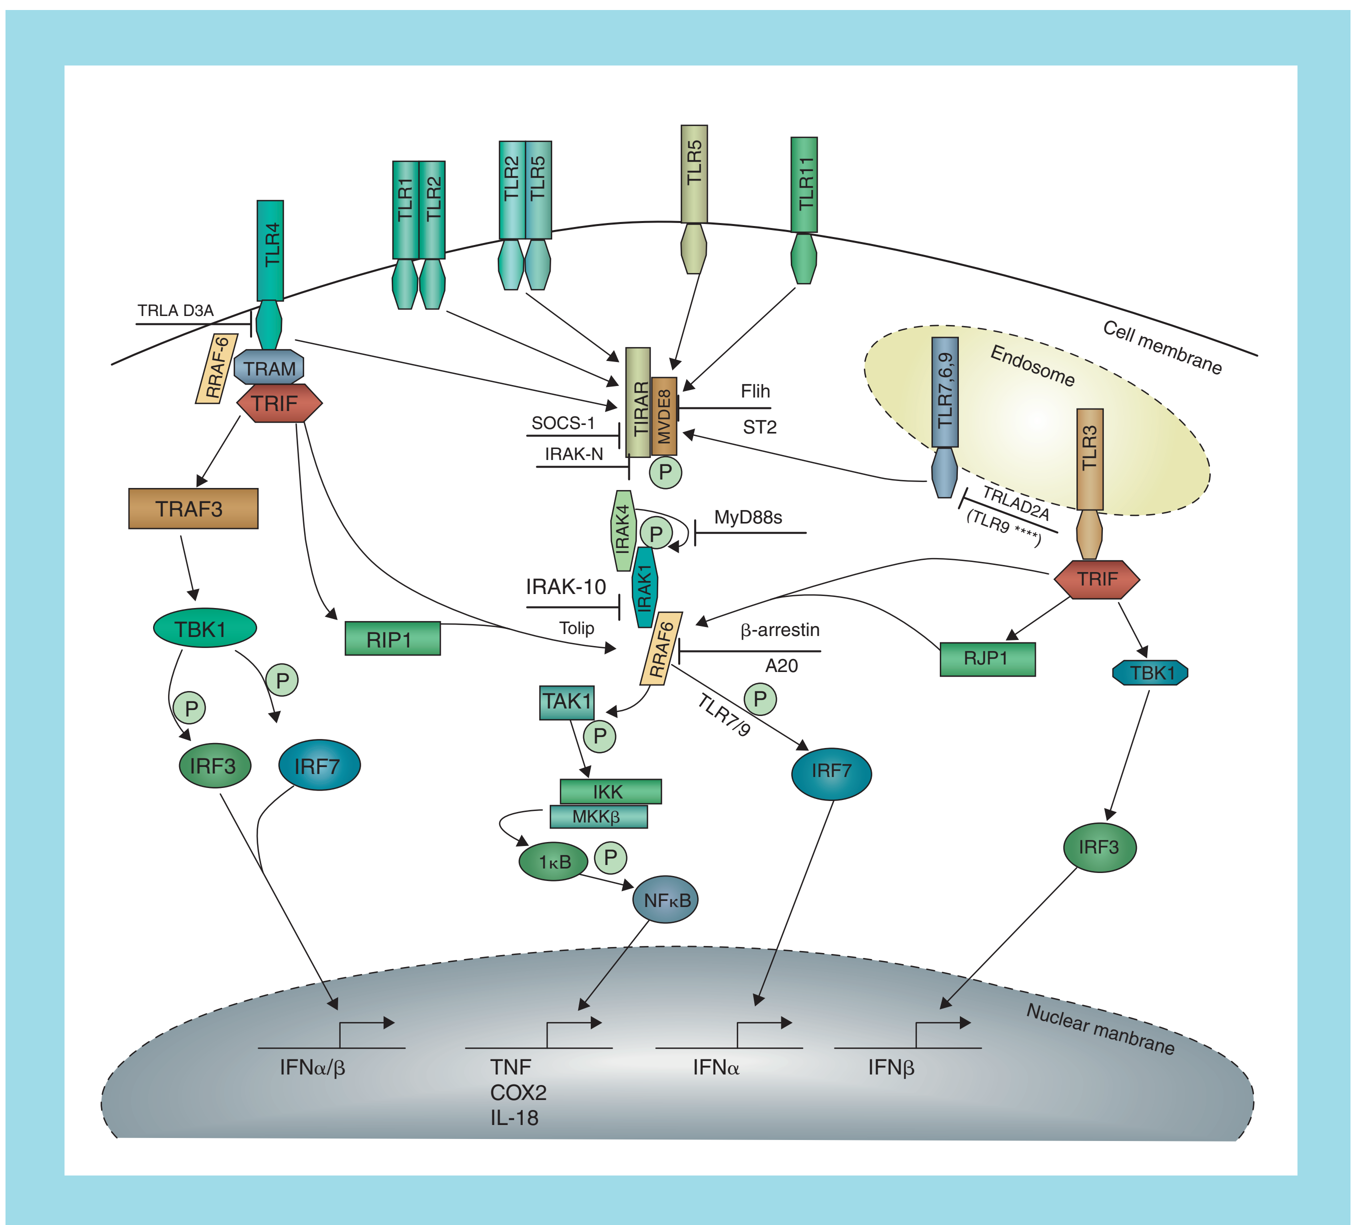

Figure 58.2 TLR signaling (Albiger, 2007a).

can lead to changes in susceptibility to an infecting pathogen or host response once actually infected.

Based on investigations of various pathogens, it seems that there is not one standard panel of factors which predisposes to all infections. Rather, immunity to a given pathogen may depend on the nature of the infecting organism, site of entry, its growth characteristics and/or morphology, and its biochemical composition. Thus, it seems logical that in studies to date, varying host genetic factors have been implicated in either susceptibility to or prognosis with different infectious pathogens. Given that there have been numerous studies in host susceptibility to infections, this chapter will focus on the most common and well-studied Gram-positive and Gram-negative bacterial infections as well as mycobacterial infections. We will compare and contrast the available data for genetic associations and infection with selected pathogens, and highlight potential areas for future exploration.

Methods of Study

Much has been written regarding the different approaches to study host genomics as it relates to infectious diseases, and the limitations of certain study designs are well-recognized. Most infectious diseases can be classified as complex, with multifactorial contributions from environment, biological factors, and inheritance. Susceptibility to an infectious disease may follow a Mendelian pattern of inheritance, but the majority of infectious diseases are due to polygenic factors. It may be difficult to distinguish between these two origins, because other genes can influence expression of a Mendelian trait and expression of a polygenic trait may be heavily influenced by a single gene. While both linkage and association are important, association studies are more commonly employed in studies of genetics and infectious diseases susceptibility (Bochud et al., 2007). While powerful, linkage studies of infectious diseases are relatively uncommon for a number of reasons. First, it is challenging to identify and recruit affected sibling pairs or family members to establish well-characterized pedigrees during the time frame that the study is conducted. The rapid mortality associated with many infectious diseases also makes it difficult to identify affected persons and recruit them for study participation. In addition to these issues, most infectious diseases are expected to have a small contribution from individual genetic regions which would not necessarily be apparent given the limited sample size and power of such studies (Burgner et al., 2006). Thus, case–control association studies including unrelated affected versus non-affected persons are more common than linkage and association studies which might more closely explore genetics among family members. Association studies are not without problems, however. The biggest problem with these study designs is power, and almost all published data for genetic association and infectious diseases are based on underpowered studies. One group has suggested that at least 1500 case–control diads or case–parent triads are necessary for a sufficiently powered association study using a candidate-gene approach. A genome-wide association study could be sufficiently powered with 1000 cases and 1000 controls; however, studies of this kind are subject to a high false discovery rate. New technologies are making such studies more feasible, both from a technical and financial perspective. Given the issues with power and the potential for spurious findings, association studies should be validated in subsequent studies using independent cohorts (see Chapter 4).

In addition to candidate-gene and genome-wide analyses, newer technologies are used to profile host-gene expression in response to different pathogens of interest (Campbell and Ghazal, 2004; Hossain et al., 2006). This approach can create a wealth of information about the functional and dynamic response to infection. For example, in a recent study murine liver cells were studied in response to challenge with *E. coli* or *S. aureus*. Seventeen genes were differentially expressed in response to these two different pathogens, including GBP-2, C-type lectin, adenylate cyclase, and genes involved in vesicle trafficking (Yu et al., 2004). The data suggested that sepsis due to these two pathogens may involve a common late host response, but initial responses to each of these bacteria were quite different. Studies such as this can yield a wealth of new information about pathways that might be important in susceptibility or response to infection. However, since they analyze so many data points, the statistical analysis must be carefully performed to minimize spurious findings. Since expression is a dynamic phenomenon, timing of the sampling and processing procedures used in the laboratory for these specimens are critical elements for this kind of research. Also, many such studies use only one particular cell line and study response of that line to challenge with the pathogen of interest *in vitro*. For many of these infections, multiple cell lines are involved in defense. Thus, incubation with only one kind of cell may not yield a complete picture of what is involved in susceptibility and response to infection *in vivo*. For these reasons, although studies such as these produce a tremendous amount of information, they should be considered hypothesis generating and generally require further validation (Modlin and Bloom, 2001).

HOST GENOMICS AND GRAM-POSITIVE, GRAM-NEGATIVE AND MYCOBACTERIAL INFECTIONS

Gram-Positive Organisms

A few Gram-positive infections have been investigated in human studies for genetic associations and immunity (Table 58.2). Importantly, these organisms lack lipopolysaccharides (LPS), so other mechanisms are responsible for host recognition and defense against these pathogens. In Gram positives, lipoteichoic acid (LTA) is a prominent player in triggering host recognition of the bacteria. LTA and peptidoglycan in Gram positives have been noted to be recognized by TLR2. Gene expression studies have suggested that the initial response to Gram-positive pathogens involves recognition by TLR2, which leads to a NF-κB mediated response with release of cytokines including IL-1 and TNF as well as IL-6 and IL-8. Subsequently, a later TLR-independent response arises in response to the pathogen or its

TABLE 58.2 Examples of host genetic factors implicated in association with select bacterial pathogens in the *in vitro*, animal model, or human studies

Disease	Factors
Gram-positive organisms	
S. pneumoniae	TLR1, TLR2, TLR4, TLR6, TLR9, MyD88, CD14, LBP, NOD1, NOD2, IκB, NFκB-1 A, NFκB-1E, MBL, FC-γRIIA
S. aureus	TLR1, TLR2, TLR6, MyD88, CD14, CD36, NOD2, TNF-α R1, peptidoglycan-recognition proteins
Listeria monocytogenes	TLR2, MyD88, NOD2
Gram-negative organisms	
Gram-negative sepsis/infections	TLR1, TLR2, TLR4, LPB, CD14, MyD88
Legionella	TLR2, TLR4, TLR5, MyD88, Naip5
Neisseria meningitidis	TLR4, MBL, properidin, ACE, FC-γR, TNFα, TNFβ, IL10, IL6, IL1, IL1-R antagonist
Mycobacteria	
M. tuberculosis	TLR1, TLR2, SLC11A1(NRAMP1), Class I and II HLA, MBL2, SP-A, SP-D, P2X7, DC-SIGN, DRB1, HLA-DR, INF-γ, VDR, IL12, IL-12R, IL-10, IL-1R antagonist, TNF-α, TNF-αR1, STAT-1
M. leprae	TLR1, TLR2, TAP-2, HSPA 1 A, DC-SIGN, TNF, VDR, MHC region 6p21, 10p13, HLA-DR, PARK2/PACRG

Based on Hirschhorn et al., 2002; Mira et al., 2004; Mira, 2006; Roy et al., 1997; Roy et al., 1999.

metabolites inside the host cell. These responses appear to be quite pathogen-specific, and differ among various microorganisms. Studies investigating host genomics and *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Listeria monocytogenes* have been completed and help further define the role of candidate genes for each of these infections.

Of the Gram-positive pathogens, *S. pneumoniae* has been the most studied in regards to host immunity and susceptibility to infection. *S. pneumoniae* is a common cause of pneumonia, bacteremia, meningitis, and otitis media. TLR1, TLR2, TLR4, TLR6, and TLR9 have been associated with recognition and immune response to the pneumococcus (Albiger et al., 2007b; Echchannaoui et al., 2002; Echchannaoui et al., 2005; Knapp et al., 2004; Koedel et al., 2003; Malley et al., 2003; Schroder et al., 2003b; Srivastava et al., 2005; Yoshimura et al., 1999). Much of this evidence comes from animal models of pneumococcal infection. Knockout mice deficient in TLR2 appear to be more susceptible to *S. pneumoniae* meningitis. Reduced survival has also been reported among TLR2 knockout mice with intraperitoneal *S. pneumoniae* infection (Khan et al., 2005). However, in another study, knockout mice deficient in TLR2 did not appear to be at increased risk of pneumococcal pneumonia following intranasal infection. TLR4 has been suggested to have protective effects through its recognition of bacterial pneumolysin, which can potentially reduce colonization and subsequent infection. These benefits may also extend to pneumonia, as evidenced by experimental models in mice with pneumococcal pneumonia. Knockout mice deficient in TLR4 had higher colony counts, although this did not result in increased mortality in this model (Branger et al., 2004). In a model of intravenous infection, TLR4 deficiency did not result in reduced survival or increased colony counts in infected mice (Benton et al., 1997), further suggesting that the role of TLR4 on immunity to *S. pneumoniae* may be limited to the airways. A recent study in human, however, did not find any significant associations between mutations in TLR2 or TLR4 and invasive pneumococcal infection (Moens et al., 2007). In this cohort, neither Caucasian Belgians with invasive pneumococcal disease nor healthy controls were homozygous for mutations in TLR2 R753Q, TLR2 P631H, or TLR2 R579H. Heterozygotes were identified in TLR2 R753Q (6.1% cases, 5% controls, $p=0.94$) and TLR2 P631H (5.1% cases, 8.9% controls, $p=0.34$), but were not significantly different between cases and controls. Similarly, there were no differences in either homozygous or heterozygous mutations in TLR4 D299G between cases and controls. Clinical outcomes were not different among those who were heterozygous or homozygous for TLR2 and TLR4 mutations at these sites, compared to those that had homozygous wild-type genotypes. In this cohort, cases and controls were not matched for gender or age, and the small number of subjects with homozygous mutations in TLR2 and TLR4 limited the power of the study. Additional studies in a larger, more well-defined population with carefully selected controls may be necessary to establish the role of TLR2 and TLR4 mutations and susceptibility to pneumococcal infection.

Other factors such as myeloid differentiation factor 88 (MyD88) and CD14 have also been shown to increase risk of

S. pneumoniae infection in animal models (Albiger et al., 2005). MyD88 is important in the cell signaling cascade triggered by TLR or IL-1 family receptors, while CD14 serves as a co-receptor for LPS. Other proteins may also play a role in recognition and response to pneumococcus, including LPS-binding protein (LBP) and the nucleotide-binding oligomerization domains (Nod) Nod1 and Nod2 (Opitz et al., 2004). The role of these proteins in defense against pneumococcus, particularly in the context of other signaling pathways, has yet to be fully elucidated in animal models and humans.

Recently, mutations in the IκB family of receptors has been associated with invasive pneumococcal disease among hospitalized patients in the United Kingdom (Chapman et al., 2007a). This study included a large cohort of Caucasian UK residents with invasive pneumococcal disease who were identified as part of two other studies (Maskell et al., 2005; Roy et al., 2002) and one control group identified as part of a previous study as well as an independently collected cohort of 370 healthy adult volunteers from the United Kingdom. SNPs were identified in the first cohort of infected patients (including bacteremia, pneumonia, and meningitis) and controls, and then confirmed in the second set of Gram-positive infection (limited to empyema) cases and controls. The investigators identified 43 SNPs in three IκB genes for analysis. Of these, six SNPs in NF-κB-IA or NF-κB-IE appeared to be associated with pneumococcal infection in the first analysis. In the second group of those with Gram-positive empyema (not limited to pneumococcus), the investigators did not find any association between the three most common SNPs and thoracic empyema. When this analysis was limited to the small number of subjects with pneumococcal empyema (42 subjects), mutations in NF-κB-IA (rs3138053 and rs2233406) appeared to be protective, and were similar to that found in the first study cohort with invasive pneumococcal infection. Mutations in NF-κB-IE (rs529948) were significant in the first invasive pneumococcal cohort, but did not appear so in the group of pneumococcal empyema subjects. These data are considered preliminary and should be validated in subsequent studies.

MBL has been suggested to play a role in host defense against *S. pneumoniae.* This protein can phagocytose some bacteria by binding oligosaccharides on the bacterial cell surface (Bocchino et al., 2005). Homozygous mutations in the MBL gene on chromosome 10 have been associated with an increase in invasive pneumococcal infection (Garred et al., 2003; Kronborg et al., 2002; Moens et al., 2006a). In a large study of 225 white adults and children from the United Kingdom with invasive pneumococcal disease (blood, cerebrospinal fluid, joint fluid, etc.) and 353 white adult blood and transplant donors, homozygous mutations for MBL at codons 52, 54, or 57 occurred in 28 infected persons (12%) versus 18 controls (5%) (OR 2.59, 95% CI: 1.39–4.83). This finding was validated in a second cohort of 108 additional cases of invasive pneumococcal infection and 679 healthy neonates from the United Kingdom matched for ethnicity and geographical area of residence. Homozygotes among cases and controls were 10% and 5%, respectively ($p = 0.046$). Frequency of heterozygotes as well as a functional promoter polymorphism at position -221 in both cohorts were similar, and not different between cases and controls. In addition, homozygotes did not have significantly different sites of infection, lengths of stay, disease severity, or survival from those heterozygous for these mutations. The results of this study have been confirmed in two smaller studies. One limitation of this particular study is that cases and controls were not matched for age, despite the fact that the infected cohorts included both children and adults with a wide age range. Age was more closely matched in one of the subsequent studies. In addition, those with concomitant illnesses which would contribute to the risk of invasive pneumococcal disease were not excluded from some of the early studies. Such patients were excluded from the later confirmatory study. Vaccination status of study subjects with pneumococcal vaccine was not described by the investigators of these studies, and could potentially confound the study results. Given the time frame of the study, vaccination among children was probably rare, but from the time period of 1993 to 2003 uptake of pneumococcal vaccination was more than 20% among those 65 years of age and older (Noakes et al., 2006). However, the efficacy of pneumococcal vaccination in those with MBL deficiency is unknown.

In a more recent study using samples from the same cohort of UK residents with invasive pneumococcal infection and non-infected controls, polymorphisms in the FCN2 gene were not found to be associated with this infection (Chapman et al., 2007b). FNC2 encodes for *L*-ficolin, which has been shown to bind Gram-positive organisms, and activates the lectin-complement pathway as well as working directly as an opsonin.

Other studies in humans have investigated mutations in Fcγ-receptor IIA and pneumococcal disease, with conflicting results (Moens et al., 2006b). Fcγ-receptor IIA is thought to play an important role in phagocytosis of bacteria once they have been bound by IgG2. In very small studies, patients who were homozygous for Fcγ-receptor IIA polymorphisms at amino acid 131 appeared to be at increased risk of invasive pneumococcal infection (i.e., bacteremia) than controls (Yee et al., 1997; Yee et al., 2000; Yuan et al., 2003). In a more recent study of 55 Belgians with invasive pneumococcal disease and 100 gender and geographical matched non-infected controls of a wide age distribution, there was no difference in prevalence of Fcγ-receptor IIA genotypes between cases and controls (Fcγ-RIIA–R/R131 genotype 21.8% versus 31% in cases and controls, respectively ($p = 0.047$)). In general, all of these studies were limited by very small sample sizes.

Although *S. aureus* also has LTA in its cell wall, lipoproteins and peptidoglycans may be even more important in its recognition by host TLR2 (Hashimoto et al., 2006). For *S. aureus*, knockout mice deficient in TLR2 experienced greater rates of mortality compared to wild-type mice with *S. aureus* infection. Similarly, mice deficient in MyD88, a downstream adaptor molecule involved in cell signaling, had substantially reduced survival which was even more pronounced than the TLR2 deficient mice. Colony counts in the organs of the Myd88 deficient mice indicated that these mutants were even more susceptible to *S. aureus* infection than the TLR2 deficient mice (Takeuchi et al., 2000). A study in 91 white French patients who had participated

in a study of the role of TNF-alpha in septic shock found that 2 of 22 patients (9%) with Gram-positive septic shock had a mutation in TLR2 (Arg753Gln) while this mutation was not identified among 69 subjects with other causes of septic shock. Both subjects were heterozygous for Arg753Gln mutation, and had shock due to *S. aureus* infection. Allelic frequency of this mutation among non-infected controls was 3% (Lorenz et al., 2000). This finding has yet to be confirmed from other studies to date (Moore et al., 2004). Other important elements of host recognition and response to *S. aureus* may include TLR1, TLR6, CD14, CD36, NOD2, TNF-alpha receptor 1 (TNFR1), and peptidoglycan recognition proteins (Fournier and Philpott, 2005). The specific role and association of these molecules with *S. aureus* infection has yet to be established or studied in humans.

Listeria monocytogenes may also be recognized by TLR2, and in animal models knockout mice deficient in TLR2 and MyD88 were more susceptible to this infection (Seki et al., 2002; Torres et al., 2004). In addition, NOD2 may play a role in defense against *Listeria*, as evidenced by knockout mice who were more susceptible to oral *Listeria* infection (Kobayashi et al., 2005). A number of other factors may be important to defense against *L. monocytogenes* and have been explored in animal models, but all of these findings have yet been validated in human studies of *Listeria* infection (Pamer, 2004).

Gram-Negative Organisms

Enterobacteriaceae and Other Gram-Negative Rods

LPS in the cell wall of Gram-negative bacteria are responsible, once recognized by host-cell receptors, for triggering a cascade of events leading to adhesion of neutrophils to endothelial cells, clotting, and activation of secondary inflammatory mediators such as interleukins and leukotrienes. LPS is recognized by TLR4, LBP, and CD14. Some Gram-negative organisms also contain membrane proteins in the cytoplasm or outer cell membrane that are recognized by host-cell receptors such as TLR2 and TLR1. Several studies in mice have demonstrated that MyD88 signaling may be critical for the early host response to *Ps. aeruginosa* lung infections (Power et al., 2004; Skerrett et al., 2004).

TLR4 may be important for a number of Gram-negative pathogens; however, results in human studies have yielded conflicting results. In one *in vitro* study using human cell lines, TLR4 but not TLR2 was the major factor mediating host-cell activation in response to *Salmonella minnesota*- and *E. coli*-derived LPS (Tapping et al., 1993). This was recently validated in a study where TLR4 ligands seemed to predominate for Enterobacteriaceae. In contrast, responses to *Ps. aeruginosa* were dependent on both TLR4 and TLR2.

Several small studies in humans have explored the role of TLR4 in Gram-negative infections. Among Europeans, TLR4 Asp299Gly and Thr399Ile SNPs have been found to cosegregate in 98% of individuals, while in African populations both an Asp299Gly and an Asp299Gly/Thr399Ile haplotype is present (Schroder and Schumann, 2005). In a case–control study of 91 Caucasian patients with septic shock and 73 healthy non-infected blood donors in France, a TLR4 Asp299Gly mutation occurred exclusively among those with septic shock (5/91 cases (5.5%) versus 0/73 controls (0%)) (Lorenz et al., 2002). There was a similar rate of dual mutations at the 299 and 399 position (i.e., TLR4 Asp299Gly/Thr399Ile) in both cases and controls, 6/91 (6.6%) and 8/73 (11%) respectively. Among those with septic shock, solo mutations in 299 were present exclusively in those with Gram-negative infections ($n = 4$) or polymicrobial infections ($n = 1$). Survival and SAPS II scores of these subjects were similar to those with wild-type or dual mutation genotypes at the 299 and 399 position. Only one subject in this study was homozygous for the 299 mutation, and she died of rapidly progressive urosepsis and *E. coli* bacteremia. Based on these findings, the authors concluded that risk of Gram-negative septic shock may be higher among those with TLR4 299 mutations. Additional studies in a larger study population with more carefully selected controls should be performed to confirm these findings.

In another study of 80 Spanish hospital inpatients with either acute ($n = 24$) or chronic ($n = 56$) osteomyelitis due to Gram-negative ($n = 23$) or Gram-positive ($n = 57$) organisms and 155 healthy blood donors matched by age and gender, polymorphisms in TLR4 Asp299Gly appeared to be associated with Gram-negative infections (Montes et al., 2006). In this cohort, three cases were homozygotes for polymorphisms at this site (Asp299Gly G/G) and two of these had Gram-negative infections. No controls were found to have homozygous polymorphisms in TLR4 Asp299Gly ($p = 0.038$). Allelic frequencies did not suggest that patients with osteomyelitis had higher frequency of mutant carrier alleles for this site than controls ($p = 0.08$). Similar results were found for TLR4 Thr399Ile. Polymorphisms in TLR2 (Arg753Gln) were not significantly different between cases and controls. Those with TLR4 Asp299Gly heterozygous or homozygous polymorphisms had higher rates of Gram-negative infections (60% versus 21.5% respectively, $p = 0.0086$), higher incidence of hematogenous osteomyelitis (40% versus 11% respectively, $p = 0.013$) and chronic osteomyelitis more frequently (93.3% versus 64.6% respectively, $p = 0.031$) than those who did not have these mutant alleles. Functional significance of these polymorphisms in TLR4 Asp299Gly were explored, and the investigators observed reduced apoptosis of neutrophils after incubation with LPS among those with osteomyelitis compared to non-infected controls, and among those with mutant alleles. In addition, phosphorylation of IκB after incubation with LPS was reduced among those homozygous for the Asp299Gly mutant alleles. Furthermore, neutrophils from those with these mutant alleles did not demonstrate increases in IL-6 secretion, as was observed in non-infected controls and those homozygous for the wild-type alleles. As with previous studies, there was a very low number of subjects who were homozygous for the TLR4 Asp299Gly mutation in this study, which limits its ability to make powerful statistical comparisons. Also, the authors did not apparently control statistically for the large number of comparisons used in this study. This may bias the study findings, especially considering its small sample size and rather heterogenous population.

Thus, the Asp299Gly/Thr399Ile haplotype of TLR4 does not conclusively appear to increase risk of Gram-negative

infections. While several studies have implicated TLR4 haplotypes containing only the Asp299Gly (or Thr399Ile) SNPs, the small number of patients with these haplotypes in each of these studies limits our ability to make conclusions about these haplotypes and their role in Gram-negative infections.

Legionella

A few studies have investigated immunogenetic factors specific to *Legionella* spp. infections. *Legionella* is a flagellated Gram-negative rod, and *in vitro* TLR2, TLR4, and TLR5 have been shown to recognize this pathogen (Akamine et al., 2005; Girard et al., 2003; Hawn et al., 2003; Hawn et al., 2005; Kikuchi et al., 2004). In murine models TLR2 and MyD88 have been shown to be important (Hawn et al., 2006b). However, studies in animals have produced conflicting evidence regarding the role of TLR4 and *Legionella*. TLR4 polymorphisms have been suggested to play a protective role in a human cohort exposed to *Legionella* at a flower show in the Netherlands. In a study of 108 subjects who contracted Legionnaire's disease following this exposure and 508 controls that were exposed but not clinically ill, Legionella pneumonia was significantly less common among those with the Asp299Gly SNP. In this study, only heterozygotes for Asp299Gly were found, and Thr399Ile cosegregated with Asp299Gly in this European population. As the authors note, it is not clear why TLR4 polymorphisms are associated with a protective effect against *Legionella*, especially since these polymorphisms have been associated with no effect or increased risk of infection due to other Gram-negative pathogens. This phenomenon may be due to the unique LPS structure of *Legionella* that results in differential cell recognition and signaling. However, additional studies are needed to validate these findings.

Recently Naip5, which is important for intracellular signaling and the apoptosis mechanism of macrophages, has been suggested to play a role in the intracellular pathogenicity of *Legionella* (Wright et al., 2003). Naip5 can activate macrophages via TLR5 and MyD88-independent mechanisms (Delbridge and O'Riordan, 2007). Mice with polymorphisms in Naip5 have been shown to be at increased susceptibility to *Legionella* infection (Diez et al., 2003). No human studies to date have investigated Naip5 and Legionnaire's Disease.

Neisseria meningitidis

Neisseria meningitidis is an encapsulated Gram-negative diplococcus that is a common cause of meningitis and sepsis. A study of siblings in the United Kingdom suggested that genetic factors in the host accounted for approximately 33% of risk of meningococcal disease among siblings of those with meningococcal infection (Haralambous et al., 2003). Multiple mechanisms appear to be involved with recognition and host immunity to meningococcus. Innate and adaptive immunity mechanisms have been demonstrated in response to meningococcal challenge, as well as complement activation and subsequent shock/coagulopathy. Studies of genetics and meningococcal disease have suggested that polymorphisms in key molecules can result in increased susceptibility to this infection or more severe phenotypes.

Inherited complement deficiencies have been reported in association with meningococcal disease, but these are relatively rare in the general population and probably not the primary reason for susceptibility to this infection.

Among candidate genes, polymorphisms in TLR4 have not been strongly associated with either increased susceptibility to or severity of infection (Read et al., 2001; Smirnova et al., 2003). A study of UK residents with meningococcal infection found no association between the TLR4 polymorphism Asp299Gly and meningococcal infection. Although most of the subjects with meningococcal infection ($n = 1047$) were <1 year of age, the investigators used a control population consisting of 879 healthy adult blood donors. However, the investigators also stratified the infected cohort by age group and serotype and found no associations between TLR4 Asp299Gly polymorphism among these strata and fatality. A recent study suggested that polymorphisms in TLR4 Asp299Gly and The399Ile were associated with increased susceptibility to meningococcal disease among European Caucasian children less than 12 months of age. There was no significant difference in the rate of meningococcal disease among those 3 years of age and older who were heterozygotes or homozygotes for the Asp299Gly and The399Ile SNPs compared to healthy controls, however (Faber et al., 2006). The authors suggest these mutations may be particularly relevant among infants who have an immature immune system.

Polymorphisms in TLR2 have not appeared to increase susceptibility to meningococcal disease, but have not been extensively studied.

Studies of MBL polymorphisms have yielded more substantial associations for meningococcal infection (Hibberd et al., 1999). Heterozygotes and homozygotes for variant alleles of MBL have been shown to have substantially lower circulating MBL concentrations. Several reports have suggested that those with variant alleles are at increased risk for meningococcal infection (Bax et al., 1999; Salimans et al., 2004). A recent study also suggested that combined polymorphisms in properidin and MBL results in an increase risk of *N. meningitidis* meningitis (Bathum et al., 2006). Three properidin deficiency variant types have been identified and have been associated with increase severity of meningococcal infection and clinical outcome. However, additional genetic factors may influence mortality and severity of disease among individuals with properidin deficiencies (Densen et al., 1987; Fijen et al., 1999; Spath et al., 1999; Westberg et al., 1995).

Angiotensin-converting enzyme (ACE) has pro-inflammatory properties and in one study, the DD genotype that imparts higher circulating levels of ACE was associated with increased severity of meningococcal disease (Harding et al., 2002).

Other elements of acquired immunity may be important for susceptibility to and severity of meningococcal disease. For example, mutations in FCγ receptors have been associated with meningococcal sepsis and were more frequent in those with meningococcal disease than controls in some studies (Bredius et al., 1994; Platonov et al., 1998; van der Pol et al., 2001). However, these results were not consistent across investigations (Domingo et al., 2002; Fijen et al., 2000).

Polymorphisms in cytokines such as TNFα, TNFβ, IL10, IL6, IL1, and IL1 receptor antagonist may be important but have produced inconsistent results in human studies of meningococcal disease.

Mycobacteria

There are several indicators that TB infection might be associated with genetic susceptibility (Bellamy, 2005). These include a potential role of innate immunity of the disease, whereby only 30–40% of close contacts of an infected individual contract TB infection (National Center for HIV SATPC, 2005). In addition, numerous animal models and human investigations have demonstrated the potential role of interferon-γ, TNF-α, reactive nitrogen intermediates, and other immunomodulators as well as CD4+ and CD8+ T cells in controlling the disease (Stead, 1992).

Numerous reports provide supportive data for genetic susceptibility to tuberculosis. Some of the most convincing data come from a tragic accident involving BCG (Bacilli Calmette-Guerin) vaccine in Germany to 249 infants in 1926 (Dubos and Dubos, 1952). Unfortunately, one strain of live *M. tuberculosis* was administered to all of these children, resulting in subsequent death of 76 babies within 1 year. Since only one strain was involved, this incident suggested that there was a differential response to tuberculosis infection in this population. Other factors that could have impacted response to infection were rather limited in this population due to age and disease exposure. Other evidence comes from selective pressure within a relatively homogenous population of Qu'Appelle Indians who experienced an annual death rate of 10% of their population from tuberculosis infection in 1890. This rate declined to less than 0.2% after two generations, suggesting a selective advantage among families with the ability to fight *M. tuberculosis* (Motulsky, 1960). Further evidence for the role of genetics in TB comes from a study of more than 25,000 residents of racially integrated nursing home in Arkansas (Stead et al., 1990). Development of a new TB infection (as evidenced by skin test conversion with 60 days of a negative test) while in the nursing home was approximately twice as likely among blacks and whites, with 13.8 versus 7.2% experiencing new infections, respectively (relative risk 1.9, 95% CI: 1.7–2.1). Even when the source patient was white, blacks became infected more frequently. However, once infected, individuals from both races appeared to be at similar risk of progressing to clinical infection. Finally, other studies in monozygotic twins compared to dizygotic twins in older studies found TB concordance rates twice as high among monozygotic twins, further suggesting a genetic role in susceptibility to disease.

Subsequent investigations in the genomic era have furthered our understanding of genetic factors and susceptibility to tuberculosis. *In vitro* studies and animal models of infection have been established to help describe the role of innate immunity against mycobacteria. Studies in humans have included analysis of individual patients with disastrous consequences following vaccination with other mycobacterial species, candidate-gene approaches using case–control designs, and genome-wide scans using families. The populations included in these various studies of genetic association and linkages have mostly included African (Gambian or South African) and Asian (Japanese, Chinese, Koreans, Taiwanese, and Hong Kong) populations. Only a few have included Europeans, Indians, or Mexicans (Fernando and Britton, 2006).

Based on these studies, a number of genes have been identified that may have a role in increased or decreased risk of mycobacterial diseases (Table 58.2). These include: interferon-γ, IL-10 and IL-12 receptor, TNF-α receptor 1, STAT-1, vitamin D receptor (VDR), solute carrier 11a1 protein (SLC11A1) (formerly known as natural resistance-associated macrophage protein (NRAMP1)), Class I and Class II HLA, mannose-binding lectin (MBL2), pulmonary surfactant proteins SP-A and SP-D, the purinergic receptor P2X7, TLR2, IL-1 receptor antagonist, and TNF-α (Soborg et al., 2007; Stein et al., 2007). To date, associations with heat shock protein 1A (HSPA1A) and transporter associated with antigen processing-2 (TAP-2) have only been reported in association with *M. leprae* infections. In addition to loci, microsatellite markers have been identified on the X chromosome, as well as chromosome 15 which suggest association with TB in Gambians (Bellamy et al., 2000). Genome-wide scan approaches in *M. leprae* infections identified other microsatellite markers on chromosome 6, 10, and 20 that may be important.

A study in Turkish patients with tuberculosis and non-infected controls suggested that the Arg753Gln polymorphism of TLR2 was associated with increased susceptibility to TB. Homozygotes for the AA genotype were more frequent among those with TB (OR 6.04 (95% CI: 2.01–20.08)), and this remained significant when the analysis was restricted to those with pulmonary TB. Heterozygotes were also more frequent among those with TB, although this finding was less substantial (OR 1.6 (95% CI: 1.01–2.55)) (Ogus et al., 2004). A recent study also suggested that TLR2 genotype 597CC were associated with susceptibility to tuberculous meningitis in Vietnamese subjects (Thuong et al., 2007). This association was not found for pulmonary tuberculosis in this case–control study. Another analysis of this cohort suggested that a SNP in the TLR1 receptor domain (C558T) was associated with tuberculosis, and more strongly with tuberculous meningitis (Hawn et al., 2006a).

In those with lepromatous leprosy, the Arg677Trp mutation of TLR2 was found in 10 of 45 subjects, but was absent in those with tuberculoid leprosy and healthy controls (Kang and Chae, 2001). This mutation was later shown to eliminate activation of NF-κB mediated by TLR2, in response to challenge with *M. leprae* (Bochud et al., 2003). Subsequent studies have not replicated the findings of the Arg677Trp mutation in other cohorts, however, and additional studies are necessary to establish the role of this TLR2 mutation (Alcais et al., 2005; Sanchez et al., 2004; Schroder et al., 2003a).

Another study has suggested that the isoleucine to serine mutation at position 602 on TLR1 was protective against leprosy among Turkish Caucasians (Johnson et al., 2007). TLR1 has been suggested to be an important co-receptor for TLR2. The 602S mutation was quite common among Caucasians and substantially more frequent than in those of African or East Asian descent. The authors suggest that these differences may

contribute to the increased and unexplained risk of tuberculosis among African Americans in previous studies.

Several recent studies have also investigated variation in the C-type lectin DC-SIGN and mycobacterial diseases such as tuberculosis and leprosy. Numerous studies indicate that variation in repeats in the neck region of DC-SIGN had no association with susceptibility to tuberculosis infection among South African Coloureds, Colombians, and Tunisians (Barreiro et al., 2007; Ben-Ali et al., 2007; Gomez et al., 2006). Variations in the neck region of *L*-SIGN (or DC-SIGNR) were also not associated with susceptibility to tuberculosis among South Africans. Promoter polymorphisms in DC-SIGN have been implicated in tuberculosis susceptibility among South Africans in one study (Barreiro et al., 2006a) but not other studies of Tunisians and West Africans (Olesen et al., 2007). The correlation among South Africans may reflect Eurasian descent of the population, in contrast to the other populations studied.

DC-SIGN variations were also recently studied in association with leprosy in a cohort of 194 infected Pakistanis and 78 non-infected controls (Barreiro et al., 2006b). 109 patients had lepromatous disease, while 85 had tuberculoid leprosy. In a cold binding assay, DC-SIGN expressing cells showed substantial binding to *M. leprae,* and the proportion was similar to binding of *M. tuberculosis*. However, there was no association between SNPs in DC-SIGN and susceptibility to leprosy. Since the number of cases/controls was relatively small, the study was potentially limited in its power to detect these differences. Future studies may be helpful to determine if DC-SIGN has a role in susceptibility to leprosy.

2009 UPDATE

The promise of genomic approaches for the identification and diagnosis of bacterial infections continues to be explored with fervor. Several recent reviews discuss the many approaches that can be taken to the design and conduction of genomic studies (Farber et al., 2008, Polpitiya et al., 2009; Yang et al., 2008). Additional methods such as transcriptomic (RNA) and proteomic (protein) analyses may provide further insight as novel diagnostics are applied to infectious diseases (Polpitiya et al., 2009). Clinical studies demonstrating these concepts are still somewhat limited, which reflects the substantial challenges that still face investigators in this area. These challenges include (1) establishing communication and uniform methods among researchers from various backgrounds and with disparate skill sets; (2) having both the experience and the necessary technical proficiency to produce reliable data; and (3) developing and implementing novel applications to facilitate data management and analysis (Polpitiya et al., 2009).

One recent microarray study performed using neutrophilic RNA from septic Australian ICU patients identified a unique expression profile for sepsis (Tang et al. 2008). This method did not distinguish between gram-positive and gram-negative bacterial sepsis using a rather large gene expression analysis of 18,664 genes involved in inflammation, immune regulation and mitochondrial function, but did distinguish infected (n = 55) from non-infected (n = 17) patients. The authors suggest that the lack of discrimination between gram-positive and gram-negative sepsis in this investigation and others (Nau et al., 2002; Boldrick et al. 2002) may be due to a common general response of gene expression when the host is challenged with these pathogens.

Genetic associations and immunity to bacterial infections continue to be explored as well. A recent case series of nine children with invasive pyrogenic bacterial infections provided human evidence for the role of Myd88 deficiency in susceptibility to infection (von Bernuth et al. 2008). Myd88 deficiency in these children appeared to be the result of an autosomal recessive trait, which resulted in loss of Myd88 function. However, unlike phenotypes observed with this deficiency in mouse models of infection, these children were not universally vulnerable to all pathogens and retained immunity to most bacteria, viruses, and parasites. These patients appeared to be particularly susceptible to bacteria such as *S. pneumoniae*, *S. aureus*, and *Ps. aeruginosa*. These data suggest that the role of Myd88-dependent signaling in TLRs may be especially important among infants, before other adaptive or TLR-independent innate immune mechanisms fully develop.

Another recent paper suggested an independent association between donor polymorphisms in mannose-binding lectin 2 (MBL2) and the rate of clinically significant infections among orthotopic liver transplant recipients following transplantation (Worthley et al. 2009). In this study, donor MBL2 polymorphisms were associated with low MBL serum concentrations in transplant recipients, who experienced a variety of post-transplant infections such as pneumonia, bacteremia and peritonitis due to numerous pathogens, including cytomegalovirus, gram-positive bacteria such as *S. aureus* and *Enterococcus spp.* and gram-negative bacteria such as *Ps. aeruginosa*, *K. pneumoniae* and *Enterobacter cloacae*. When controlling for other clinical factors such as CMV infection, donor/recipient CMV serostatus, organ rejection, age, and MELD score, donor MBL2 genotype (hazard ratio = 2.8, p = 0.002) and the receipt of CMV prophylaxis (hazard ratio = 2.6, p = 0.005) were independent predictors of clinically significant infection in the post-transplant period. These results confirm the findings of a smaller study that was previously performed in liver transplant recipients (Bouwman et al. 2005), but remain to be validated in other populations.

An association between NOD2 and TLR4 polymorphisms and acquisition of bacteremia was recently demonstrated in a study of 774 medical intensive care unit patients of Western European descent (Henckaerts et al., 2009). Data

regarding the incidence of gram-positive versus gram-negative bacteremia were not presented, but the authors state that this association persisted whether patients had gram-positive bacteremia, gram-negative bacteremia, or both. The association remained significant even after adjusting for other known risk factors for acquisition of bacteremia in the ICU. There was a higher rate of death among patients with both at least one NOD2 variant and a TL4 mutation, but not among those with variants in either gene alone. Those with both NOD2 and TL4 variants had higher APACHE II scores on admission to the ICU, which could have impacted mortality rates among those patients. Variants of other candidate genes such as TLR2, IL4, IL5, IL6, IL10, TNF-alpha, NOD1, and MBL2 were not found to be associated with acquisition of bacteremia in this cohort. However, those with variants of MASP2, a mediator in the MBL pathway of the complement system, also appeared to have a higher rate of death.

Variants in TLR1 were implicated in gram-positive bacteremia in a study of sepsis in the ICU from one cohort of 1183 Canadian medical/surgical ICU patients and a separate cohort of 237 patients with severe sepsis in the United States (Wurfel et al. 2008). In both cohorts, homozygotes for the TLR1 variant -7202 GG were found to have a higher rate of gram positive organisms, but their overall rate of infection from all causes was similar to others with septic shock. These subjects were found to have higher mortality and higher rates of organ failure.

Together these data provide additional insights in identifying markers of infection and patients at risk for infection. However, more studies are needed to further develop and apply these concepts in the clinical arena.

CHAPTER

Genomics in the Evaluation and Management of Sepsis

Christopher W. Woods, Robert J. Feezor and Stephen F. Kingsmore

INTRODUCTION

An 18-year-old female college freshman who lives in a dormitory with 50 other women presents to her local acute care center with 12 h of fever and headache. She is referred to the emergency department and develops a petechial rash while in transit. In the emergency department she becomes hypotensive and lethargic. She is admitted to the intensive care unit (ICU). Blood and cerebrospinal fluid cultures taken at the time of admission grow *Neisseria meningitidis*, serogroup C. She dies 2 days later with multi-organ failure despite aggressive attempts at resuscitation and support. No other students in her dormitory become ill after prophylaxis is provided. Her devastated parents wish to know if her two siblings are at high risk of bad outcome with a similar infection.

A 64-year-old hospitalized, African American veteran is admitted to the ICU after developing fever and hypotension subsequent to aortobifemoral bypass graft procedure. Blood cultures grow enteric Gram-negative rods. His fever persists and he develops disseminated intravascular coagulopathy, acute renal failure, acute lung injury, and succumbs to his illness after 3 weeks. His physicians considered drotrecogin alfa, but chose not to give it in the setting of recent surgery.

A 52-year-old woman with a several month history of fever with negative evaluation including blood cultures presents with acute renal failure and severe aortic regurgitation. A transthoracic echocardiogram reveals vegetations on her aortic valve leaflet. Immunohistochemistry at the time of valve replacement confirms *Bartonella henselae*. The patient raises feral cats. Her primary care physician is frustrated that he was unable to diagnose the infection earlier.

Each of these cases represents extremes of the heterogeneity of the sepsis spectrum and, yet, each highlights the potential benefits of the genomic revolution in the way we identify and care for patients presenting with the sepsis syndrome. In the past decade new techniques have been developed to investigate the causes of complex diseases. In this chapter, we will review the relevant literature and look toward the future.

Sepsis is a common, heterogeneous clinical entity that is defined by the physiological changes known collectively as the systemic inflammatory response syndrome (SIRS) that occur in response to a presumed infectious etiology (Table 59.1) (Bone et al., 1989, 1992; Sands et al., 1997). The insulting agent may be bacterial, viral, fungal, or parasitic with more than 80% of cases originating from a pulmonary, genitourinary, or abdominal source (Opal and Cohen, 1999). However, sepsis is not a single disease, but rather a heterogeneous syndrome that is expressed through the interaction of networks of biochemical mediators and inflammatory cascades. Clinical expression is variable and its severity is influenced by the infectious etiology, the genetic background of the patient, comorbid conditions, the time to clinical intervention, and the supportive care provided by the physician.

Patients with coincident acute organ dysfunction are considered to have severe sepsis. Patients with sepsis who fail to maintain their blood pressure despite adequate hydration

TABLE 59.1	Criteria for systemic inflammatory response syndrome and sepsis
SIRS	• Temp >38 C or <36 C • Heart rate >90 beats per minute • White Blood Cell count >12,000 cell/cc, <4000 cells/cc, or >10% band forms • Respiratory rate >20 breaths per minute or $PaCO_2 < 32$ torr
Sepsis	SIRS criteria and evidence of infection, or: • White cells in normally sterile body fluid • Perforated viscus • Radiographic evidence of pneumonia • Syndrome associated with high risk of infection
Severe Sepsis	Sepsis criteria and evidence of organ dysfunction including: • Cardiovascular: SBP ≤ 90 mmHg, MAP ≤ 70 mmHg for at least 1 hour despite adequate volume resuscitation or the use of vasopressors • Renal: urine output <0.5 mL/kg body weight/hour for 1 hour despite adequate volume resuscitation • Pulmonary: PaO_2/FiO2 ≤250 if other organ dysfunction present or ≤200 if the lung is the only dysfunctional organ • Hematologic: platelet count <80,000/cc or decreased by 50% within 3 days • Metabolic: pH ≤7.3 or base deficit >5.0 mmol/L and plasma lactate >1.5 x upper limit of normal

are considered to have septic shock. Severe sepsis is a major cause of morbidity and mortality with an annual incidence of 50–100 cases per 100,000 persons in several industrialized nations (Martin et al., 2003). In the United States, there are approximately 750,000 new cases of severe sepsis annually with an economic impact approaching $17 billion (Angus and Wax, 2001). Despite an enormous investment in critical care resources, 20–50% of patients with sepsis died; it is the third leading cause of infectious death and tenth leading cause of death overall.

The incidence of severe sepsis is increasing by approximately 9% annually. Between 1979 and 2000, the incidence increased from 82.7/100,000 to 240.4/100,000 (Martin, 2003). This increase is multifactorial, resulting from increased awareness and documentation of sepsis, "graying" of the population, greater use of invasive procedures for the diagnosis and monitoring of critically ill patients, emergence of antibiotic-resistant organisms, and increasing prevalence of immunocompromised patients (e.g., malignancy, AIDS, transplant recipients, diabetes mellitus, alcoholism, and malnutrition) (Parrillo et al., 1990). Furthermore, the relative contribution of etiological organisms has changed substantially over time. Gram-positive organisms superseded Gram-negative organisms in predominance in 1987, and fungal sepsis has increased by more than 200% since 1980 (Martin, 2003).

Genomic medicine appears well situated to assist in the identification of individuals at substantial risk for certain infections, to stratify subsets of individuals who are likely to progress to adverse outcomes or most benefit from therapeutic intervention, and to facilitate the rapid identification of etiological organisms. However, the complex physiology and epidemiology of sepsis, together with the diversity of physicians confronted by this illness, have slowed progress. Much of the literature focuses on the tremendous achievements in describing the genomes of various bacterial, viral, and fungal pathogens; however, this chapter focuses on the human genome and its response to the infectious perturbations that result in sepsis.

GENETIC POLYMORPHISMS ASSOCIATED WITH SEPSIS

Microbiological infections and their complications, such as sepsis and severe sepsis, occur at the interface of host genes, microbial genes, and the environment. While exposure to a microbial agent is necessary, it is not sufficient to cause sepsis in the host. Regardless of etiology, sepsis stimulates the host's immune, inflammatory, and coagulation responses (Figure 59.1). Although the general direction of activation is similar between persons, there are notable differences in response to infection that may have important clinical implications (Bellamy and Hill, 1998; Burgner and Levin, 2003; Choi et al., 2001). Therefore, sepsis progression depends on the relative weight of host defense versus microbe virulence. Several recent studies have shown evidence that host and pathogen molecular interactions drive adaptive evolution of the immune system – a host:pathogen genetic arms race (Hughes and Nei, 1988; Sackton et al., 2007; Schlenke and Begun, 2003). Accordingly, it is useful to evaluate how the genotype of patients determines their individual susceptibility and response to infection.

Family and twin studies have demonstrated familial or twin aggregation of some, but not all sepsis outcomes and clinical presentations on a common genetic basis (Härtel et al., 2007; Jepson et al., 1995). There are several dramatic examples of lack

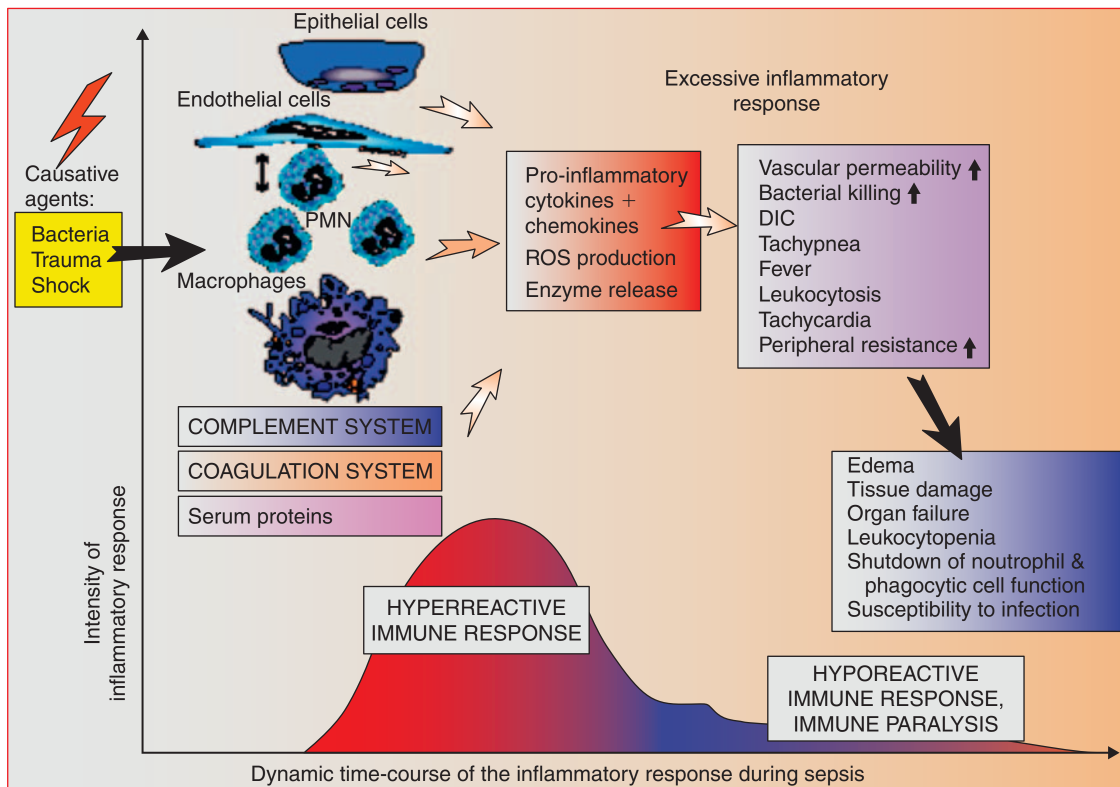

Figure 59 .1 Time course and intensity of host immune inflammatory and coagulation responses during sepsis (reproduced with permission from Riedemann, N.C., Guo, P.-F. and Ward, P.A. (2003) "Novel Strategies for the treatment of sepsis". *Nat. Med.* 9: 517–524). Microbiologic antigens and factors cause activation of the innate and cognate immune system, inflammatory response and coagulation system in sepsis, leading to production of proinflammatory cytokines, activation of the alternate pathway of complement and upregulation of adhesion and signaling molecules on white blood cells and blood vessel endothelium. ROS: Reactive oxygen species. DIC: Disseminated intracascular coagulation.

of host defense factors resulting from Mendelian mutations. For example, autosomal dominant inheritance in meningococcal meningitis susceptibility in a few large families due to a defective properdin gene in the alternative complement pathway (Densen et al., 1987). Mutations in ATP-sensitive K^+ channels expressed in murine endothelial cells and coronary artery smooth muscle may cause profound susceptibility to mouse cytomegalovirus (Croker et al., 2007). Other examples of susceptibility alleles are variants in immune response genes, including the MHC, CCR5 in HIV infection, and Toll receptor 2 in Mycobacteria and non-immune response genes such as Nramp in Mycobacteria (Drennan et al., 2004; Liu et al., 1996; Samson et al., 1996; Skamene et al., 1998). Linkage-based methods and candidate gene-based association studies are being extensively applied to microbial infection outcomes and sepsis but, to date, have met with limited success in the identification of risk alleles for host gene:pathogen interaction (Botstein and Risch, 2003; Freimer and Sabatti, 2004; Hill, 2006). In sepsis, most studies have investigated candidate genes that are involved in pathogen detection (e.g., toll-like receptors, TLRs), the inflammatory response (e.g., tumor necrosis factor, TNF-α) or coagulation (e.g., plasminogen activator inhibitor, PAI). Several reviews of the associations between candidate gene polymorphisms and the risk and outcome of sepsis have been published (Arcaroli et al., 2005; Lin and Albertson, 2004; Majetschak et al., 2002; Mira et al., 1999). However, ultimately, complex diseases like sepsis represent the cumulative effect of many minor susceptibility alleles and/or a small number of alleles of large effect. Several of those alleles of potential large effect are discussed briefly in this chapter and in more detail in adjoining chapters in this volume.

Limitations of Sepsis Gene-Association Studies

The analysis of single nucleotide polymorphisms (SNPs) among various susceptibility genes, such as those coding for pro- and anti-inflammatory mediators, in the response to sepsis has the potential to nominate prediction tools that will permit the clinician to more precisely determine the type of therapy a particular patient should receive. In fact, early identification of a genotypic risk may even help guide the introduction of prophylactic therapy. However, unraveling the genetic variation in sepsis is complicated and close attention must be paid to study design issues, including the selection of an appropriate study population and sample size and understanding gene–environment interactions.

A lack of replication among studies provides considerable concern in the interpretation of results. For example, an initial study may identify an allele with large estimated genetic effects, but subsequent studies fail to corroborate the results (Goring et al., 2001; Hirschhorn et al., 2002; Ioannidis et al., 2001; Lander and Kruglyak, 1995). Biological explanations of inconsistent results include unacknowledged confounding heterogeneity, such as poorly defined phenotypes, heterogeneous genetic sources for the phenotype (genocopies), population diversity (ethnic ancestry), population-specific linkage disequilibrium (LD), heterogeneous genetic and epigenetic backgrounds, or heterogeneous environmental influences (phenocopies). Analytic reasons for problems with reproducibility include failure to control the rate of false discoveries, lack of power, model misspecification, and heterogeneous bias in estimated effects among studies (Cardon and Bell, 2001; Cardon and Palmer, 2003; Redden and Allison, 2003; Sillanpaa and Auranen, 2004). Among these, the most frequent source of non-replication has been lack of power due to the limited number of individuals genotyped and phenotyped (Lohmueller et al., 2003; Risch, 2000).

Pathogen Recognition/Signaling

Toll-Like Receptors

There has been substantial progress in defining variants of several genes and pathways implicated in infectious disease susceptibility; however, none have caused more excitement than investigation of genes affecting innate immunity, particularly newly discovered pattern recognition receptors and their associated signaling pathways. The TLRs have captured the attention of most investigators in this field.

Innate immunity, recognition of invading microorganisms, is mediated by a set of soluble and membrane receptors that recognize conserved, pathogen-associated molecular patterns (PAMPs) shared among each class of infectious agents but absent in higher eukaryotes. Having a cytoplasmic domain that bears homology to the interleukin (IL)-1 receptor, TLRs have been conserved throughout diverse life forms including plants, insects, and mammals. Thus far, 10 human TLRs have been identified that play a role in sensing pathogens. Activation of TLRs stimulates macrophages resulting in the elaboration of proinflammatory cytokines and antimicrobial molecules such as nitric oxide and defensins. Concurrently, stimulated dendritic cells migrate to lymph nodes and over-express antigen MHC and costimulatory molecules (CD80/CD86). Therefore, TLRs are an essential link between innate and adaptive immunity.

The discovery and characterization of TLRs as a key pattern recognition molecules for pathogens (or PAMPs, Beutler and Reitschel, 2003) and initiators of the innate immune responses (Akira et al., 2001; Creagh and O'Neill, 2006) stimulated many investigators to further characterize the relevance of polymorphisms in these receptors and susceptibility to infectious disease. Sepsis was an early target for characterization of the relevance of polymorphisms in TLRs. The TLR4 protein activated NF-kappa B and increased expression of the pro-inflammatory cytokines, IL-1, IL-6, and IL-8 in cultured human cells. and TLR4 deficient mice were resistant to systemic endotoxin exposure, but remained susceptible to Gram-negative infections (Oureshi et al., 1999). Asp229Gly and Thr399Ile are common TLR4 missense mutations that affect the extracellular domain and some reports suggest an association with varied human responses to inhaled endotoxin (Arbour et al., 2000). A number of small studies associated the Asp299Gly variant of the *TLR4* gene with increased susceptibility to either Gram-negative infections (Agnese et al., 2002; Lorenz et al., 2002) or SIRS (Child et al., 2003). However, an evaluation of an intravenous lipopolysaccharide (LPS) challenge did not reveal an association with TLR4 mutations (Calvano et al., 2006). In addition, Smirnova et al. found an excess of rare TLR4 coding changes in meningococcal cases compared with controls (Smirnova et al., 2003). However, the study did not support an association with the functional Asp299Gly or Thr399Ile polymorphisms of *TLR4*. The absence of an association was also supported by a much larger case–control study (Read et al., 2001). Together, these studies of TLR4 polymorphisms suggest that individuals with the 299/399 polymorphisms may have an aberrant response to certain, but not all, Gram-negative bacterial diseases, resulting in an increased susceptibility to infection and severity of disease.

TLR2 and TLR5 have also been targets of interest. TLR2 is most notable for detecting a wide repertoire of pathogens, including Gram-positive or Gram-negative bacteria, mycobacteria, fungi, viruses, and parasites. Largely this results from an ability to recognize ligands as a heterodimer with TLR1 or TLR6 (Lorenz, 2006). Of particular importance, TLR2 has been linked to the recognition of Gram-positive bacteria, which are now the leading cause of sepsis (Martin, 2003). TLR2 accomplishes this via response to peptidoglycan, lipoteichoic acid, and a variety of macromolecules in Gram-positive bacteria such as *S. aureus*. The relationship between TLR2 polymorphisms (primarily Arg753Gln) and *S. aureus* infection has been examined in several studies with contradictory results (Lorenz et al., 2000; Moore et al., 2004). Therefore, additional investigations are warranted to confirm this association.

TLR5, which recognizes bacterial flagellin from both Gram-positive and Gram-negative bacteria, activates NF-kappa B and the release of pro-inflammatory cytokines in response to this bacterial antigen (Hayashi et al., 2001). A stop codon polymorphism (Arg392TER) has been identified in the TLR5 gene and is associated with an increased susceptibility to *Legionella pneumophila* (Hawn et al., 2003). suggesting that this allele may increase susceptibility to pneumonia associated with flagellated organisms.

NOD-Like and RIG-Like Receptors

TLRs are involved in the recognition of all types of pathogens regardless of location. In contrast, NOD-like receptors (NLRs) primarily recognize cytoplasmic bacterial pathogens (Inohara and Nunez, 2003). Many NLRs have caspase recruitment domains (CARD). These domains are involved in the assembly of protein complexes that promote apoptosis. These CARD proteins may also participate in NF-kappa B signaling pathways. Hill et al. have studied a truncation variant of the human

CARD8 gene and found that African children homozygous for this inactivating mutation are susceptible to non-typhoidal Salmonella bacteremia (Hill, 2006).

A third family of pattern recognition receptors described more recently is the DExD/H Box RNA helicase family of RIG-I-like receptor (RLR) genes, which includes MDA5 as well as RIG-1 (Creagh et al., 2006). These receptors appear to differentially recognize double-stranded RNA from various viruses (Kato et al., 2006). An amino acid change in MDA5 has been associated with susceptibility to type 1 diabetes lending support to a viral etiology for this disease (Smyth et al., 2006).

Mannose-Binding Lectin

Mannose-binding lectin (MBL) is an acute-phase protein that can opsonize many bacterial and fungal pathogens and activate complement (Kuhlman et al., 1989). Approximately one-third of most human populations are heterozygous for one of the variants in the coding region of exon 1 that lead to lower MBL concentrations. Individuals with 2 copies of low MBL haplotypes have a higher risk of pneumococcal sepsis (Kronborg and Garred, 2002; Roy et al., 2002), and there is less well-replicated evidence for susceptibility to other bacterial pathogens and candidiasis.

Although multiple studies indicate that MBL plays a role in mitigating certain pathogens, the high rates of haplotypes that specify low MBL levels in certain ethnic groups suggest that a relative lack of MBL might be beneficial to the host under other circumstances. In particular, studies of the MBL-MASP pathway suggest that it may play a role in reducing reperfusion injury in the heart and resulting in relative protection against the complications of myocardial infarction (Walsh et al., 2005).

CD 14

CD14 functions as an anchor protein and is a ubiquitous pattern recognition receptor, specific for LPS and other ligands. Performing as a co-receptor for TLR4, it is shed by monocytes to facilitate LPS signaling for all other cells. Two polymorphisms at the promoter region of the CD14 gene have been widely explored. The -159 T allele has been associated with increased prevalence of Gram-negative infections and sepsis, but not with shock or survival (Gibot et al., 2002; Sutherland et al., 2005). However, other studies have yielded contradictory results. More recently, the -260 T allele has been linked to increased survival in a Brazilian sepsis population (D'Avila et al., 2006).

Intracellular Signaling Molecules

The IL1 receptor-associated kinase-4 (IRAK4) is an intracellular kinase that transduces intracellular signals conveyed by the TLRs and IL1 receptors. Patients with IRAK4 deficiency are at increased risk for invasive bacterial disease (Von Bernuth et al., 2005). Homozygous individuals for either of the two known variant alleles appear to have completely inhibited expression of IRAK4, thereby inhibiting activation of NF-kappa B and NF-kappa B-dependent pro-inflammatory mediators (Lasker et al., 2005).

Cytokine Polymorphisms

Genetic variation in the pro-inflammatory cytokines TNF-α, TNF-β, IL-6, IL-8 and macrophage migration inhibitory factor (MIF) and the anti-inflammatory cytokines IL-10 and IL-1 RA are the most extensively studied in relation to sepsis. Patients predisposed to a balanced anti-, pro-inflammatory response appear to have better chances for survival (Figure 59.1). Defects in regulation occur when the balance is shifted and allows for unmitigated inflammation causing tissue and organ damage or the inability to extirpate invading pathogens.

Pro-inflammatory Cytokines

TNF-α is a primary mediator in sepsis and an initial trigger of the immune response. Most studies have investigated the significance of the -308 A allele of the promoter region and have yielded mixed results on outcome of sepsis and no association with the expression of TNF-α (Mira et al., 1999; Stüber et al., 1996). Potential associations with polymorphisms at −376 and position −238 are also not convincing. Bayley et al. reviewed the functional impact of genomic variations within the TNF- α locus and showed that most of the variation had no impact on the expression of TNF-α or had contradictory results (Bayley et al., 2004).

TNF-β binds to the same receptor as TNF-α and a number of polymorphisms have also been described. In particular, the TNF-β 250 SNP has been the target of multiple investigations. However, LD with heat shock protein 70 alleles confounds interpretation and more advanced models will be necessary before inferences of TNF-β variability in sepsis can be made.

Both IL-1α and IL-1β engage the same receptor and are potent pro-inflammatory cytokines released by macrophages involved in the systemic inflammatory response and are capable of inducing the symptoms of septic shock and organ failure in animal models (Leon et al., 1992). Despite the finding that a homozygous TaqI genotype (−511) correlates with expression of IL-1β, no association with incidence or outcome of sepsis has been determined (Ma et al., 2002; Pociot et al., 1992).

IL-6 plays a role in lymphocyte stimulation and its levels consistently associate with severity and mortality in sepsis (van der Poll and van Deventer, 1999). Allelic variation has been described in the promoter region (-174 G/C). A German study demonstrated improved survival with the -174 G/C SNP, but not incidence of sepsis (Schluter et al., 2002). It is possible that variation at the IL-6 gene may contribute to the outcome of sepsis, but variable association of specific SNPs with IL-6 levels and the potential for LD with several alleles obscure the clinical significance of these results.

Similar studies for the identification of polymorphisms in IL-8 and MIF promoter regions and genes are ongoing.

Anti-inflammatory Cytokines

IL-10 is an integral part of the body's anti-inflammatory processes and is involved in the suppression of innate and adaptive immune responses. Its expression is stimulated by inflammation,

and it is a potent inhibitor of non-specific inflammatory response. In sepsis, high IL-10 levels have been consistently associated with disease severity (Wunder et al., 2004). This cytokine has several promoter variants with SNPs at −592, −819, and −1082. Several studies investigating the association of the promoter polymorphisms and sepsis severity, and survival found a higher frequency of the −1082 allele in patients with sepsis (particularly pneumococcal) and community-acquired pneumonia, but more well-designed studies are needed.

The IL-1 receptor antagonist (IL1RN) inhibits the pro-inflammatory actions of IL-1 by binding to their receptor. Polymorphisms in IL1RN may be promising candidates for genetic associations, but should be explored in relation to the rest of IL-1 peptides.

Coagulation

Activation of the coagulation cascade is a key event in the pathogenesis of sepsis. As a result, abnormalities in the antithrombin III, protein C, and tissue-factor inhibitor pathways have been implicated in the pathogenesis of sepsis. Recombinant human activated protein C (APC) is the only pharmacotherapy shown to be effective in the treatment of a subset of patients with severe sepsis (Bernard et al., 2001). Protein C −1641 AA genotype is associated with decreased survival, more organ dysfunction, and more systemic inflammation in patients having severe sepsis (Walley and Russell, 2007). APC not only inhibits factors Va, Xa, and PAI-1, but also neutrophil adherence, chemotaxis, and cytokine release. In animal models of septic shock genetic deficiency of tissue factor reduces mortality (Texereau et al., 2004). In contrast, genetic deficiencies of the anticoagulants thrombomodulin, antithrombin II, and protein C increase mortality. Several SNPs and other genetic polymorphisms have been described in genes of hemostatic factors, including thrombin fibrinogen, factor V, PAI-1, protein C, and endothelial protein C receptor.

Factor V and the Protein C Pathway

Factor V influences protein C activation by promoting thrombin generation. Three independent SNPs of factor V have been described that all make factor Va partially resistant to inactivation by APC, resulting in a pro-thrombotic state (Nicolaes and Dahlback, 2003). The frequency of this polymorphism in certain populations suggests that it confers some evolutionary advantage. In a large study of children with meningococcal disease, factor V Leiden heterozygosity was not only associated with increased incidence of purpura fulminans, but also a trend toward reduced mortality (Kondaveeti et al., 1999). In a substudy of PROWESS, factor V Leiden carrier status was associated with lower 28-day mortality and with less vasopressor use (Bernard et al., 2001). However, it did not determine responsiveness to recombinant human APC infusion. Biomarker studies have demonstrated, however, that plasma protein C levels do predict usefulness of recombinant human APC infusion (Shorr et al., 2006).

Plasminogen Activator Inhibitor-1 and the Fibrinolytic System

PAI-1 not only promotes clot stability, extension, and resistance to lysis, but also acts as an acute-phase reactant (Hoekstra et al., 2004). Increased PAI-1 is a risk factor for cardiovascular disease, but may confer a survival benefit in meningococcal sepsis (Kornelisse et al., 1996). A common PAI-1 promoter SNP is characterized by 4G and 5G alleles. 4G homozygosity is not only associated with an increase in PAI-1 transcription and higher rates of myocardial infarction, but also a higher risk for mortality and vascular complications among patients with sepsis (Haralambous et al., 2003; Hermans and Hazelzet, 2005; Zhan et al., 2005). Genetic polymorphisms of other constituents of the fibrin formation and degradation pathways also deserve further study.

Future Investigations

To address the complexity of the sepsis response and to predict its outcome, multiple surrogate markers that reflect the nature and severity of the inflammatory response, the status of the coagulation and fibrinolysis systems, and the magnitude of organ injury are likely to be more effective in identifying patients at risk of an adverse outcome and those who may benefit from interventional therapies. Such strategies will inherently require the use of multiplex approaches that have sufficiently high throughput to be cost effective (Kingsmore, 2006). An example of the use of multivariable models for prediction of sepsis is shown in Figure 59.2. A combination of measurements of five serum or plasma

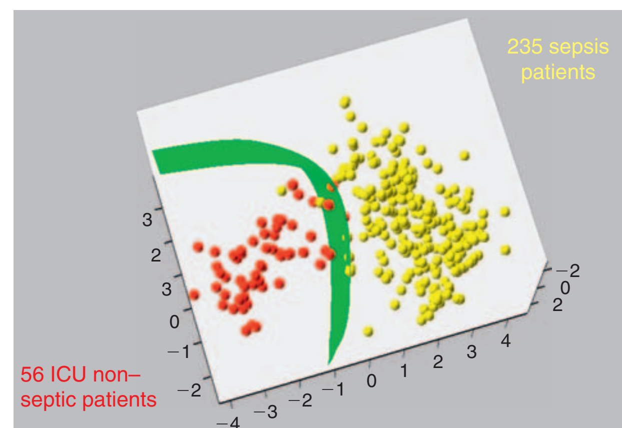

Figure 59 .2 Multiple serum biomarkers effectively distinguish patients with sepsis from ill, non-septic patients (Kingsmore et al., 2005). Individual host protein biomarkers, such as IL6, demonstrate good diagnostic sensitivity for sepsis, but poor specificity. Principal component analysis with a quadratic decision surface (green curved surface) is shown for values of five serum protein biomarkers measured in 235 patients with sepsis (yellow spheres) and 56 patients without sepsis (red spheres), but with severe illness necessitating ICU admission. Multiplexed serum biomarkers exhibited a sensitivity of 100% and specificity of 99% (positive predictive value of 96%).

cytokines showed high sensitivity and specificity in distinguishing between acutely ill, septic and non-septic patients, whereas individual cytokine measurements lacked specificity. Therefore, isolated, candidate gene-by-gene, or protein-by-protein approaches, may be rendered obsolete by these constraints.

MOLECULAR SIGNATURES AND SEPSIS

The recognition and treatment of sepsis have posed a daunting challenge for clinicians despite the improvements in technology and the principles of critical care medicine. In addition to a broad array of infectious etiologies, many of the clinical signs of overwhelming sepsis such as fever, tachycardia, and leukocytosis are non-specific and can also be seen with systemic inflammation that is induced by non-infectious causes like mesenteric ischemia-reperfusion, pulmonary embolus, pancreatitis, or trauma. Regardless, empirical broad spectrum antibiotic use is the rule as a component of early goal-directed therapy (Rivers et al., 2001).

The characterization of the human genome has provided a mechanism to study infection at the molecular level. Whereas former techniques have focused on obtaining fluid or tissue from a body compartment and incubating the sample to determine the cause of infection (if any), the study of genomics provides another means. The discovery of surface receptors that recognize microbial invasion and transmit signals to the immune system has led scientists to try to characterize the molecular and genetic changes in the host organism as it is invaded by exogenous infections. From as little as 100 ng of total cellular RNA isolated from whole blood or any tissue, the relative expression of all known genes, expressed sequence tags, and open-reading frames can be evaluated simultaneously. More importantly, the global interaction among these thousands of genes can be studied without any specific selection bias. By studying global expression, one can devise methods of class prediction based on global gene expression activity and this can be done without prior knowledge of the function of any of the genes.

Functional genomics relates these technologies to clinical medicine. Although most investigations have focused on the changes in one or relatively few genes in response to a disease or treatment, these newer technologies are exploring the changes in gene expression of the entire genome. This has resulted in functional genomics offering two unique perspectives on sepsis biology: the ability to use "patterns" of gene, protein or metabolite expression to class predict or classify tissue responses (i.e., to develop a "signature" or "fingerprint" for a specific tissue, pathogen, or outcome) and to explore the underlying biological changes that occur in health and disease while not being limited to a subset of selected genes, proteins, or metabolites.

Similarly, during the past year, a novel genetic approach – genome-wide association (GWA) – has demonstrated its potential to identify common genetic variants associated with complex diseases such as diabetes, inflammatory bowel disease, and cancer (Kingsmore et al., 2008). GWA studies seek statistically significant associations between a disease phenotype and genotypes of hundreds of thousands of common single nucleotide variants distributed throughout the genome in hundreds or thousands of affected individuals and matched controls. GWA studies are anticipated to have broad impact on drug discovery and development by providing molecular understanding of common diseases and tools for molecular stratification of patients. As yet, no GWA studies of sepsis have been published, although several are underway.

Challenges Associated with Applying Genomic Science to Sepsis

Data acquisition from microarray analyses is not problematic; however, quality control, data analysis, and information extraction remain particularly challenging. Traditional statistical and bioinformational approaches are not appropriate for the simultaneous analyses of the large number of analytes on most microarrays. In addition to using probabilities to define confidence intervals among groups, false discovery rates are often applied (Steinmetz and Davis, 2004; Storey and Tibshirani, 2003). Equally problematic are the issues of how such vast quantities of data are analyzed or presented in a manner that can be readily understood. Heat maps, dendrograms, cluster, and principal component analyses, and network analyses are generally used to extract meaningful information (Eisen et al., 1998).

As methods for accruing and analyzing data are improved, investigators can turn to other important issues to maximize the utility of genomic methodologies. The correlation between transcript abundance patterns in the peripheral blood and those within local cells at the site of infection is unclear. Clearly, the boundaries are not distinct. Furthermore, human clinical samples other than blood, cells, and tissue from the primary site of infection might be useful for genomic analysis.

Pathogen Signatures

Recognition of microbial invasion is one of the hallmarks of innate immunity. Antigen-presenting cells, as well as cells of epithelial and endothelial origin, express surface receptors that can recognize PAMPs. With the recent description of TLRs, considerable effort has been directed at examining the genome-wide expression response to different microbial pathogens. Nau et al. found that human macrophages have a profound genetic perturbation that is demonstrated following infection by any of a number of exogenous bacteria (Nau et al., 2002). The shared responses alter the baseline expression of genes that encode for other cell surface receptors, signal transduction proteins, and transcription factors. Other investigators have examined the genomic responses to exogenous microbial stimuli using varying populations of cells. Calvano et al. examined the genome-wide response of leukocytes from healthy volunteers inoculated with endotoxin. Out of 44,000 genes studied, there were 3714 genes whose expression signal changed significantly with *in vivo* stimulation (Calvano et al., 2005). This proved, on a genomic level, that the systemic perturbations of infection were more vast than clinically evident.

Even with proof of the vast alterations in gene expression that infection can induce, genomic technology has been used to discriminate among types of infections. Huang et al. not only confirmed a large shared response among dendritic cells exposed to *E. coli*, *Candida albicans*, and influenza virus, but they also showed a differential response based on the pathogen (Huang et al., 2001). Feezor et al. stimulated whole blood from human volunteers with *E. coli* LPS or heat-killed *Staphylococcus aureus* (SAC) and found that there were 758 distinct genes whose expression level differentiated between the Gram-negative and Gram-positive exposures (Feezor et al., 2003). These investigators demonstrated that the families of genes affected by different pathogenic stimuli were strikingly unique (Figure 59.3). For instance, Gram-negative infection tended to alter the expression of genes involved in global immune response, signal transduction, and plasma membrane function while Gram-positive infection altered the expression of genes that are believed to control ribosomal proteins and cell cycle regulation.

Chung et al. sought to characterize a genomic profile that would indeed distinguish between sepsis and presumably sterile systemic inflammation (Chung et al., 2006). In parallel analyses of murine and human models, they compared these two cohorts. Genomic data from spleens of septic and injured patients were used to create a septic profile, the accuracy of which was 67.1%; in the murine model, the accuracy of the genomic predictor profile was as high as 96%.

Most recently, Ramilo and colleagues have demonstrated distinctive gene expression patterns in peripheral blood leukocytes from patients with confirmed systemic bacterial (*E. coli, S. aureus, S. pneumoniae*) and viral (influenza A) infections (Ramilo et al., 2007). Furthermore, distinctive gene expression patterns were observed in patients with respiratory infections of different etiologies demonstrating the utility of blood in the evaluation of infections of different organ systems. Similar results were documented in a cohort of military trainees with febrile respiratory illness (Thach et al., 2005).

These studies are the first to show that molecular characterization can be performed to distinguish between the infected and non-infected states, even in the face of very similar clinical presentations. These data also serve to highlight the grossly insensitive criteria used in clinical medicine to determine infection or sepsis, and the power of genomic science to provide a molecular characterization of a clinical dilemma. On a macrosystem level, the whole body response to either stimuli has been well established: fever, leukocytosis, tachycardia, with the potential of devolving into multi-system organ failure. Functional genomics is a better test of the cause of the patient's global dysfunction and may one day be used to guide initial therapy or to tailor ongoing therapy.

Progression Signatures

The need for rapid, accurate identification of disease progression in sepsis has increased dramatically with the upcoming availability of several novel treatment regimens. While novel sepsis therapies are improving sepsis outcomes, they are creating new patient management and diagnostic challenges for physicians. In 2001, the Food and Drug Administration (FDA) approved APC (Xigris, Eli Lilly and Company, Indianapolis, IN) for treatment of patients with severe sepsis (SS) and Acute Physiology and Chronic Health Evaluation II score of ≥25 — one of the first examples of inclusion of a biomarker in the indication for a therapy. In the pivotal phase III trial of APC in SS (PROWESS), 28-day mortality was decreased by 6% (Bernard et al., 2001). The greatest reduction in mortality (13%) and cost effectiveness was observed in the most seriously ill patients (those with APACHE II score ≥25). APC benefit was also observed in patients with pneumonia. In contrast, APC exhibited modest survival benefit and cost-ineffectiveness in patients with APACHE II score <25. However, APC therapy is associated with a 1–2% incidence of major bleeding. For these reasons, appropriate use of APC is most likely to occur following development of an objective, accurate, rapid diagnostic test for progression to severe sepsis. Diminution of protein C activity in citrated plasma was recently shown to be a surrogate marker for APC efficacy in patients with severe sepsis (Shorr et al., 2006).

Prompt and accurate diagnosis is especially important for effective sepsis management and contributes significantly to positive outcomes (Rivers et al., 2001). Rates of progression of severe sepsis to organ failure, septic shock and death heterogeneous are largely independent of the specific underlying infectious disease process. For example, case-fatality rates in those with culture-negative severe sepsis are similar to those with positive cultures (Rangel-Frausto et al., 1995). Case-fatality rates in sepsis are, however, critically dependent upon disease staging. Current differentiation of SIRS, sepsis, severe sepsis, and septic shock relies exclusively on clinical assessment (Balk, 2000). Thus, a key unmet diagnostic need is for rapid, quantitative, objective determination of the stage of sepsis development and likelihood of progression to severe.

Several currently available clinical indices do provide quantitative assessment of staging and severity of sepsis, but with limitations. They include sequential organ failure assessment (SOFA) score, APACHE II score, and blood lactate level (Pacelli et al., 1996). APACHE II score, although quantitative, is largely subjective, complex, cumbersome, and has a relatively narrow dynamic range. Blood lactate levels are quantitative, but limited by false negative normal values in elderly patients and by confounding comorbidities such as liver failure, diabetes mellitus, and the use of certain medications. The clinical picture in sepsis patients is highly dynamic, and assessment of such indices tends to be subjective and to occur with insufficient frequency. Furthermore, sepsis is very heterogeneous in terms of pathogen, source of infection, associated comorbidity, course and complications. Delayed or errant diagnosis of severe sepsis may result in failure of timely treatment. Thus, an early, rapid, objective diagnostic of severe sepsis would be a significant adjunct to these clinical indices and would significantly advance patient management.

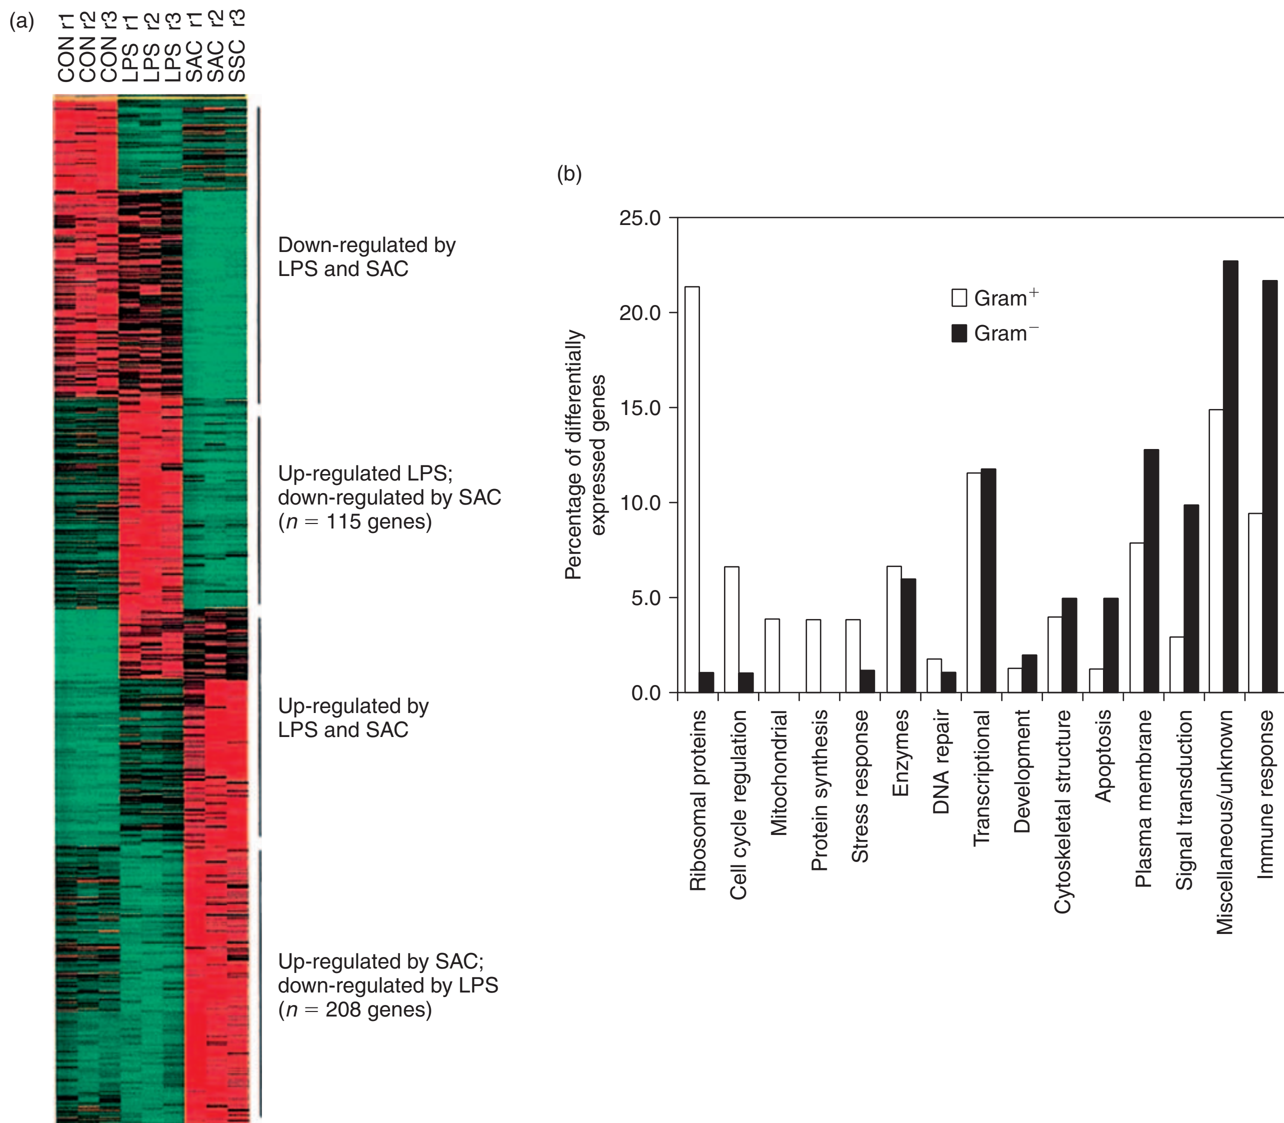

Figure 59.3 Heat map and gene ontologies of leukocytes when ex vivo whole blood is stimulated with either LPS or heat-killed *S. aureus*. (a) K-means cluster analysis on 780 genes whose expression significantly changed in response to ex vivo stimulation. Patterns of gene expression could be classified into bins on the basis of the similar and disparate responses to Gram-negative and Gram-positive pathogens. CON, control. (b) Differences in gene expression between the two stimuli based on the ontologies for the 780 genes. Gram-positive (Gram+) stimulus (heat-killed *S. aureus*) preferentially altered the expression of ribosomal and mitochondrial proteins and cell cycle proteins, whereas the Gram-negative (Gram) stimulus altered the expression of genes involved in signal transduction and the immune response. Figure is from Feezor et al. (2003).

Elevations of IL-6, IL-8, IGFBP1, IL-2sR and MIF in sepsis have been widely documented. Furthermore, levels of IL-6, IL-8 and IL-2sR have variously shown correlation with sepsis severity, progression to septic shock, organ failure, and mortality. However, many other conditions elevate blood levels of these analytes, and diagnostic sensitivity and specificity of individual analyte levels has been insufficient for diagnosis of sepsis or severe sepsis (Delogu et al., 1995; Martin et al., 1994; Selberg et al., 2000).

Using an antibody microarray on specimens from patients from the PROWESS study (Bernard et al., 2001; Perlee et al., 2004), including sepsis non-survivors, 133 analytes were measured in 139 matched serum and plasma samples (between day 0 and 28) from 12 severe sepsis patients (7 survivors and 5 who died) and 8 normal individuals. Sixty-three candidate sepsis biomarkers were identified (35 in serum and 48 in plasma); each exhibited greater than twofold change between severe sepsis patients and controls on day zero. The top biomarker was IL-6

(26-fold increase) (Kingsmore et al., 2005). Multivariable models were more effective than single analytes in prediction of sepsis (Figure 59.2). A combination of measurements of five serum or plasma cytokines showed high sensitivity and specificity in distinguishing between acutely ill, septic, and non-septic patients, whereas individual cytokine measurements lacked specificity.

In an additional study, biomarkers predictive of sepsis death were identified by at least a twofold difference in average level between sepsis survivors and non-survivors in the days immediately preceding death (days 0–4). A total of 10 candidate sepsis mortality biomarkers were identified. The top biomarker was follistatin (15-fold difference).

DNA microarray-based gene transcript profiling of the responses of primates to infection has begun to yield new insights into host–pathogen interactions; however, this approach remains plagued by challenges and complexities that have yet to be adequately addressed. The rapidly changing nature over time of acute infectious diseases in a host, and the genetic diversity of microbial pathogens present unique problems for the design and interpretation of functional-genomic studies in this field. In addition, there are more common problems related to heterogeneity within clinical samples, the complex non-standardized confounding variables associated with human subjects and the complexities posed by the analysis and validation of highly parallel data. Various approaches have been developed to address each of these issues, but there are still significant limitations that need to be overcome. The resolution of these problems should lead to a better understanding of the dialog between the host and pathogen.

2009 UPDATE

As noted throughout this chapter, the genome revolution holds great promise for both scientific and therapeutic advances related to sepsis. Although we anxiously await genomic breakthroughs in the ability to identify patients at high risk for certain infections, to stratify those at risk for progression, or to rapidly determine etiology, investigators are still early in developing the cohorts and technological innovations needed for validation of initial findings. Regardless, a number of tempting observations have been recently reported.

Due to its heterogeneity, the absence of a clear genetic "cause" of sepsis is not surprising. Though we continually add to our nuanced understanding of the impact of a growing array of SNPs, the genetic risk is likely polygenic with a strong environmental component affecting likelihood of exposure to certain pathogens. Among the best-understood pattern recognition pathway genes, the Toll-like receptors remain the focus of attention. The previously described association with sepsis susceptibility for polymorphisms in innate immunity genes was further evaluated in a large cohort ($n = 774$) intensive care unit patients. The study analyzed genes involved in infection, inflammation, and coagulation. The combination of at least one variant in both *NOD2* (which synergizes with *TLR2*) and *TLR4* that occurs in 5% of the population was associated with bacteremia. However, the variants did not affect the type of infection (e.g., gram negative or positive) or the source of infection (pulmonary, catheter, etc.). Furthermore, the presence of variants of *MASP2* gene (9% of population) or the *NOD2/TLR4* combination both predispose to death (Henckaerts et al., 2009). In addition to the longstanding interest in *NOD2* and *TLR4*, *TLR9* has recently been described as having a dual role as a potent proinflammatory stimulator as well as bactericidal activity related to bacterial clearance (Sjolinder et al., 2008). Continued advances in the analysis of gene expression profiling via microarrays and proteomics not only reveal how pathogens affect the host's gene expression patterns but also a wealth of candidate genes for genetic susceptibility studies. To more accurately identify novel genes with different clinical outcomes, genome wide expression analyses are now being combined with genetic studies (Thuong et al., 2008).

Gene expression changes can indicate both general infection and disease-specific responses. Investigators are increasingly interested in the dynamics of gene expression over the course of infection, beginning with the presymptomatic period in high risk patients, through recovery or death. McDunn and colleagues recently defined the concept of the "Riboleukogram" (McDunn et al., 2008). The authors focused on ventilator associated pneumonia (VAP) and, in a mouse model, were able to develop RNA profiles capable of distinguishing the severity of the insult and the type of infectious agent. Using principal components analysis on gene expression data from a group of mechanically ventilated patients, they examined the behavior of the human orthologs to the genes identified in the mouse study and although there was a conserved peripheral leukocyte transcriptional response, the information did not appear to be more useful than current clinical criteria. However, by explicitly accounting for variance over time, a set of 85 genes could identify a subset of patients whose expression levels changed before the clinical diagnosis of VAP. Although numerous mouse studies suggest distinct signatures for different bacterial pathogens, a definitive clinical study demonstrating that capacity in humans remains elusive (Tang et al., 2008). The fact that these studies are typically small and use different analytic techniques highlights the importance of study design and methods.

Transcriptional profiles may also be expected to aid prognosis and response to treatment as is now the case in oncology. However, most studies in sepsis and infectious diseases have just begun to classify patients with clinical phenotypes that may benefit from genomic directed therapy.

CHAPTER

Genomics and the Management of Hepatitis

N.A. Shackel, K. Patel and J. McHutchison

INTRODUCTION

Viral hepatitis is a significant global health problem with hepatitis B (HBV) and hepatitis C (HCV) infecting in excess of 300 million people. HBV and HCV are complicated by chronic persistent infection characterized in a proportion of patients by progressive hepatic injury leading to complications of end-stage liver disease including hepatocellular carcinoma (HCC). HCC is the fifth most prevalent human malignancy, and the majority of cases can be directly attributed to liver injury secondary to chronic HBV and/or HCV infection. Although both HAV and HEV are significant health problems they are typically characterized by a self-limiting course and are not complicated by significant clinical sequelae in the majority of cases. Therefore, research into infectious hepatitis has focused mainly on HBV and HCV pathogenesis, including the development of liver fibrosis, the immune response in acute infection, mechanisms of viral persistence and the development of HCC. The use of functional genomics approaches has significantly advanced our understanding of viral hepatitis pathogenesis and as well as our understanding of therapeutic strategies.

VIROLOGY OF HEPATITIS VIRUSES

The hepatitis viruses are characterized by specificity for the liver and in particular the hepatocyte (Figure 60.1). However, the mechanism by which these viruses are specific for the liver is largely unknown but is thought to involve hepatocyte receptor and co-receptor interactions and possible involvement of liver-specific pathways such as lipoprotein trafficking and synthesis.

Hepatitis A (HAV) is an RNA virus of the *Hepatovirus* genus belonging to *Picornaviridae* family (Flehmig, 1990; Lee, 2003; Martin and Lemon, 2006). HAV is a positive strand RNA virus that has a 7.5 kb genome that is translated into a 2225 to 2227 polyprotein that gives rise to a number of structural and non-structural proteins. The viral particles are 27–32 nm in diameter and there are distinct genotypes and sub-genotypes of HAV. In contrast to another hepatotrophic RNA virus, HCV, HAV has a high degree of genomic and resultant antigenic conservation. The spontaneous mutation rate of HAV is low and antibody-mediated immunity from previous exposure or vaccination is effective in preventing HAV infection. HAV is characterized by slow replication, and it is rarely cytopathic and is stable in the environment for at least a month.

(a)

Virus	Family	Length	RNA/DNA	Transmission	Chronic	Comments
HAV	*Hepatovirus*	2.2 kb	RNA+	Faeco-oral	No	Can cause fulminant liver failure
HBV	*Hepadnaviruses*	3.2 kb	DNA+	Blood borne Sexual Vertical	Yes	Can cause fulminant liver failure
HCV	*Flaviviridae*	3.0 kb	RNA+	Blood borne Vertical	Yes	Fulminant liver failure is rare
HDV	Deltavirus	1.6 kb	RNA−	Blood borne Sexual	Yes	Requires HBV surface antigen Can cause fulminant liver failure
HEV	HEV-like viruses	7.5 kb	RNA+	Faeco-oral	No	Can cause fulminant liver failure

Figure 60.1 Hepatitis virus virology. (a) The virology of viral hepatitis (HAV to HEV) is summarized. (b) The HBV circular DNA and the multiple overlapping reading frames. (c) In contrast to HBV the HCV has a linear RNA genome encoding viral proteins. The HCV 5′ and 3′ internal ribosome re-entry site (IRES) are important viral regulatory elements.

HBV is a circular DNA virus that belongs to the *hepadnaviruses* that include woodchuck hepatitis virus and ground squirrel hepatitis virus (Chisari, 1992; Lee, 1997; Lok, 2000). The partially double stranded HBV genome is 3.2 kb in length and is organized with multiple overlapping open reading frames (ORF) (Chisari, 1992; Lee, 1997; Lok, 2000) (Figure 60.1). Greater than half of the genome is translated in more than one ORF and this limits the viral mutations that will be tolerated. HBV DNA incorporates into the host genome (Lau and Wright, 1993; Moyer and Mast, 1994). The viral proteins include the surface (envelope) protein, core, polymerase and X-proteins. Variations of the nucleotide sequence and corresponding amino acids that constitute the HBV surface protein give rise to 8 common HBV genotypes (A–H).

HCV is a positive strand RNA virus, a member of the *Flaviviridae* family that includes flaviviruses and pestiviruses (Shimotohno, 2000). There is considerable diversity in the HCV genome with at least 6 distinct genotypes, more than 50 subtypes and a propensity of the virus to mutate giving rise to "*quasi species*" (Forns and Bukh, 1999; Forns et al., 1999). The virus genome is 9.5 kb that encodes a large single polyprotein of 3010 to 3033 amino acids (Forns and Bukh, 1999) (Figure 60.1). The 5′ and 3′

untranslated regions are important for the replication of the virus and translation of the polyprotein. The HCV proteins comprise the structural proteins; core protein and the envelope glycoproteins E1, E2 and p7 followed by the non-structural proteins; proteases, helicase (NS2 and NS3), protease cofactor (NS4A), NS4B, replication associated phosphoprotein (NS5A) and the RNA-dependent polymerase (NS5B) (Shimotohno, 2000; Simmonds, 1996). Possible receptors for HCV have been identified and these include CD-81, SRB-1 and Claudin-1.

Hepatitis D (HDV also known as delta hepatitis) is unlike any other transmissible agent in animals (Taylor, 2006a, b). This minus strand circular RNA virus requires the hepatitis B surface antigen (HBsAg) for encapsulation and entry into hepatocytes. HDV only co-infects up to 5% individuals with HBV infection. Importantly, the prognosis of HDV co-infection is worse than with HBV alone.

Hepatitis E (HEV) is related to *Calciviradie* but now has been classified into a separate genus of *hepatitis E-like viruses* (Krawczynski et al. 2000; Worm et al., 2002). The HEV genome consists of a single positive RNA strand of 7.5 kb that is translated into three polyproteins as there are three overlapping ORF. Consequently HEV has stable genome sequence and exists as a single serotype and at least four unique genotypes. HEV is stable in the environment and is common waterborne pathogen especially in developing countries.

ACQUISITION AND PREDISPOSITION TO VIRAL HEPATITIS

HAV is characterized by an enteric route of infection and classically is transmitted via personal contact, illicit drug use or ingestion of contaminated food or water (Martin and Lemon, 2006). The incubation period following exposure can be up to 90 days. HAV infection typically occurs in sporadic outbreaks as well as isolated cases and can be endemic in poorly developed countries with poor sanitation. Although molecular phenotyping of the virus helps trace outbreaks, there is very little known about individual genetic factors that may predispose to HAV infection. Host genetic factors may not be that important as indicated by the epidemiologic studies showing that HAV infection is often transmitted to persons with similar risk factors. HEV is similarly transmitted to HAV and is characterized by a great propensity for waterborne transmission. Like HAV, HEV is endemic in many poorly developed countries. HEV has the propensity to be associated with miscarriage and an increased mortality in pregnant women especially during the third trimester. The basis for this is unclear, but a number of host factors are clearly important in determining susceptibility to infection.

HBV or HCV enter the host through blood contact by direct inoculation (i.e., needle or transfusion) or via a disrupted percutaneous barrier (i.e., sexual or perinatal transmission) (Shimotohno, 2000; Simmonds, 1996). Entry of HBV or HCV into liver hepatocytes is not understood, and there are extra-hepatic reservoirs of infection in peripheral blood leukocytes (Cabrerizo et al., 2000; Yoffe et al., 1990). Receptor-based cell entry has been implicated in the both HBV and HCV pathogenesis (Cocquerel et al., 2006; Pileri et al., 1998; Yerly et al., 2006). The immunopathogenesis of both HBV and HCV infection is characterized by both an innate and adaptive immune response to the virus resulting in predominantly non-specific inflammation. Typically, neither HBV nor HCV are directly cytopathic as viral load does not correlate with organ damage and the level of antigen expression in hepatocytes does not correlate with hepatocyte injury (Chisari and Ferrari, 1995). Importantly, both HBV and HCV *in vivo* infectivity is limited to higher primates (chimpanzees and humans).

Predisposing factors to viral hepatitis include a number of non-genetic and genetic factors (Thomas, 2000; Wasley and Alter, 2000; Yee, 2004) (see Table 60.1). HBV and HCV are more prevalent in communities with increased rates of intravenous drug use, unsafe therapeutic injections and with the use of unscreened blood products (Maddrey, 2000; Merican et al., 2000; Wasley and Alter, 2000). Fortunately, the recognition of routes of transmission, the use of safe injecting practices and the adoption of volunteer donor blood transfusion services are widely instigated global public health measures used to control the spread of viral hepatitis. Vertical transmission of HBV is dependent on the stage of maternal HBV infection and the viral antigen expression. Approximately, 10–20% of surface antigen positive mothers transmit the virus to their offspring. However, both surface and HBeAg expression is associated with a 90% rate of transmission. Maternal acute HBV infection results in a 10% neonatal rate of infection in the first trimester, which increases to 80–90% if acute infection occurs in the third trimester. HCV infection is characterized by lower rates of vertical transmission with only 2.7–8.4% of offspring being infected. The presence of HIV co-infection increases the rate of vertical transmission of both HBV and HCV. Transmission via sexual activity with mucosal disruption is more prevalent in HBV than HCV infection.

Genetic factors predispose to persistence of HBV infection given the rate of concordance for surface antigen expression is greater in monozygotic compared to dizygotic twins (Table 60.1). The twin concordance data in HCV infection are not as convincing. There are a number of HLA alleles which are associated with both the persistence and the clearance of both HBV and HCV (Wang, 2003; Yee, 2004). Interestingly, in contrast to HIV progression homozygosity for HLA class II locus increases the risk of HBV persistence. The HLA class II locus DRB1*1302 is associated with HBV clearance and the DQB1*0301 locus is associated with a self-limiting course of HCV infection. Non-HLA immunogenic is also implicated in viral hepatitis with TNF promoter polymorphisms resulting in higher TNF secretion being associated with HBV clearance. The killer cell immunoglobulin-like receptors (KIR) genes interact with HLA class I molecules and specific KIR heliotypes are associated with HCV clearance (Martin and Carrington, 2005; Williams et al., 2005). Importantly, the majority of genetic predispositions identified in viral hepatitis is linked to viral persistence or clearance and can be directly implicated in the adaptive immune response. The current

TABLE 60.1 Viral hepatitis genetic susceptibility associations

Allele/Polymorphism	Hepatitis C	Hepatitis B	Comment
HLA-DRB1*1302 and HLA-DRB1*0301		Spontaneous elimination of infection	
HLA-DQA1*0501, DQB1*301, HLA-DRB1*1102 and HLA-DRB1*0301		Persistence of infection	
HLA-DRB1*0101, HLA-DRB1*0401, HLA-DRB1*15, HLA-DRB1*1101, HLA-DRB1*0301, HLA-A*2301, HLA-A*1101, HLA-A*03, HLA-B*57 and HLA-Cw*0102	Spontaneous elimination of infection		
HLA-DRB1*0701, HLA-A*01-B*08-Cw*07-DRB1*0301-DBQ1*0201, HLA-Cw*04, HLA-Cw*04-B*53	Persistence of infection		
TNF promoter	Viral replication and clearance	Viral replication and clearance	Polymorphisms at -308 and -238 best characterized
Interleukin-10		Spontaneous elimination of infection	
Vitamin D receptor		Control of viral replication	Expressed on monocytes and lymphocytes
GDNF family receptor alpha 1	At risk of HCC in HCV		
Chemokine (C-X-C motif) ligand 14	At risk of HCC in HCV		Previously known as SCYB14

HCC: Hepatocellular carcinoma.

documented genetic disease associations with viral hepatitis are of limited use in clinical practice. Presently genome-wide association studies are being undertaken to comprehensively characterized hepatitis genetic susceptibility. Therefore, future clinical practice is likely to see panels of genetic susceptibility markers being screened to determine prognosis and the likelihood of a treatment response.

SCREENING AND DIAGNOSIS OF VIRAL HEPATITIS

HAV and HEV are characterized by jaundice, fever and a diarrhea illness. Given the propensity for epidemic outbreaks and known endemic regions of the globe (mainly developing countries) establishing the diagnosis is not difficult. HAV and HEV are readily diagnosed using serology with acute infection distinguished by the presence of antiviral IgM (Acharya and Panda, 2006; Panda et al., 2006). The diagnosis of HDV is also made on serology and anti-HDV IgM is detectable by 30 days following infection (Fiedler and Roggendorf, 2006; Weston and Martin, 2001).

HBV and HCV infections results in a comparatively non-specific cluster of symptoms ranging from asymptomatic viral infection (most common in HCV), jaundice and fever (30–50% of HBV infections) to fulminant hepatic failure and death (<1% of HBV and exceedingly rare in HCV). Importantly, both HBV and HCV viral replication can be associated with a normal liver panel. Although routine liver tests such as transaminases are used to monitor disease effects on the liver, they do not provide prognostic information and cannot be used for the diagnosis of viral hepatitis. The cornerstone of screening and diagnosis is serology for viral-specific antibodies and antigens. The commonly available serology of HBV is complex with the pattern of antibody and antigen expression determining the nature and timing of infection (Table 60.2).

HCV antibody production is a simpler test of exposure which becomes positive within 4 weeks of exposure (Bhandari and Wright, 1995). The commonly used HCV antibody screening is performed with using an enzyme immunoassay (EIA) and is prone to false positive readings. Specificity of the EIA has improved with successive generations of test but confirmation of a positive result with supplemental methodology is considered mandatory. A positive HCV EIA is routinely confirmed using a

TABLE 60.2 Hepatitis B virus serology and DNA quantitation

Serologic markers	Definition/clinical use
HBsAg – Hepatitis B surface antigen	• General marker of infection • First serologic marker to appear after infection • Persistence for >6 months = chronic infection
HBeAg – Hepatitis B e antigen	• Indicates active replication of virus
Anti-HBs – Antibody to hepatitis B s antigen	• Documents recovery and/or immunity to HBV • Detectable after immunity conferred by HBV vaccination
Anti-HBe – Antibody to hepatitis B e antigen	• Marker of reduced level of replication
Anti-HBc (IgM) – Antibody to hepatitis B core antigen	• Marker of acute HBV
Anti-HBc (IgG) – Antibody to hepatitis B core antigen	• Marker of current or past infection
HBV DNA – Hepatitis B virus genomic DNA	• Marker of HBV replication • Used for monitoring response to therapy

recombinant immunoblot assay in which serum reactivity to a number of HCV recombinant viral proteins is assessed.

Detection of HBV DNA and HCV RNA is not recommended routinely to establish the diagnosis (Acharya and Panda, 2006; Mondelli et al., 2005; Patel et al., 2006; Servoss and Friedman, 2004). However, as viral replication can occur with normal biochemistry and antibody titers do not demonstrate viral replication quantitative assessment of viral nucleotide presence is used in many centers as the final confirmatory diagnostic test for active HBV or HCV infection. Quantitation of HBV DNA or HCV RNA is used in planning and following treatment of the infection. HBV DNA can be quantitated using an approach of capturing HBV DNA on a full length HBV RNA transcript and using antibodies to detect the RNA:DNA hybrid (known as capture assays or "Digene"™). An alternative approach uses quantitative PCR methodologies to amplify the HBV DNA (COBAS Amplior™) or a variation of the capture approach using branched DNA ("Versant"™).

HBV and HCV viral levels are typically determined once the infection has been confirmed as they carry prognostic significance as well as being used to monitor treatment responses. HBV genotyping is not routinely performed in the clinical setting unless the patient is being considered for interferon-alpha therapy.

An important aspect of screening and diagnosis of viral hepatitis involves an assessment of the extent of liver injury attributable to the virus. In particular the extent of hepatic inflammation and fibrosis has implications for the progression and the likely response to treatment. Routine biochemistry gives only limited information about the extent of inflammation or fibrosis, and most centers will use imaging of the liver with ultrasound or other modalities combined with a liver biopsy in assessing virus induced liver injury. However, biopsy is an invasive procedure prone to significant sampling and observer error (Siegel et al., 2005). This has led to the development of a number of new non-invasive screening modalities. The most promising approaches use multiple variables to assess for liver injury, and these methods are likely to become commonplace in the next decade.

PATHOGENESIS OF VIRAL HEPATITIS

It is clear from the natural history and prognosis that the aim of chronic HBV and/or HCV treatment is to stop the development of cirrhosis and the sequelae of hepatic decompensation and HCC. Genomic medicine is likely to have a significant impact in the future determination of viral hepatitis outcomes and identification of at risk individuals for development of cirrhosis and sequelae such as HCC. Genomic studies have made significant contributions to our understanding of HBV and HCV pathogenesis and treatment responses (see Table 60.3). The pathogenesis of viral hepatitis is unique for HBV and HCV (Chisari and Ferrari, 1995; Lee and Locarnini, 2004; Tanikawa, 2004). However, there are similarities in the mechanisms of HBV and HCV clearance and persistence. The initial innate immune response characterized by interferon (IFN) and IFN stimulated gene (ISG) expression. Chronic infection with either virus is characterized by both antigen-specific and non-specific CD4+ and CD8+ T-cell responses that are pivotal in virus clearance or in chronic infection responsible for ongoing inflammation resulting in liver injury. Further, both HBV and HCV employ the strategy of mutational escape to evade the adaptive immune response. The mode of entry of HBV or HCV into the hepatocytes is unknown. Receptor-mediated viral entry is thought likely, given the restricted cell population infected (Cocquerel et al., 2006; Pileri et al., 1998; Yerly et al., 2006). In HBV carboxypeptidase D (gp180) has been shown to interact with the preS portion of the large viral surface protein (Yerly et al., 2006). In HCV CD-81, scavenger receptor class B type 1 and claudin-1 have all been implicated in viral entry (Cocquerel et al., 2006; Pileri et al., 1998). Currently, no conclusive evidence of a

Table 60.3 Key findings arising from genomic studies of viral hepatitis

	Hepatitis C	Hepatitis B	Comments
Acute infection	Interferon stimulated gene expression (Mx1, ISG15) correlated with viral clearance	"Stealth virus" Innate immune response is abrogated Immune evasion	Acute HBV or HCV infection is poorly characterized by genomic studies
Chronic infection	Th1 immuno-phenotype perpetuating chronic injury	T-cell effector function activated and latter B-cell related gene expression observed	
Treatment responses	Interferon stimulated gene induction correlate with treatment responses		HBV treatment response have been poorly characterized by genomic studies
Hepatocellular carcinoma	HCV core protein oncogenic	HBV x (HBx) protein oncogenic	
Bio-markers	A number of non-specific inflammatory markers identified Potential tumor markers identified	A number of non-specific inflammatory markers identified	
Future studies	Predicting HCV IFN treatment responses	Predicting HBV IFN and nucleotide/nucleoside treatment responses	Determining the pathogenesis of and predicting chronicity, disease progression and development of sequelae such as HCC

single receptor or the presence of a receptor complex has been demonstrated for either HBV or HCV (Cocquerel et al., 2006; Yerly et al., 2006).

There are marked differences in the pathogenesis of both HBV and HCV. Innate immune responses are blunted and do not appear to play an important role in HBV clearance. In contrast a strong innate immune response is thought to be important in HCV clearance. Finally, antibody-derived immunity is present in HBV infection whilst it appears to be of no importance in HCV infection.

HBV Pathogenesis

HBV infection results in the formation of a double-stranded HBV genome in the nucleus that is converted into a covalently closed circular double-stranded DNA (cccDNA). Further, HBV DNA integrates into the host genome and this has significant implications in the long-term management of HBV, as the complete elimination of the virus is not possible and viral reactivation characterized by active replication is possible in the future. The cccDNA acts as a template for the formation of an RNA replicative intermediate, which is prone to a high rate of mutation of 1 in 10^5 bases. However, HBV replication after infection is characterized by low level replication reaching levels of 10^2–10^4 genome equivalents per ml for up to 6 weeks after infection. Once established HBV is associated with extremely high viral titers of 10^8–10^{13} genome equivalents per ml. This has led to the assertion that HBV initially evades the immune response before becoming established. Importantly, once established, active HBV replication can result in infection of 100% of the intrahepatic hepatocytes.

The innate immune activation in HBV infection is abrogated. However, HBV clearance can occur prior to the induction of an adaptive immune response. This is thought to be mediated by IFN-α and -β (type I IFN) in a non-classical manner that is proteosome dependent. Further antigen independent natural killer (NK) cell activation is thought to be responsible for IFN-γ induction and induction of an adaptive immune response.

Adaptive immunity in HBV is characterized by CD8+ T-cell response to surface antigen epitopes with secretion of IFN-γ and TNF which have direct antiviral effects principally by controlling HBV replication at the stage of formation of the RNA replicative intermediate. In contrast to HCV, HBV antibody-mediated humoral immunity effectively neutralizes the virus. However, antibody production is often absent in chronic HBV infection by mechanisms that are poorly understood. Viral protein such as the X-protein inhibit proteosome dependent control of virus replication also both surface antigen and precore protein act as tolerogens abrogating the T-cell response to the virus.

HCV Pathogenesis

HCV replication involves formation of a negative sense replicative RNA strand and the subsequent formation of dsRNA. This has several important implications for HCV pathogenesis. First, the formation of RNA intermediates means that there is no stable genomic replicative form of the virus and as a result HCV must produce new viral RNA and proteins to maintain persistence.

Secondly, the formation of dsRNA associated with HCV replication is a target for endogenous RNA interference and elicits the endogenous IFN response (Yu et al., 2000). Further, the NS5B RNA polymerase of HCV lacks proof reading activity and as a result virus replication is highly error prone (1 in 10^3 bases) resulting in remarkable genetic diversity. HCV is currently divided into six major genotypes with many subtypes that differ by up to 35% in their nucleotide sequence. HCV infection is characterized by a rapid increase in circulating levels to 10^5–10^7 equivalents per ml. The rapid induction of an immune response means that not all hepatocytes are infected although the true proportion of hepatocytes infected is unknown.

The innate immune response is characterized by induction of type I IFN, interferon-stimulted genes (ISGs) and a NK response. The IFN gene expression is induced by the induction of endogenous RNA interference pathways, the formation of dsRNA that binds to the RNA helicases RIG-1 and MDA5 and binding of the phagocytosed infected cell fragments to toll-like receptor (TLR)-3 (Honda et al., 2006; Kato et al., 2006; Yoneyama et al., 2005). These upstream events then signal through IRF-3 phosphorylation resulting in IFN gene transcription. The IFN gene expression then signals via cognate receptors and activates the JAK/stat pathway resulting in the induction of ISGs including protein kinase R, RNA–specific adenosine deamsinase-1 (ADAR-1), P56 and 2′-5′ oligoadenylate synthetase. Most of these ISGs act on the formation of the negative replicative strand of HCV. The cellular innate immune response is characterized by induction of an NK cell response. NK cells destroy infected cells in an antigen independent manner via cytotoxic cell lysis. These activated NK cells secrete large amounts of IFN-γ, which activates and maintains a cellular adaptive immune response.

Adaptive immune responses in HCV infection is characterized by the virus-specific CD4+ and CD8+ T-cell response to multiple HCV epitopes, including many highly promiscuous epitopes formed due to the high spontaneous rate nucleotide mutation rate associated with HCV replication (Bowen and Walker, 2005a, b). This T-cell response is accompanied and maintained by induction of IFN-γ and TNF, both of which can directly inhibit viral replication without killing an infected cell. Although HCV antibody production is universal in immunocompetent individuals, it does not prevent infection or correlate with outcome. Further the virus-specific T-cell response is maintained for decades after HCV clearance in contrast to the antibody responses which can become undetectable.

Genomic Analyses of HCV Infection

Gene array analysis of HCV recurrence in liver transplant allografts has provided novel insights into the molecular mechanisms of viral recurrence (Mansfield and Sarwal, 2004; McCaughan and Zekry, 2004). HCV recurrence in the liver graft is associated with expression of IFN-γ associated genes such as CXCL10 (IP-10), CXCL9 (HuMIG) and RANTES (McCaughan and Zekry, 2004). Further, antiviral IFN-α associated gene expression is seen in chronic HCV recurrence and during acute rejection associated with HCV recurrence (McCaughan and Zekry, 2004). Additionally, upregulation of NF-kappa β pathway during acute rejection in association with HCV recurrence appears to alter cellular apoptosis via changes in the expression of TRIAL-associated genes (McCaughan and Zekry, 2004). Importantly chronic HCV recurrence in grafts is associated with Th1 associated gene expression similar to that seen in chronically HCV infected individuals that have not been transplanted (McCaughan and Zekry, 2004). In contrast cholestatic HCV recurrence, which follows an aggressive course, is associated with a Th2 cytokine profile (McCaughan and Zekry, 2004). This suggests that the Th1 immune response suppresses viral replication whilst being profibrogenic (McCaughan and Zekry, 2000, 2004; Shackel et al., 2002). In cholestatic HCV recurrence, the unchecked viral replication is directly fibrogenic (McCaughan and Zekry, 2004; McCaughan and Zekry, 2000).

A particular challenge in the study of the effect of viruses on liver cells is the difficulty in infecting liver cells with virus. The studies described below have involved models in which cultured cells are infected with viral proteins or viral genome. Progress in this field has been rapid and most recently, a cellular model of HCV infection has been reported that is likely to stimulate further study (Heller et al., 2005; Lindenbach et al., 2005).

Proteomic methodologies have been applied to a number of aspects of HCV-related liver injury. However, to date most proteomic studies have focused on the identification of a number of biomarkers of disease rather than trying to unravel aspects of HCV pathobiology. Proteomic studies have defined potential protein therapeutic targets that interact with HCV in detail. Large-scale proteome analysis of a full-length HCV replicon revealed prominent expression of proteins involved in lipid metabolism (Jacobs et al., 2005). Several *in vitro* proteomic studies have identified proteins that interact with specific HCV proteins. Heat shock protein 27 (Hsp27) was shown to specifically interact with NS5A via the N-terminal regions (Choi et al., 2004). Fourteen cellular proteins binding to the core protein were identified by proteomics (Kang et al., 2005). These proteins include DEAD-box polypeptide 5 (DDX5) and intermediate microfilament proteins, including cytokeratins (cytokeratin 8, cytokeratin 19 and cytokeratin 18) and vimentin. Interestingly, DDX5 gene polymorphisms are associated with accelerated fibrosis development in HCV infected individuals (see Chapter 50) (Huang et al., 2006).

The development of HCC and IFN treatment response are two further aspects of HCV infection studied using proteomics. In the study of HCV-related HCC development, over-expression of alpha enolase was identified and correlated with poorly differentiated HCC (Kuramitsu and Nakamura, 2005; Takashima et al., 2005). The response of hepatocyte cell lines to IFN-γ treatment has uncovered over 54 IFN response genes, including many novel targets an approach that may pave the way for novel therapies. Examination of protein extracts that bind to the HCV IRES

has identified a number of novel protein targets such as Ewing Sarcoma breakpoint 1 region protein EWS and TRAF-3. The final aspect of HCV liver injury receiving attention is the study of potential biomarkers such as heat shock protein 70 Hsp-70 associated with HCV infection progression to HCC (Takashima et al., 2003).

THERAPEUTICS AND PHARMACOGENOMICS

The principal treatment goal in viral hepatitis is clearance of the virus with a secondary goal of averting or delaying the onset of cirrhosis, hepatic decomposition and HCC. Immune modulators in the form of IFN treatment have been the mainstay of treatment for years (see Table 60.4). Antiviral therapy has now become an effective treatment option in HBV, but in HCV is useful only when combined with IFN treatment. Finally, HAV and HBV infection are reliably protected against by immunization. There is no prospect in the foreseeable future of a vaccine for HCV. The treatment options for viral hepatitis are summarized in Table 60.4. Predicting individual's treatment responses based on gene expression is likely to be an area in which genomic medicine will enable highly directed individual therapy in treatment of viral hepatitis.

Treatment of HBV Infection

IFN is the only treatment shown to clear HBV infection in chronically infected individuals without the development of drug resistance. In both HBeAG positive and negative individuals with chronic HBV infection, IFN treatment for 4–6 months has been shown to normalize liver function abnormalities, result in clearance of HBsAg and HBeAg and result in a sustained loss of HBV DNA. In a meta-analysis of 15 studies, suppression of HBV DNA was seen in 37% of patient's loss of HBeAg was seen in 33% of subjects and HBeAg seroconversion was seen in 18% of patients. Subjects responded to treatment if they had lower pretreatment HBV DNA levels and higher pretreatment liver transaminase levels. The advent of long-lasting IFN preparations using pegylated IFN has been shown to have an additional benefit over conventional IFN in treating HBV infection resulting in improved HBsAg and HBeAg seroconversion. However, the current meta-analysis of the treatment outcomes with IFN in HBV does not support its use in preventing HCC. Compared to nucleoside analogs, discussed below, one principle advantage of IFN therapy for HBV is the durability of the treatment response with $<10\%$ of individuals having a relapse in HBeAg expression up to 8 years latter.

Nucleoside analogs are now being increasingly used to treat HBV infection and these agents target the HBV DNA polymerase. Lamivudine is the most widely used nucleoside analog and effectively suppresses HBV replication as evident by a greater than two log decline in HBV viral DNA titers. Lamivudine results in 16–18% HBeAg seroconversion in 1 year and 50% after 5 years. The durability of the response is 77% at 3 years. However, the sustained virological response in other studies has been reported as 39% at 4 years, and sustained response to lamivudine following cessation of therapy is significantly less than IFN. Continued treatment with lamivudine results in sustained suppression of HBV viral replication but is limited by the appearance of mutant forms of the HBV polymerase typically in a conserved YMDD motif at methoine 204 of the enzyme. After 1 year resistance develops in 14–32% of cases and this increase to 50% at 2 years and 74% at 5 years.

Other approved nucleoside analogs include adefovir, tenofovir, telbirudine and entecavir. All have significant activity against HBV replication although both tenofovir and entecavir would appear to have greater activity against HBV. Importantly resistance with all of these newer agents is uncommon, with entecavir resistance being less than 5% at 2 years. Unfortunately resistance to these newer agents appears inevitable. In a situation analogous to HAART treatment of HIV-1 infection, combination therapy is now being studied in HBV infection. The conclusive outcome of these studies is not yet available but the initial results are promising especially in cases of lamivudine resistance.

TABLE 60.4 Treatment of viral hepatitis

Virus	Chronicity	Treatment	Vaccine	Comments
HAV	No	Immune globulin	Yes	
HBV	Yes	Immune globulin Nucleoside Analogues (target DNA polymerase) Immune mediators (i.e., IFN-α)	Yes	Viral resistance to nucleoside analogues common
HCV	Yes	Immune mediators (i.e., IFN-α and Ribavirin)	No	Small molecular inhibitors in clinical trials
HDV	Yes	Treatment of HBV	No	
HEV	No	None	No	No specific treatment Avoidance

Treatment of HCV Infection

IFN treatment is the only effective antiviral therapy available for the treatment of HCV. The current recommendations are for a 24–48 week course of treatment using pegylated IFN combined with the antiviral ribavirin. Ribavirin is a guanasine analog able to inhibit the replication of viruses but in the absence of IFN has no significant effect on HCV RNA levels. The overall chance of a sustained virological response (SVR) varies according to HCV genotype. In genotype 1 infection, SVR can be achieved in 42–46% of patients, with better response rates of 76–88% for those with genotype 2 or 3 infection. Virologic response to treatment can be predicted from the decline in HCV RNA at 12 weeks; The absence of a 2 log drop or undetectable HCV RNA at week 12 has a high negative predictive value for the absence of SVR in genotype 1 patients with continued therapy. In genotype 2 and 3 the decline in viral load at 4 weeks may be predictive of achieving SVR with only 12–16 weeks of therapy. The treatment of patients with cirrhosis is controversial but there appears to be a benefit in avoiding progression of disease, decompensation, and the development of HCC. However, in the presence of hepatic decompensation, IFN-based treatment is contraindicated and patients should be referred for transplant evaluation.

Genomic Studies Related to the Treatment of Viral Hepatitis

IFN-α is currently part of the standard of care treatment for HCV infection. Several studies have used microarray analysis to identify the mechanisms by which IFN-α acts on hepatocytes and the HCV. IFN-α activated the multiple signal transducer and activator of transcription factors (STAT) 1, 2, 3, 5 in cultured hepatocytes (Radaeva et al., 2002). Other upregulated genes include a variety of antiviral and tumor suppressors/pro-apoptotic genes. Downregulated genes include c-myc and c-Met and the hepatocyte growth factor (HGF) receptor (Radaeva et al., 2002). In a second and comparable study, IFN-α antiviral efficacy was associated with 6–16 (G1P3) expression. Involvement of STAT3 in IFN-α signaling was confirmed (Zhu et al., 2003). Resistance to IFN-α antiviral activity may be mediated the HCV viral protein, NS5A. To identify the mechanisms through which NS5A blocks IFN activity, gene expression profile was studied in IFN-treated Huh7 cells expressing NS5A. The strongest effect of NS5A on IFN response was observed for the OAS-p69 gene (Girard et al., 2002). Another key response of hepatocytes to the HCV virus is cellular proliferation. Gene array studies identified upregulation of growth-related genes, in particular wnt-1 and its downstream target gene WISP (Fukutomi et al., 2005). In another study, CDK activity, hyperphosphorylation of Rb, and E2F activation was shown to be associated with hepatocyte proliferation induced by a full-length HCV clone (Tsukiyama-Kohara et al., 2004).

Global quantitative proteomic analysis in a human hepatoma cell line (Huh7) in the presence and absence of IFN was performed to examine liver-specific responses to IFN and the mechanisms of IFN inhibition of virus replication (Yan et al., 2004). Fifty-four proteins were induced by IFN and 24 were repressed, representing several novel and liver-specific key regulatory components of the IFN response.

Molecular markers used on an individual patient basis might improve prediction of treatment responses prior to commencement of therapy. Previously Chen and colleagues examined liver biopsies prior to IFN-α and ribavirin therapy from 16 responders, 15 non-responders and 20 normal individuals by gene array analysis and determined that 18 genes were predictive of an SVR (Chen et al., 2005). These investigators identified a gene expression signature of 8 genes that could predict the likelihood to achieve an SVR in 30 of 31 individuals (GIP2/IFI15/ISG15, ATF5, IFIT1, MX1, USP18/UBP43, DUSP1, CEB1, and RPS28) (Chen et al., 2005). The striking outcome from this study was that these genes, known to be involved in IFN responsiveness, were overexpressed in non-responders and formed part of the predictive gene signature profile. Additionally, two genes (ISG15/IFI15 and USP18/UBP43) were identified as part of a previously unrecognized novel IFN regulatory pathway (Chen et al., 2005; Randall et al., 2006). In a further study of peripheral blood mononuclear cells (PBMC), a relative lack of ISG expression was associated with a poor response to antiviral therapy with pegylated IFN (Taylor et al., 2007) and Feld and colleagues present work demonstrating unique patterns of liver gene expression that correlate with IFN and ribavirin treatment responses in HCV genotype 1 infection (Feld et al., 2007).

Pharmacogenomics of Viral Hepatitis

Pharmacogenomic studies of viral hepatitis are currently evolving as the treatment options become better and the understanding of the disease pathobiology improves. In HBV infection a group of 82 chronic active carriers received standard IFN-α treatment for 6 months (King et al., 2002; Randall et al., 2006). These patients were concurrently studied for single nucleotide polymorphisms (SNPs) in genes involved in the JAK/stat signaling of IFN and in genes leading to the expression of ISGs (King et al., 2002; Randall et al., 2006). Two SNPs were identified that appeared to predict response; one in the promoter region of the ISG MxA and the other in the IFN regulated eIF-2α gene. This study is significant in demonstrating that host polymorphisms may correlate with treatment response in HBV infection (King et al., 2002; Randall et al., 2006). In HCV infection the non-structural protein NS5a is known to bind viral RNA and alter HCV replication (Feld et al., 2007; Goyal et al., 2006; Kohashi et al., 2006; Taylor et al., 2007). Amino acid substitutions within the interferon sensitivity-determining region (ISDR) of NS5A correlates with IFN-α treatment responses (Feld et al., 2007; Goyal et al., 2006; King et al., 2002; Kohashi et al., 2006; Taylor et al., 2007; Watanabe et al., 2005). A meta-analysis of ISDR NS5a mutations demonstrates a relative risk of 4.66 to 5.73 of IFN-α treatment response compared to non-mutant ISDR

HCV (Goyal et al., 2006; Schinkel et al., 2004). However, this effect is more pronounced in Japanese compared to European patients (Goyal et al., 2006; Kohashi et al., 2006; Pascu et al., 2004; Schinkel et al., 2004). These studies highlight the gaps in our knowledge of disease pathogenesis and host genomics that influence disease and the lack of high-specific treatment options means that pharamacogenomic measures are still in their infancy.

2009 UPDATE

There has been renewed interest in adopting emerging high-throughput technologies for large-scale gene expression profiling to predict antiviral treatment response in chronic hepatitis C (CHC) patients. A hepatic gene expression study in biopsies from 69 CHC patients identified a two-gene signature (*IFI27* and *CXCL9*) that could predict treatment response in 79% of patients (Asselah et al., 2008). This confirms prior observations in studies using both PBMC and liver tissues (ISG) appear to be upregulated in pre-treatment liver tissues from patients that do not respond to current standard-of-care antiviral therapy with pegylated IFN-alpha and ribavirin. A defective hepatic response to IFN may be mediated through activation of suppressor of cytokine signaling 3 (*SOCS3*) (Huang et al., 2007). An association study that evaluated three SNPs of *SOCS3* in 162 CHC genotype-1 nonresponder and 184 CHC sustained responder patients noted that *SOCS3*-4874 AA genotype was strongly associated with nonresponse to IFN-based therapy, and these patients had significantly higher *SOCS3* mRNA and protein levels (Persico et al., 2008). The IFN-gamma promoter SNP -764G/C also appears functionally important in determining viral clearance and treatment response in HCV infection (Huang et al., 2007).

Emerging specific targeted antiviral therapies for HCV will continue to be combined with IFN and there is likely to be continued interest in determining mechanisms of IFN resistance and predictors of virologic response to therapy through SNP associations of cytokine and other host signaling pathways (Selzner et al., 2008). Plasma proteome profiling studies incorporating emerging quantitative and identification bioinformatics tools to assess CHC virologic responses to IFN-based therapy are ongoing. In contrast, the availability of several oral nucleoside and nucleotide analogs that are effective against HBV may explain the absence of functional genomic or plasma protein profiling studies to assess therapeutic responses in chronic hepatitis B infection.
