Table of Contents

Preface ix

Abbreviations xi

Contributors xix

1 The Foundations of Genomic and Personalized Medicine 1
Geoffrey S. Ginsburg and Huntington F. Willard

SECTION 1 BASICS

2 Organization, Variation and Expression of the Human Genome 13
Huntington F. Willard

3 DNA Sequencing for the Detection of Human Genome Variation 27
Samuel Levy and Yu-Hui Rogers

4 Genome-Wide Association Studies and Genotyping Technologies 38
Kevin V. Shianna

5 Copy Number Variation and Human Health 46
Charles Lee, Courtney Hyland, Arthur S. Lee, Shona Hislop and Chunhwa Ihm

6 DNA Methylation Analysis: Providing New Insight into Human Disease 60
Susan Cottrell, Theo de Vos, Juergen Distler, Carolina Haefliger, Ralf Lesche, Achim Plum and Matthias Schuster

7 DNA Microarrays in Biological Discovery and Patient Care 73
Andrew J. Yee and Sridhar Ramaswamy

8 Proteomics: The Deciphering of the Functional Genome 89
Li-Rong Yu, Nicolas A. Stewart and Timothy D. Veenstra

9 Comprehensive Metabolic Analysis for Understanding of Disease 97
Christopher B. Newgard, Robert D. Stevens, Brett R. Wenner, Shawn C. Burgess, Olga Ilkayeva, Michael J. Muehlbauer, A. Dean Sherry and James R. Bain

SECTION 2 INFORMATICS

10 Bioinformatic and Computational Analysis for Genomic Medicine 111
Atul J. Butte

11 Systems Biology and Systems Medicine 131
Nathan D. Price, Lucas B. Edelman, Inyoul Lee, Hyuntae Yoo, Daehee Hwang, George Carlson, David J. Galas, James R. Heath and Leroy Hood

12 Electronic Medical Records in Genomic Medicine Practice and Research 142
Glenn S. Gerhard, Robert D. Langer, David J. Carey and Walter F. Stewart

13 Online Health Information Retrieval by Consumers 151
Mark S. Boguski

SECTION 3 TRANSLATIONAL

14 Translational Genomics: From Discovery to Clinical Practice 163
Geoffrey S. Ginsburg

15 Pharmacogenetics and Pharmacogenomics 175
Iris Grossman and David B. Goldstein

16 Clinical Implementation of Translational Genomics 191
Wendy K. Chung

17 The Role of Genomics in Enabling Prospective Health Care 201
Ralph Snyderman

18 Genome Policy Considerations for Genomic Medicine 209
Susanne B. Haga

19 Federal Regulation of Genomic Medicine 223
Janet Woodcock

20 Economic Issues and Genomic Medicine 233
David L. Veenstra, Louis P. Garrison and Scott D. Ramsey

21 Public Health Genomics 245
Alison Stewart, Marta Gwinn, Ron Zimmern and Muin Khoury

SECTION 4 CLINICAL (CARDIOLOGY)

22 The Genomics of Hypertension 259
Chana Yagil and Yoram Yagil

23 Lipoprotein Disorders 269
Sekar Kathiresan and Daniel J. Rader

24 Genomics of Myocardial Infarction 289
Carlos A. Hubbard and Eric J. Topol

25 Acute Coronary Syndromes 303
L. Kristin Newby

26 Heart Failure in the Era of Genomic Medicine 313
Ivor J. Benjamin and Jeetendra Patel

27 Genomic Assessment of Cardiac Transplant Rejection 326
Michael Pham, Mario C. Deng, Jay Wohlgemuth and Thomas Quertermous

28 Genetics and Genomics of Hypertrophic Cardiomyopathy 336
J. Martijn Bos, Steve R. Ommen and Michael J. Ackerman

29 Genetics and Genomics of Arrhythmias 350
Jeffrey A. Towbin and Matteo Vatta

30 Genetics and Genomics in the Management of Hemostasis and Thrombosis 374
Richard C. Becker and Felicita Andreotti

31 Genomics of Congenital Heart Disease 390
Jessie H. Conta and Roger E. Breitbart

SECTION 5 CLINICAL (ONCOLOGY)

32 Genomics in the Management of Lymphomas 407
Lisa Rimsza

33 Genomics in Leukemias 421
Lars Bullinger, Hartmut Dohner and Jonathan R. Pollack

34 Genomics in the Diagnosis and Management of Lung Cancer 432
Hasmeena Kathuria, Avrum Spira and Jerome Brody

35 Genomics in the Diagnosis and Management of Breast Cancer 446
Erich S. Huang and Andrew T. Huang

36 Colorectal Cancer 457
G.L. Wiesner, T.P. Slavin and J.S. Barnholtz-Sloan

37 Genomic Evaluation and Management of Prostate Cancer 477
Phillip G. Febbo and Philip W. Kantoff

38 Genomic Assessment of Ovarian Cancer 493
Tanja Pejovic, Matthew L. Anderson and Kunle Odunsi

39 Genomic Evaluation of Pancreatic Neoplasms 501
Asif Khalid and Kevin McGrath

40 Genomic Evaluation of Head and Neck Cancer 511
Giovana R. Thomas and Yelizaveta Shnayder

41 Genomic Evaluation of Brain Tumors and Gliomas 522
Sean E. Lawler and E. Antonio Chiocca

42 Targeted Therapies for Cancer 532
Jeffrey S. Ross

SECTION 6 CLINICAL (INFLAMMATORY DISEASE)

43 Genomics in the Evaluation and Management of Rheumatoid Arthritis 551
Robert M. Plenge and Michael E. Weinblatt

44 Genomic Evaluation of Multiple Sclerosis 566
Francisco J. Quintana and Howard L. Weiner

45 Genomic Assessment of Inflammatory Bowel Disease 575
Ad A. van Bodegraven and Cisca Wijmenga

46 Asthma Genomics 590
Scott T. Weiss, Benjamin A. Raby and Juan C. Celedón

47 Genomics in the Evaluation and Management of Chronic Obstructive Pulmonary Disease 603
Peter J. Barnes

48 Genetics and Genomics of Interstitial Lung Disease 616
Paul W. Noble and Mark P. Steele

49 Peptic Ulcer Disease 627
John Holton

SECTION 7 CLINICAL (METABOLIC DISEASE)

50 Genomics in Pathogenesis of Cirrhosis 645
N.A. Shackel, K. Patel and J. McHutchison

51 Genomic Medicine and Obesity 661
J. Alfredo Martínez

52 Diabetes 676
Maggie Ng and Nancy J. Cox

SECTION 8 CLINICAL (NEUROLOGICAL DISEASE)

53 Genetics and Genomics of Dementia 687
Robert L. Nussbaum

54 Genetics and Genomics of Parkinson's Disease 700
Shushant Jain and Andrew B. Singleton

55 Genomic Considerations in Ophthalmology 712
Janey L. Wiggs

56 Genomics in the Diagnosis and Management of Depression 722
Brigitta Bondy

SECTION 9 CLINICAL (INFECTIOUS DISEASE)

57 Genomic Approaches to the Host Response to Pathogens 733
M. Frances Shannon

58 Host Genomics and Bacterial Infections 744
Melissa D. Johnson and Mihai Netea

59 Genomics in the Evaluation and Management of Sepsis 760
Christopher W. Woods, Robert J. Feezor and Stephen F. Kingsmore

60 Genomics and the Management of Hepatitis 774
N.A. Shackel, K. Patel and J. McHutchison

Index 787

Preface

With the completion of the Human Genome Project at the beginning of this decade and the rapid development and application of new advances in our ability to understand and query the human genome and its gene set, it is time already to review the early sketches of a much-anticipated transformation of the practice of medicine. We have seen the very first signs of a fundamental shift in how we behold human physiology and pathology, how we view the concept of what is "normal", how we consider individuals and their prospects for lifelong health, and how we design health care systems that are equally adaptable to the demands of population-wide epidemics and the opportunities for personalized care that utilizes genome-based information to consider individual susceptibility to disease and therapeutic options.

Genome-based data, information, knowledge, and eventually wisdom will make possible the kind of health care that has been dreamed of since the advent of disease-based medicine early in the 20th century. A system of health care that harnesses the data intensity of the genome and its derivatives, along with imaging, clinical, and environmental information, will empower physicians and other health care providers to do what they have always aspired to do – make medical care as individualized as possible. But this newfound information and knowledge will also allow each of us as consumers of health care to take more control of our futures and to develop a more strategic and prospective approach to health. We stand at the dawn of a profound change in science and medicine's predictive nature and in our understanding of the biological underpinnings of health and disease. Even in this early light, we can see the outlines of a coming ability to:

- predict individual susceptibility to disease, based on genetic, genomic, and other factors;
- provide more useful tools and individualized programs for disease prevention, based on knowledge of one's susceptibility;
- detect the onset of disease earlier and before it is clinically evident, based on newly discovered biological markers that arise from changes at the molecular level;
- preempt disease progression, as a result of early detection; and
- target medicines and their dose more precisely and safely to each patient, on the basis of a deep understanding of disease mechanism and the role that genetic and genomic factors play in the individual response to drugs.

The time for this revolution in genomic and personalized medicine has come. As its name suggests, this book is intended to lay out the essentials of this new approach to medicine and to emphasize for particular conditions the clinical opportunities that present themselves today. It is designed to complement the more comprehensive two-volume book *Genomic and Personalized Medicine*, published last year, which presented in substantial depth the foundations of this new science, outlined the early opportunities for the practice of medicine to incorporate genome-based analysis into health care, and anticipated the many conditions to which genomic and personalized medicine will apply in the years ahead.

This volume on *Essentials of Genomic and Personalized Medicine* describes an emerging field that spans the breadth of clinical medicine, with many challenges for society at large and for health care systems in particular. Nonetheless, we are optimistic that the appropriate delivery models and economic incentives will be developed in a trustworthy framework that will be embraced by societies around the globe.

Our intended audience is clinically oriented but broad, ranging from medical students to residents and fellows to practitioners in any of the health care professions – physicians in any of the medical specialties, surgeons, nurses, genetic (and genomic) counselors, and laboratory directors.

In times of transformation, we are all students. We hope that this *Essentials* volume will help usher in this new era of genomic and personalized medicine and will provide a useful and thorough introduction to the science and practice of this new approach to human health.

Geoffrey S. Ginsburg, M.D., Ph.D.
Huntington F. Willard, Ph.D.
June 2009

Abbreviations

2D-DIGE	Two-dimensional difference gel electrophoresis
2D-PAGE	Two-dimensional polyacrylamide gel electrophoresis
5-HT	5-Hydroxytriptamine or serotonin
5-HTT	5-HT transporter
5-HTTLPR	5-HTT gene-linked polymorphic region
6-MMP	6-Methylmercaptopurine
6-MP	6-Mercaptopurine
6-MTIMP	6-Methyl-thioinosinemonophosphate
6-TGN	6-Thioguanine nucleosides
6-TIMP	6-Thioinosinemonophosphate
AAU	Acute anterior uveitis
ABCA1	Adenosine triphosphate-binding cassette protein A1
ABCB1	Adenosine triphosphate-binding cassette, sub-family B
ABI	Ankle brachial index
ACC	American College of Cardiology
ACE	Angiotensin converting enzyme
aCGH	Array comparative genomic hybridization
ACR	Acute cellular rejection
AD	Alzheimer's disease
AD	Aortic dilation
ADH	Autosomal dominant hypercholesterolemia
ADHD	Attention deficit hyperactivity disorder
ADIGE	Autosomal dominant idiopathic generalized epilepsy
ADJME	Autosomal dominant juvenile myoclonic epilepsy
ADNFLE	Autosomal dominant nocturnal frontal lobe epilepsy
ADP	Adenosine 5-diphosphate
ADR	Adverse drug reaction
AED	Antiepileptic drug
Ago2	Argonaute 2 mRNA endonuclease
AHA	American Heart Association
AIDS	Acquired immune deficiency syndrome
AIMs	Ancestry informative markers
AJCC	American Joint Committee on Cancer
ALL	Acute lymphoblastic leukemia
ALOX5AP	Arachidonate 5-lipooxygenase-activating protein
AMACR	Alpha methylacyl CoA reductase
AML	Acute myeloid leukemia
AMR	Antibody mediated rejection
AOO	Age of onset
Apo(a)	Apolipoprotein(a)
ApoE	Apolipoprotein E
APOE	Apolipoprotein E (gene name)
AR	Androgen receptor
AR	Autosomal recessive
ARACNe	Algorithm for the Reconstruction of Accurate Cellular Networks
ARE	Androgen response element
ARH	Autosomal recessive hypercholesterolemia
ARJP	Autosomal recessive juvenile Parkinsonism
ARVC	Arrhythmogenic right ventricular cardiomyopathy
AS	Ankylosing spondylitis
ASCA	Anti-*Saccharomyces cerevisiae* antibodies
ASCO	American Society for Clinical Oncology
ASCVD	Atherosclerotic cardiovascular disease
ASD	Atrial septal defect
ASO	Anti-sense oligonucleotides
ASPE	Allele-specific primer extension
ATM	Ataxia telangiectasia mutated
ATP	Adenosine triphosphate

ATP Adult Treatment Panel
ATR Ataxia-telangiectasia and RAD3-related
AZT Azidothymidine

B1-AR β1-adrenergic receptor
BBB Blood–brain barrier
BCAA Branched-chain amino acids
Bcl B-cell lymphoma protein
BCL-2 B-cell lymphoma 2
Bcl-Abl Breakpoint cluster region – Abelson kinase fusion protein
BDNF Brain-derived neurotrophic factor
BER Base excision repair
BEST β-Blocker Evaluation of Survival Trial
BH Bcl-2 homology domain
BLAST Basic local alignment and search tool
BLAT BLAST-like alignment tool
BMC Bone marrow cell
BMI Body mass index
BMP-7 Bone morphogenic protein-7
BOLD Blood oxygen level-dependent
BPDE Benzo (a) pyrene diol epoxide
BPH Benign prostatic hypertrophy
BRCA Breast cancer gene
BRCA1 Breast cancer 1, early onset, protein
BRCA2 Breast cancer type 2 susceptibility protein
BRD2 Bromodomain containing 2 (gene)
BSML Bioinformatic sequence markup language

CA Capsid (viral protein)
CAD Coronary artery disease
CADASIL Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy
CAE Childhood absence epilepsy
CALGB Cancer and leukemia group B
CAP College of American Pathologists
CARD Caspase recruitment domain (gene)
CARGO Cardiac Allograft Rejection Gene Expression Observational study
CAV Cardiac allograft vasculopathy
CBD Cortical basal degeneration
CBP CREB-binding protein
CBZ Carbamazepine
CCD Charge coupled device
CCL Chemokine (C-C motif) ligand
CCND1 Cyclin D1, a proto-oncogene
CD Cluster of differentiation
CD Crohn's disease
CDAI Crohn's disease activity index
CDC Centers for Disease Control
cDNA Complementary deoxyribonucleic acid
CDS Clinical decision support
CED-4 Cell death abnormality gene 4
CETP Cholesteryl ester transfer protein
CF Cystic fibrosis
CFTR Cystic fibrosis transmembrane conductance regulator
CGAP Cancer Genome Anatomy Project
CGH Comparative genomic hybridization
CGHa Comparative genomic hybridization array
CGP Cancer Genome Project
CHD Congenital heart disease
CHD Coronary heart disease
CHF Congestive heart failure
CHMP Committee for Medicinal Products for Human Use
CHRNA4 Cholinergic receptor, nicotinic, alpha 4 (gene)
CIBEX Center for Information Biology Gene Expression
CIC Citrate/isocitrate carrier
CICR Calcium-induced calcium release
CKD Chronic kidney disease
CLI Critical limb ischemia
CLIA Clinical Laboratory Improvement Amendments
CML Chronic myelogenous leukemia
CMT Charcot-Marie-Tooth disease
CMV Cytomegalovirus or human herpes virus 5
CNS Central nervous system
CNV Copy number variant
COPA Cancer outlier profile analysis
COR C-terminal of ROC domain
COX Cyclooxygenase
COX-2 Cyclooxygenase-2
CPOE Computerized provider order entry
CRC Colorectal cancer
CREB Cyclic AMP response binding protein
CRF Circulating recombined form
CRP C-reactive protein
CS Cell signaling factor
CSA Comparative sequence analysis
CSF Cerebrospinal fluid
CSF1 Colony stimulating factor 1
CTC Circulating tumor cells
CTGF Connective tissue growth factor
CTL Cytotoxic T lymphocytes
CTLA Connective tissue late antigen
CTSA Clinical and Translational Science Awards
CX32 Connexin-32
CX37 Connexin-37
CYP Cytochrome P450
CYP2C19 Cytochrome P450 2C19
CYP2D6 Cytochrome P450 2D6

D2R Dopamine-2 receptor
DAI Disease Activity Score (for Ulcerative Colitis)
dbSNP NCBI SNP database
DCM Dilated cardiomyopathy
DGGE Denaturing gradient gel electrophoresis
DGI Diabetes Genetics/Initiative
DHF Diastolic heart failure

DHLPC	Denaturing high performance liquid chromatography
DLB	Diffuse Lewy body
DLBD	Diffuse Lewy body disease
DLDA	Diagonalized linear discriminant analysis
DLG	Disc large homologue (gene)
DMEs	Drug-metabolizing enzymes
DNA	Deoxyribonucleic acid
DNase	Deoxyribonuclease
DNMTs	DNA methyltransferases
DOPAC	Dihydroxyphenylacetic acid
ds	Double stranded
dsRNA	Double-stranded ribonucleic acid
DTC	Direct-to-consumer
DU	Duodenal ulcer
DZ	Dizygotic
EAE	Experimental autoimmune encephalomyelitis
EBI	European Bioinformatics Institute
EBV	Epstein–Barr virus
ECL	Eenterochromaffin-like cells
ECM	Extracellular matrix
EDG-1	Endothelial differentiation gene-1
EGAPP	Evaluation of Genomic Applications in Practice and Prevention
EGF	Epidermal growth factor
EGFR	Epidermal growth factor receptor
EHR	Electronic health record
EIA	Enzyme immunoassay
EL	Endothelial lipase
ELISA	Enzyme-linked immunosorbent assay
ELMO1	Engulfment and cell motility 1
EM	Extracellular matrix protein
EMB	Endomyocardial biopsy
EMBL-EBI	European Molecular Biology Laboratory–European Bioinformatics Institute
EMEA	European Medicines Evaluation Agency
ENCODE	Encyclopedia of DNA Elements
EOAD	Early-onset Alzheimer's disease
EPIYA	Single letter codes for amino acids
eQTL	Expression quantitative trait loci
ERK	Extracellular signal-regulated kinase
ESR	Erythrocyte sedimentation rate
ESRD	End-stage renal disease
EST	Expressed sequence tag
FA	Fanconi anemia
FACS	Fluorescent-activated cell sorting
FANCA	Fanconi anemia proteins A
FANCD2	Fanconi anemia protein D2
FAP	Familial adenomatous polyposis
FCHL	Familial combined hyperlipidemia
fCJD	Familial Creutzfeldt–Jakob disease
FCS	Familial hyperchylomicronemia syndrome
FD	Familial dysbetalipoproteinemia
FDA	Food and Drug Administration (USA)
FDB	Familial defective apoB-100
FFPE	Formalin-fixed, paraffin-embedded
FGF	Fibroblast growth factor
FGF-2	Fibroblast growth factor-2
FH	Familial hypercholesterolemia
FHTG	Familial hypertriglyceridemia
FISH	Fluorescence *in situ* hybridization
FKBP	FK506-binding protein
FL	Follicular lymphoma
FLT-3	FMS-like tyrosine kinase-3
fMRI	Functional MRI
FNA	Fine needle aspirate
FOV	Field of view
FSGS	Focal segmental glomerulosclerosis
FTD	Frontotemporal dementia
FUSION	Finland–United States Investigation of NIDDM genetics
GABBR1	GABA B receptor 1 (gene)
GABRG2	GABA A receptor, gamma 2 (gene)
GAIN	Genetic Association Information Network
GAPDH	Glyceraldehyde-3-phosphate dehydrogenase
GBM	Glomerular basement membrane
GBS	Guillain–Barre Syndrome
GCKR	Glucokinase regulatory protein
GC-MS	Gas chromatography–mass spectrometry
GCSF	Granulocyte colony-stimulating factor
GDNF	Glial cell line-derived neurotrophic factor
GEFS+	Generalized epilepsy with febrile seizures plus
GEO	Gene Expression Omnibus
GEP	Gene expression profiling
GFAP	Glial fibrillary acidic protein
GFP	Green fluorescent protein
GLEPP1	Glomerular epithelial protein 1
GLP	Good laboratory practice
GM-CSF	Granulocye macrophage–colony stimulating factor
GO	Gene ontology
GPI	Globus pallidus interna
GR	Glucocorticoid receptor gene
GSEA	Gene set enrichment analysis
GSIS	Glucose-stimulated insulin secretion
GSTT	Glutathione *S*-transferase
GU	Gastric ulcer
GWAS	Genome-wide association study
GZM	Granzyme
H	Heterozygosity
HAART	Highly active anti-retroviral therapy
HAV	Hepatitis A
HBV	Hepatitis B
HCC	Hepatocellular carcinoma
HCM	Hypertrophic cardiomyopathy
HCV	Hepatitis C
HDAC	Histone deacetylase

HDL	High-density lipoproteins
HDM2	Human double minute 2
HDV	Hepatitis D
HeLa	Cervical cancer cell line
HEPS	Highly exposed persistently seronegative individuals
HER2	Human epidermal growth factor receptor 2
HEV	Hepatitis E
HF	Heart failure
HFPEF	Heart failure with preserved ejection fraction
HGF	Hepatocyte growth factor
HGPRT	Hypoxanthine phosphoribosyl transferase
HHS	Health and Human Services (U.S.)
HHV-6	Human herpes virus 6
HITSP	Healthcare Information Technology Standards Panel
HIV	Human immunodeficiency virus
HKMT	Histone lysine methyltransferases
HL	Hepatic lipase
HL7	Health Level 7
HLA/*HLA*	Human leukocyte antigen/(gene)
HLI	Hind limb ischemia
HMT	Histone methyltransferase
HNPCC	Hereditary nonpolyposis colorectal cancer
HNSCC	Head and neck squamous cell carcinoma
HP-1	Heterochromatin-associated protein-1
HPV	Human papilloma virus
HPV-16	Human papilloma virus-16
HR	Homologous recombination
HRPC	Hormone refractory prostate cancer
HS	Hyper-spectral
HSC	Hepatic stellate cell
HSP	Heat shock protein
HSV-1	Human herpes simplex virus type 1
HSV1-TK	Herpes simplex virus type 1-thymidine kinase
HSV-2	Human herpes simplex virus type 2
hTERT	Human telomerase reverse transcriptase
HTLV-I	Human T-cell leukemia/lymphoma virus type I
HTLV-III	Human T-cells lymphotropic virus type 3
HTS	High-throughput screening
HVJ	Hemagglutinating virus of Japan
IBD	Inflammatory bowel disease
IBDQ	Inflammatory bowel disease questionnaire
IC	Intermittent claudication
IC	Interstitial cystitis
ICAM	Intracellular adhesion molecules
ICD	Implantable cardioverter defibrillator
ICD	International Classification of Diseases
ICDc	Cytosolic, NADP-dependent isocitrate dehydrogenase
iDC	Immature dendritic cells
IDCM	Idiopathic dilated cardiomyopathy
IDDM	Insulin-dependent diabetes mellitus
IDL	Intermediate-density lipoproteins
IDO	Indolemaine 2,3-dioxygenase
IFN	Interferon
IFN-β	Interferon-beta
IFN-γ	Interferon-gamma
Ig	Immunoglobulin
IgA	Immunoglobulin-A
IGF-I	Insulin-like growth factor-I
IHC	Immunohistochemistry
IHE	Integrating the Healthcare Enterprise
IKBL	Inhibitor of κB-like (gene)
IL	Interleukin
IL (4/13)	Interleukin (4/13)
IL-1β	Interleukin-1 beta (gene)
IL-1ra	Interleukin-1 receptor antagonist
IL-6	Interleukin-6
IL-10	Interleukin-10
IMAGE	Invasive Monitoring Attenuation through Gene Expression study
iMC	Immature myeloid cells
IN	Integrase (viral protein)
IOM	Institute of Medicine (U.S.)
IS	Insertion sequence
ISB	Institute for Systems Biology
ISG	Intreferon stimulated gene
ISHLT	International Society for Heart and Lung Transplantation
IT	Information technology
IVDMIA	*In vitro* diagnostic multivariate index assay
JCA	Juvenile chronic arthritis
JHDM1	JmjC domain-containing histone demethylase-1
JME	Juvenile myoclonic epilepsy
Kb	Kilobase
KEGG	Kyoto Encyclopedia of Genes and Genomes
LARGO	Lung Allograft Rejection Gene expression Observational study
LAV	Lymphadenopathy-associated virus
LB	Lewy body
LCAT	Lecithin cholesterol acyltransferase
LCM	Laser capture microdissection
LD	Linkage disequilibrium
LDL	Low-density lipoproteins
l-DOPA	Levodopa
LOAD	Late-onset Alzheimer's disease
LOD	Logarithm of the odds
LOH	Loss of heterozygosity
LOINC	Logical Observation Identifiers, Names, and Codes
LOR	Line of response
Lp(a)	Lipoprotein(a)
LPA	Lysophosphatidic acid
LPL	Lipoprotein lipase
LPS	Lipopolysaccharide
LRR	Leucine-rich repeat

LRRK2	Leucine rich repeat kinase 2
LSD1	Lysine-specific demethylase-1
LTA	Lymphotoxin alpha
LTA4H	Leukotriene A4 hydrolase
LTB4	Leukotriene B4
LTNP	Long-term non-progression
LV	Left ventricle
LVAD	Left ventricular assist device
LVEDP	Left ventricular end-diastolic pressure
LVEF	Left ventricular ejection fraction
LVH	Left ventricular hypertrophy
LVOT(O)	Left ventricular outflow tract (obstruction)
MA	Matrix (viral protein)
mAb	Monoclonal antibodies
MADH6	Mothers against decapentaplegic homolog 6
MAGE-ML	MicroArray and Gene Expression Markup Language
MAGUK	Membrane-associated guanylate kinase
MAM	Metastasis-averse microenvironment
MAO	Monoamine oxidase
MAOA	Monoamine oxidate A
MAP	Mitogen-activated protein
MAPK	Microtubule-associated protein kinase
MAPK	Mitogen-activated protein kinase
MAQC	Microarray quality control
Mb	Megabase
MBD	Methylated DNA binding domain protein
MCD	Malonyl CoA decarboxylase
MCD	Minimal change disease
MCP	Monocyte/macrophage chemoattractant protein
MCP-1	Monocyte chemoattractant protein 1
MCS	Multi-species conserved sequence
M-CSF	Macrophage colony-stimulating factor
MDM2	Mouse double minute 2
MDP	Muramyl dipeptide
MDR	Multidrug resistance (gene)
MedDRA	Medical Dictionary for Regulatory Activities Terminology
MEF2A	Myocyte-enhancing factor 2A
Megsin	Mesangial cell-specific gene with homology to serpin
MEN	Multiple endocrine neoplasm
MeSH	Medical Subject Headings
MeV	Multiexperiment viewer
MGED	Microarray Gene Expression Data society
MGMT	O6-Methylguanine-DNA methyltransferase
MHC	Major histocompatability complex
MI	Myocardial infarction
MIAME	Minimal Information About a Microarray Experiment
MIM	Metastasis-inclined microenvironment
miR-192	MicroRNA-192
miRNA	Micro-ribonucleic acid
MITF	Microphthalmia transcription factor
MLEM	Maximum likelihood expectation maximization
MLPA	Multiplex ligation-dependent probe amplification
MMP	Matrix metalloproteinase
MMP-3	Matrix metalloproteinase-3
MMR	Mismatch repair
MPSS	Massively parallel signature sequencing
MPTP	1-Methyl-4-phenyl-1, 2, 3, 6-tetrahydropyridine
mQTL	Metabolite quantitative trait loci
mRNA	Messenger ribonucleic acid
mRSS	Modified Rodnan Skin Score
MS	Multiple sclerosis
MS	Multispectral
MS/MS	Tandem mass spectrometry
MSA	Multiple system atrophy
MTDNA	Mitochondrial DNA
MTHFR	Methylenetetrahydrofolate reductase (gene)
mTOR	Mammalian target of rapamycin
MTP	Microsomal triglyceride transfer protein
MTX	Methotrexate
MudPIT	Multidimensional protein identification technology
MVP	Mitral valve prolapse
MZ	Monozygotic
NAAT	Nucleic acid amplification testing
NAD(P)H	Nicotinamide adenine dinucleotide phosphate reduced form
NAFLD	Non-alcoholic fatty liver disease
NASH	Non-alcoholic steatohepatitis
NAT2	*N*-Acetyltransferase 2
NAWM	Normal appearing white matter
NC	Nucleocapsid (viral protein)
N-CAM	Neural cell adhesion molecule
NCBI	National Center for Biotechnology Information
NCE	New chemical entity
NCEP	National Cholesterol Education Program
NCI60	Refers to a set of 60 cancer cell lines curated at the NCI (National Cancer Institute)
ncRNA	Non-coding RNA
NEF	NEgative regulatory Factor (viral protein)
NER	Nucleotide excision repair
NF1/2	Neurofibromatosis1/2
NHGRI	National Human Genome Research Institute
NHR	Non-homologous recombination
NIEHS	National Institute of Environmental Health Sciences (NIH)
NIH	National Institutes of Health
NK	Natural killer
NMR	Nuclear magnetic resonance
NNRTI	Non-nucleosidic reverse transcriptase inhibitor
NOD	Nucleotide oligomerization domain (gene)
NPV	Negative predictive value

NQO1	Nicotinamide adenine dinucleotide phosphate oxidoreductase
NRTI	Nucleosidic reverse transcriptase inhibitor
NSAID	Non-steroidal anti-inflammatory drug
nt	Nucleotides
NUD	Non-ulcer dyspepsia
NYHA	New York Heart Association
OBO	Open Biomedical Ontologies
OCTN	Organic cation transporter (gene)
OHCA	Out of hospital cardiac arrest
OMIM	Online Mendelian Inheritance in Man
OMP	Outer membrane protein
OmpC	Outer membrane porin C of E. coli
opn	Osteopontin (gene)
OPN	Osteopontin (protein)
OR	odds ratio
ORESTES	Open reading frame expressed sequence tags
ORF	Open reading frame
OSEM	Ordered subset expectation maximization
p53BP1	p53 Binding protein 1
PAD	Peripheral arterial disease
PAGE	Polyacrylamide gel electrophoresis
PAI	Pathogenicity island
PAM	Prediction analysis of microarrays
pANCA	Perinuclear antineutrophil cytoplasmatic antibodies
PAOD1	Peripheral arterial occlusive disease
Pap	Papanicolaou
Parvo B19	Human parvovirus B-19
PBC	Primary biliary cirrhosis
PBL	Peripheral blood lymphocytes
PBMC	Peripheral blood mononuclear cell
PC	Pyruvate carboxylase
PCA	Principal components analysis
PCNA	Proliferating cell nuclear antigen
PCR	Polymerase chain reaction
PCSK9	Proprotein convertase subtilisin/kexin type 9
PCV	Procarbazine/CCNU/vincristine
PD	Parkinson disease
PD	Pharmacodynamic
PDA	Patent ductus arteriosus
PDA	Personal digital assistant
PDD	Parkinson disease with dementia
PDGF	Platelet-derived growth factor
PDGFR	Platelet-derived growth factor receptor
PDH	Pyruvate dehydrogenase
PDTC	Pyrrolidine dithiocarbamate
PDYN	prodynorphin (gene)
PFGE	Pulse field gel electrophoresis
PGE2	Prostaglandin E2
PGx	Pharmacogenetics and pharmacogenomics
PHT	Phenytoin
PI	Protease inhibitor
PI3K	Phosphotidylinositol triphosphate kinase
PIN	Prostatic intraepithelial neoplasia
PK	Pharmacokinetics
PLTP	Phospholipid transfer protein
PMAGE	Polony Multiplex Analysis of Gene Expression
PMBC	Peripheral blood mononuclear cells
PML-RAR	Pro-myelocytic leukemia retinoic acid receptor oncoprotein
PON1	Paraoxonase
PPI	Percutaneous peripheral intervention
PPV	Positive predictive value
PR	Protease (viral)
PrEC	Prostate epithelial cells
PRIDE	Proteomics Identifications Database
PRNP	Prion protein (gene)
PS	Pulmonary stenosis
PSA	Prostate-specific antigen
PsA	Psoriatic arthritis
PSC	Primary sclerosing cholangitis
PSP	Progressive supranuclear palsy
PTEN	Phosphatase and tensin homolog
PTM	Pre-trans-splicing molecule
PUD	Peptic ulcer disease
PZ	Plasticity zone
QPCR	Quantitative PCR
qRT	Quantitative real-time PCR
qRT-PCR	Quantitative reverse-transcriptase polymerase chain reaction
QTL	Quantitative trait locus
QT-PCR	Quantitative real-time polymerase chain reaction
QV	Quality value
R&D	Research and Development
RA	Rheumatoid arthritis
RAAS	Renin-angiotensin-aldosterone system
RAPD-PCR	Random amplified polymorphic deoxyribonucleic acid–polymerase chain reaction
RB	Retinoblastoma
RB	Retinoblastoma (gene)
RCM	Restrictive cardiomyopathy
REPAIR-AMI	Reinfusion of enriched progenitor cells and infarct remodeling in acute myocardial infarction
RET	Ret proto-oncogene
REV	REgulator of Virion protein expression (viral protein)
RFLP	Restriction fragment length polymorphism
RISC	RNA interference silencing complex
RNA	Ribonucleic acid
RNAi	Ribonucleic acid interference
ROC	RAS in complex proteins
ROCO	ROC (RAS of complex proteins)/COR (C-terminal of ROC)

ROS	Reactive oxygen species
RP	Rapid progression
RPA	Ribonuclease protection assay
RSV	Respiratory syncytial virus
RT	Reverse transcriptase (viral protein)
RT-PCR	Real-time polymerase chain reaction
RT-PCR	Reverse transcription – polymerase chain reaction
RV	Right ventricle
RVHF	Right ventricular heart failure
SACGHS	Secretary's Advisory Committee on Genetics, Health and Society (U.S.)
SAGE	Serial Analysis of Gene Expression
SALSA	Scoring algorithm for spectral analysis
SAM	*S*-Adenosyl-l-methionine (AdoMet)
SAM	Significance analysis of microarrays
SAM	Systolic anterior motion of mitral valve
SAP/Exo I	Shrimp alkaline phosphatase/exonuclease I
SARS	Severe acute respiratory syndrome
SBE	Single-base extension
SCD	Sudden cardiac death
SCID	Severe combined immunodeficiency
SCN1A	Voltage-gated sodium channel, type 1, alpha subunit (gene)
SCOTS	Selective capture of transcribed sequences
SCX	Strong cation exchange
SD	Standard deviation
SDO	Standards development organization
SE	Shared epitope of HLA (human leukocyte antigen) genes
SE	Spongiform encephalopathies
SEBASTIAN	System for Evidence-Based Advice through Simultaneous Transaction with an Intelligent Agent across a Network
SEC	Sinusoidal endothelial cell
SERPA	Serological proteome analysis
SHF	Systolic heart failure
shRNA	Short hairpin ribonucleic acid
SIP1	Smad-interacting protein 1
siRNA	Small interfering ribonucleic acid
SIV	Simian immunodeficiency virus
SJS/TEN	Stevens–Johnson syndrome/toxic epidermal necrolysis
SLC12A3	Solute carrier family 12 member 3
SLE	Systemic lupus erythematosus
SLN	Sentinel lymph node
SMD	Stanford Microarray Database
SN	Substantia nigra
SNOMED CT	Systematized Nomenclature of Medicine, Clinical Terms
SNP	Single nucleotide polymorphism
SNpc	Substantia nigra pars compacta
SNR	Substantia nigra pars reticulata
SOX10	SRY-box containing gene 10
SpA	Spondyloarthropathy
SPARC	Secreted protein, acidic, and rich in cysteine, osteonectin
SPMS	Secondary progressive MS
SR-BI	Scavenger receptor, class BI
ss	Single-stranded
SSc	Systemic sclerosis
SSCP	Single strand conformation polymorphism
SSRP	Simple sequence repeat polymorphism
SSTR2	Somatostatin receptor type 2
STAT	Signal transducers and activators of transcription
STEMI	ST segment Elevation Myocardial Infarction
STK11 gene	Serine/threonine kinase 11
STN	Subthalmic nucleus
SU	Surface (viral protein)
SVAS	Supravalvar aortic stenosis
SVR	Sustained viral response
SWOG	Southwest Oncology Group
TAM	Tumor associated macrophages
TAT	TransActivator of Transcription (viral protein)
TBB	Transcriptomic-based biomarkers
TCF7L2	Transcription factor 7-like 2
TCR	T-cell receptor
TDM	Therapeutic drug monitoring
TF	Transcription factor
TFAP2B	Transcription factor activating protein 2β
TGF	Transforming growth factor
TGF-β	Transforming growth factor beta
TH	Tyrosine hydroxylase
Th1	T-helper cell, type 1
Th2	T-helper cell, type 2
TIGR	The Institute for Genomic Research
TIMP	Tissue inhibitor of metalloproteinase
TIMP-1	Tissue inhibitor of metalloproteinase-1
TK	Tyrosine kinase
TLE	Temporal lobe epilepsy
TLR	Toll-like receptor
TLS	Trans-lesion DNA synthesis
TM	Trans-Membrane (viral protein)
TNF	Tumor necrosis factor
TNF-α	Tumor necrosis factor-alpha
TNF-β	Tumor necrosis factor-beta
TNM	Tumor-node-metastasis stage
TOF	Tetralogy of Fallot
TPMT/*TPMT*	Thiopurine methyl transferase/(gene)
Treg	Regulatory T-cells
TSA	Trichostatin A
TSG	Tumor suppressor gene
TSP	Thrombospondin
UADT	Upper aerodigestive tract
UC	Ulcerative colitis

UCSC	University of California at Santa Cruz
UMLS	Unified Medical Language System
UNAIDS	United Nation mission on AIDS
US	Ultrasound
US	United States of America
USF1	Upstream transcription factor 1
USpA	Undifferentiated spondyloarthropathy
UTR	Untranslated region (three prime or five prime)
V-ATPase	Vacuolar adenosine triphosphatase
V-CAM	Vascular cell adhesion molecule
VEGF	Vascular endothelial growth factor
VF	Ventricular fibrillation
VIF	Virion infectivity factor
VLDL	Very low-density lipoproteins
VPR	Viral protein R
VPU	Viral protein U
VS	Ventricular septal defect
VT	Ventricular tachycardia
VZV	Varicella zoster virus
WGA	Whole-genome amplification
WGAS	Whole Genome Association Studies
WGS	Whole genome shotgun
WHO AIDS	World Health Organization mission on AIDS
WHO	World Health Organization
WNV	West Nile virus
WSS	Western-specific sequence
WTCCC	Welcome Trust Case Control Consortium
XMRV	Xenotropic murine leukemia virus-related virus
ZDV	Zidovudine
ZFP	Zinc finger protein

CHAPTER

The Foundations of Genomic and Personalized Medicine

Geoffrey S. Ginsburg and Huntington F. Willard

GENOMIC AND PERSONALIZED MEDICINE

The Human Genome Project, completed in 2003, has provided scientists and clinicians with a diverse set of novel molecular tools that can be used to understand health and manage disease. Variation in the human genome has long been the cornerstone of the field of human genetics (see Box 1.1), and its study led to the establishment of the medical specialty of medical genetics (Nussbaum et al., 2007). Now genome sequencing, copy number variation, transcriptional readouts, and comprehensive measurements of micro RNA, protein, and metabolite levels provide a "systems approach" to probe and predict human health and disease states that has greatly broadened the impact of principles of genetics and genomics on clinical medicine. These advances have provided both a conceptual and technological underpinning for the development of the field of genomic medicine as a driver of personalized health care. For the first time in the history of medicine, health care providers as well as patients can use predictive tools to develop a new model for health care based on health planning that is *proactive* and preventive, as opposed to the current model in health care that is *reactive*, episodic, and geared toward acute crisis intervention once disease is already manifest and largely irreversible.

The growing transformation of clinical practice in the era of genomic and personalized medicine is perhaps best exemplified today in the field of cancer care, as illustrated in some detail in subsequent chapters of this volume. Oncologists now practice with a suite of genomic testing opportunities that include *BRAC1/BRAC2* testing in familial syndromes of breast and ovarian cancers. In colorectal cancer, Hereditary Non-polyposis Colon Cancer (HNPCC) or Lynch syndrome and familial adenomatous polyposis (FAP) coli are conditions for which there is testing for mismatch repair gene mutations (for HNPCC) or *APC* mutations (FAP) that has been widely adopted. The paradigm for oncology is largely based on the principle that accurate prognosis and proper therapy can be matched to the molecular characteristics of the individual patient's tumor. Thus, at the time of diagnosis, whole-genome expression data are now being used routinely to identify subtypes of cancer not previously recognized by traditional methods of analysis (Bullinger and Valk, 2005; Dave et al., 2006; Potti et al., 2006a; Staudt, 2003; Valk et al., 2004).

There is now compelling evidence of clinical adoption of genomic testing by oncologists: in 2008, for example, RNA expression signatures were used for risk stratification and prognosis in breast cancer for more than 39,000 "treat" versus "no-treat" decisions (Securities and Exchange Commission, 2009). However, there continues to be a need to develop the

BOX 1.1 Genetics and Genomics

Throughout this and the many other chapters in this *Essentials* volume, the terms "genetics" and "genomics" are used repeatedly, both as nouns and in their adjectival forms. While these terms seem similar, they in fact describe quite distinct (though frequently overlapping) approaches in biology and in medicine. Having said that, there are inconsistencies in the way the terms are used, even by those who work in the field. To some, genetics is a subfield of genomics; to others, genomics is a subfield of genetics. Arguably, depending on the perspective one has in mind, both may be right!

Here, we provide operational definitions to distinguish the various terms and the subfields of medicine to which they contribute.

The field of *genetics* is the scientific study of heredity and of the genes that provide the physical, biological, and conceptual bases for heredity and inheritance. To say that something – a trait, a disease, a code, or information – is genetic refers to its basis in genes and in DNA.

Heredity refers to the familial phenomenon whereby traits (including clinical traits) are transmitted from generation to generation, due to the transmission of genes from parent to child. A disease that is said to be inherited or hereditary is certainly genetic; however, not all genetic diseases are hereditary (witness cancer, which is always a genetic disease, but is only occasionally an inherited disease).

Genomics is the scientific study of a genome or genomes. A *genome* is the complete DNA sequence, containing the entire genetic information of a gamete, an individual, a population, or a species. As such, it is a subfield of genetics when describing an approach taken to study genes. The word "genome" originated as an analogy with the earlier term "chromosome," referring to the physical entities (visible under the microscope) that carry genes from one cell to its daughter cells or from one generation to the next. Genomics gave birth to a series of other "-omics" that refer to the comprehensive study of the full complement of genome products – for example, proteins (hence, *proteomics*), transcripts (*transcriptomics*), or metabolites (*metabolomics*). The essential feature of the "omes" is that they refer to the complete collection of genes or their derivative proteins, transcripts, or metabolites, not just to the study of individual entities. While formally the field of genomics refers to the study of genomes (and hence, DNA) only, it sometimes takes on the broader meaning of referring to any large-scale approach; the less specific term "genome sciences" is also sometimes used to refer to all of the -omics to connote global and comprehensive approaches to the study of biology and medicine.

By analogy with genetics and genomics, *epigenetics* and *epigenomics* refer to the study of factors that affect gene (or, more globally, genome) function, but without an accompanying change in genes or the genome. Some typical epigenetic factors involve changes in DNA methylation or modifications to chromatin that change genome structure and hence influence gene expression even in the absence of changes in the DNA sequence. The *epigenome* is the comprehensive set of epigenetic changes in a given individual, tissue, tumor, or population. It is the paired combination of the genome and the epigenome that best characterize and determine one's phenotype.

Medical genetics is the application of genetics to medicine with a particular emphasis on inherited disease. Medical genetics is a broad and varied field, encompassing many different subfields, including clinical genetics, biochemical genetics, cytogenetics, molecular genetics, the genetics of common diseases, and genetic counseling. Medical genetics is one of 24 medical specialties recognized by The American Board of Medical Specialties, the preeminent medical organization overseeing physician certification in the United States. As of 2007, there were approximately 2300 board-certified medical geneticists in the United States.

Genetic medicine is a term sometimes used to refer to the application of genetic principles to the practice of medicine and thus overlaps medical genetics. However, genetic medicine is somewhat broader, as it is not limited to the specialty of Medical Genetics but is relevant to health professionals in many, if not all, specialties and subspecialties. Both medical genetics and genetic medicine approach clinical care largely through consideration of individual genes and their effects on patients and their families.

By contrast, *genomic medicine* refers to the use of large-scale genomic information and to the consideration of the full extent of an individual's genome, proteome, transcriptome, metabolome, and/or epigenome in the practice of medicine and medical decision-making. The principles and approaches of genomic medicine are relevant well beyond the traditional purview of medical genetics and include, as examples, gene expression profiling to characterize tumors or to define prognosis in cancer, genotyping variants in the set of genes involved in drug metabolism or action to determine an individual's correct therapeutic dosage, scanning the entire genome for millions of variants that influence one's susceptibility to disease, or analyzing multiple protein biomarkers to monitor therapy and to provide predictive information in presymptomatic individuals.

Finally, *personalized medicine* refers to a rapidly advancing field of health care that is informed by each person's unique clinical, genetic, genomic, and environmental information. The goals of personalized medicine are to take advantage of a molecular understanding of disease to optimize preventive health care strategies and drug therapies while people are still well or at the earliest stages of disease. Because these factors are different for every person, the nature of disease, its onset, its course, and how it might respond to drug or other interventions are as individual as the people who have them. In order for personalized medicine to be used by health care providers and their patients, these findings must be translated into precision diagnostic tests and targeted therapies. Since the overarching goal is to optimize medical care and outcomes for each individual, treatments, medication types and dosages, and/or prevention strategies may differ from person to person – resulting in unprecedented customization of patient care.

The principles underlying genomic and personalized medicine and their applications to the practice of clinical medicine are presented throughout the chapters that comprise this volume.

---

evidence that these signatures will enhance outcomes across a broad population of women with breast cancer. A prospective cooperative group clinical trial has been initiated in Europe (MINDACT) that aims to measure the effectiveness of a gene expression predictor of breast cancer prognosis to guiding adjuvant chemotherapy when compared to predictions based solely on the traditional clinical parameters for prognoses (Bogaerts et al., 2006). A study sponsored by the US National Cancer Institute (TAILORx) aims to use an RNA signature to identify low risk breast cancer patients unlikely to benefit from

chemotherapy (Sparano, 2006). Similar studies are getting started for prognostic signatures in lung cancer (Potti et al., 2006a). These are exemplars of the approach of genomic and personalized medicine and serve as clear examples where a genome-based approach has resulted in the opportunity to redefine disease phenotypes and at the same time redefine therapeutic strategies.

Of equal if not greater importance in achieving the goal of personalized treatment is an ability to predict response to specified therapies, particularly for those regimens that are part of routine clinical practice today. The selection of therapy for many cancer patients is still largely empiric and guided by large randomized clinical trials on populations of patients. Estimates of benefits from this approach for individuals are extrapolations from the effects seen in these large trials and do not necessarily apply to individual patients.

Genomic signatures that predict response and resistance to a spectrum of cytotoxic chemotherapies may now allow assignment of patients to effective treatment regimens best suited to the unique characteristics of their tumor (Potti et al., 2006b). Genomic predictors of chemotherapy response thus provide an opportunity to determine which drug would be optimal for an individual patient in clinical scenarios for which past studies have not shown a clear superiority for any of the currently available drugs.

Beyond cancer, other fields of medicine are also benefiting from whole-genome approaches that are defining both susceptibility to complex disease through genome-wide association studies (GWAS) or genome resequencing (see below), as well as signatures that define disease states and predictive outcomes based on analyses from both disease tissues and from blood (Altshuler et al., 2008; Aziz et al., 2007). Blood-based gene expression profiling is particularly important as it presents the opportunity to report on disease processes from remote and often inaccessible sites for direct analyses. Instead of analyzing single genes, global gene expression provides a "molecular signature" that may distinguish between one disease state and another. In addition to identifying signatures or patterns of gene expression that represent a disease state, analyses can be constructed to identify representative pathway genes that might point to novel pathophysiology relevant to the underlying disease state. Peripheral blood gene expression signatures have now been reported in a variety of conditions described in subsequent chapters, including rheumatoid arthritis (Lequerré et al., 2006; Shou et al., 2006), systemic lupus erythematosis (Rus et al., 2004), multiple sclerosis (Bomprezzi et al., 2003; Singh et al., 2007), asthma (Brutsche et al., 2002), malignancies (Alizadeh et al., 2000; Golub et al., 1999), solid organ transplantation (Baron et al., 2007; Horwitz et al., 2004), as well as environmental exposures (Dressman et al., 2007; Lodovici et al., 2007; Meadows et al., 2008; Wu et al., 2003). Many of these conditions have an inflammatory component and thus affect immune cells in the vascular compartment. It is hypothesized that these cellular changes are the basis for the differences in gene expression that is observed in RNA extracted from whole blood specimens or from specific circulating cell types. The greatest potential of this approach would be the enhancement in accurately classifying patients by the type and severity of their disease and to individualize the therapy based on the biology of the disease in an individual patient. Significant power can be anticipated from approaches that combine *both* assessment of an individual's constitutional genome and evaluation of gene expression signatures of one's health status (Figure 1.1) (Hardy and Singleton, 2009).

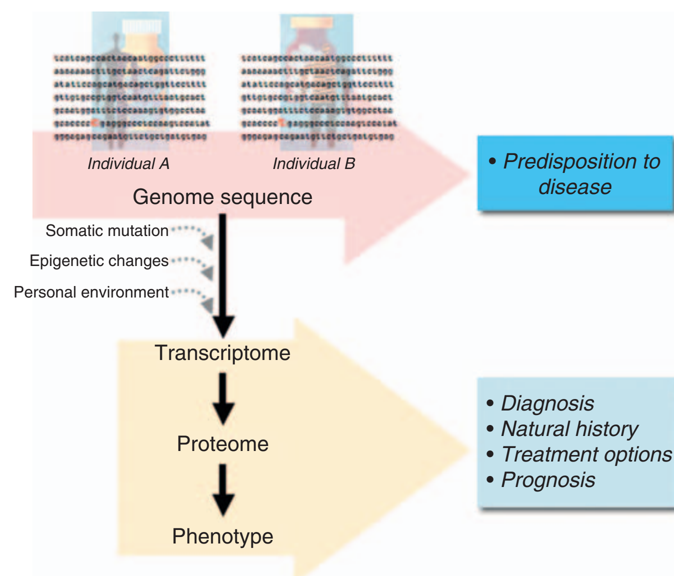

Figure 1.1 The promise of personal genomics in the era of genomic and personalized medicine.

GENES, GENOMES, AND DISEASE

In the context of genomic and personalized medicine, a key question is to what extent genetic variation influences the likelihood of disease onset; determines or signals the natural history of disease; and/or provides clues relevant to the management of disease. Variation in one's constitutional genome can have a number of different direct or indirect effects on gene expression, thus contributing to the likelihood of disease (Frazer et al., 2009). It is not, however, just the human genome whose variation is relevant to an individual's state of health, but there are thousands of microorganisms, both symbiotic and pathogenic, whose genomes are also relevant to human phenotypes, and sequence determination of their genomes is providing new insights and approaches for the diagnosis, study, and treatment of infectious disease (see Box 1.2).

Contemporary frameworks for considering the impact of variation in the human genome on disease build on decades of success in establishing the role of individual, typically rare, mutations as causal determinants of now more than 2000 simple Mendelian diseases (Online Mendelian Inheritance in Man, 2009). As a result of that success, much of which paralleled the development of technologies in the early stages of the Human Genome Project (Altshuler et al., 2008; Peltonen and McKusick, 2001), attention has now turned to the genes presumed to underlie susceptibility to common complex diseases, which are the subject of many of the subsequent chapters in this book.

There are two distinct, but nonexclusive models for thinking about human genetic variation and disease (Altshuler and Clark, 2005; Fearnhead et al., 2005; Florez et al., 2003; Pritchard, 2001). One – the "common allele, common disease" hypothesis – posits that variation common in the population accounts for the relatively higher or lower risk that some individuals (and their families) have for a particular condition. Under this model, the collection of 10–15 million common variants in the genome (see Chapter 2) underlies the range of susceptibility that one finds in the general population, modulated by the particular and often variable environmental inputs and factors that are present in that population and that may, in fact, shift or even obscure the relative impact of inherited factors. An alternative model – the rare variant hypothesis – argues that genetic susceptibility to disease is due to the accumulated risk conferred by multiple rare variants in an individual's genome, variants therefore not likely to be captured by study of the common variants identified by studies to date (Goldstein, 2009).

These two hypotheses suggest different approaches that will likely be informative for delineating the genetic contribution to disease, both for designing research studies and for eventual clinical surveillance. It is worth emphasizing that these two hypotheses are not mutually exclusive and are each likely to be correct in some cases; indeed, there is already evidence supporting each for different diseases (Frazer et al., 2009).

Genome-Wide Association Studies

The common allele, common disease hypothesis has been explored with notable success in a number of conditions, utilizing large cohorts of well-phenotyped patients and high-throughput methods to genotype up to 500,000 or a million variants (so-called single nucleotide polymorphisms [SNPs], see Chapter 2) in the genome (Manolio et al., 2008). These

BOX 1.2 The Genomes Within

The human genome is not the only genome relevant to the practice of medicine.

Both in states of health and disease, our own genome is vastly outnumbered by the genomes of a host of microorganisms, many living peacefully and continuously on various body surfaces, especially throughout the gastrointestinal tract, others wreaking havoc as adventitious viral, bacterial, or fungal pathogens.

The genomes of thousands of microorganisms have been determined and are being utilized to provide rapid diagnostic tests in clinical settings, to predict antibiotic or antifungal efficacy, to identify the source of airborne, water, or soil contaminants, to monitor hospital or community environments, and to better understand the contribution of microbial ecosystems and various environmental exposures to diverse human phenotypes.

The human colon contains more than 400 bacterial species comprising some 10^{13}–10^{14} microorganisms. Each adult's gut provides a unique environment – the *microbiome* – whose origins and impact on human disease are just being explored. The microbiotic gene set is significantly different from that of the human genome and thus has the capacity to alter the metabolic profile of different individuals or different populations, with clinically meaningful effects on drug metabolism, toxicity, and efficacy (Gill et al., 2006; Li et al., 2008; Palmer et al., 2007). The applications to microbiomes of approaches in genomics (as well as proteomics and transcriptomics) are revolutionizing clinical diagnostics, for example, to identify unknown viral infections (Delwart, 2007; Long et al., 2004; Wang et al., 2003) or to diagnose antibiotic-resistance infections such as methicillin-resistant *Staphylococcus aureus* (MRSA) (Francois et al., 2007).

The field of *metagenomics* explores this heterogeneous ecosystem by comprehensive sequence analysis of the collected genomes from biological specimens (such as stool, urine, sputum, water sources, and air), followed by both taxonomic and bioinformatic analysis to deconvolute the many genomes contained in such specimens and to define the different organisms, their genes, and genome variants. This approach is particularly informative for characterizing organisms that cannot be cultured in standard microbiology labs. A number of diseases have been associated with large-scale imbalances in the gut microbiome, including Crohn's disease, ulcerative colitis, antibiotic-resistant diarrhea, and obesity (Frank and Pace, 2008; Ley et al., 2006; Turbaugh et al., 2006).

Undoubtedly, the states of health and disease are determined in part by the balance of genomes both within us and external to us. The full complement of genomic information from both of these sources of genomes will provide insights into defining the states of health and disease and the basis for unsurpassed precision in both the prevention of disease and its treatment.

GWAS report the statistical association of one or more variants in a narrow genomic region (which may or may not contain an annotated gene) with the presence or absence of the clinical condition. The reported SNPs define immediately accessible risk factors for that condition, at least in the population(s) under study and can provide novel insights into the biology of the disease. It should be stressed, however, that in most instances, causality of the reported SNP(s) and the increased risk has not been proved; it may be that the actual causal variant is not the SNP itself but is a currently undetected variant that lies in linkage disequilibrium with the SNP (Frazer et al., 2009).

In the most favorable cases, the associated SNP may be a nonsynonymous variant, leading to a pathological amino acid change in the relevant gene (Thorleifsson et al., 2007), or may be a variant in an RNA splice site, leading to a clinically meaningful change in the production of the gene's transcript(s) (Heinzen et al., 2007). But in most instances, the functional impact of the associated SNP is obscure, notwithstanding very clear genetic evidence of a role of genome variation in susceptibility to the particular condition. SNPs are but one of several types of genome variation that can influence gene expression and/or disease (see Chapter 2). Copy number variants have also been associated with some disorders (reviewed in Estivill and Armengol, 2007), and it will require integrated genomic, genetic and functional studies to elucidate the precise basis for the role(s) of genome variation in different diseases.

Medical Resequencing in Search of Rare Variants

While GWAS certainly establish that common alleles do indeed increase susceptibility to common disease in some instances, they do not allow one to conclude that this is always the case. Indeed, in most (but not all) cases to date, the common SNPs found to be associated with disease only explain a small fraction of the total genetic variation, implicating an as yet undiscovered (and presumably rarer) basis for most genetic variation underlying a given condition. While such association is sufficient to conclude that a particular variant does indeed contribute to disease in the population under study, such a finding is insufficient to say anything declarative about the cause of our likelihood of disease in a particular case. This conclusion is, of course, highly relevant to the prospects of genomic and personalized medicine.

An alternative or complementary approach to genome-wide genotyping of common variants is to resequence specific genes in a cohort of affected individuals, in an effort to uncover rare variants responsible for (or at least statistically associated with) the disease in question. To date, most efforts have focused on one or several genes that were believed to be strong candidates for the phenotype understudy; the notable exception thus far is exemplified by the whole-genome resequencing of the HuRef genome and correlation of novel variants detected in that study with his family and personal medical histories (Levy et al., 2007). Rare variants, including nonsynonymous variants, in relevant candidate genes have been detected at a statistically significant higher frequency in the genomes of patients with colorectal adenomas (Fearnhead et al., 2004), with low-plasma high-density lipoprotein cholesterol (HDL-C) (Cohen et al., 2004), with triglyceride levels in the lowest quartile (Romeo et al., 2007), and with familial cases of X-linked mental retardation (Tarpey et al., 2009).

These successes point to a strategy of resequencing relevant genes in individuals at the extremes of the population distribution for measurable traits (Topol and Frazer, 2007) in which the only limiting parameters are the cost of sequencing and the quality of the phenotypic or quantitative data. In a proof-of-principle for this case-control approach, a recent study sequenced coding exons and splice junctions of 58 genes in nearly 400 obese and lean individuals, at the >95th or <10th percentile of body mass index (Ahituv et al., 2007). Of the ~1000 variants detected, most were rare variants, including over 270 nonsynonymous mutations; many were found only in the obese cohort and thus become strong functional candidates for a role in obesity.

Searching for Somatic Mutations

While GWAS are restricted to inherited variation, medical resequencing studies can target either inherited or somatic variants. In cancer especially, it is of interest to use medical resequencing to search for somatic mutations in tumor tissue in order to identify genes potentially relevant to cancer development and/or progression (Stratton et al., 2009). Two important points emerge from such studies (Greenman et al., 2007; Jones et al., 2009; Sjoblom et al., 2006). First, the genes implicated by virtue of discovering rare somatic variants in multiple cases of a particular cancer tend to be different from those identified in previous genetic studies as inherited risk factors. This provides novel insights into the biology of human cancer and suggests candidates for further exploring mechanisms of tumorigenesis or metastasis or for developing therapeutic approaches. Second, however, the large number of mutations uncovered by this approach introduces the need for caution, as many will be "bystander" or "passenger" mutations only associated with cancer, not genes involved directly in cancer.

FROM THE GENOME TO PERSONALIZED MEDICINE

Of all the promises of the current scientific and social revolution stemming from advances in our understanding of the human genome and its variation, genomic and personalized medicine has been the most eagerly awaited. The prospect of examining an individual's entire genome (or at least a significant fraction of it) in order to make individualized risk predictions and treatment decisions is an attractive, albeit challenging, one (Bentley, 2004; Kraft and Hunter, 2009; Willard et al., 2005).

Having access to the reference human genome sequence has been transformational for the fields of human genetics and

genome biology but by itself is an insufficient prerequisite for genomic medicine. As alluded to above and discussed in subsequent chapters, equally important are the various complementary technologies to reliably capture information on individual genomes, their epigenetic modification, and their derivatives in the transcriptome, proteome, and metabolome for health and disease status (Figure 1.1). Each of these technologies provides information that, in combination with clinical data and evaluation of environmental triggers, will in time contribute to assessment of individual risks and guide clinical management and decision-making. Critical enablers of this new approach have been innovations in laboratory technology (to address biologically and medically relevant questions on a scale and with a throughput hardly imaginable just a few decades ago), paired with equally transforming developments in informatics and information systems to handle the onslaught of genomic data (West et al., 2006).

Personal Genomics

At the heart of the genomic approach to personalized medicine will be information from individual genomes, a fast-moving area of technological development that is spawning a social and information revolution among consumers. Dramatic improvements in sequencing technology (Bentley, 2006; Mardis, 2008) have reduced the cost and time of resequencing projects to a level that invites conjecture about the long awaited "$1000 genome" (Dalton, 2006; Service, 2006; Wolinsky, 2007). The much-ballyhooed release of the genome sequences of Craig Venter ("HuRef") (Levy et al., 2007) and James Watson (Wheeler et al., 2008) has stirred up concerns about "celebrity genomics" (Check, 2007); however, while the Venter and Watson sequences may have been the first, they have been rapidly followed by several others (see Chapter 2), and numerous additional genomes are already in various sequencing pipelines.

What remains unsettled for now is what degree of genome surveillance will be most useful, either for research or for clinical practice, a topic that is discusssed frequently in subsequent chapters. Some have argued that, while whole-genome sequencing is increasingly possible, it is unlikely to provide more information about established disease associations than would high-density, genome-wide genotyping to detect both SNP and copy number variation. Targeted resequencing of, for example, exons and known regulatory regions would allow detection of rare variants in portions of the genome most relevant to disease at a fraction of the cost of whole-genome sequencing (Hodges et al., 2007).

The availability of associated clinical data is variable among the studies announced to date, but there exists, at least among some participants, a strong sense of "health-information altruism" to contribute to the much needed large-scale correlation of genotype and phenotype (Kohane and Altman, 2005). Notwithstanding individual's willingness to make genome sequence data (much less medical information) available more-or-less publicly, substantial concerns have been raised about privacy, since a surprisingly (to some) small number of SNPs or other genome variants are sufficient to allow identification of individuals (Lin et al., 2004; McGuire and Gibbs, 2006; McGuire et al., 2008). Absolute privacy and anonymity may be an impossible standard.

A Consumer Revolution

While the genome revolution has without doubt been driven by technological improvements and by an explosion in the availability of genome data, the push for incorporation of genome information into clinical practice may come as much or more from consumers as from professionals. A half dozen or more companies are already offering genome-wide SNP profiles to the public, some with associated risk estimates for relevant clinical conditions. At least a few companies will also sequence individual genomes for a cost that, while high currently, is not out of reach for some individuals. There is a clear and important research agenda that needs to be developed in concert with these technological breakthroughs that allows health providers and the public to understand the information and more so to believe that is accurate, informative, and actionable (Feero et al., 2008; Hunter et al., 2008; McGuire et al., 2007, 2008). With the vast amount of information contained in the human genome sequence, the stakes are high for patients, physicians, and the public to ensure proper reading, interpretation, and communication of the information are carried out (Janssens et al., 2008). This may be a "disruptive technology" in health care delivery with the provision of health and disease risk information to consumers without physician intervention and guidance. It will not be long before a patient will bring a report of a whole genome to a physician's office and ask for guidance. What will the physicians of today, armed with a paucity of genomic training, tell them?

CHALLENGES IN THE TRANSLATION OF GENOMICS TO HUMAN HEALTH

Despite the clear advances in technology to bring genomic information closer to physicians, patients, and the public, looming ever closer are issues that are outside of the sphere of the scientists that have been involved in the discovery and early translational activities. In the United States, the Institute of Medicine has convened a Roundtable on Translating Genomics to Health (Institute of Medicine, 2007), the Centers for Disease Control has independently developed a pilot project on the Evaluation of Genomic Applications in Practice and Prevention (EGAPP, 2004), and the Genomic and Personalized Medicine Act of 2007 (Personalized Medicine, 2007) was introduced in Congress to also address similar issues.

Recently, Scheuner et al. (2008) carried out an extensive meta-analysis of studies using genomics toward clinical application in chronic disease. This study aimed to understand the current state of translation focusing on the following questions: "What are the outcomes of genomic medicine? What is the current level of consumer understanding about genomic medicine and what information do consumers need before they seek services? How is genomic medicine best delivered? What are the

challenges and barriers to integrating genomic medicine into clinical practice?"

Using a total of 68 articles in their analysis, the authors synthesized information on the delivery of genomic medicine for common adult-onset conditions (Scheuner et al., 2008). The major findings of the study were not surprising in terms of the genome policy issues that have been previously summarized (Haga and Willard, 2006).

- Education – The primary care workforce feels woefully unprepared to integrate genomics into regular practice. Consumers are also unclear about genetics and genetic testing for common diseases.
- Privacy – Consumers are worried about the possible adverse consequences of genetic testing, particularly the privacy issues and discrimination against receiving employment and health insurance.
- Evidence – There needs to be outcome data for genetic testing and chronic disease to assess whether patients who receive the test do better clinically.
- Cost – Cost uncertainty (both in terms of delivery and reimbursement) is an important issue to many of the stakeholders of genomic issues.

Health Professional and Public Education

Education of health professionals and the public will be essential to advancing the use of genomics into health care (Frueh et al., 2005). With all of the rapid advancements in genomics research and technologies, it will be challenging to keep health professionals informed about the benefits, risks, and limitations of new tools as they become available. In addition, the public and health care workforce will need to understand the appropriate applications of genomic tools, including their benefits, risks, and limitations; how they may improve clinical management; inherited versus acquired genomic variations (e.g., implications for family members); and privacy and confidentiality. Although several surveys have documented the below average physician knowledge of genetics (Metcalfe et al., 2002), none has assessed knowledge of the newer field of genomics. But, several papers have been published recognizing the importance of pharmacogenetics (Frueh and Gurwitz, 2004), and steps are underway to develop more educational materials in this area.

Privacy Fears

There has been ongoing debate about the uniqueness of genetic information and whether it warrants special protections beyond those in place for standard medical information (Haga and Willard, 2006). In the United States, fear of discrimination by employers and health insurers is the main concern, whereas in the United Kingdom, use of genetic information by life insurers is the major concern (Apse et al., 2004; Hall et al., 2005). Despite the outcome of these debates, the attention paid to genetics by the popular press and public has raised concern about genetic information. The potential for genetic discrimination has been a major concern for researchers, health professionals, patients, and the public. In order for genomic biomarkers to be integrated into routine clinical practice, associated fears with this type of testing must be put to rest. In 2008, the United States enacted legislation to protect against genetic discrimination by employers and health insurers. This is an important step in allaying public fears that may otherwise hinder a comprehensive genomic and personalized approach to medicine.

Building the Evidence for Clinical Utility

Perhaps the most important factor hindering the appropriate integration of genomics into clinical practice is the lack of evidence for its clinical utility (i.e., evidence that use of a genomic technology actually improves health outcomes). Evidence generation needs to be more practicable and practical. There is also a need for greater collaboration among stakeholder groups and for innovation in both study design and analysis methods. Clinical outcome studies are needed that demonstrate the clinical utility of genomic interventions that are linked to specific, actionable clinical recommendations, or practice guidelines. Public–private partnerships are likely to be required to generate the evidence base for genomic medicine. These collaborations are desirable because no signal stakeholder group is likely to have sufficient resources or expertize to conduct the necessary studies.

Cost Issues

As with any new innovation, genomic testing must be demonstrated to be clinically useful and cost effective and of value. But, because genomic technologies inherently involve diagnostic or prognostic testing, in addition to the complexities of incomplete gene penetrance and multiple gene × environment interactions, their assessment can be more challenging. In addition, perhaps more than in any other area of medicine, questions have arisen in regard to the economic incentives to develop these technologies. Formal health economics frameworks can be used to gain insights into these issues and provide guidance for research and development (Carlson et al., 2005; Flowers and Veenstra, 2004; Stallings et al., 2006). It is important to examine the drivers of cost effectiveness of genomic technologies and to consider approaches that include value-based reimbursement for genomic testing technologies. A particularly challenging area is pharmacogenomics, in which the economic incentives for developing diagnostics linked to therapeutics in the pharmaceutical industry are unclear. An integrated business model is needed that will be favorable for the effective delivery of genomic information to patients and clinicians.

THE FUTURE OF PERSONALIZED MEDICAL CARE

While the human genome sequence is now available, it is important to acknowledge that our knowledge of the genome and its biological complexity is nowhere near complete, and the use of genomic protocols in standard clinical care faces many challenges. There are a host of clinical, economic, insurance, privacy, and

commercialization concerns that will need to be addressed and that vary substantially among different countries. As a field, we can confront those with the certainty that the science behind genomic medicine is sound and the practice of medicine that it informs is evidence based. These issues are being dealt with systematically, and the prospects of using genomic information to offer patients health care that is truly personalized in nature – as will clearly see in the subsequent chapters – is finally within our reach.

CHAPTER

Organization, Variation and Expression of the Human Genome

Huntington F. Willard

INTRODUCTION

The genetic variation that can influence health and disease has been a central, if not widely practiced, principle of medicine for over a hundred years, since the prescient observations of the British physician Sir Archibald Garrod established the concept of "chemical individuality" over a century ago (Garrod, 1902). What has limited broad application of this principle until now has been the generally presumed rarity or special nature of clinical circumstances or conditions to which genetic variation was relevant – rare disorders such as Garrod's alkaptonuria, inherited conditions limited to specific populations such as sickle cell anemia, or specialized situations such as the role of ABO incompatibility in blood transfusion. Now, however, with the availability of a "reference sequence" of the human genome, with emerging appreciation of the extent of genome variation among different individuals, and with a growing understanding of the role of common, not just rare, variation in disease, we are poised to begin to exploit the impact of that variation on human health on a broad scale, in the context of genomic and personalized medicine.

Variation in the human genome has long been the cornerstone of the field of human genetics, and its study led to the establishment of the medical specialty of medical genetics (Nussbaum et al., 2007). A crucial set of connections joining Mendel's principles of heredity, Garrod's concept of chemical individuality, the practice of medicine and the sequence of the genome came with Pauling's discovery of the molecular basis of sickle cell anemia and the direct correspondence between an individual's genetic make-up and the type of hemoglobins present in that individual's red cells (Pauling et al., 1949). The general nature and frequency of gene variants in the human genome became apparent with the classic work in the 1960s on the incidence of polymorphic protein variants in populations of healthy individuals (Harris and Hopkinson, 1972; Lewontin, 1967; reviewed in Harris, 1980).

Calculations based on those protein polymorphism data – now extended in a robust and comprehensive manner with the analysis of variation on a genome scale – lead to the inescapable conclusion that virtually every individual should be found to have his or her own unique constitution of gene products, the implications of which provide a conceptual foundation for what today we call "personalized medicine" as a new-age rediscovery of Garrod's "chemical individuality." Thus, with the availability of the human genome sequence (International Human Genome Sequencing Consortium, 2001, 2004; Venter et al., 2001) and determination of the extent of human genome variation, both within and among populations (International HapMap Consortium, 2003, 2007) and within individual genomes (Levy et al., 2007; Wheeler et al., 2008), awareness of widespread human variation can begin to be applied generally to the exploration of common human disease.

In this chapter, the organization, variation and expression of the human genome is presented as a foundation for the many chapters to follow on human genomics, on genome technology and informatics, on approaches in translational genomics and, finally, on the principles of genomic and personalized medicine as applied to specific diseases.

THE HUMAN GENOME

The typical human genome consists of approximately 3 billion (3×10^9) bp of DNA, divided among the 24 types of nuclear chromosomes (22 autosomes, plus the sex chromosomes, X and Y) and the much smaller mitochondrial chromosome (Tables 2.1, 2.2). The genome can be represented and evaluated in different ways, with different levels of resolution and degrees of sensitivity, depending on the clinical need (Figure 2.1).

Individual chromosomes can best be studied at metaphase in dividing cells, and karyotyping of patient chromosomes has been a valuable and routine clinical laboratory procedure for decades (Trask, 2002); various staining or hybridization-based analytical techniques have the ability to detect chromosome abnormalities ranging from an extra or missing whole chromosome (aneuploidy), to translocations or rearrangements involving just a portion of a chromosome(s), to deletions or duplications involving as little as perhaps a megabase (10^6 bp; Mb) of DNA.

More recent technologies involving overlapping sets (called "tiling paths") of isolated segments of the genome arrayed on microscope slides have provided vastly improved resolution and precision capable of evaluating in a rapid and comprehensive way the proper dosage (and in some cases the organization) of the corresponding DNA segments within an individual's genome (Figure 2.1b) (see Chapter 5). The ultimate resolution, of course, comes from direct sequence analysis, and a number of new technologies have reduced the cost and improved the throughput of sequencing individual genomes, facilitating comparisons with the reference human genome sequence and enabling medical resequencing of patient samples (see later section in this chapter) to search for novel variants or mutations that might be of clinical importance (Bentley, 2006) (Figure 2.1c, d) (see Chapter 3).

Genes in the Human Genome

While the human genome contains a currently estimated 20,000–25,000 genes (Clamp et al., 2007; International Human Genome Sequencing Consortium, 2004), the coding segments of those genes comprise less than 2% of the genome; as represented in Figure 2.1c, most of the genome, therefore, consists of DNA that lies between genes, far from genes or in vast areas spanning several Mb that appear to contain no genes at all ("gene deserts"). A *caveat* for this statement is that the process of gene identification and genome annotation remains very much a work-in-progress; despite the apparent robustness of recent estimates (Clamp et al., 2007), it is conceivable that

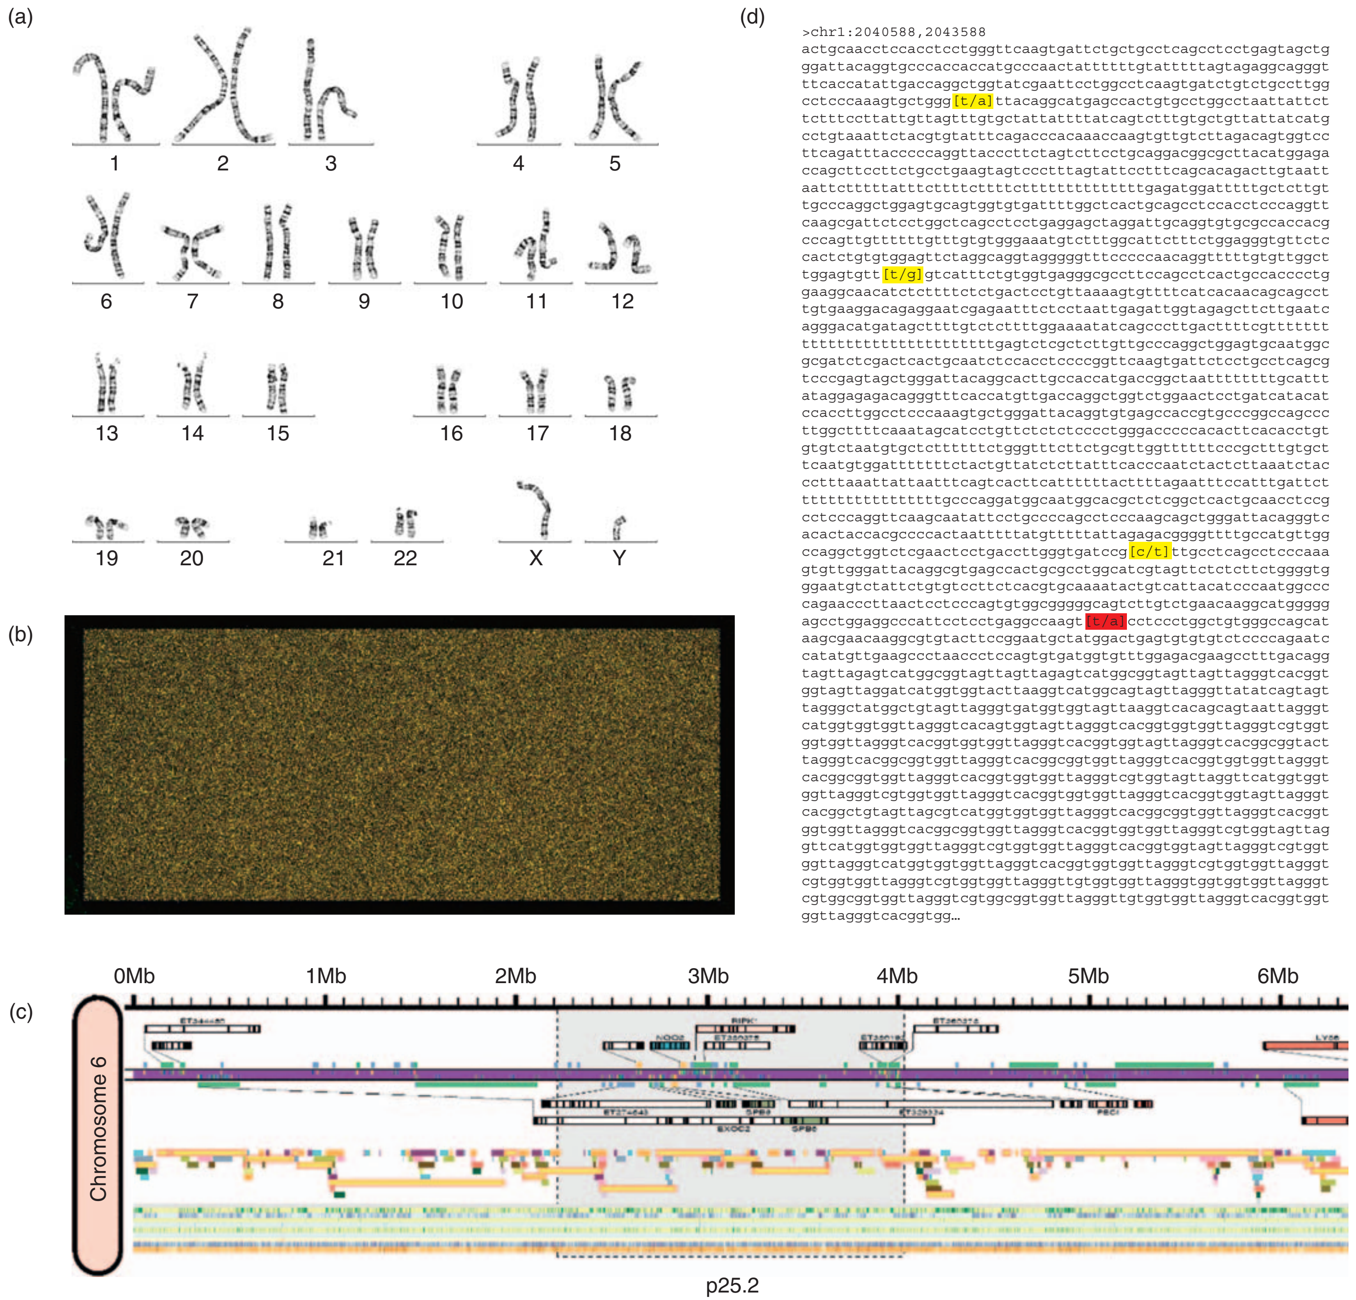

Figure 2.1 Four views of the human genome. (a) Karyotype of a normal male donor, HuRef, whose genome was the first individual diploid genome to be sequenced (Levy et al., 2007). The 24 types of human chromosome are shown after conventional G-banding – 22 pairs of autosomes and the two sex chromosomes, X and Y. (b) An array of genomic segments, showing 244,000 genomic elements hybridized to DNA from HuRef. (c) Schematic representation of the content of ~6 Mb from the short arm of chromosome 6, including the location of various genes and other features from the HuRef genome. (d) DNA sequence from the genome of James D. Watson, showing 3000 bp from chromosome 1. Watson's sequence is heterozygous at four positions, three (in yellow) that are known polymorphisms in various populations and one (in red) that is a novel variant. Figures in (a) and (b) were provided courtesy of Steve Scherer, Hospital for Sick Children, Toronto, Canada. (c) is part of a large poster representing the complete diploid HuRef genome (Levy et al., 2007).

there are some genes, including clinically relevant genes, that are currently undetected or that display characteristics that we do not currently recognize as being associated with genes. A maximum of 5% of the genome consists of DNA that has been quite well conserved through evolution, one indication of an important function. These and other considerations have led to the estimate that at most 20% of the genome is of functional importance (Pheasant and Mattick, 2007). Nonetheless, the statement that the vast majority of the genome consists of spans of DNA that are non-genic, of no obvious function, and of uncertain clinical relevance remains true.

In addition to being relatively sparse in the genome, genes are distributed quite non-randomly along the different human chromosomes. Some chromosomes are relatively gene-rich, while others are quite gene-poor, ranging from a high of ~22 genes/Mb to a low of ~3 genes/Mb (excluding the Y chromosome and the mitochrondrial chromosome) (Table 2.2). And even within a chromosome, genes tend to cluster in certain regions or in particular bands, a point of clear clinical significance when evaluating genome integrity, dosage or arrangement in different patient samples.

Coding and Non-Coding Genes

There are a number of different types of gene in the human genome. Most genes are protein-coding and are transcribed into messenger RNAs (mRNAs) that are ultimately translated into their respective proteins; their products comprise the list of enzymes, structural proteins, receptors and regulatory proteins that are found in various human tissues and cell types. However, there are additional genes whose functional product appears to be the RNA itself. These so-called non-coding RNAs (ncRNAs) have a range of functions in the cell, and some do not as yet have any identified function. But the genes whose transcripts make up the collection of ncRNAs represent about a sixth of all identified human genes (Table 2.1).

Some of the types of ncRNA play largely generic roles in cellular infrastructure, including transfer RNAs (tRNAs) and ribosomal RNAs (rRNAs) involved in translation of mRNAs on ribosomes, spliceosomal RNAs involved in control of RNA splicing, and small nucleolar RNAs (snoRNAs) involved in modifying rRNAs (Griffiths-Jones, 2007; Mattick and Makunini, 2006). Other ncRNAs play roles in gene regulation, for example in epigenetic gene silencing (Ogawa and Lee, 2002).

A class of small RNAs of growing importance are the microRNAs, ncRNAs of only ~22 bases in length that suppress translation of target genes by binding to their respective mRNAs and thus regulate protein production from the target transcript(s) (Filipowicz et al., 2008). Some 255 microRNA genes were identified in the human genome initially (Lim et al., 2003), although the total number of such genes is now thought to be closer to 1000 (Bentwich, 2005; Griffiths-Jones, 2007) (Table 2.2). Some are evolutionarily conserved, while others appear to be of quite recent origin during primate evolution, thus underscoring the difficulty of determining the precise number and identity of human genes (Clamp et al., 2007). MicroRNAs have been shown to downregulate hundreds of mRNAs each, with different combinations of target RNAs in different tissues (Lim et al., 2005); combined, the microRNAs are thus predicted to control the activity of as many as 30% of all protein-coding genes in the genome (Filipowicz et al., 2008). While this is a fast-moving area of genome biology, several microRNAs have already been implicated in various human diseases, including cancer, developmental disorders and heart disease (Chang and Mendell, 2007; van Rooij et al., 2008).

Genome Composition and Landscape

As observed earlier, the distribution of genes in the genome is non-random, both within and between chromosomes. This in part is a reflection of the distribution of different types of DNA sequence, as the genome is partitioned into domains spanning hundreds of kilobasepairs to megabases, reflecting large-scale variation in the G+C content of DNA. These so-called "isochores" have been known for decades and, at a very gross level, mimic the pattern of light- and dark-staining bands that one observes in metaphase chromosomes (e.g., Figure 2.1a, c) (Eyre-Walker and Hurst, 2001). While the driving force behind the evolution of isochores is not clear, they influence the G+C content of genes contained within them (and, by virtue of the genetic code, therefore, the amino acid composition of the encoded proteins), the patterns of mutation and polymorphism detected, and the nature of various families of repeated DNA that reside there. Further – and most strikingly – different isochore domains contain clusters of genes that are highly or weakly expressed in a coordinated manner in different tissues (Caron et al., 2001; Gierman et al., 2007; Hurst et al., 2004). Thus, isochores reflect both the functional as well as structural organization of the genome. (See later section on "Expression of the Human Genome" for further discussion.)

VARIATION IN THE HUMAN GENOME

With completion of the reference human genome sequence, attention turned to the discovery and cataloging of variation in that sequence among different individuals (including both healthy individuals and those with various diseases) and among different populations. It has been estimated that there are some 10–15 million common sequence variants that are of sufficient frequency (minor allele frequency >5%) in one or more populations to be considered polymorphic in our species. In addition, there are countless very rare variants, many of which probably exist in only a single or a few individuals. In fact, given the number of individuals in our species, essentially each and every base pair in the human genome is expected to vary in someone somewhere around the globe. It is for this reason that the original genome sequence is considered a "reference" sequence, derived as a consensus of the limited number of individual

Table 2.3 Common variation in the human genome

Type of variation	Size range (approx.)[a]	Effect(s) in biology and medicine
Single nucleotide polymorphisms (SNPs)	1 bp	Non-synonymous ⟶ functional change in encoded protein? Others ⟶ potential regulatory variants? Most ⟶ no effect? ("neutral")
Copy number variants (CNVs)	10 kb to 1 Mb	Gene dosage variation ⟶ functional consequences? Most ⟶ no effect or uncertain effect
Insertion/deletion polymorphisms (in/dels)	1 bp to 1 Mb	In coding sequence: frameshift mutation? ⟶ functional change Most ⟶ uncertain effects
Inversions	Few bp to 100 kb	? break in gene sequence ? long-range effect on gene expression ? indirect effects on reproductive fitness Most ⟶ no effect? ("neutral")
Segmental duplications	10 kb to >1 Mb	Hotspots for recombination ⟶ polymorphism (CNVs)

[a]Abbreviations: bp = basepair; kb = kilobasepair; Mb = megabasepair.

genomes whose sequencing was part of the Human Genome Project, but actually identical to no individual's genome.

Types of Variation

Early estimates were that any two randomly selected individuals have sequences that are 99.9% identical or, put another way, that an individual genome would be heterozygous at approximately 3–5 million positions, with different bases (i.e., a T or a G) at the maternally and paternally inherited copies of that particular sequence position. The majority of these differences involve simply a single unit in the DNA code and are referred to as single nucleotide polymorphisms (SNPs) (Table 2.1) (see Chapter 3). The remaining variation consists of insertions or deletions (in/dels) of (usually) short sequence stretches, variation in the number of copies of repeated elements or inversions in the order of sequences at a particular locus in the genome (Figure 2.2). The total amount of in/del variation is more than originally anticipated and approaches 0.5%, not 0.1%, between any two randomly selected individuals (Levy et al., 2007). Any and all of these types of variation can influence disease and thus must be accounted for in any attempt to understand the contribution of genetics to human health (Table 2.3).

While the overall estimate of SNP heterozygosity is approximately 1 in 1500 bp, there is much more variation in non-coding sequences than in the coding segments of genes, reflecting strong selective pressure during evolution against certain types of change in gene sequences. The combination of particular alleles along chromosomes is also non-random, with particular combinations (haplotypes) being more prevalent over short distances, due to the relative inefficiency of meiotic recombination to separate alleles at sites that are physically close together (International HapMap Consortium, 2007; Nussbaum et al., 2007). The resulting patterns of linkage disequilibrium are relevant for designing strategies to examine genetic variation genome-wide, both as a practical matter (i.e., reducing the number of SNPs that need to be tested to reveal the underlying patterns of variation) and for evaluating the potential functional importance of any particular SNP allele (see Chapters 4 and 15).

Copy Number Variation

Over the past few years, a number of important studies have identified a previously unanticipated prevalence of structural variants in the genome, which collectively account for more variation in genome sequence than do SNPs (e.g., Levy et al., 2007; Redon et al., 2006; Sebat et al., 2004; Tuzun et al., 2005). The most common type of structural variation involves changes in the local copy number of sequences (including genes) in the genome, and these are generally referred to as copy number variants (CNVs) (Figure 2.2) (see Chapter 5).

A number of different technology platforms are now being used to detect CNVs, including arrays and direct genome sequencing (Korbel et al., 2007; Levy et al., 2007; Wong et al., 2007). As many such CNVs encompass genes (including microRNA genes; Wong et al., 2007) and as a significant number of novel CNVs are uncovered with every new population studied, a dedicated effort is underway to cataloged CNVs in the human genome worldwide and to associate these with clinical phenotype (Feuk et al., 2006; Scherer et al., 2007; Sharp et al., 2006). While most variation of this type is inherited, some CNVs occur *de novo* or even in somatic cells; in these cases, an individual will have different repeat lengths than do either of his or her parents.

Array-based methods (see Chapter 5) have rapidly gained acceptance for evaluating the association of both inherited and *de novo* CNVs with mental retardation and other developmental disorders (de Vries et al., 2005; Friedman et al., 2006; Lee et al., 2007; Weiss et al., 2008). It is of considerable ongoing interest to

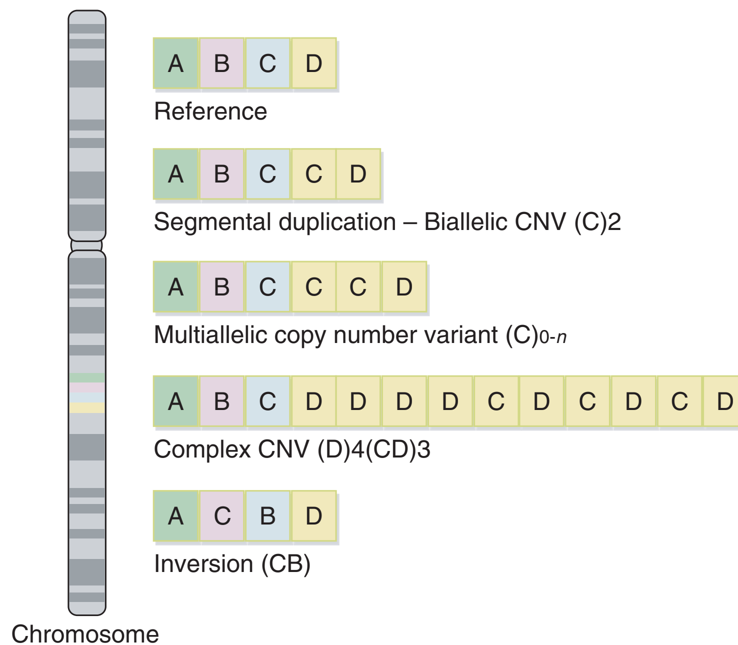

Figure 2.2 Schematic representation of different types of structural polymorphism in the human genome, leading to deletions, duplications, inversions and CNV changes relative to the reference arrangement. From Estivill and Armengol (2007), with permission.

evaluate the role of CNVs and other structural variants including deletions (Conrad et al., 2006) and inversions (Korbel et al., 2007; Stefansson et al., 2005; Tuzun et al., 2005) in the etiology of more common, complex diseases or traits of adulthood, including neurological and psychiatric conditions as well as pharmacogenetic traits (Beckmann et al., 2007; Buckland, 2003).

Variation in a Single Genome

The most extensive current inventory of the amount and type of variation to be expected in any given genome comes from the direct analysis of the diploid genome sequence of a single male individual, HuRef (Levy et al., 2007). Over 4 million variants were described, spanning some 12.3 Mb of DNA. About 20 Mb of "new" sequence was determined that was not previously available as part of the human reference sequence, reflecting in part the still unfinished nature of the human genome sequence and in part the particular patterns of inserted or deleted sequences that distinguish different genomes. Several hundred thousand in/dels were also found in this single genome. In addition, several hundred CNVs were detected, which overlapped at least 95 well-annotated genes. While most of these variants are identical to those found in other individuals in the population, others are likely to be what are termed "private" mutations, specific to HuRef and his family.

In the HuRef genome, at least 850 genes known to be involved in inherited disease contained at least one heterozygous variant, and over 300 of them contained at least one non-synonymous SNP (i.e., a SNP that, by virtue of the genetic code, is predicted to change the encoded amino acid). Of course, additional genes may also impact disease, and, overall, more than 4000 genes in the HuRef genome contained one or more non-synonymous SNP. Thus, at least 17% and perhaps as many as 44% of the genes in the HuRef genome were heterozygous and could encode proteins that differ in their amino acid sequence and/or are produced in different amounts (Levy et al., 2007). These estimates underscore the impact of gene and genome variation on human biology and on medicine. They also provide remarkable validation of the original estimates of Harris and Lewontin decades ago of the proportion of genes that are heterozygous in any given individual (Harris, 1980; Lewontin, 1967).

Table 2.3 and Figure 2.2 capture the general types of and characteristics of the most common variation in the human genome and in human genes. However, it is clear that we are still in a mode of discovery, as relatively few genomes or populations have been assessed to date; no doubt millions of additional SNPs remain to be uncovered, as well as many additional in/dels, inversions and CNVs, a portion of which will be expected to involve genes and other sequences of direct relevance to medicine. The issue of "what is normal?" – an essential concept in clinical medicine – remains very much an open question when it comes to the human genome (Shianna and Willard, 2006).

Variation in Populations

Most of the heterozygosity in the human genome is believed to be due to variants with a minor allele frequency of at least

1%. Taking advantage of major technological developments that have greatly increased the throughput of genotyping on a genome-wide scale, several large-scale projects have validated these estimates by gathering genotypic information on millions of SNPs worldwide (Hinds et al., 2005; International HapMap Consortium, 2003, 2007). Most of the studies to date, however, have been restricted to a small number of populations of Northern European, African and Asian origin used for SNP detection. From these and a large number of earlier studies that examined more populations but for many fewer variants, it has been concluded that some 85–90% of the variation found in our species is shared among different population groups; a relative minority of variants, therefore, are specific to or highly enriched/depleted in genomes from a particular population.

It is possible to use population-specific variants to obtain information on the geographic origin of a genome or of particular segments within a genome. Given the many millions of SNPs now available, there are at least hundreds of thousands of SNPs that are informative for such studies (so-called "ancestry informative markers," AIMs) (Kittles and Weiss, 2003; Paschou et al., 2007; Tian et al., 2008). This had led to two related, but distinct applications of such markers. First is the use of admixture mapping, tracing the location of particular SNPs associated with disease in populations of patients whose genomes are a mixture from at least two original populations, for example, African-Americans or Latinos (Price et al., 2007; Smith et al., 2004). Such an approach has already been used to map genes associated with several phenotypes whose frequency differs markedly between different population groups, including prostate cancer (Freedman et al., 2006), hypertension (Deo et al., 2007), skin pigmentation (McEvoy et al., 2006) and white blood cell count (Nalls et al., 2008).

The second use of AIMs is for ancestry testing unrelated to disease studies (Kittles and Weiss, 2003; Shriver and Kittles, 2004). While the motivations behind such testing and the potential uses (and, some fear, abuses) of biogeographic information are varied, the commercial availability and interpretation of genetic ancestry testing is controversial (Bolnick et al., 2007). Nonetheless, the availability of such information as an intentional or unwitting by-product of wide-scale genome analysis is inevitable, and both consumers/patients and health professionals need to be aware of this as genetic variation is explored in the context of individual genomes (see Chapter 18).

EXPRESSION OF THE HUMAN GENOME

A key question in exploring the origins, structure and function of the human genome is to understand how proper expression of our 20,000–25,000 genes is determined, how it can be influenced by either genetic variation or by environmental exposures or inputs, and by what mechanisms such alterations in gene expression can lead to pathology evident in the practice of clinical medicine. The control of gene activity – in development, in different tissues, during the cell cycle, and during the lifetime of an individual both in sickness and in health – is determined by a complex interplay of genetic and epigenetic features.

By "genetic" features, we here refer to those found in the genome sequence, which plays a role, of course, in determining the identity of each gene, its particular form (alleles), its level of expression (regulatory elements such as promoters, enhances, splice sites, etc.), and its particular genomic landscape (domains, isochores). By "epigenetic" features, here we mean packaging of the DNA into chromatin, in which it is complexed with a variety of histones as well as innumerable non-histone proteins that influence the accessibility and activity of genes and other genomic sequences. The structure of chromatin – unlike the genome sequence itself – is highly dynamic and underlies the control of gene expression that shapes in a profound way both cellular and organismal function (Felsenfeld and Groudine, 2003).

Genomic and Epigenomic Aspects of Gene Expression

Identifying the genomic sequences and features that direct spatial and temporal aspects of gene expression remains a formidable challenge in genome annotation. While several decades of work in molecular biology have defined critical regulatory elements such as promoters and enhancers for many individual genes, it is a tall order to perform such studies on a genome-wide scale.

At the genetic level, such studies have depended on identifying highly conserved elements, whose demonstrated sequence conservation over, in some cases, hundreds of millions of years provides *prima facie* evidence of their importance (Bejerano et al., 2004; Margulies et al., 2003). Several such ultraconserved elements have been validated *in vitro* as gene enhancers, providing some confidence that others identified in this way will also play a role in regulating gene expression (Pennacchio et al., 2006). However, by definition, such approaches will overlook regulatory elements that are not well conserved at the sequence level and/or that are newly evolved on the human lineage.

A complementary epigenetic approach has been to explore the characteristics of chromatin that are associated with active or repressed genes as a step towards identifying the transcriptional regulatory code for the human genome (Barrera and Ren, 2006; Bernstein et al., 2007). Such studies, largely employing the method of chromatin immunoprecipitation followed by array or sequence analysis (Hawkins and Ren, 2006), have uncovered predictive chromatin "signatures" for promoters and enhancers in the human genome (Heintzman et al., 2007; Kim et al., 2005). These analyses are part of a broad effort to explore epigenetic patterns in chromatin genome-wide to better understand control of gene expression in different tissues or disease states (ENCODE Project Consortium, 2007; Brena et al., 2006).

Increasing evidence points to a role for epigenetic changes in human disease in response to environmental influences

(Feinberg, 2007). The dynamic nature of epigenetic regulation – changes in DNA methylation or in histone modification over time, between different tissues, or in various disease states – allows for what has been called "phenotypic plasticity," relevant both to the origins and potential treatment of disease (Feinberg, 2007) (see Chapter 6). That monozygotic twins (who share identical genomes, but are frequently discordant with respect to clinical phenotypes) show epigenetic differences in DNA methylation demonstrates the potential for epigenetic effects to extend or modify information contained in the genome and thus to underlie at least some phenotypic differences (Fraga et al., 2005).

Allelic Imbalance

Other than well-known examples of monoallelic gene expression where only one of the two copies of a gene in a diploid cell is expressed (such as genomic imprinting and X chromosome inactivation; Nussbaum et al., 2007), it is commonly assumed that the vast majority of autosomal genes in the genome are expressed from both homologs at comparable levels. Recent evidence, however, using expressed SNPs to distinguish transcripts from the two alleles, has demonstrated widespread differential allelic expression for up to 20% of genes in the genome (Serre et al., 2008). This phenomenon, whose epigenetic or genetic basis is unknown, may be related to similar variability observed among X-linked genes in heterozygous females (Carrel and Willard, 2005). Further complexity is suggested by the finding of monoallelic gene expression, random with respect to parental origin, for approximately 5% of genes tested (Gimelbrant et al., 2007). This is an area of ongoing study and further implicates interactions between the genome and epigenetic control mechanisms as a determinant of gene expression in the human genome.

Genetic Control of Gene Expression Levels

It has been appreciated for decades that there is high variability in gene expression levels among individuals. A number of groups have begun to examine this variation as a complex quantitative trait, under genetic control (Cheung and Spielman, 2002). Several thousand loci exhibiting such variation have now been studied, and the factor(s) controlling the variation mapped around the genome (Cheung et al., 2005; Morley et al., 2004; Stranger et al., 2007a, b). A significant proportion of such effects map to the genes themselves, a result consistent with local sequence variation influencing the expression of such genes; many such local regulatory variants map to the promoter region of the gene or to the 3′ untranslated region (Cheung et al., 2005). Most of the mapped variation could be accounted for by SNP variation, but nearly 20% was due to CNVs (Stranger et al., 2007a, b), underscoring the functional importance of this type of genome variation. It is likely (though unproven in specific instances) that the discovered regulatory variants will correlate with the patterns of epigenetic modifications described earlier (Heintzman et al., 2007; Kim et al., 2005) and with the finding of widespread allelic imbalance around the genome (Serre et al., 2008).

Other determinants of gene expression variation map not to the variable locus itself, but to another locus elsewhere in the genome. This implies a network of regulatory interactions among different gene products in the cell, a finding that lends itself to a systems biology approach to begin to better define such networks.

Some of the differences in gene expression also vary among populations. Where examined, the phenotypes are attributable to common genetic variants that are more common in particular populations than in others (Spielman et al., 2007; Stranger et al., 2007a, b). These findings, therefore, may be relevant to complex genetic diseases whose prevalence differs among populations.

GENOME SEQUENCING

As described in the previous chapter, the cost of sequencing whole genomes is falling rapidly, with a number of new technologies that will soon invite practical consideration of if, when and how to introduce genome sequencing into medical practice (Mardis, 2008). The highly publicized release of the genome sequences of Craig Venter ("HuRef") (Levy et al., 2007) and James Watson (Wheeler et al., 2008) have been followed by the full sequences of at least four other genomes (*see 2009 Update*), and numerous additional genomes are already well underway (Table 2.4).

Table 2.4 Individual sequenced human genomes (as of May 2009)

Individuals	Nature of genome	Method	Year completed/ anticipated	References
"RP11"[a]	Partial haploid	Sanger sequencing	2003	Osoegawa et al., 2001; International Human Genome Sequencing Consortium, 2001

2009 UPDATE

The past year has seen enormous progress in our understanding of the human genome, especially in three areas: genetic variation among different individuals, magnitude and role of structural variation in genetic disease, and widespread transcription of the human genome.

With now six individual human genomes having been sequenced, from at least four geographically and/or ethnically distinct populations (Northern Europe, China, Korea and Nigeria) (see Table 2.4), it is possible to get a precise view of the amount of genetic variation to be found between any two individuals. Each of the sequenced genomes has revealed approximately 3–4 million SNPs, of which at least 15–30% are considered "novel," having not been previously documented. It is thus clear that much human genetic variation remains to be

discovered. Consistent with previous analyses involving smaller data sets, the average (autosomal) heterozygosity is about 1 SNP per 1300 bp, although this figure is significantly higher (1 SNP per 1000 bp) in a Yoruba genome from Nigeria, reflecting the higher level of genome diversity expected in African populations (Bentley et al., 2008; Tishkoff et al., 2009). Relevant to consideration of potential phenotypic effects of SNP variation, each of the sequenced genomes contained about 4000–5000 SNPs in coding sequences that would be predicted to result in a nonconservative amino acid change in the encoded protein, as well as over a hundred premature stop codons (Bentley et al., 2008; Levy et al., 2007; Wheeler et al., 2008). These become attractive candidates for functional studies.

SNPs represent only one type of human genetic variation. As initially tallied by Levy et al. (2007), far more variation between genomes can be accounted for by structural variants (insertions, deletions, inversions and copy number variants [CNVs]) (Kidd et al., 2008; Levy et al., 2007). While the exact amount of DNA involved is a matter of ongoing investigation, a comparison of two "typical" genomes appears to suggest about 99.5% identity, reflecting a higher level of sequence variation than widely popularized in the years immediately following the initial human genome sequence.

Eichler and colleagues (Itsara et al., 2009) examined the distribution of large CNVs in the general population, studying the genomes of some 2500 individuals. They found variants greater than 500 kb in size in 5–10% of individuals, with variants >1 Mb in 1–2% of the population. Given the large number of subjects examined, they could provide robust estimates of the excess of CNVs found in patients with autism, mental retardation and schizophrenia (Need et al., 2009; Stefansson et al., 2008; Sebat et al., 2007; Walsh et al., 2008), highlighting the phenotypic importance of rare copy number variation in the human genome. The role of such CNVs in human disease is particularly apparent in neuropsychiatric conditions (Cook and Scherer, 2008).

In addition to studies of genetic variation, recent work has greatly increased understanding of the genome itself and its transcription. Long-standing estimates had indicated that about 2% of the genome was transcribed into genic segments. It is clear now, however, that there is substantially more transcription that previously appreciated (see main chapter). Two particular classes of noncoding RNA (ncRNA) have emerged that greatly challenge preconceptions about what "genes" are and how one evaluates what is "important" in the genome. Both small and long ncRNAs, especially in promoter regions of genes, are predominant in transcriptome studies (Affymetrix ENCODE Transcriptome Project, 2009; Carninci, 2009). More generally, on the basis of telltale chromatin signatures in otherwise evolutionarily nonconserved portions of the genome, over a thousand large ncRNAs up to 20 kb in size were discovered (Guttman et al., 2009). This class of ncRNAs, initially uncovered nearly 20 years ago in the case of the *H19* and *XIST* noncoding genes, has been speculated to be involved in transcriptional control.

Application of new sequencing platforms to transcription profiling (so-called "RNA seq") has permitted global views of transcription and RNA processing (Wang et al., 2009). This approach has provided particular insight into genome-wide patterns of alternative splicing, its abundance and tissue-specificity (Castle et al., 2008; Pan et al., 2008; Sultan et al., 2008). Lastly, in a proof-of-concept study, RNA seq was used to detect novel gene fusions in a series of cancer cell lines and tumors (Maher et al., 2009).

It is clear that the availability of next-generation sequencing capability is revolutionizing the study of the human genome, its variation, its expression and its perturbation in disease.

CHAPTER

DNA Sequencing for the Detection of Human Genome Variation

Samuel Levy and Yu-Hui Rogers

INTRODUCTION

The discovery and characterization of DNA polymorphisms in human populations is an important step toward understanding the contribution of genome sequence variants to predisposition, onset and progression of disease phenotypes. By way of example, molecular epidemiology studies have been able to establish the importance of the wide range of DNA variants that cause monogenic disorders such as cystic fibrosis, where over 1000 mutations in the CFTR gene have been identified and implicated in the disease phenotype (Rowntree and Harris, 2003). The impact of the mutational landscape of the CFTR gene on biological function is complex, and emerging evidence implicates additional modifier genes contributing to the range of disease phenotypes observed (Davies et al., 2005). The situation is likely to be compounded further when identifying and characterizing the contribution of multiple genetic loci to phenotypes found in polygenic diseases such as coronary heart disease, diabetes and hypertension (see Chapter 2). While our understanding of how polymorphisms can contribute either singly or collectively to either disease onset or progression is still actively being developed, so too are the technologies that enable their detection and ascertainment in human populations.

Human DNA polymorphism detection has been greatly empowered in the last decade by the production of a high quality, mostly finished, DNA sequence of the human genome. The production of this sequence, and the fact that several distinct DNA sources were employed, enabled the direct identification of 2.1 million single nucleotide polymorphisms (SNPs) (Lander et al., 2001; Venter et al., 2001) to supplement those already found in the public variant databases (dbSNP). The discovery of these SNPs in a small number of humans set the stage for an ambitious experiment, the HapMap project, to define common haplotypes through the use of 4 million SNP types in 269 distinct humans (Consortium, 2005). It is anticipated that these datasets will enable the identification of a set of informative SNPs with which disease association studies can be accomplished with improved success. Indeed, early successes highlighting the utility of the HapMap data in identifying alleles implicated in complex diseases such as asthma (Laitinen et al., 2004), age related macular degeneration (Klein et al., 2005) and type II diabetes (Sladek et al., 2007), amongst others, have clearly set the stage for more studies of this kind (see Chapter 4). Essentially, one potential study design would likely involve the use of SNPs as markers for a disease in an affected DNA population compared to a control DNA population. Subsequently, any marker statistically associated with the disease group would inform the genomic loci requiring further sequence analysis to detect the causative variant. There are currently over 10 million SNPs and other polymorphisms such as insertion/deletion variants (indels) in public databases that potentially provide a marker set for efficient disease-gene association studies. It is important to note that even this large variant

set still might not represent the variants causative of diseases. This is likely due to the fact that significant polymorphism discovery efforts to date have been performed in a random fashion across the genomes of only a limited number of individuals. Therefore, we still need to discover genetic variation in regions of functional DNA sequence in the genomes of individuals with disease, in order to provide an accurate understanding of disease etiology.

In this chapter, we outline the sequencing protocols and the attendant computational approaches employed for the discovery and initial characterization of DNA variants, with an emphasis on the most commonly used Sanger-based sequencing (Sanger et al., 1977) methodologies established in our laboratories. These polymorphisms range from the substitution of single bases (i.e., SNPs) to the insertion or deletion of nucleotides in size ranges from 1 basepair (bp) to greater than 20,000 bp. Recent reports on the unexpected number and scope of larger scale copy number variants or structural variants ranging from 1–3 million bases (Mb) in size (Redon et al., 2006; Sebat et al., 2004) will not be addressed here since current methods used for their analysis involve either genotyping or microarray-based comparative genome hybridization, as presented elsewhere (see Chapter 5).

We also highlight, where possible, how the application of these methods and advances has impacted our understanding of human biology. Several recent reviews addressed the methodologies and development of advanced sequencing methods and recent commercial platforms that exploit their use (Fan et al., 2006; Shendure et al., 2004). These advances in genome sequencing for variant detection are of particular importance as we have begun to see genome sequences and complete variants sets of individual humans, including as of this writing James D. Watson by 454 Life Sciences (Wheeler et al., 2008) and J. Craig Venter (Sanger-based sequencing (Levy et al., 2007)). The discussion in this chapter will focus primarily on mature approaches for use in high-throughput experimental environments, as well as on the types of experimental results that can and have been generated. It will be evident that comprehensive experimental designs and economies of scale are possible when applying these techniques in a production environment.

DNA SEQUENCING

DNA sequencing methods applied to either single or multiple DNA samples provide the definitive approach to discovering polymorphisms. These polymorphisms can be detected at the genomic and/or the mRNA level depending on the source of the material employed. For example, genomic DNA subcloned into BACs or in small to medium insert size bacterial libraries were created to produce a finished human genome sequence and genomic variants therein (Osoegawa et al., 2001). Other sequencing projects have employed expression sequence tag (EST) or cDNA sequencing of mRNA libraries to characterize variants primarily at the transcript, and by inference, at the protein level (Strausberg et al., 2003). All these approaches benefit from the random sampling of DNA regions by selecting bacterial colonies containing DNA inserts, DNA sequence determination using capillary-based electrophoresis of incorporated dye terminator nucleotide bases and subsequent sequence alignment of reads to construct reliable assemblies of genomic or mRNA molecules. Other approaches to DNA sequence elucidation that will be covered in this section involve the targeted amplification of defined genomic loci typically for study in large populations, the use of microfabricated high-throughput bead or surface-based sequencing devices and high-density oligonucleotide arrays. A comparison of these distinct methodologies is provided in Table 3.1.

Whole Genome Shotgun Sequencing

Polymorphism discovery on a genome-wide level can be accomplished by applying the Sanger sequencing technique (Sanger et al., 1977) and the whole genome shotgun (WGS) strategy (Fleischmann et al., 1995; Venter et al., 2001; Venter et al., 1996) on a small pool of DNA samples.

Owing to its high accuracy, versatility and ability to generate complete DNA sequence information, the Sanger sequencing method has been considered the definitive approach for DNA variant discovery. The WGS methodology relies upon generating a random sampling of genomic regions at a sufficiently deep coverage level to produce enough sequence data that can then be assembled by sequence alignment methods. First, multiple copies of the genome are randomly shredded into pieces of approximately 2–40 kilobasepairs (Kb) in size and subsequently cloned into a vector or plasmid. These constructs are then replicated in bacteria and sequenced from both ends to produce pairs of linked sequences, termed "mate pairs", representing 500–800 bp at the end of each insert. These sequence reads are then assembled computationally to generate a set of contiguous high-quality regions with potential information regarding any associated sequence gaps of a known size.

Currently, the Sanger-based WGS sequencing process, excluding the library construction step, is typically fully supported by equipment automation, as outlined in Figure 3.1, and managed as a production "pipeline" with varying degrees of integration between different steps employing a laboratory information management system.

Library Construction

Genomic DNA is randomly sheared via nebulization to produce fragments with a distribution of approximately 2–40 Kb. The DNA fragments are ligated to adapters after end-polishing and size selection. After several rounds of purification, the fragments are inserted into plasmid vectors. The resulting library is electroporated into *E. coli* cells.

Colony Plating and Picking

The *E. coli* cells containing the plasmid vectors with inserted DNA fragments are then spread onto agar plates and incubated to form *E. coli* colonies. The colonies are picked into liquid media and incubated for further growth to generate sufficient

Table 3.1 Comparison of distinct approaches in DNA sequence acquisition and the detection of variants

	Sanger based WGS	**Targeted PCR**	**Sequence by synthesis**	**Sequence by hybridization**
Current platforms	ABI 3730 xl	ABI 3730 xl	Roche-454, Illumina/ Solexa, ABI SOLiD (strictly hybridization-ligation chemistry)	Affymetrix, Perlegen, Nimblegen
Read length (bp)	500–800	500–800	25–400	60–100
Detection SNP/Indel	Y/Y	Y/Y (up to amplicon size)	Y/Y	Y/Y (primarily deletions in sample)
Construction of long-range haplotypes	Y	Limited to targeted regions	Uncertain	Limited to targeted regions
Current cost per sample < $2 million	N	Uncertain	Y	Y

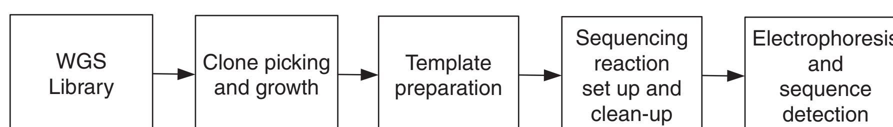

Figure 3.1 Whole Genome Shotgun sequencing process flow.

numbers of plasmid template copies. Subsequently, these template copies are isolated and purified from the host cells.

Template Preparation

The alkaline lysis plasmid isolation approach (Sambrook et al., 1989) is the most widely utilized method for plasmid template isolation due to its robustness. Bacterial cells are lysed, cell debris removed by centrifugation and plasmid DNA recovered from the cleared lysate by isopropanol precipitation.

Sequencing Reactions

For DNA sequence determination, the most widely used technique is the Sanger dideoxy sequencing method (Sanger et al., 1977). It mimics the natural process of DNA replication in vivo with the presence of target DNA molecules, universal M13 sequencing primers, polymerase, deoxynucleotides (dNTPs) as well as chain terminating dideoxynucleotides which interrupt chain elongation upon incorporation generating DNA fragments of different lengths. Several improvements have been made to the original method to greatly enhance its throughput, robustness and detection sensitivity. These include the development of multicolor fluorescent detection (Smith et al., 1986), fluorescently tagged chain-terminators (Prober et al., 1987), a cycle sequencing protocol (McCombie et al., 1992) and fluorescence resonance energy transfer (FRET) dyes (Ju et al., 1995; Lee et al., 1997). Currently, most sequencing reactions are carried out using FRET dye terminators, modified *Taq* polymerase and a cycle sequencing protocol.

Sequence Detection

The technology for the electrophoresis-based separation of Sanger sequenced DNA fragments and the detection of individual bases have advanced substantially in the past two decades. As a result, the throughput, detection sensitivity and costs of sequencing, as well as the accuracy and quality of the data generated by these sequencers, have improved significantly. The invention of multicolor fluorescent sequencing in 1986 (Smith et al., 1986) replaced laborious and hazardous radioisotope labeling techniques (Sanger et al., 1982) with automated signal detection, high-speed computational recording and signal processing. In the mid-1990s, the successful integration of the capillary-based electrophoresis and multicolor fluorescent detection (Bashkin et al., 1996a; Bashkin et al., 1996b; Behr et al., 1999) further enabled the creation of the true high-throughput sequencing machines. Today, state-of-the-art capillary-based sequencers have the ability to read over 1 million bp of sequence per 24-hour period with long read lengths (an average of >800 bp per read) and an average quality value (QV) of greater than 30 (99.9% accuracy).

Whole Genome Assembly

The whole genome assembly process utilizes several aspects of experimental design to ensure that unambiguous construction of long contiguous sequence can be generated. These include the generation of sequence reads from each end of clone inserts using universal primers pairs to ensure that a majority of inserts will have their ends sequenced. This enables both the generation

Figure 3.2 Display and detection of a single nucleotide polymorphism in a human genome assembly of a single DNA donor. Sequence reads overlap and can be assembled to form the consensus sequence of the contig where 5 of the 12 reads show a T variation at a C consensus base (variant position is highlighted with an arrow). T = type of sequence read, either assembled contig or individual read, I = unique identifier, R = co-ordinates of alignment, O = strand orientation that aligns.

of contiguous sequence and the potential for ordering and orienting larger sequence segments essentially created by sequence alignment of the individual reads whose mate pair relationship is known. A variety of genome assembler software packages have been designed with this basic rationale at their core (Celera Assembly (Myers et al., 2000), Phusion (Mullikin and Ning, 2003)). The Atlas assembler uses as input both BAC-based clone sequences and reads generated via the WGS strategy (Havlak et al., 2004), an approach that was used to assemble the rat genome (Gibbs et al., 2004).

There are two basic steps to assembly: (i) the creation of unique regions of contiguous (contigs) assemblies from the sequence overlaps between reads and (ii) the sequential end-to-end organization of contigs by employing the mate pair information contained in the reads constituting each contig. The successful application of this strategy was a significant challenge for the sequencing and assembly of human DNA since greater than 45% of the genome sequence is repetitive in nature (Lander et al., 2001; Venter et al., 2001). The repetitive nature of the human and other mammalian genomes thus confounds the ability to determine accurate read sequence overlaps and the placement of contigs into the correct order and orientation. Our solution is to employ clone insert libraries of a size larger than the corresponding repeat regions, typically either fosmid or BAC libraries (40 kb and >100 kb respectively), thus enabling the spanning of repeats by assembling adjacent unique sequence (Venter et al., 2001). The selection of a range of insert sizes libraries is typically built into the experimental design when sequencing a new genome.

Variant Detection

Variants can be reliably detected from assembled sequence reads from either a single or multiple DNA donors in the region of unique genome sequence assembly. The example in Figure 3.2 show the reads assembled from a single human identifying a known SNP found in a coding region of the APOE gene and, as expected, displays a close to equiprobable occurrence of both allelic forms (five reads with the T allele and seven reads with C allele). This approach has been employed with success to identify 974,400 heterozygous variants in a single canine individual (Kirkness et al., 2003). The inclusion of random shotgun sequence reads from distinct DNA donors is another approach to employing genome assembly and read placement to identify polymorphic site. This approach was employed using five DNA donors in the initial shotgun sequence assembly of the human genome (Venter et al., 2001). An important factor in using a WGS assembly approach to detecting polymorphic sites is that enough sequence coverage from a single donor should be available. In this manner it is possible to provide a good quality assembly with associated consensus sequence and associated allelic variants. This means that additional donors can be included either post-assembly or as part of the assembly process if the species in question does not possess extensive interindividual polymorphism. Recent work attempting to detect both SNP and indels in an individual human sample suggests that detection of heterozygous variants, with 99% probability using a Sanger chemistry-based WGS approach, necessitates a variant being reported by 20 reads or more (Levy et al., 2007).

Another challenge to polymorphism detection during genome assembly is the occurrence of many small heterozygous indel polymorphisms in human DNA, typically between 1–20 bp length (Ball et al., 2005). These indel events result in the occurrence of long and short alleles, requiring a methodology to accurately separate the reads from each allele, thereby providing an accurate representation of the indel. Subsequently, a practical decision needs to be made regarding which form will be

represented in the consensus sequence. Typically this can be the "major" allele even though in a single donor this will be present effectively at equal probability.

Lastly, a strategy needs to be implemented to best catalog the occurrence and type of the other allele or alleles, in the case of sequencing multiple DNA donor samples. An example of the detection and display of an indel from a genome assembly of a single DNA donor can be seen in Figure 3.3. The figure displays the consensus sequence (the contig sequence) containing the short, major, allele since gaps are included in the alignment, whilst the long form (inclusion of ATTCT) is found in two of the eight assembled reads. We recently applied a modified sequence assembly algorithm to detect heterozygous indels variants from the diploid genome sequence of an individual human (Levy et al., 2007). Using this approach we detected over 345,000 heterozygous indels events of lengths 1–571 bp with at least 200 indels in protein-coding regions of genes.

PCR Amplicon Re-Sequencing

The goal of directed sequencing or re-sequencing is to use the existing sequence data from a particular genomic locus or loci to determine sequence variations of these same loci in different DNA samples. This provides the nature and the frequency of DNA polymorphisms and can be used to assess whether these variants could be implicated in, for example, either disease onset or progression.

PCR re-sequencing methodology is widely accepted as the gold standard (Kwok and Chen, 2003) for the discovery of polymorphisms (both SNPs and indels) in targeted regions since it provides the most complete information including the genotype, the location and sequence context. This approach has been applied to understand sequence variation in populations (Crawford et al., 2004) and for the identification of variants and haplotypes that could potentially explain disease phenotypes in cancer (Cox et al., 2005). It combines the powerful PCR technique (Mullis et al., 1986) with the informative Sanger sequencing method (Sanger et al., 1977). Rapid advancement of the technologies and dramatic reduction in costs for direct sequencing of PCR products, as well as the completion of the reference human genomes in 2001 (Lander et al., 2001; Venter et al., 2001) has enabled the systematic large-scale discovery of polymorphisms in targeted regions. The approach generally involves PCR primer design, the amplification of the targeted region from whole genomic DNA using PCR, followed by Sanger sequencing and the analysis of the targeted sequences (Figure 3.4).

Primer Design

The goal of directed sequencing is to provide reliable amplification of a single genomic region, and this is readily achieved via the design of unique pairs of oligomers for priming of the PCR. The resulting amplicon encompassing the targeted region can vary in size; however reproducible and robust assays range from 350 bp to 1000 bp in length per amplicon. In order to provide coverage of a larger genomic locus with this amplicon size, it becomes necessary to tile PCR products with some overlap (typically 100 bp) between amplicons. The primer design process attempts to generate oligomers for products with similar melting temperatures whilst avoiding primer-dimerization forming interfering secondary structures. Other factors to permit specific amplification would be the G+C content of the region, the proximity

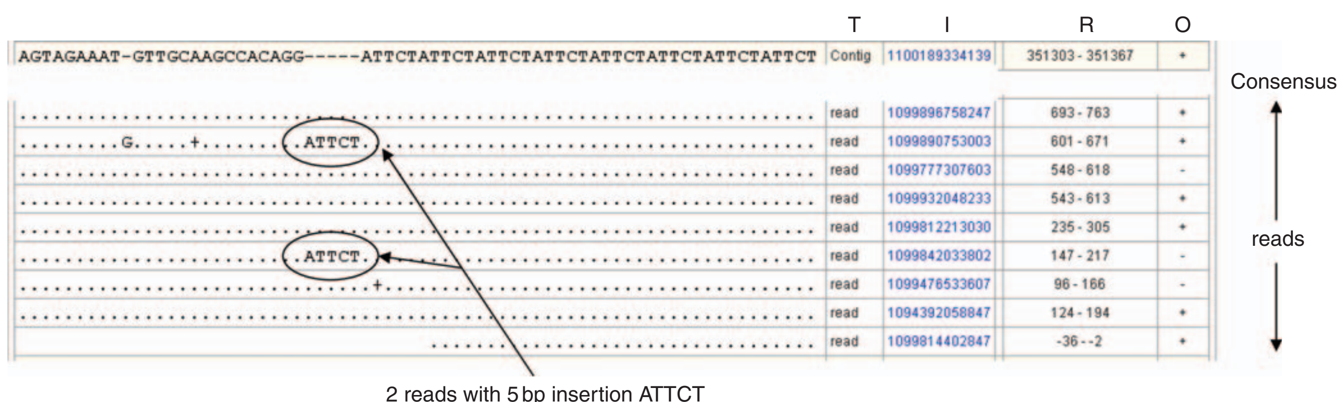

Figure 3.3 Display and detection of a 5 bp insertion/deletion polymorphism in a human genome assembly of a single DNA donor. The consensus sequence displays the "short" allelic form whilst the "long" form (ATTCT) is found in 2 of the 8 sequence assembled reads. T = type of sequence read, either assemblyed contig or individual read, I = unique identifer, R = co-ordinates of alignment, O = strand orientation that aligns. "+" = gap inserted into read to permit correct alignment.

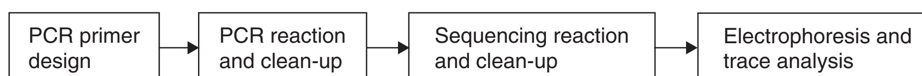

Figure 3.4 PCR directed sequencing process flow.

of repeat regions, the uniqueness of the oligomer sequences in the genome and the absence of known DNA variants in the primer binding sites. These considerations can be embodied in a computational pipeline as illustrated in Figure 3.5. The sequence context, in this case percent G+C quantity, are considered before identifying a candidate genomic region for primer design. In a high-throughput directed sequencing pipeline, it is frequently desirable to employ few, or preferable one, PCR protocol, and in our experience G+C content allows a distinction between at least two desired PCR conditions (high and low G+C content). Once the PRIMER3 software (Rozen and Skaletsky, 2000) generates candidate primer pairs for a desired target region, these are further assessed for their product uniqueness (low and high copy repeat regions) and to ensure that resulting amplicons contains only one type of complex sequence, i.e. homopolymer or known indel polymorphism. The last requirement is important since sequence detection is performed using capillary-based detection methods and chromatograms potentially contain a mixture of alternate alleles at any one mobility position. This renders the process of allelic definition potentially difficult in the case of multiple indel events in a single amplicon.

PCR Set-Up and Clean-Up

As described in the primer design section, due to the variable G+C content within the genome, application of different PCR primer design criteria, as well as different PCR protocols might be necessary when targeting different regions. In our laboratory, we have two fully validated high-throughput amplification protocols (Rand et al., 2005), one for regions of normal G+C content and another for amplicons with melting temperatures (T_m) >82°C. AmpliTaq Gold® DNA polymerase (Applied Biosystems) is used to perform hot-start PCR to minimize the formation of primer–dimers and spurious amplicons and ensure efficient, consistent and specific amplification results in a high-throughput environment.

A Shrimp Alkaline Phosphatase/Exonuclease I (SAP/Exo I) mix is used to digest excess dNTPs and amplification primers. (While SAP is commonly used to remove 5′ phosphate groups from DNA, it also degrades dNTPs.) The SAP/Exo I method provides an effective, single tube approach to PCR clean-up that is easily automated and scalable.

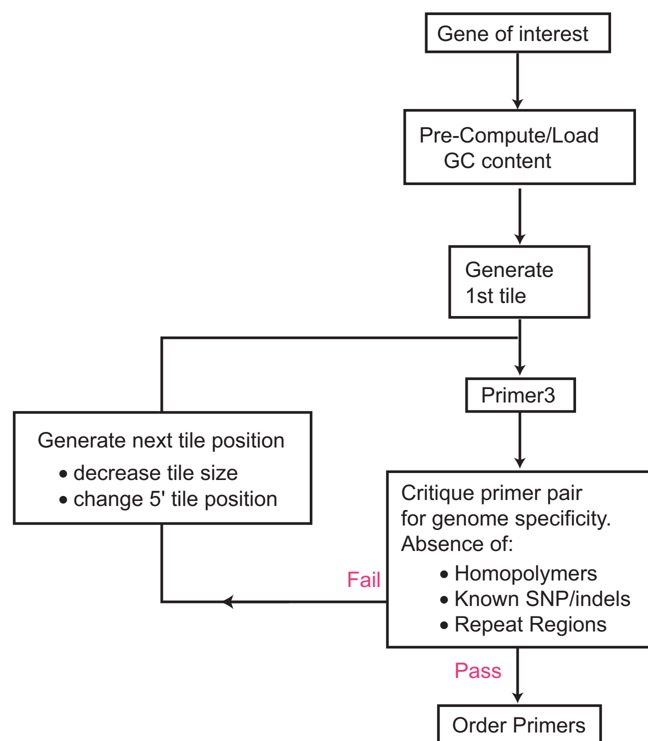

Figure 3.5 Primer design pipeline for PCR based directed sequencing.

Sequencing Reaction Set-Up and Clean-Up

In order to simplify the downstream sequencing process, the PCR primers are frequently tagged with M13 forward and reverse sequences on their 5′ ends. The resulting amplicons can then be sequenced using universal M13 sequencing primer sets and a standard sequencing protocol (see previous section). Reaction products can be purified with sodium acetate and ethanol prior to analysis on the sequencers.

Electrophoresis and Trace Analysis

The state-of-the-art technology for the electrophoresis-based separation of Sanger sequenced DNA fragments and the detection of individual bases can be accomplished by a combination of trace filtering, trace separation and mixed base calling. Electropherogram peaks are described as "mixed" in that a primary peak is detected with a secondary but significantly present sub-peak due to two distinct and different allelic forms contributing to the locus, We have developed a trace analysis pipeline that applies digital signal filters to reduce the occurrence of secondary, typically noisy, sequence peaks (Figure 3.6), thus enabling the accurate distinction of a single position with mixed peaks. This approach has enabled a substantial improvement of common artifacts observed in diploid genomic regions sequenced after PCR amplification that include dye-blob, PCR slippage and primer synthesis length errors, all of which confound mixed peak detection. After generating either a raw (unfiltered) or digital signal filtered chromatogram, it is then possible to identify mixed peaks that vary significantly in height, area and width to characterize departures from the reference sequence. This general approach can be performed with many different software tools in the public domain (Polyphred, Mutation Surveyor, novoSNP and SNPdetector, InSNP), the most extensively tested of which is Polyphred. In the most recent version of this software, detailed parameterization was performed using sequence reads from PCR-amplified diploid samples and a statistical framework was developed to report evidence of genotypes being called (Stephens et al., 2006).

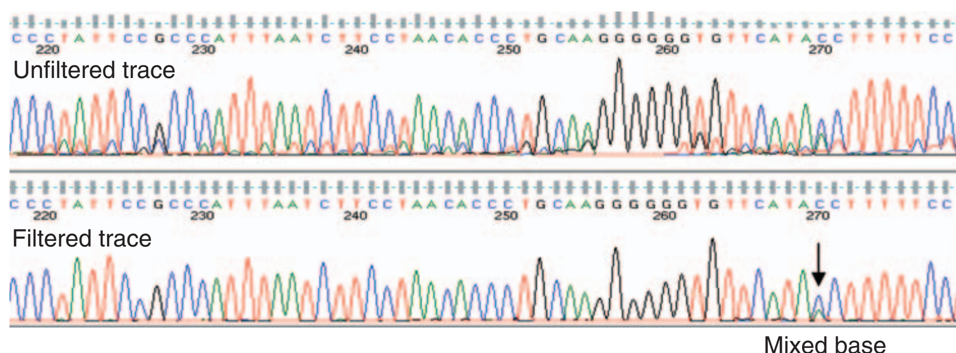

Figure 3.6 Sequence chromatograms of a locus revealing a SNP before and after digital signal filtering were applied to remove PCR slippage artifacts due to the presence of proximal (not seen) homopolymeric DNA.

Heterozygous indel polymorphisms result in significant changes in the chromatograms from diploid DNA samples where typically traces contain mixed peaks from the point of the insertion/deletion onwards. One can develop computational methods that essentially separate the traces to enable the definition of the long and short alleles (Bhangale et al., 2005; Bhangale et al., 2006). Polyphred, InSNP (Manaster et al., 2005) and Mutation Surveyor are all capable of detecting heterozygous indels, but as of this writing an unbiased detailed comparison of performance has not yet been attempted.

Sequencing by Synthesis

Recently implemented sequencing by synthesis technologies can employ PCR (Mullis et al., 1986) to achieve clonal amplification of single DNA molecules. In addition, the sequencing by synthesis principle in a massively parallel format has been developed by Rothberg and colleagues (Margulies et al., 2005) and by Church and colleagues (Shendure et al., 2005). In each of these new technologies, different chemistries are applied to interrogate, tag and detect the sequence bases.

For example, utilizing nanotechnology and pyrosequencing chemistry (Nyren et al., 1993), coupled with an enzymatic luminometric inorganic pyrophosphate detection technique, Rothberg and colleagues at 454 Life Sciences recently developed a novel and highly parallel system capable of sequencing approximately 100 million bp in a 7-hour period by sampling over 400,000 sequence clones. They were able to illustrate this technological advance by sequencing and assembling the *Mycoplasma genitalium* and *Streptococcus pneumoniae* genomes (0.6 and 2.1 Mb respectively in size). Compared to the current state-of-the-art Sanger DNA sequencing and capillary-based electrophoresis platform, their system generates "raw" data with approximately 100 times higher throughput. However, compared to the Sanger/electrophoresis-based sequencing approach, it still has several limitations, such as the short sequence read lengths which, averaging 200–250 bases per read, are only a quarter of Sanger read lengths. Another problem is that the accuracy of base calling on individual reads is low especially for genomic regions containing homopolymers. This leads to the increased likelihood of spurious polymorphism detection. In addition, the 454 sequencing methodology currently does not incorporate the use of mate pairs that come from large insert libraries (>10 kb), which for the successful assembly of repeat rich genomes, like those of most eukaryotes, are important in order to span large repeat regions. Nonetheless, this technology has been employed to generate some sequence data from DNA extracted from fossil remains (Green et al., 2006) and has been employed most recently to generate sixfold coverage of an individual genome (Wheeler et al., 2008).

Some of these problems can be circumvented by adopting a hybrid sequencing approach, that is one that employs, in addition to the sequencing-by-synthesis approach (454), a small number of large insert clones (typically fosmid libraries) sequenced by Sanger technology to provide order and orientation in the final genome assembly. While this approach has been successfully employed for a number of bacterial genomes (Goldberg et al., 2006), establishing the most efficient mix of the sequence-by-synthesis contribution and fosmid libraries will be the challenge for the completion of larger mammalian genomes. Each of the sequencing-by-synthesis approaches mentioned above share similar advantages as well as limitations. However, they do show great promise for the discovery of polymorphisms in a rapid, cost effective manner.

The massively parallel sequencing-by-synthesis approach enabled by the 454 picoliter plate technology can also be utilized for targeted polymorphism discovery. In this manner, PCR amplicons that contain the targeted genomic regions are extensively sampled since it is possible to generate currently up to 400,000 clonal amplifications of the PCR product per experiment. This approach has potentially great value for the discovery and detection of DNA variations present in low frequency in the samples. This is especially applicable for mutation detection in tumor tissue, in which potentially only a few cells carry activating mutations and the surrounding cell population contributes to the "contamination" of the tumor DNA. The lowest detection level thus far obtained has been for alleles present in the sample as low as 9% for indel mutations in the EGFR gene in lung adenocarcinoma specimens (Thomas et al., 2006) and at a similar frequency for non-synonymous point mutations in the FGFR1 gene from glioblastoma samples (Strausberg et al., personal communication). In both of these cases the corresponding PCR-amplified,

Sanger sequence chromatograms lack the necessary secondary peak signal to detect a variant above the background noise level, where the limit of detection of a secondary allele is thought to be between 15–25%.

Sequencing by Hybridization

The sequencing by hybridization on microarray approach has also become a widely utilized tool for SNP detection and analysis (Kukita et al., 2005; Patil et al., 2001; Maraganore et al., 2005; Kozal, 1996; Cronin et al., 1996; Chee et al., 1996; Hacia et al., 1996; Kapranov et al., 2002) due to the technological advances that make the manufacturing of high-density DNA arrays possible. The genomic DNA is generally prepared by PCR to amplify the regions of interest or by using a whole genome amplification methodology (Dean et al., 2002) and tagged with fluorescent dyes for detection prior to hybridizing to the oligonucleotide array.

This approach allows the detection of sequence present in a test sample via direct hybridization and was able to detect the unique (non-repeat) contiguous sequence from human DNA chromosome 21 conserved with mouse and dog (Frazer et al., 2001) and the haplotype block structure of chromosome 21 in 24 human DNA samples (Patil et al., 2001). In both cases, this was accomplished by creating a tiling array where each position was interrogated for all possible bases using a set of eight distinct oligonucleotide probes comprising the position in question and 12 bp flanking to provide for binding specificity. The interspecies hybridization experiments revealed additional putative exonic region of current genes and identified other regions of significant sequence conservation that could represent other forms of functional sequence. The human population study revealed that 80% of the DNA samples could be described by three common haplotypes. Such knowledge of chromosomal block structure and inheritance patterns enables the choice of a smaller set of variants with which one can perform disease-gene association studies (see Chapter 4). The sequencing-by-hybrization approach clearly necessitates that all the sequence being tested is present on the microarray. While this may be a limitation for discovering novel sequence in some genomes, even for the multiple, yet to be sequenced, human genomes, the methodology is well suited and has been extensively employed for the genotyping of known SNPs in disease conditions and deletions in arrayed sequence. Recent whole genome association studies employing large-scale SNP assays performed on microarrays have identified genes as either biomarkers or therapeutic targets in Parkinson's disease (~200,000 loci) (Maraganore et al., 2005) and copy number variations and deletions in mental retardation (100,000 loci) (Friedman et al., 2006).

2009 UPDATE

Individual human genome sequencing

DNA sequencing has witnessed an incredible increase in throughput, cost reduction and facility of application over the last two years. The so-called "Next Generation" sequencing platforms as provided by Roche-454 GS (**G**enome **S**equencer), Illumina-Solexa GA (**G**enome **A**nalyzer) and ABI SOLiD (**S**upported **O**ligonucleotide **Li**gation and **D**etection) have been used in a variety of sequencing approaches. Most recently, 454 and Illumina GA have been employed to detect comprehensive sets of polymorphisms in individual human genomes (Bentley et al., 2008; Wang et al., 2008; Wheeler et al., 2008). These data reveal a trend in the catalogue of variants found in now four individuals of distinct ethnicity whose genomes have been sequenced, whereby SNPs occur in the millions, insertion/deletion polymorphisms (<1 kb) occur in the hundreds of thousands and structural variants (>1 kb) occur in the thousands.

The sequencing platforms that produced these individual human genomes are continuing to improve in sequence accuracy, read length and the complexity of DNA libraries to enable their use for *de-novo* genome assembly, which to date has only be accomplished by mature ABI Sanger chemistry and a dedicated genome assembly tool (Levy et al., 2007). The sequence variation discovered using the new platforms has been achieved by mapping of individual reads or paired end reads to the existing human genome reference sequence (http://www.ncbi.nlm.nih.gov/projects/genome/assembly/grc/index.shtml) using a variety of tools like Newbler for Roche 454, MAQ (Li et al., 2008) and SOAP (Li et al., 2008a) of Illumina-Solexa, and Corona Lite and SHRiMP for ABI SOLiD. Typically these software tools provide the placement of reads on the reference genome and knowledge of any variant bases contained within any read. Some statistical inference can then be performed to assess the presence of SNPs or indels, as has been developed for the 454 platform (Quinlan et al., 2008). Larger scale human polymorphism, like structural variation, can be detected by comparing the mapping distance between paired reads from known insert size libraries onto the universal human reference genome. This pair-end mapping approach has been performed for fosmid inserts (~40 kb) whose ends were sequenced with ABI Sanger chemistry to detect structural variants in humans (Kidd et al., 2008) and has shown to work with library sizes as small as 3 kb (Korbel et al., 2007) that were sequenced with Roche-454. An ongoing challenge remains the detection of copy number variants in the human genome using sequencing approaches

alone, since they have been more extensively studied with comparative hybridization approaches to date (Redon et al., 2006).

It is clear that some variation detection can be achieved via sequence read mapping using "Next Generation" platform data sets. However, the relationships among variants (that is, haplotype data) will only be revealed by some preceding genome assembly or haplotype inference. Therefore, the need to perform *de-novo* genome assembly with short reads generated by these platforms still remains an important if difficult challenge and some groups have produced tools that appear to work with non-mammalian genomes (Jeck et al., 2007; Warren et al., 2007; Butler et al., 2008; Hernandez et al., 2008; Zerbino and Birney, 2008). The size and repeat sequence diversity of the human genome render genome assembly a complex problem; however, the continued improvement of read length on "Next Generation" platforms promises to reduce this complexity.

Targeted sequencing

Despite the incredible sequencing throughput capabilities of the current commercial platforms, genetic association studies employing the whole genome shotgun sequencing strategy alone are still quite costly and time consuming to accomplish at a large scale. Consequently, the use of targeted sequencing approaches that employ locus-specific capture methods coupled with sequencing is still favored. The approaches have been supplemented beyond PCR by the development of microarray-based methodologies to target regions (currently exons), resulting in the specific isolation of up to 200,000 exons *en masse* (Albert et al., 2007; Hodges et al., 2007; Okou et al., 2007; Porreca et al., 2007). These methods have been able to show, in some cases, the identification of 98% of targeted exons with 55-85% of captured sequence reads derived from the targeted regions. These massively multiplexed regional capture methods, coupled with a "Next Generation" sequencing platform, promise to provide variant detection at high accuracy and throughput.

Future projects

The vastly improved sequence data throughput provided by the Roche-454 GS, Illumina-Solexa GA and ABI-SOLiD platforms have enabled large scale, international sequencing projects in human populations (e.g., 1,000 Genomes and The Cancer Genome Atlas Projects). These projects attempt relatively low coverage (2-6x) of the human genome to detect variants and/or mutations in either chronic diseases or distinct tumor types. These project designs are likely to reveal the complex nature of polymorphism in disease populations, and such study designs have been fueled by radical technology improvement in sequencing. Further improvements in sequencing technologies are likely to push study design toward the detection and analysis of polymorphism in multiple individual human genomes, including both common and rare variants.

CHAPTER

Genome-Wide Association Studies and Genotyping Technologies

Kevin V. Shianna

INTRODUCTION

Since the completion of the International HapMap Project (International HapMap Consortium, 2005; The International HapMap Consortium, 2003), a wealth of genetic information within the human genome has been uncovered. Over 12 million single nucleotide polymorphisms (SNPs) have been identified (Wheeler et al., 2007). This dense map of common genetic variation has revolutioni zed the field of human genetics. Genome-wide linkage scans can now be performed using efficient and cost-effective high-throughput SNP genotyping technologies, while at the same time achieving a fine map at a density not previously possible when performing earlier-generation genome scans based on microsatellite polymorphisms. The SNP map, along with recent technological gains, has also made it possible to comprehensively study complex diseases and traits by allowing for the genotyping of hundreds of thousands of SNPs for many samples. Also, with the identification of a specific type of SNP, called tagging SNPs, almost complete genomic coverage of common variation can be attained.

This chapter will provide an introduction to genome-wide association studies, followed by an overview of two commonly used genome-wide genotyping platforms, the Illumina Infinium Assay and the Affymetrix GeneChip. The methods and concepts discussed here complement those described elsewhere in this book.

PRINCIPLES OF GENOME-WIDE ASSOCIATION STUDIES

Before performing a genome-wide association study, it is essential to begin with a fully developed plan. The key issues to consider are the kind of study to perform, the required sample size, the importance of a well-defined phenotype, the need to correct for population stratification and the technologies available for genome-wide genotyping. This section will provide an introduction to the basic experimental design for a genome-wide association study.

Type of Study

First, the study should be focused on a key question based on a specific phenotype or disease. As an example, a study could be established to identify genetic variants associated with epilepsy. The key would be to collect a large cohort of individuals that have a definitive and well-defined diagnosis of epilepsy (cases) and compare these individuals to a group that does not have epilepsy (controls). In the past it was always necessary to collect matched controls, but with an abundance of control samples containing data from the various genome-wide array-based studies, it is now possible to use control genotyping data from the available databases. One example is the database made available by Illumina (iControlDB) where individual users have deposited genotyping data for control samples from previously processed samples. It has been demonstrated that the use of general control

	Illumina HumanHap 300	TCF7L2, AHI1-LOC441171 region	500/497	(Salonen et al., 2007)
	Illumina HumanHap 300	TCF7L2, IDE–KIF11–HHEX and EXT2–ALX4	1363	(Sladek et al., 2007)
Type 1 Diabetes	Illumina HumanHap 550	KIAA0350	563/1146	(Hakonarson et al., 2007)
	Affymetrix Human Mapping 500	Chromosome regions 18q22, 12q24, 12q13, 16p13 and 18p11	4000/5000	(Todd et al., 2007)
	Affymetrix Human Mapping 100	IFIH1	2029/1775	(Smyth et al., 2006)
Restless leg syndrome	Affymetrix Human Mapping 500	MEIS1, BTBD9	401/1644	(Winkelmann et al., 2007)
Colorectal cancer	Illumina HumanHap 550	8q24.21 locus	930/960	(Tomlinson et al., 2007)
	Affymetrix Human Mapping 100	8q24 locus	1257/1336	(Zanke et al., 2007)
Prostate cancer	Illumina HumanHap 300	TCF2	1501/11290	(Gudmundsson et al., 2007)
	Illumina HumanHap 300	8q24	1453/3064	(Gudmundsson et al., 2007)
	Illumina HumanHap 300	8q24	1172/1157	(Yeager et al., 2007)
Atrial fibrillation	Illumina HumanHap 300	Chromosome region 4q25 near PITX2	550/4476	(Gudbjartsson et al., 2007)
Celiac disease	Illumina HumanHap 300	IL2, IL21	778/1422	(van Heel et al., 2007)
Crohn's disease	Illumina HumanHap 300	IL23R	2877/1345	(Tremelling et al., 2007)
	Illumina HumanHap 300	IL23R	567/571	(Duerr et al., 2006)
Macular degeneration	Affymetrix Human Mapping 100	CFH	96/50	(Klein et al., 2005)
Asthma	Illumina HumanHap 300	ORMDL3	994/1243	(Moffatt et al., 2007)

samples across studies is feasible (Wellcome Trust Case Control Consortium, 2007). This greatly decreases the cost to run a project and potentially allows for the inclusion of more cases (if available). A study could also be arranged to look at a specific continuous phenotype or quantitative trait within a group of individuals. Using the previous example, one could study how individuals with epilepsy responded to a specific drug or series of drugs.

Sample Size

The sample sizes required for a genome-wide association study are dependent on several factors. The first is the effect size of an unknown genetic variable. Of course, this is impossible to know in advance; however, power calculations can be performed to determine how many samples would be required to identify a variant with a specific effect size. These calculations can serve as a guide when deciding how many samples to include in the study. Purcell and colleagues (2003) have created a web-based genetic power calculator (http://pngu.mgh.harvard.edu/~purcell/gpc/) that can be used to determine power of a study. Another factor that is important when determining sample size is the type of study: case/control or a continuous phenotype. The current view for case/control studies is that large sample sizes are needed (1,000 of each), but this is not always true. A few studies have identified associated variants with only 150–200 samples (Table 4.1). Again, it is impossible to know the effect size of an unknown variant so it is best to include a large number of samples when designing a study. For a continuous phenotype, studies have had success while using fewer samples (Table 4.1).

Importance of Phenotype

The most important aspect when designing a genome-wide association study is the quality and discrete nature of the phenotype. It is essential that the studied phenotype is evaluated carefully for accuracy and is well defined across all samples. The inclusion of incorrectly phenotyped samples in a study could lead to a decrease in the statistical power to identify associated variants. This could consist of control samples that are in fact cases, but have yet to be identified with the specific phenotype/diagnosis or a misdiagnosis

of an individual within the cases. For some complex diseases, the phenotypic characteristics overlap with other closely related diseases. This can make it difficult when choosing which samples should be included in the study and, because of genetic heterogeneity, will decrease the power of the study.

Population Stratification

When analyzing the data from genome-wide association studies, it is essential to evaluate and account for population stratification between cases and controls. Cryptic population structure can generate false positive and/or negative associations. This can happen if allele frequencies are different in any unknown subgroups. One solution to correct for this difference in ancestry is described by Price and colleagues (2006). Left uncorrected, population stratification can lead directly to false associations.

Genotyping Technologies, Tagging SNPs and Genomic Coverage

Another necessity for genome-wide association studies is to have a method to genotype hundreds of thousands of genetic variants around the genome. Fortunately, there are now standard products that allow for screening of very large numbers of SNPs. Depending on the chosen platform, the SNPs on the arrays have been selected based either on even spacing or on the basis of certain SNPs being able to represent multiple SNPs. The SNPs in the second approach are termed "tagging SNPs" and greatly increase the genomic coverage that can be obtained compared to SNPs that are evenly spaced across the genome (Barrett and Cardon, 2006; Pe'er et al., 2006). Reflecting now the well-established patterns of linkage disequilibrium (Hinds et al., 2005; International HapMap Consortium, 2005), these tagging SNPs work by acting as proxies for other nearby associated SNPs, making it possible to genotype only the tagging SNP and yet capture the content of other associated SNPs in the region. There are currently commercially available arrays (SNP chips) that contain close to 1 million tagging SNPs, representing most of the common variation in the human genome. Products where the SNPs have not been specifically chosen based on the close association with other SNPs will have much less genomic coverage, because the SNPs have not been optimally chosen for the ability to tag. For example, Illumina's HumanHap300 array, containing around 300,000 tagging SNPs, has essentially the same statistical genomic coverage as Affymetrix's Mapping 500K Array Set, which contains 500,000 evenly spaced SNPs (Barrett and Cardon, 2006; Pe'er et al., 2006). Further background information on genome-wide association studies and tagging SNPs has been elegantly presented elsewhere (Hirschhorn and Daly, 2005).

PLATFORM OVERVIEW

Illumina Infinium Assay

The Illumina genotyping technology is based on 3 μ silicon beads that have hundreds of thousands of DNA oligomers attached to

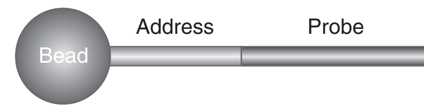

Figure 4.1 An example of a bead on the Illumina Infinium BeadChip. A schematic of a single bead, containing a 75-nucleotide oligomer consisting of an address and a specific probe sequence, as described in the text.

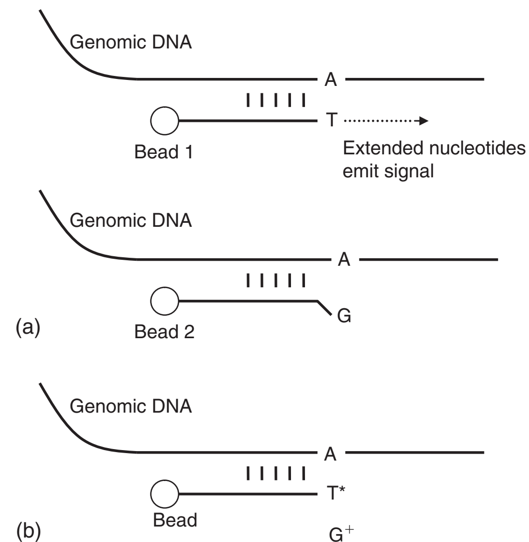

Figure 4.2 Infinium I and II assay. (a) A graphical representation of the Infinium I assay. This assay uses an ASPE and requires two bead types to detect a single SNP. (b) A depiction of an SBE reaction as used for the Infinium II assay. Only one bead type is required to detect a single SNP. The diagram shows a single dideoxy base (T) being added to the 50-base oligomer on the bead.

the surface (Shen et al., 2005). For Illumina's Infinium whole-genome genotyping BeadChip, the attached oligomers consist of a stretch of 75 nucleotides (Gunderson et al., 2005; Steemers et al., 2006) (Figure 4.1). The first 25 nucleotides (the address) serve as a barcode to identify the location of specific beads on the array, and the next 50 bases (the probe) are complementary to a genomic region containing a specific SNP (or copy number variant). On average, there is an 18-fold redundancy of each bead type on the BeadChip. The placement of the beads on the BeadChip is a random process, thus requiring a decoding step. The decoding involves multiple hybridizations to the 25 oligomer address. This not only identifies the location of each bead, but performs a functional quality control for each bead on the BeadChip.

There are two Infinium chemistries, type I and II (Figure 4.2). The Infinium I assay uses an allele-specific primer extension (ASPE) reaction in which fluorescently labeled nucleotides are inserted at the 3′ end of the primer. With this assay it takes two bead types to determine the genotype at a single SNP. The Infinium II assay involves a single-base extension (SBE) reaction that occurs on a single bead type for each SNP. Most of Illumina's off-the-shelf BeadChips use the Infinium II assay.

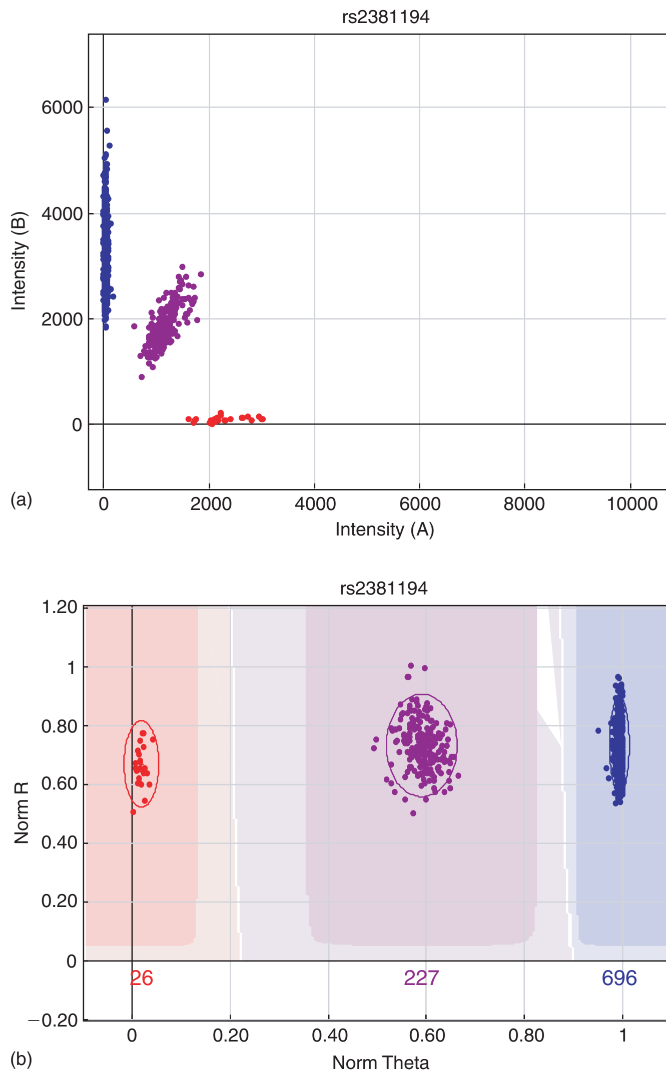

Figure 4.3 Raw and normalized data for SNP genotyping, using the Illumina platform. (a) Raw data from genotype analysis of one SNP (rs2381194) from 949 individuals. Each dot corresponds to a single individual. Blue, homozygote for one allele ($n = 696$); Purple, heterozygous ($n = 227$); Red, homozygote for other allele ($n = 26$). (b) Same SNP and individuals as in (a), but after normalization using Illumina's BeadStudio software.

The steps for the Infinium II assay are as follows: (1) 750 ng of intact genomic DNA is whole-genome amplified (WGA); (2) the amplified product is fragmented; (3) the fragmented DNA is hybridized to a BeadChip; (4) an SBE reaction is performed directly on the chip with the insertion of a labeled (2,4-dinitrophenol or biotin) dideoxy base; (5) the inserted base is stained with a fluorescently labeled antibody and (6) fluorescence on the beads on the BeadChip is detected by scanning with the Illumina BeadStation. An average of the raw intensity per bead type is then imported into the Illumina BeadStudio software, where the data can be efficiently managed and individual SNPs can be automatically or manually called. The quality of the raw and normalized genotype calls can be visually confirmed within this software (Figure 4.3).

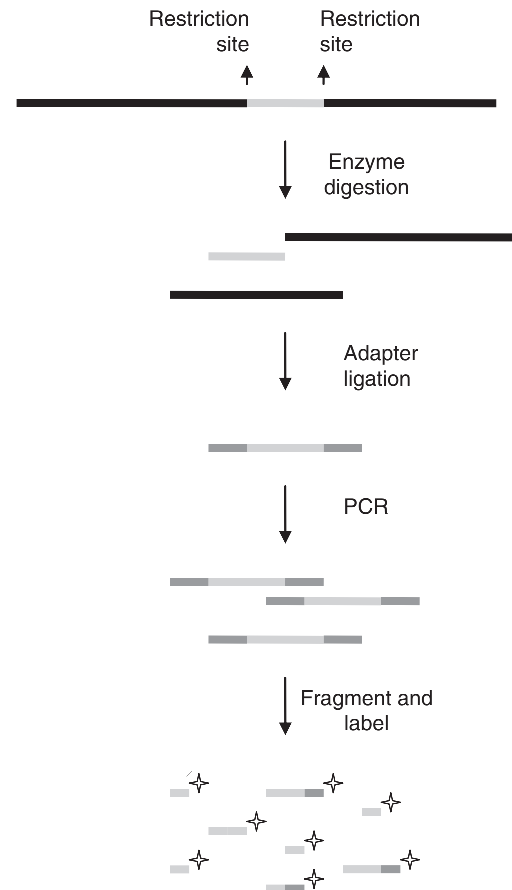

Figure 4.4 Overview of DNA processing steps for the AffymetrixGeneChip. The diagram demonstrates the steps implemented to reduce the genomic complexity allowing for efficient allele-specific hybridization.

Affymetrix GeneChip

The Affymetrix genotyping GeneChip is manufactured using the same principles as for the expression GeneChip, using a technology called photolithography. This has been described in great detail (Dalma-Weiszhausz et al., 2006; Matsuzaki et al., 2004), including elsewhere in this book. However, the genotyping GeneChip contains additional probes for each interrogated SNP, to allow for differentiation of true signal over noise (Dalma-Weiszhausz et al., 2006).

The steps required to process a DNA sample in preparation for hybridization to the GeneChip lead to a reduction in genome complexity allowing for allele-specific hybridization (Figure 4.4). The following is the procedure for processing a sample: (1) perform separate genomic DNA (250 ng) digestions using the *NspI* and *StyI* restriction enzymes; (2) ligate specific adapters containing a single universal primer binding site to the digested DNA; (3) pool the DNA fragments from the separate digestions and amplify using a single universal PCR primer specific to the primer site within the adaptor; (4) fragment the amplified products; (5) end label the DNA; (6) hybridize to a GeneChip and (7) scan the chip. The raw data can then be converted into genotype calls by using the appropriate algorithms (from Affymetrix).

Platform Comparison

Numerous laboratories worldwide have successfully used both the Illumina and Affymetrix platforms to identify genetic variants involved with complex disease (Table 4.1). This section will describe potential benefits of each platform, paying particular attention to (1) differences in the basic design of the chips; (2) statistical tagging power (genomic coverage); (3) ability to detect copy number variation (CNV); (4) processing issues and (5) overall quality of the final raw genotyping data.

The length of the probes to detect an SNP during hybridization constitutes one of the major differences between the platforms. The probe length on the Affymetrix GeneChip is 25 nucleotides, while on the Illumina BeadChip the probes contain 50 nucleotides. This difference in length for hybridization provides for higher specificity for probes on the Illumina BeadChip. The other main difference is the content of the probe for each SNP. For Affymetrix, each SNP is represented by a series of probes consisting of mismatches and perfect homology, allowing for differentiation between signal and noise. The Illumina BeadChips do not require specific mismatch probes for every SNP because of the increased length of the probes for hybridization, but contain control beads that detect the overall level of background noise. The probe length constitutes the major difference between the two platforms and is most likely directly linked to the differences in quality between the platforms.

Most of the SNPs on the Illumina Infinium BeadChips were selected as tagging SNPs, resulting in excellent genomic coverage for most populations (based on HapMap populations) (International HapMap Consortium, 2005). On the other hand, the Affymetrix GeneChips are based on SNPs that are evenly spaced throughout the genome. The positive aspect of even spacing is better physical coverage for detecting CNVs (Redon et al., 2006). One disadvantage of this approach is less statistical power to capture the known common variation when compared to arrays that contain tagging SNPs. A multimarker or haplotype-tagging approach may gain increased power/coverage, but the downstream statistical analyses become more difficult. Multiple groups (Barrett and Cardon, 2006; Magi et al., 2007; Pe'er et al., 2006) have performed statistical comparisons of the Illumina HumanHap300 and the HumanHap550 BeadChips with the Affymetrix Mapping 500 K Set. From these analyses it is evident that the Illumina array with only around 300,000 tagging SNPs has essentially the same statistical genomic coverage as the Affymetrix Mapping 500 K Set, while the Illumina HumanHap550 array is statistically superior for genome-wide association studies.

Overall, both platforms provide good quality results (Table 4.1). However, a comparison of the SNP conversion rate (percentage of SNPs that work) between the two technologies reveals a significant difference. In our hands, for example, when using the Illumina pre-defined cluster, an average sample call rate of 99.6% is achieved, with an average reproducibility of over 99.99%. With the Affymetrix platform, the average sample call rate is variable and depends greatly on the chosen stringency within the calling algorithm, but a typical call rate would be in the range of 95–98% (personal communications). As discussed above, the increased SNP conversion rate with the Illumina BeadChip is most likely related to the size of the probe (50 nucleotides) which increases the specificity during the hybridization step.

Recently, there has been a push to detect CNVs throughout the human genome by using genome-wide genotyping chips (Komura et al., 2006; Redon et al., 2006) (see Chapter 5). Using these SNP-based arrays is an efficient method to detect large deletions or duplications. The Affymetrix GeneChip with its even spacing of SNPs has great genomic coverage to detect large CNVs. Most of the BeadChips from Illumina have specific SNPs or non-polymorphic probes added in regions where there are known CNVs. In general, both arrays are capable of detecting large CNVs. However, with the current SNP densities, the detection of small CNVs is difficult with the use of SNP-based arrays.

Raw Data Quality Control

Genetic association studies using genome-wide genotyping chips produce very large amounts of data. A typical project with 2,000 samples, each containing over 500,000 SNPs per sample, will result in over one billion data points. With this much data, the probability for false positives becomes much greater. A few reasons that can attribute to this are samples being prepared using different purification methods and the processing of the chips in different labs. These slight variations can lead to minor differences in intensity, thus making it more difficult to accurately call the genotypes. To prevent false positives from clouding the results from the statistical analyses, it is of utmost importance to begin with a clean or curated data set. This is accomplished by establishing a high threshold of sample and SNP quality. The number of SNPs that are obtained for each sample (the "call rate") and the raw fluorescent intensity are the main variables that can be analyzed to determine whether a sample should be included or excluded. If any sample's call rate is much lower (>1–2%) than the average call rate for the project, the sample should be excluded. A 1% difference can represent as many as 5,000 fewer SNPs being called in a sample when compared with the average number of SNP calls in a population of samples.

There are many variables that can be used to assess SNP quality. Metrics such as call frequency (number of samples that are being called for an SNP), cluster separation (degree of split between the heterozygote grouping and homozygotes, e.g. Figure 4.3), extreme deviation from Hardy–Weinberg proportions and overall raw signal intensity should be evaluated for all SNPs. A very aggressive approach to maintaining a clean data set is to adhere to a rigorous level of acceptable SNP call frequency. We have established a high threshold for SNP inclusion and have coined the phrase the "1% rule"; we delete any SNP that has greater than 1% of the samples not being called or called ambiguously. This rule was established from personal experiences when attempting to extract as much genotype data as possible. After performing statistical analyses, we noticed a large number of false positives due entirely to poor genotyping calls. For the 1% rule to work effectively, each new experiment needs to be reclustered using its own raw data. With the 1% rule, the use of predetermined cluster files will not work, because slight variations

from experiment to experiment can result in slight shifts of intensity and cluster separation (i.e., separation of heterozygote and homozygote clusters), resulting in incomplete calling of truly callable samples for a large number of SNPs.

When applying the 1% rule, it is a balance between including a greater number of samples or a greater number of SNPs. Attempting to keep good but lower quality samples can result in the deletion of many SNPs that fail to meet the 1% rule standard. By deleting a few extra samples across the entire data set, it is possible to keep many of the SNPs that would have violated the 1% rule. In practice, in our experience, a typical project will have between 1% and 3% samples deleted (not all because of 1% rule) across all SNPs and between 1% and 2% of SNPs deleted because of violating the 1% rule. We have successfully used this approach for multiple studies (Fellay et al., 2007).

After completing the first pass of statistical tests, the SNPs with the lowest 100–200 *p*-values should be manually checked for genotyping data quality. Visualization of the raw/normalized genotype call can increase one's confidence in any potentially associated SNP with a low *p*-value. Inspecting the data is especially important if a data set has not been stringently curated under the 1% rule. For a given SNP, if only 95% of samples are called, over 50 samples from a sample set of 1,000 samples will not have a genotype call. Across a very large data set (over 500,000 SNPs), this loosened threshold can result in many false positives solely because of the increased opportunity for an imbalance of the case/control ratio in the uncalled samples.

Sample Collection, Processing and Throughput

It is now feasible for institutional core facilities or small- to medium-sized labs to run hundreds of samples per week using genome-wide genotyping chips. For each platform described here, there are off-the-shelf kits allowing for easy processing of many chips/samples at once with minimal variation across experiments. Also, with the implementation of automation developed specifically for each assay, sample throughput and tracking have all been simplified.

Genome-wide genotyping chips require less than 1 μg of DNA, a very low amount considering the amount of data generated from this sample. In general, high-quality genomic DNA should be used. DNA of lesser quality or WGA DNA can be used, but will result in a lower sample call rate. The Affymetrix platform is more amenable to the use of WGA DNA, because of the lack of an initial WGA step as in the Illumina Infinium assay. However, WGA DNA will work for the Infinium platform, although lower call rates will be achieved (personal communication). Formalin-fixed, paraffin-embedded (FFPE) tissue samples represent a rich and abundant source of well-annotated material, but DNA isolated from FFPE samples using currently available methods is not amenable to genome-wide genotyping assays. The main reason for this is that the interaction of the formalin with the DNA prevents efficient enzymatic amplification of the DNA. Creating methods to successfully perform whole-genome genotyping on FFPE samples will be of great importance. This will benefit current projects by allowing for the potential increase in sample sizes. Also, precious samples obtained only via FFPE tissues could then be included in genome-wide association studies.

2009 UPDATE

Since the completion of this chapter, there has been an exponential increase in the number of published genome-wide association studies. Examples of some of the major findings include the identification of associated variants with prostate cancer (Gudmundsson et al., 2008; Eeles et al., 2008; Thomas et al., 2008), type 2 diabetes (Yasuda et al., 2008; Unoki et al., 2008; Bouatia-Naji et al., 2009; Lyssenko et al., 2009; Prokopenko et al., 2009), lung cancer (Thorgeirsson et al., 2008; Hung et al., 2008; Amos et al., 2008) and obesity (Thorleifsson et al., 2009; Willer et al., 2009; Loos et al., 2008). The raw data for some of these projects as well as others may be accessible at the dbGaP database (http://www.ncbi.nlm.nih.gov/gap).

As for the genotyping platforms, the rapid advances that have occurred over the past few years with the genome-wide genotyping chips have now stabilized. This is positive for researchers who are now pursuing a genome-wide association study or are screening for copy number variants (CNVs). The current options for the most complete genomic coverage (SNP and CNV) are the Illumina Human 1M-Duo BeadChip and the Affymetrix Human Genome-Wide SNP Array 6.0. Both of these platforms contain tagging SNPs to provide greater coverage of the common variation across the genome. Specific probes have also been added to detect known CNVs and to cover regions of the genome that until now were sparsely covered by probes.

Looking forward, the creation of a new genome-wide genotyping chip with increased SNP content will not add much value or power to most studies screening for common variants associated with a specific phenotype. However, there will be a great need for platforms that allow for the screening of tens of thousands SNPs specific to one's phenotype. This type of custom chip will be a valuable component of the initial next-generation sequencing projects in which small subsets of samples (25-50) are sequenced. Any newly identified single nucleotide variants/CNVs can then be screened across a larger set of relevant samples using the custom designed SNP chip. This type of two-step approach will be useful until it becomes feasible to simply and cost-effectively sequence the entire genomes of thousands of individuals.

CHAPTER

Copy Number Variation and Human Health

Charles Lee, Courtney Hyland, Arthur S. Lee, Shona Hislop and Chunhwa Ihm

INTRODUCTION

Early cytogenetic studies recognized that microscopically visible aberrations such as duplications or deletions of entire chromosomes (aneuploidy) were associated with specific congenital developmental disorders. For example, an extra copy of chromosome 21 (i.e., trisomy 21) has long been established as being correlative with the mongoloid phenotype that was first recognized in 1866 by John Langdon Down (Down 1866; Lejeune et al., 1959). However, recent development of high-resolution assays, capable of detecting small segmental genetic alterations in a genome-wide fashion, have led to the detection of widespread copy number variation (CNV) among the genomes of healthy individuals (Iafrate et al., 2004; Sebat et al., 2004). This finding has now sparked intense efforts to identify and characterize the extent of this type of genetic variation in human populations and to understand its impact on human health.

BASIC PRINCIPLES OF CNVs

CNVs have been operationally defined as genomic gains and losses of 1 kb or larger (Freeman et al., 2006; Feuk et al., 2006). This definition helps to differentiate it from other forms of polymorphism and/or repeated DNAs in the human genome (see Chapter 2), which include indels, microsatellites, minisatellites, simple repeats (e.g., dinucleotide repeats, trinucleotide repeats, etc.), telomeric and centromeric repetitive DNAs, and most interspersed repetitive elements (although LINES and other long interspersed repeats have repeat elements greater than 1 kb in size). In addition, since CNVs are considered subchromosomal imbalances, they are differentiated from whole chromosomal aneuploidies, such as trisomy 21 or monosomy X.

When CNV data are available for many individuals within or across different human populations, CNVs can be categorized into biallelic or multiallelic states (Figure 5.1). Biallelic CNVs have only two alleles and thus produce three different genotypes. For example, a CNV that exists solely in the form of a 1-copy allele or a 2-copy allele (Figure 5.1a, right) can produce diploid copy numbers of 2 (1 allele+1 allele), 3 (1 allele+2 allele), or 4 (2 allele+2 allele) (Figure 5.1a, left). CNVs with greater than two alleles are considered multiallelic and result in more than three different genotypes (Figure 5.1b and Figure 5.2).

Heritable CNVs are thought to arise from germline genomic rearrangements (or in some cases, possibly very early somatic events). The genomic rearrangements (mutational events) that are thought to cause CNVs can be broadly categorized as arising via one of two mechanisms: (i) Non-allelic homologous recombination (NAHR) – where homologous recombination

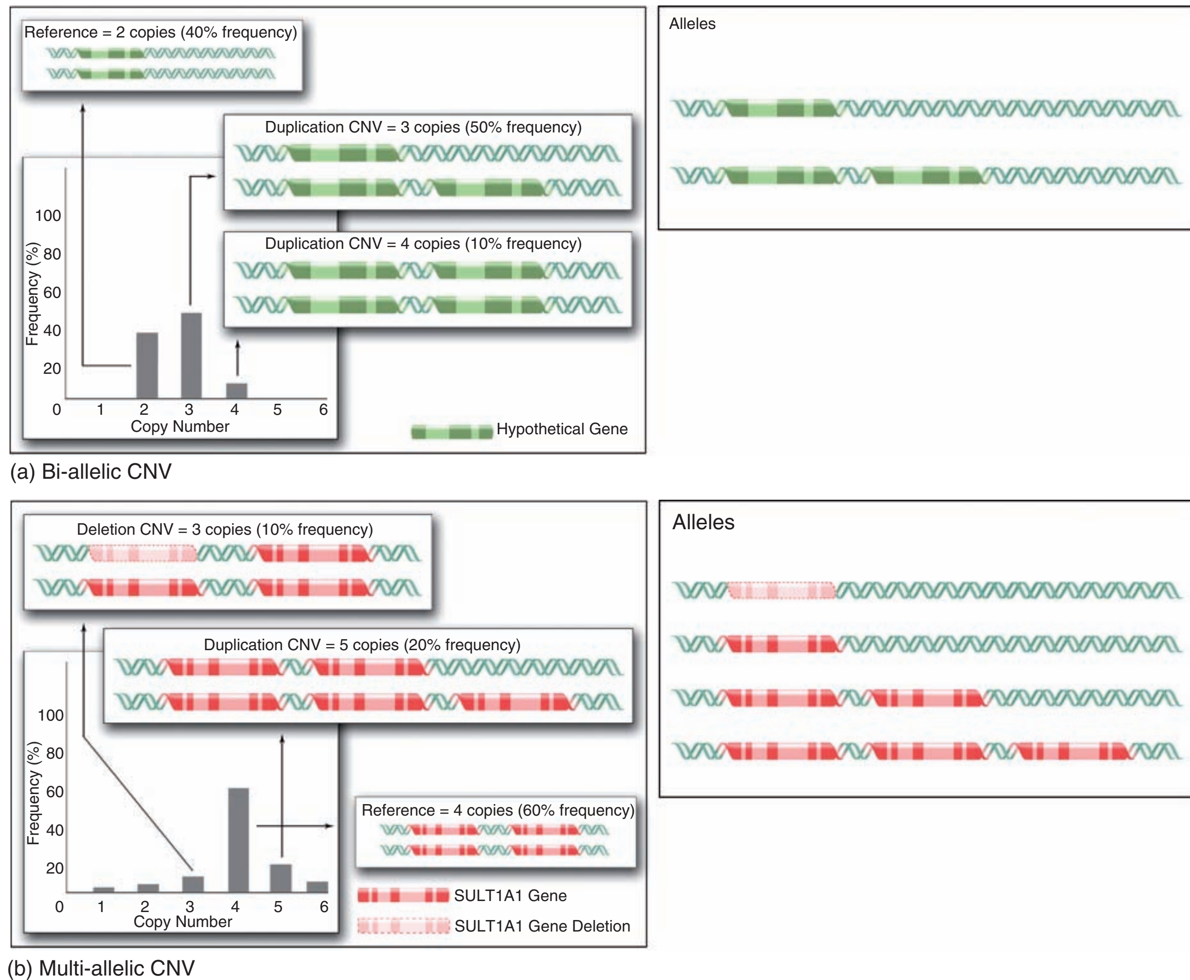

Figure 5.1 Examples of bi-allelic and multi-allelic CNVs. a) An example of a bi-allelic CNV that has a 1-copy allele and a 2-copy allele. The reference individual has two 1-copy alleles but 50% of individuals in this population have a total of three copies of this gene per cell. All bi-allelic CNVs have three genotypes per diploid cell, and in this case, copy numbers of 2, 3, and 4 per diploid cell. b) An example of a multi-allelic CNV that has a 0, 1, 2 and 3 copy alleles, resulting in six genotypes in this population. Only the allelic combinations for the three most common genotypes are shown.

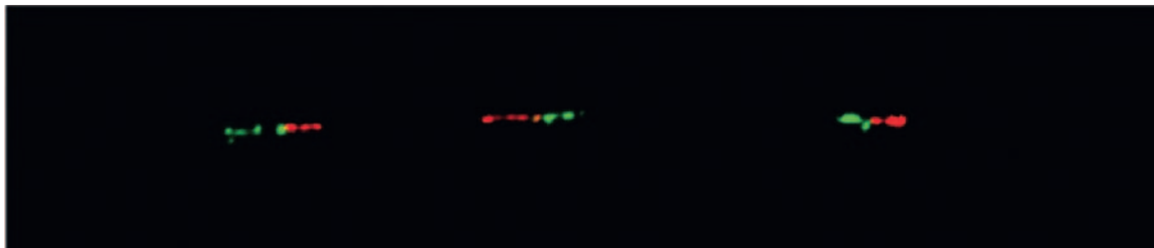

Figure 5.2 The amylase gene is considered a multiallelic CNV with diploid copy number estimates ranging from 2 to 15 among humans (Perry et al., 2007). Here, a two-color fiber-FISH experiment of the amylase gene (each copy of the gene is represented by a red+green combination) shows three copies on a DNA fiber from a single chromosome. It is interesting to note here that the second amylase gene copy is inverted relative to the others.

occurs between highly identical sequences in the genome, such as segmental duplications or related interspersed repetitive elements (Figure 5.3) and (ii) non-homologous end joining (NHEJ) – a repair mechanism whereby double-strand breaks that occur in the genome are ligated together with the assistance of specific protein complexes that form at the sites of the double-strand breaks (Figure 5.4). The rate for NHEJ is likely influenced significantly by environmental factors and localized DNA

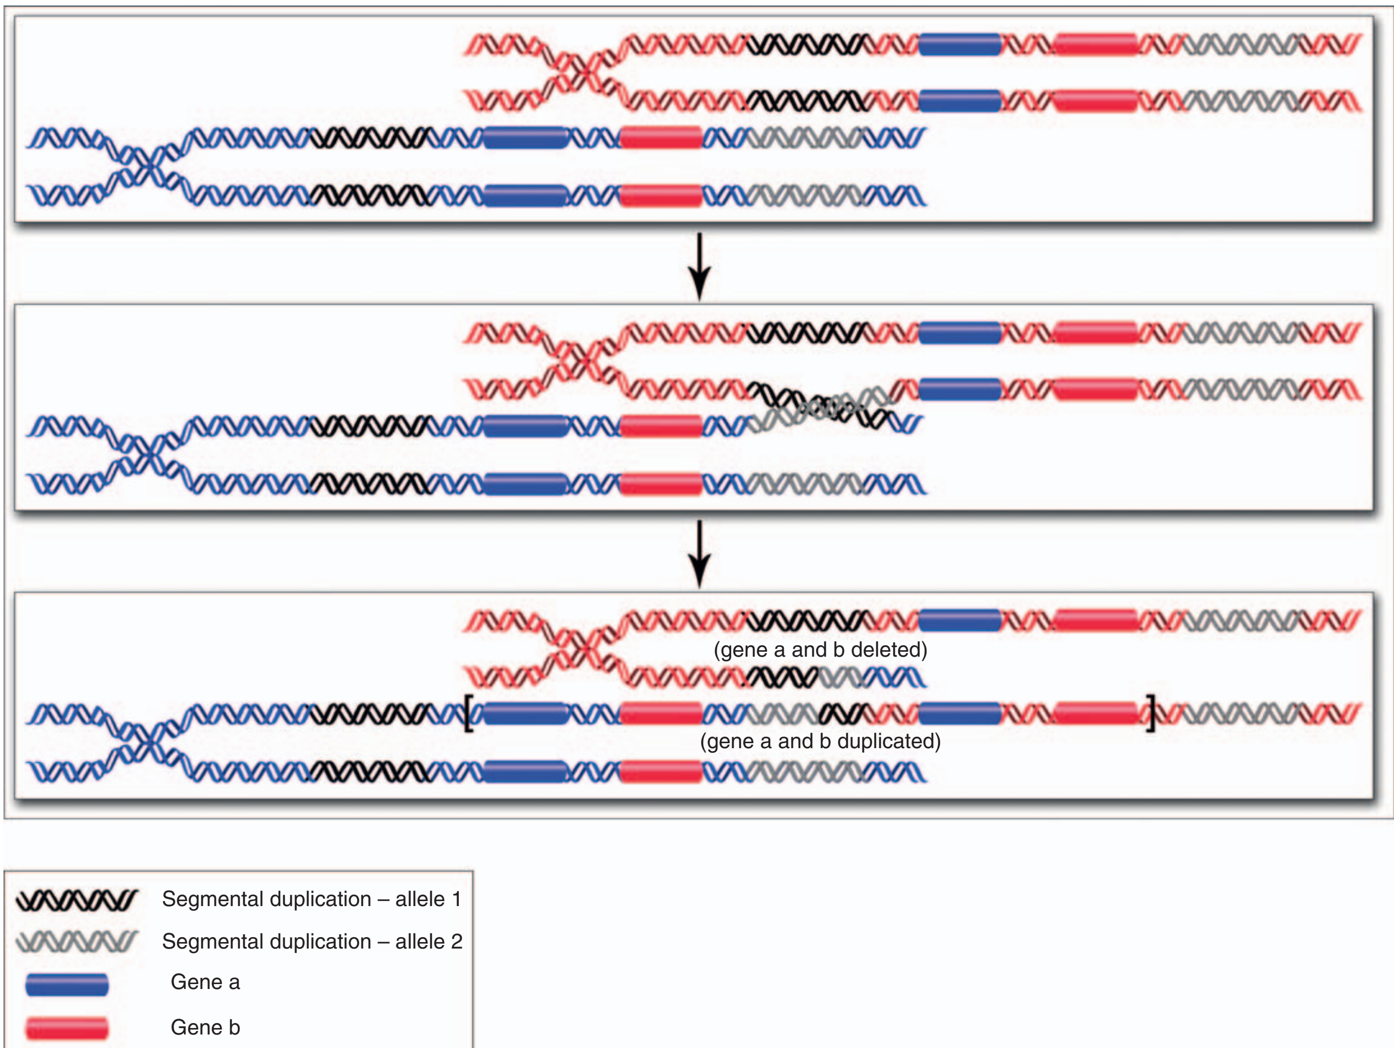

Figure 5.3 Non-allelic homologous recombination (NAHR) is a mechanism for generating CNVs where recombination between non-allelic repeats with >90% sequence homology (indicated by black- and gray-colored DNA segments). Intervening DNA sequences are deleted and duplicated on different chromatids.

conformations, but in general has been estimated to occur at a rate of less than 10^{-7} per generation, similar to the 10^{-8} per generation estimated mutation rate of single nucleotide polymorphisms (SNPs) (Conrad and Hurles, 2007). NAHR events are believed to occur more frequently, with estimates of up to 10^{-4} per locus per gamete per generation (Shaffer and Lupski 2000). Since NAHR events lead to duplication and deletion of DNA sequences that lie between highly identical sequences in the genome, this mutational event tends to be associated with larger CNVs (Redon et al., 2006).

CNVs are scattered throughout the human genome with at least 6% of a chromosome's total DNA content being potentially copy number variable (Redon et al., 2006). Taken together, current estimates are that more than 500 Mb (or 18.8%) of the reference human genome is copy number variable (Scherer et al., 2007). In fact, one recent study suggested that structural genomic variation (i.e., non-SNP variation that is predominantly in the form of CNVs) account for as much as 22% of all genetic variable events found in a given individual and total 74% of all variant bases (Levy et al., 2007). Many of the earlier CNV discovery projects relied on array comparative genomic hybridization (aCGH) technologies that utilized large-insert clones (on the order of 120kb–150kb each) as individuals probles and therefore yielded CNV data with ill-defined boundaries. This has likely led to a size over-estimation for many currently identified CNVs.

Documented CNVs are being cataloged and collated in several databases. For example, CNV data from healthy individuals can be found in the Database of Genomic Variants (http://projects.tcag.ca/variation) and the human paralogy database (http://humanparalogy.gs.washington.edu/structuralvariation), while CNVs from patients affected with a neurodevelopmental disorder are being collated in databases such as DECIPHER

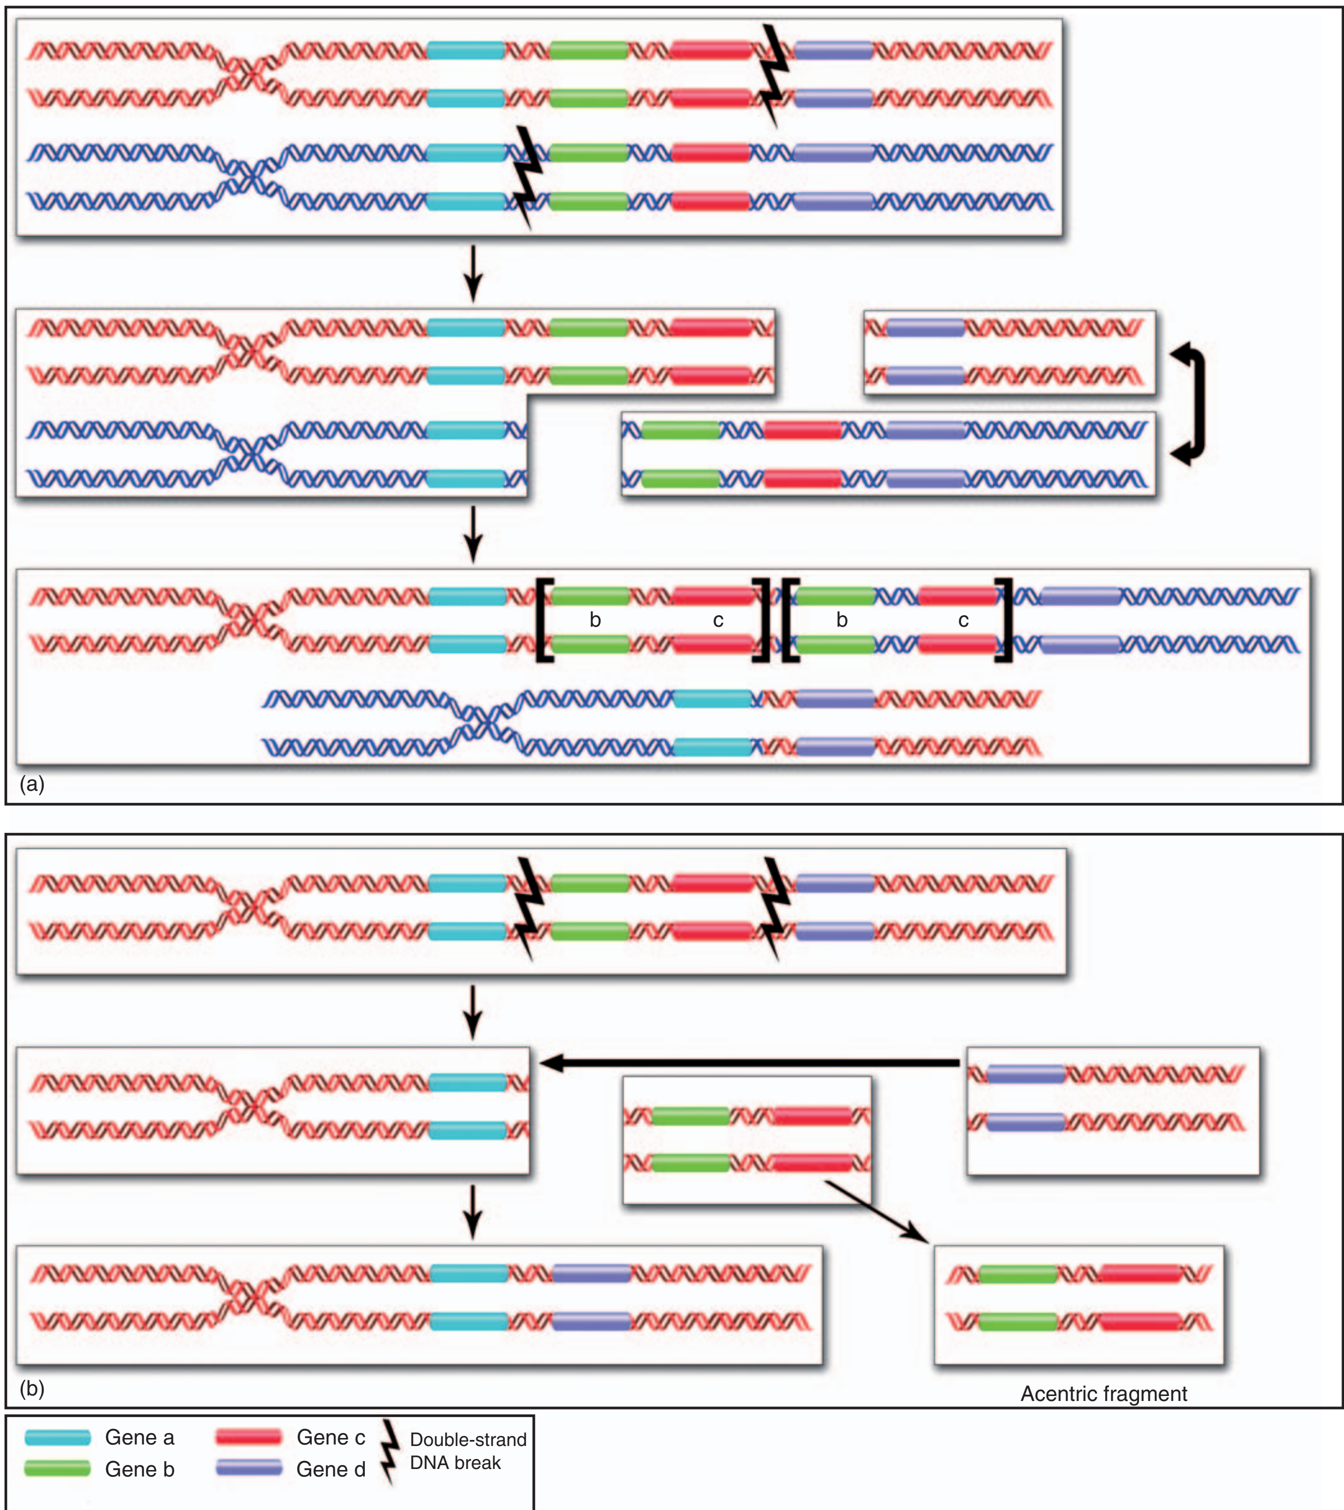

Figure 5.4 Non-homologous end joining (NHEJ) can result in a genomic rearrangement that immediately or eventually results in the gain or loss of genetic material after multiple double-strand DNA breaks occur and are repaired. (a) A balanced rearrangement has occurred and there is no immediate net gain or loss of genomic material within the cell, but it will result in gains or losses of DNA in subsequent generations depending on which chromosome is inherited. (b) In an unbalanced rearrangement, genomic material can be lost immediately (e.g., in this case, the acentric fragment containing one copy of genes b and c will be lost in subsequent cell divisions).

(http://www.sanger.ac.uk/PostGenomic/decipher/), the Chromosome Abnormality Database (http://www.ukcad.org.uk/cocoon/ukcad/) and the European Cytogenetics Association Register of Unbalanced Chromosome Aberrations (http://www.ecaruca.net).

Most CNVs found in healthy individuals are biased away from genes and reside within intergenic regions (i.e., DNA sequences between genes) (Conrad et al., 2006; Nguyen et al., 2006). Nevertheless, the remaining CNVs have been shown to overlap some 3,000 RefSeq genes and 300 genes implicated in genetic disease (as listed in the *Online Mendelian Inheritance in Man* database, http://www.ncbi.nlm.nih.gov/sites/entrez?db=OMIM). Ontology analyses of the genes thought to be copy number variable demonstrate a substantial number that can be classified as "environmental sensor/interaction" genes (Tuzun et al., 2005). These are genes that are involved in sensory perception, neurophysiological processes, drug detoxification, immunity and inflammation, as well as cell surface integrity and cell surface antigens. Clearly, such genes are not critical for early development but rather are involved in our perception and interaction with external stimuli, helping us to adapt to our ever-changing environment.

The functional impact of certain CNVs can be relatively straightforward. For example, reduced copy number of a given gene can often be correlated with reduced expression levels, while additional copies of a gene could lead to increased expression levels of the CNV gene (McCarroll et al., 2006). CNVs that involve parts of a gene could result in fusion gene products or aberrant proteins with addition or loss of specific protein domains. Some CNVs in intergenic regions could overlap regulatory elements that affect the expression of genes as far away as 4 Mb (Stranger et al., 2007), and correlations of CNVs with transcriptional levels do not necessarily have to be positive. For example, deletion of a repressor element may cause upregulation of an associated gene.

DETECTING CNVs IN A GENOME-WIDE MANNER

Array-Based Comparative Genomic Hybridization

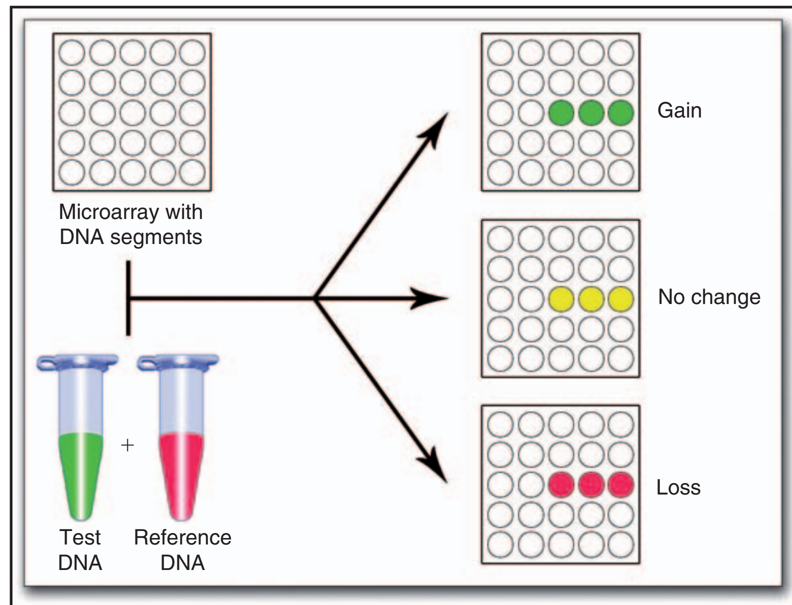
There are different genome-wide methods for detecting CNVs. By far, the most widely used method has been array-based comparative genomic hybridization (aCGH). This technology was first introduced as "matrix-CGH" (Solinas-Toldo et al., 1997) and later referred to as "array CGH" (Pinkel et al., 1998). In aCGH, the "test" genome being interrogated is labeled with one type of fluorescent molecule (e.g., Cy5), and a "normal" or "reference" control genome is labeled with another type of fluorescent molecule (e.g., Cy3) (Figure 5.5). The labeled DNAs are combined, denatured and hybridized to an array of DNA fragments or oligonucleotides on a microscope slide, with each DNA fragment or oligonucleotide representing a unique part of the human genome. The labeled DNAs are then allowed to hybridize to their complementary DNA sequences on the array, in a stoichiometric fashion, such that – by measuring the fluorescence ratio of the two fluorescent dyes at each spot on the array – one can infer the relative copy number of that particular DNA sequence in the genome being tested, with respect to the reference genome (Figure 5.5).

There have been many advances in aCGH technology over the past 5 years. Originally, aCGH platforms contained several hundred or even up to a thousand, large-insert DNA clones (e.g., BAC clones that have an average insert size of about 120–150 kb), which recapitulated the human genome with a clone per ~3 Mb. More recently, the trend has been to manufacture arrays that use smaller DNA sequences as hybridization targets but with increasing number of targets on an array. On such arrays, targets can be oligonucleotides of 45–75 bases in length that have been designed to have similar annealing temperatures (isothermic), based primarily on the length of the oligonucleotide and its GC base pair content. Two companies that produce such arrays are NimbleGen Systems, Inc. (www.nimblegen.com) and Agilent, Inc. (www.agilent.com/chem/goCGH). NimbleGen uses a programmable mirror array to synthesize 385,000 oligonucleotides (more recently 2.1 million targets) directly on a glass surface using photolithography. Agilent, on the other hand, uses ink-jet technology to synthesize 244,000 oligonucleotides (more recently 1.1 million targets), on a spot-by-spot basis.

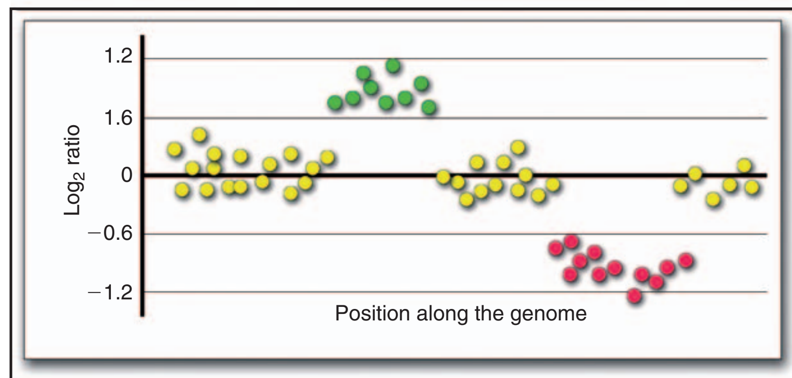
When using oligonucleotide-based arrays, it is important to note that their primary disadvantage is that each oligonucleotide probe tends to have lower signal-to-noise ratios than a large-insert genomic clone target. This results in more experimental "noise" for oligonucleotide-based aCGH assays. Indeed, the typical standard deviation of $\log_2$ ratios for an oligonucleotide-based array is approximately 0.25–0.3, five times the standard deviation of $\log_2$ ratios obtained for BAC-based arrays. However, the inclusion of hundreds of thousands to millions of targets on a given oligonucleotide-based platform provides an assay with an increased resolution. The "effective resolution" of one of these platforms depends largely on the minimum number of consecutive probes needed to confidently call a CNV, which in turn is a function of how well the target sequences were chosen to accurately and consistently respond to copy number changes. Hence, a particular platform that has 500,000 targets and requires only three consecutive probes to make a confident CNV call actually has a higher effective resolution than an array platform with one million targets, but requiring 10 consecutive probes to make a CNV call, assuming that both platforms distribute targets evenly throughout the genome.

Genotyping Arrays

High-throughput array technologies for identifying SNPs can also be used to identify CNVs (see Chapter 4). In general, these arrays contain short targets (20–30 base oligonucleotides) that make them ideal for detecting single base alterations, but less ideal for identifying CNVs (especially when compared to long oligonucleotide-based arrays). For genotyping arrays, only a single labeled DNA source ("test sample") is hybridized, and the signal intensities obtained at each hybridized target appear to have a linear relationship with respect to copy numbers of that particular



(a)



(b)

Figure 5.5 (a) A schematic of an aCGH assay where a test genome (labeled with Cy5, denoted in green) is cohybridized with a reference genome (labeled with Cy3, denoted in red). The DNA probes are mixed and allowed to hybridize to its complementary sequences on the array in a stoichiometric fashion. Fluorescence intensities of the spots on the microarray (each containing a specific DNA sequence) are measured and DNA sequences occurring in greater copy number in the test than in the reference will result in more green fluorescence for those spots on the microarray. A lower copy number of the same DNA sequences will result in more red fluorescence. (b) Typically the $\log_2$ of the fluorescence ratios for each DNA segment on the array is then plotted from one end of a chromosome to the other. A gain is indicated in green and a loss in red. DNA segments having no significant change in DNA copy number in the test sample (with respect to the reference DNA) is indicated in yellow.

DNA sequence in the test genome. For example, if a given DNA sequence has four copies in test genome "X" and only two copies in test genome "Y," the signal intensity obtained for that DNA sequence when test genome "X" is hybridized would be twice that of when test genome "Y" is hybridized. In general, genotyping platforms can detect larger CNVs (especially when there is a higher level of copy number change) or smaller CNVs (that are detectable by numerous targets on the array platform). Affymetrix (www.affymetrix.com) SNP arrays contain targets that are ~25 bases long and the predecessor to the Affymetrix 500K array was recently used to identify CNVs in 270 HapMap individuals (Redon et al., 2006). Illumina Inc. (www.illumina.com) has designed a genotyping platform that uses 50 base oligonucleotides attached to indexed beads on a glass slide. Labeled test DNAs are hybridized to this slide, followed by primer extension and then immunofluorescence detection. Peiffer et al. (2006) recently showed that the ability of Illumina genotyping platforms have also been used to detect CNVs in both constitutional and tumor samples.

Clearly, there would be significant benefits to having platforms that are capable of accurately determining both SNP and CNV genotypes, including reduced reagent costs and expenditure of minimal amounts of DNA. However, the fluorescence intensity

data obtained from these genotyping platforms typically have more noise when trying to obtain copy number information than do long oligonucleotide-based arrays. Hence, both Affymetrix and Illumina are now designing "next generation" arrays that incorporate thousands of non-polymorphic probes (i.e., probes that do not target known SNPs) that fall within known CNV regions. It is thought that a CNV can be confidently detected if enough targets are strategically chosen for a given CNV region and included in the array. In other words, one probe may not be able to reliably detect a single copy loss in a CNV region but cumulative data from one hundred targets in the same CNV region may result in a consistent and confident CNV call.

Whole-Genome Sequence Comparisons

CNVs can also be detected via whole-genome sequence comparison analyses. The main advantage of this method for identifying CNVs is that the acquisition of fine-scale genomic architecture of CNVs (i.e., accurate CNV sizes and breakpoint information). A major disadvantage of this approach is the limited number of individuals for which whole-genome sequence data are currently available. The first human whole-genome sequence was made available from the Human Genome Project. This reference human genome is actually a compilation of DNA sequences from over ten different individuals with ~67% of the DNA sequences originating from the RPCI-11 DNA library, derived from a single individual male. Tuzun et al. (2005) aligned end-sequence data from thousands of fosmid clones from the G248 DNA library (derived from a single North American female) and compared these with the human reference genome sequence. Taking advantage of the tight size restriction of fosmid clones, they were able to identify genomic gains/losses in the reference genome, when pairs of end-sequences aligned with intervening spacing significantly greater or less than the expected 40 kb. In this manner, 241 CNVs were identified in one of these two healthy and presumably normal individuals. More recently, sequencing technologies have advanced to a point where complete human genome sequences can be obtained more efficiently and cost-effectively than previously possible. For example, using Solexa or 454 DNA sequencing approaches, an individual's complete genome sequence can now be obtained within months and at costs of under $250,000. Undoubt-edly, these advances will be used to comprehensively identify and define CNVs at a DNA sequence resolution, provided that a minimal fold-coverage of the person's genome is achieved. Recent studies that have obtained complete genome sequences for different individuals have reported thousands of CNVs in a given individual, encompassing hundreds of millions of bases of DNA (Korbel et al., 2007; Levy et al., 2007).

A major advantage of utilizing DNA sequence comparison strategies is the ability to identify balanced chromosomal rearrangements that cannot be detected by aCGH-based methods. For example, Tuzun et al. (2005) found evidence for 56 inversion breakpoints in their comparative analysis of the two genomes of two individuals, and Korbel et al. (2007) found 132 inversion breakpoints when comparing the genomes of two different individuals.

ASSOCIATION OF CNVs WITH DISEASE AND DISEASE SUSCEPTIBILITY

Genomic imbalances, including CNVs, can contribute to human diseases in at least two ways. First, certain genomic imbalances appear to directly cause neurodevelopmental diseases, that can occur at birth or even later on in life. These genomic imbalances (referred by some as "pathogenic" CNVs) are usually de novo in nature and recent estimates have associated specific genomic imbalances with as many as 50 such genetic syndromes (http://www.sanger.ac.uk/PostGenomics/decipher/). Most of the remaining known genomic imbalances – sometimes referred to as "benign" CNVs because of their identification in healthy individuals – actually have more subtle consequences on human health.

Fcgr3 Variation in Glomerulonephritis

Glomerulonephritis is a major contributor to human kidney failure. *Fcgr3* is a gene that encodes for a receptor found on the surfaces of macrophages and that has low-affinity binding properties to immunoglobulin G. The copy number of *Fcgr3* can vary in humans and among rat strains from 0 to 4 per diploid cell. Individuals with fewer copies of this gene, due to deletions of paralogous *Fcgr3* genes (which appear to have a negative regulatory effect on the "full length" *Fcgr3* gene/gene products), demonstrate increased macrophage activity and an autoimmune response (Aitman et al., 2006; Fanciulli et al., 2007).

DEFB4 CNV in Crohn Disease

Human β-defensins are a family of genes predominantly secreted from leukocytes and epithelial tissues. β-defensins are small proteins (15–20 residues) that function in antimicrobial defense by penetrating a microbe's cell membrane and cause microbial death in a manner similar to that of antibiotics. In the presence of interleukin 1-alpha (IL-1α), which is secreted by macrophages and other immunologically relevant cell types at the site of tissue inflammation, the expression levels of the β-defensin gene, *DEFB4*, increases (O'Neil et al., 1999), to protect the tissue from further microbial invasion. Therefore, individuals with a lower copy number of this β-defensin have decreased immunity against microbes and increased susceptibility to Crohn disease (Inflammatory bowel disease 1) (Fellermann et al., 2006; Naser et al., 2004).

UGT2B17 Variation in Prostate Cancer

Park and colleagues (2006) found that CNV of the *UGT2B17* gene (Murata et al., 2003; Redon et al., 2006; Wilson et al., 2004) confers differential susceptibility to prostate cancer (Figure 5.6). Testosterone is normally processed into dihydrotestosterone

(DHT) and other androgens within human cells. In the presence of functioning UGT2B17 gene product, excess DHT molecules are converted into water-soluble glucuronic acid which can be subsequently eliminated from the cell. When *UGT2B17* is deleted, this process becomes less efficient and results in greater amounts of DHT within the cells. Increased intracellular DHT concentrations lead to increased interactions with androgen receptors that cause elevated cell proliferation. When this occurs in the prostate cells, it can result in prostatic tumorigenesis. Interestingly, while *UGT2B17* null deletions significantly increases prostate cancer susceptibility as a whole, stratified analysis revealed that this correlation to prostate cancer susceptibility is only significant in the Caucasian populations studied, but not among African-Americans.

The CNV of Complement Component C4 in Systemic Lupus Erythematosus (SLE)

Although a link between the complement component C4 (and its isotypes, C4A and C4B) and SLE has been previously reported (Hauptmann et al., 1974a,b), a recent study suggests that the gene's variable copy number actually serves as a significant risk factor for the disease (Yang et al., 2007). The complement system is comprised of over 20 proteins/protein fragments that normally circulate in the blood but, when activated, cause a biochemical cascade that clears pathogens from the human body, often by forming new transmembrane channels in the pathogen and causing osmotic lysis of the target cell. The median copy number of complement component C4 is 4 but can range from 0 to >5 copies among humans (Yang et al., 2007). Low copy numbers of this gene are correlated with increased risk for SLE (Fanciulli et al., 2007; Yang et al., 2007).

CCL3L1 CNVs in HIV/AIDS

A number of studies on HIV/AIDS have focused on the gene copy number and protein levels of CCL3L1 and CCR5 (Gonzalez et al., 2001, 2005) in diseased and healthy individuals. CCR5 is a major co-receptor for the HIV-1 virus as well as the CCL3L1 chemokine. It was recently found that the combination of low *CCL3L1* gene copy number, which is population-specific, and high protein levels of CCR5 showed the greatest increase in susceptibility to AIDS (Gonzalez et al., 2005). It is speculated that increased CCR5 protein levels lead to greater

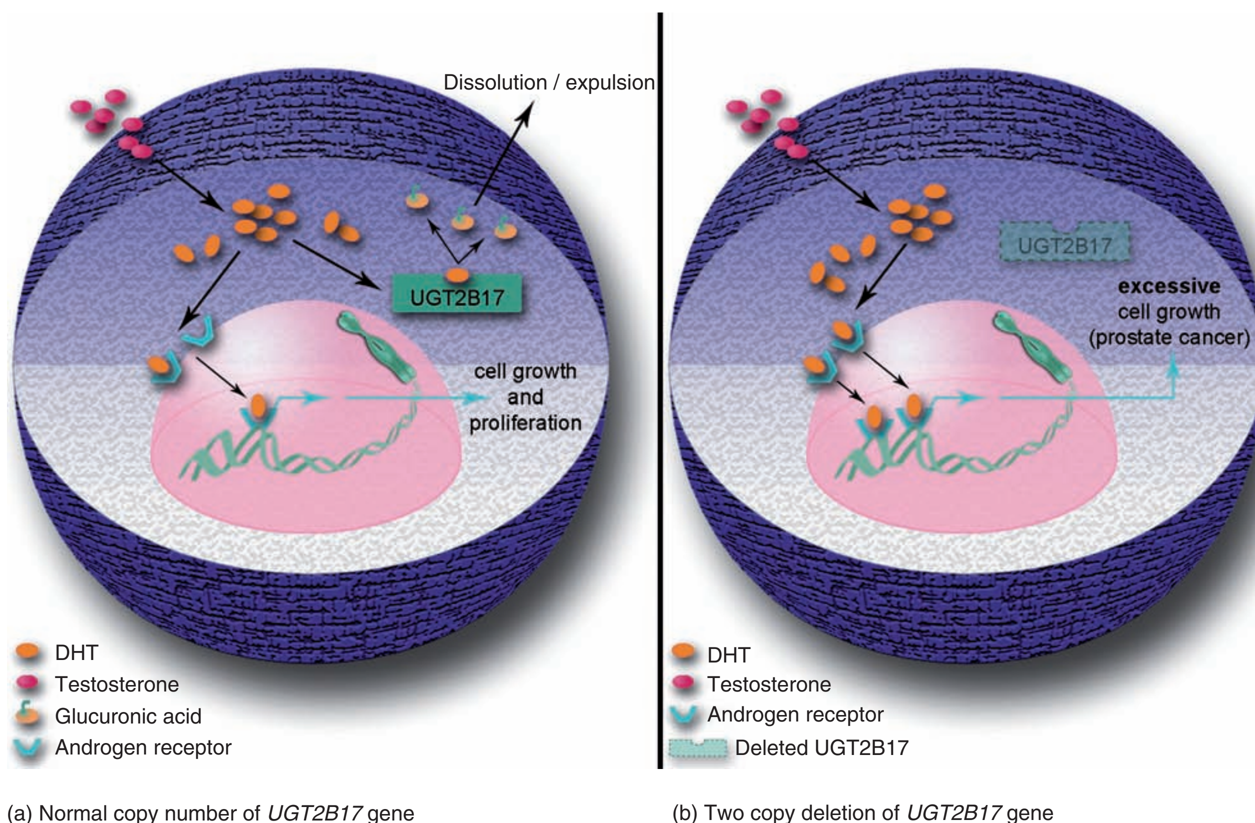


Figure 5.6 Potential mechanism of the *UGT2B17* CNV in prostate cancer pathogenesis. (a) Testosterone is normally processed into DHT and other androgens. When there are two copies of *UGT2B17*, the gene product converts excess molecules of DHT into the water-soluble glucuronic acid and is subsequently eliminated from the cell. (b) When there is a homozygous deletion of *UGT2B17*, the DHT-sequestration pathway no longer exists, increasing endogenous interaction with androgen receptors (AR) and leading to elevated cell proliferation, which in some cases can result in the development of prostate cancer (Park et al., 2006).

number of CD4+CCR5 receptor complexes on the surfaces of T cells and decreased copy number of *CCL3L1* leads to decreased expression (and protein levels) of this chemokine, leaving more CD4+CCR5 receptor complexes available for binding with the HIV-1 virus.

IMPLICATIONS OF CNVs

Disease Association Studies

SNPs have become powerful markers for identifying important disease loci in genetic association studies. However, recent analysis of the complete DNA sequence from a single human individual has shown that CNVs (and other structural genomic variants including small balanced chromosomal rearrangements) account for some 22% of all genetic variation events in the individual and 74% of the total DNA sequence variation, when compared to the human reference genome (Levy et al., 2007). Although it is premature to predict the relative contribution of CNVs to the etiology of common, complex diseases (compared to SNPs), it is clear that CNVs represent a substantial component of human genetic variation that should not be ignored in future disease association studies. Indeed, the presence of CNVs in the human genome has actually reduced the power of certain SNPs. For example, SNPs that lie within CNV regions are difficult to genotype, result in Hardy–Weinberg equilibrium distortions, and are often erroneously calculated as having reduced linkage disequilibrium to nearby causative genomic regions. Moreover, CNVs are far more complex in nature than SNPs and demand appreciation of several factors in order to use this form of genetic variation appropriately in disease association studies. First, the *absolute* copy number (rather than *relative* copy number obtained from aCGH-based experiments) needs to be established for each CNV. Second, the exact genomic location of duplicated CNVs should also be considered. For example, the presence of a third copy of a gene may have dramatically different phenotypic effects depending on where the third copy occurs in the genome. Finally, the precise boundaries (at the DNA sequence level) of each CNV should also be known, as should the specific allelic state of a CNV (e.g., two copies of a gene could be distributed as one copy per chromosome or both copies on a single chromosome). Without this level of information, the power of CNVs in genetic association studies diminishes. Indeed, of the several thousand CNVs that have been identified to date, only a small percent have actually been annotated and genotyped to this precision.

Some efforts have been made to determine if CNVs are in linkage disequilibrium with nearby SNPs. If so, this would allow for specific CNV alleles to be assayed indirectly with a subset of well-characterized SNPs (i.e., "tagging" SNPs) (see Chapter 4). Initial observations suggested that a subset of CNVs did appear to be ancestral in nature and therefore taggable by specific SNPs (McCarroll et al., 2006). Larger CNVs, especially those that are in segmental, duplication-rich areas of the genome, appear to be less taggable by known SNPs (Locke et al., 2006). Part of the reason for this may be that the mutation rate for such CNVs is higher than the mutation rates for nearby SNPs (recall that NAHR mutations rates are estimated to be substantially higher than that of SNPs). Overall, this suggests that, for association studies, a substantial number of CNVs may need to be genotyped directly.

Pharmacogenetics

Since many CNV genes are involved in metabolism and drug detoxification, it has been speculated that CNVs may also make significant contributions to future pharmacogenomic studies (Ouahchi et al., 2006). For example, the *CYP2D6* genes code for enzymes that are involved in the metabolism of more than 30 medications that include antiarrhythmics, antihypertensives, beta-blockers, etc. *CYP2D6* CNVs have been identified and shown to result in gene products with differential metabolism efficiency (Rotger et al., 2007). Similarly, CNVs of genes involved in metabolism may explain some cases of interindividual variation in drug toxicity. McCarroll et al. (2005) and Conrad et al. (2006) found more than 120 CNV genes that were homozygously deleted. Individuals harboring such homozygous deletions presumably have low toxicity tolerance to medications that depend heavily on the homozygously deleted CNV gene product for proper metabolism. Rapid and accurate identification of these individuals should be made a priority in pharmacogenomic research (see also Chapter 15).

Clinical Cytogenetic Diagnostics

Array CGH-based techniques are now being more widely used in the clinical cytogenetic diagnostic arena to identify smaller genomic imbalances that may be associated with neurodevelopmental disorders. Indeed, it has been estimated that aCGH-based assays are now detecting apparently pathogenic genomic imbalances in as much as 20% of cases that have had normal results from chromosome-banded karyotyping tests (Figure 5.7). However, the recent recognition of widespread CNVs among the genomes of healthy individuals has made interpretation of aCGH-based assays more difficult [for a recent review on this, see Lee et al. (2007)]. Specifically, all CNVs detected in an aCGH clinical test need to be assessed for their potential to contribute to the clinical presentation.

One of the primary means for assessing pathogenicity of a CNV is by determining whether or not the CNV is *de novo*. Indeed, 2–3% of children are born with a major birth defect that is sporadic in nature, and the genetic alteration causing these birth defects is similarly assumed to be sporadic in nature. This strategy for determining the pathogenicity of a genomic imbalance in "constitutional" genetic testing is not new and has been applied by cytogeneticists for decades (albeit at the chromosomal banding analysis level). Therefore, for genomic imbalances detected by aCGH assays, it must be determined if the same genomic imbalance is observed in either of the biological

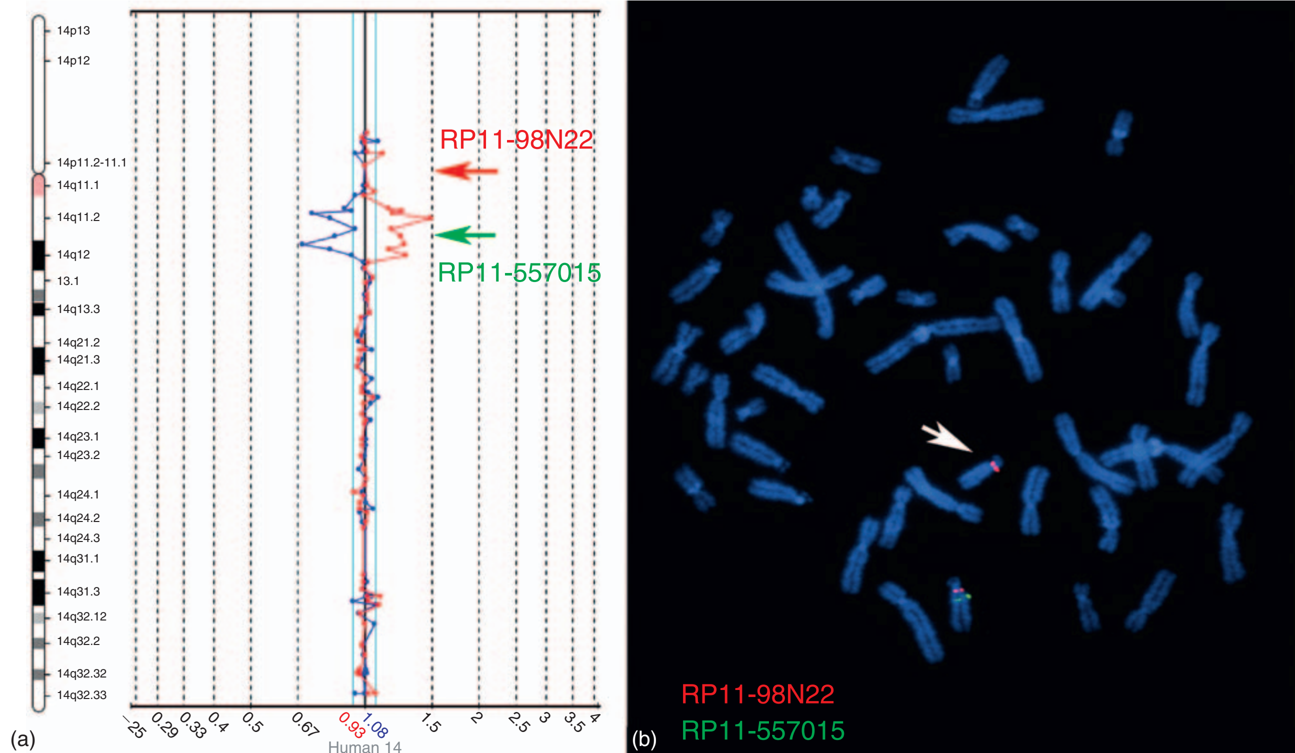

Figure 5.7 Example of a *de novo* genomic imbalance that is likely causative of the clinical phenotype of a patient seen in the clinical genetic clinic. (a) A chromosome 14 profile from a 1 Mb resolution aCGH assay that has been run in dye swap. Deviation of the red line to the right of the expected 1:1 ratio and the blue line to the left of the expected 1:1 ratio is indicative of a genomic loss in the patient DNA. Here, nine BAC clones (each clone represented by a dot on the array profile) are within the deleted region, suggesting a 9–10 Mb sized deletion. The position of BAC clones used in FISH confirmation studies are indicated in red and green. (b) A metaphase spread from the patient after a two-color FISH confirmation assay using a clone within the deletion interval (RP11-557O15) and a control clone outside of the deletion interval (RP11-98N22). The absence of the green signal on one of the chromosome 14s (indicated with a white arrowhead) confirms the aCGH findings. Parental FISH studies were normal (not shown), indicating that this chromosomal aberration was a *de novo* event.

parents, and close attention must be paid to the absolute copy number of the CNV (i.e., not just the relative copy number that is obtained from aCGH experiments), breakpoint information when available and genomic distribution of the CNV DNA segment. Similarly, determining whether a given CNV is present in affected (or unaffected) relatives can also be highly informative.

Another factor to consider is whether the CNV has been found in other unrelated but affected individuals with similar clinical phenotypes (using CNV databases such as DECIPHER) or among healthy individuals (using CNV databases such as the Database of Genomic Variants). This information is only as useful as the accuracy of the CNV entries in these databases (i.e., minimal false positives and precise definition of the architecture of each CNV entry). Moreover, the gene content within a given CNV will also dictate the clinical interpretation of that CNV. Finally, the overall size of the CNV can be a minor indicator of its pathogenicity, with the caveat that "benign" CNVs, as large as 10 Mb in size in gene-poor regions of the genome, have been documented (Hansson et al., 2007).

Accurate clinical interpretation of CNVs will improve as our knowledge of the structure and function of the human genome increases. Clearly, CNVs cannot be considered as isolated genomic aberrations and eventually should be interpreted in the context of all genomic variants, including other CNVs as well as SNPs. For example, the same deletion CNV in a healthy individual may uncover a recessive SNP mutation on the other allele in an unrelated individual – leading to a drastically different phenotype. Since we are at a stage in clinical cytogenetic diagnostics where the technology and the data being obtained are beyond our understanding of human genome function, caution continues to be advised in the application of genome-wide aCGH assays in prenatal diagnostics. Instead, targeted aCGH platforms that primarily utilize probes with well-defined associations with genetic disorders have been used for prenatal diagnoses.

2009 UPDATE

Generating CNVs during DNA replication

Genomic rearrangements that occur in germ cells can potentially lead to *de novo* CNVs in the individual's offspring. The two main mechanisms for generating CNVs have been proposed (see Figures 5.3 and 5.4 in main chapter): (1) NAHR – where homologous recombination occurs between highly identical and multiple sequences in the genome leading to duplication or deletion of DNA sequences that lie between the homologous sequences; and (2) NHEJ – where erroneous repair of double strand breaks lead to gains and losses of DNA segments near the breakpoints. NAHR events are thought to mainly occur during meiosis (although NAHR-like event could also occur mitotically – please see below) and NHEJ events occur in either G1 or G2 of the cell cycle. Most recently, it has been proposed that CNVs could also be generated from errors occurring during DNA replication (i.e. during S-phase). Occasionally, during DNA replication, the DNA replication fork stalls. At these times, the DNA replication machinery may disengage and reattach to template DNA sequences nearby ("template switching"), resulting in duplication or deletion of sequences near the site of the template switching (Lee et al., 2007). If the template switching is facilitated by the presence of cruciform(s) or other non-B DNA structures, one may expect to generate more simple CNV structures at those DNA regions. Otherwise, non-recurrent and complex CNV formations are expected. Evidence to support this mechanism for CNV formation has been provided for the Pelizaeus-Merzbacher disease region (Lee et al., 2007) as well as for MECP2 duplications (Bauters et al., 2008).

CNVs within an individual and between identical twin pairs

Genomic rearrangements that occur somatically (i.e. not in germ cells or germ cell progenitors) can lead to cell-to-cell variability with respect to genomic content per cell. Consistent with this notion, copy number variants have been detected between different tissue types within a given individual (e.g. Sharp et al., 2005; Piotrowski et al., 2008). Furthermore, the fact that CNVs have now also been identified between monozygotic twins (Bruder et al., 2008) suggests that some of these events may be occurring early during embryogenesis. The finding that monozygotic twins may differ with respect to CNVs (and possibly other structural genomic variants) is likely to lead to renewed interest in analyzing the genomic profiles of phenotypically-discordant monozygotic twins to rapidly identify candidate genes involved in the etiology of that specific phenotype.

The role of CNVs in schizophrenia and autism

Evidence is now accumulating that CNVs contribute to the etiology of autism spectrum disorder (ASD) as well as schizophrenia. Sebat et al. (2007) suggested that the burden of *de novo* CNVs was higher in sporadic rates of autism (*de novo* CNVs in 10% of patients from "simplex" families – containing a single child with autism) compared to patients with an affected first-degree relative (*de novo* CNVs in 3% of patients from "multiplex" families – containing multiple affected siblings) or controls (*de novo* CNVs in 1% of the controls). This suggested that *de novo* germline CNVs may be significant risk factors for ASD. One of the most frequently observed *de novo* CNVs identified (aside from the maternal duplication of 15q11-q13) was a 600-kb microdeletion/microduplication at chromosome region 16p11.2 (Sebat et al., 2007, Weiss et al., 2008, Kumar et al., 2008, Marshall et al., 2008). Interestingly, several neuronal synaptic complex genes have been identified within these *de novo* CNV regions including *SHANK3*, *NLGN4*, *NRXN1* (Sebat et al., 2007, Marshall et al., 2008, Weiss et al., 2008, Kumar et al., 2008), as well as genes involved in neuronal activity: *PCDH10*, *DIA1*, and *NHE9* (Morrow et al., 2008).

De novo CNVs also seem to play a role in schizophrenia. One recent study identified three deletions (CNVs ranging from 400 kb to 1.6 Mb size at chromosome regions 1q21.1, 15q11.2, and 15q13.3) that was associated with schizophrenia and psychoses (Stefansson et al., 2008). Rare, *de novo* CNVs, that are larger than 100 kb in length, also appear to contribute to schizophrenia (The International Schizophrenia Consortium, 2008), especially for sporadic (Xu et al., 2008) and early onset cases (Walsh et al., 2008).

New associations with CNVs

Psoriasis. Defensins are small, secreted antimicrobial peptides that are encoded by the *DEFB* genes. Two clusters of *DEFB* genes are found on chromosome 20 and one cluster is found on chromosome 8. On chromosome 8, at 8p23.1, a ~250 kb repeat unit exists containing six *DEFB* genes and among Europeans, the copy number of these defensin genes has been shown to vary from 1 copy to 12 copies per diploid cell (Hollox et al., 2003).

Previously, it was documented that individuals with less than 4 copies of these genes may have a significantly higher risk of developing Crohn's disease, a severe chronic inflammatory bowel disease characterized by intestinal ulceration (Fellerman et al., 2006). It is thought that in these individuals, a reduction in defensin expression leads to the breakdown of the defensin barrier lining the intestinal walls, thereby allowing the adherence and infiltration of the microbial flora into the underlying mucosa. More recently, it has been shown that individuals with increased copy number of these defensin genes, while presumably having less susceptibility to Crohn's disease, have an increased risk for developing psoriasis, a common inflammatory skin disorder. Among the Europeans studied, individuals with > 5 copies of these genes were found to have

a 1.7-fold increased relative risk of developing psoriasis (Hollox et al., 2008). In these individuals, it is thought that increased expression of defensin elicits an elevated inflammatory response upon any minor injury, by activating epidermal growth factor receptor as well as *STAT* (Signal Transducer and Activator of Transcription) signaling pathways.

In addition to the defensin genes, deletion of the late cornified envelope *LCE3B* and *LCE3C* genes also appear to be a susceptibility factor for psoriasis (de Cid et al. 2009).

Crohn's disease. Crohn's disease has now also shown to be associated with a 20 kb common deletion upstream to the autophagy-inducing *IRGM* (Immunity-related GTPase family, M) gene (McCarroll et al., 2008). The 20 kb deletion is in perfect linkage disequilibrium with the strongest Crohn's disease-associated SNP, rs13361189, and leads to different expression patterns in different cell types. Taken together, the data suggest that the deletion haplotype may be a more likely causal variant for the disease, rather than the rs13361189 SNP.

Osteoporosis. Deletion of the *UGT2B17* gene was previously shown to be associated with increased risk of prostate cancer (Park et al., 2006). While deletions of this gene may have a detrimental effect in prostate tissue, they appear to have a protective effect in bones (Yang et al., 2008). *UGT2B17* encodes for a uridine diphospho (UDP)-glucuronosyltransferase enzyme that is involved in the homeostasis and metabolism of steroid hormones. Deletions of this gene are thought to ultimately affect androgen levels such that bone formation is favored over bone resorption. Conversely, increased copy number of *UGT2B17* results in increased expression of the corresponding enzyme, ultimately leading to the reduced bone density that is characteristic of osteoporosis.

Idiopathic generalized epilepsy. A 1.5 Mb microdeletion at chromosome region 15q13.3 was previously identified in individuals with mental retardation and other neuropsychiatric features (Sharp et al. 2008). The critical genomic region of this microdeletion syndrome contains at least seven genes including *CHRNA7*, encoding for the α7 subunit of the nicotinergic acetylcholine receptor. Some individuals diagnosed with this genomic syndrome also exhibit epilepsy. Extending the screen for 15q13.3 microdeletions to 1223 individuals with idiopathic generalized epilepsy, 12 individuals were found to carry this deletion (Helbig et al. 2009). However, out of 3,699 control individuals, none had this same microdeletion. This supports the notion that deletion of *CHRNA7* is a significant risk factor for idiopathic generalized epilepsy.

Starch diet. On the short arm of chromosome 1 lies a cluster of genes that are important for starch digestion. *Amy1* genes are expressed in the saliva and *amy2* genes are expressed in the pancreas. The copy number of *amy1* genes range from 2 – 15 per diploid cell and in individuals from traditionally high starch diets, *amy1* copy number was generally higher, compared to individuals from traditionally low starch diets. Chimpanzees, having low starch in their diets, were found to consistently have 2 copies of *amy1* in each of their cells. Such data support the notion that *amy1* is under positive selection: human populations with high starch diets tend to maintain higher copy numbers of *amy1* because it is advantageous, whereas the copy number of this gene is undergoing neutral evolution or genetic drift in populations having low starch diets (Perry et al. 2007).

Development of a new and improved human reference genome

When the human reference genome was initially described, the existence of widespread structural genomic variation (including CNVs) was not known. We now know that the male individual from whom 66.3% of the reference human genome was derived (the RPCI-11 BAC library), like all individuals, actually had a substantial amount of structural genomic variation in his genome. When comparing this individual's genome with that of another (e.g. Craig Venter), 132 regions of homozygous deletions were detected in one or the other individual (Khaja et al. 2006). Extending such sequence comparisons to eight other individuals revealed another 525 novel DNA segments, that appear to have been homozygously deleted in the individual from which most of the human reference genome was built (Kidd et al. 2008). These "new" human DNA sequences, and other structural genomic variants, now need to be annotated onto a new and improved human reference sequence (http://www.ncbi.nlm.nih.gov/projects/genome/assembly/grc/index.shtml). Many common structural variants will likely be annotated first, followed by rare structural variants that are discovered via large-scale genomic studies (e.g. such as the 1000 genome project – http://www.1000genomes.org).

CHAPTER

DNA Methylation Analysis: Providing New Insight into Human Disease

Susan Cottrell, Theo deVos, Juergen Distler, Carolina Haefliger, Ralf Lesche, Achim Plum and Matthias Schuster

INTRODUCTION

The human genome contains four bases – guanine, adenine, thymine, and cytosine; but the cytosines can be either methylated or unmethylated at the fifth carbon position in the pyrimidine ring (Figure 6.1a). In general, cytosines can only be methylated when they are in the context of a CpG dinucleotide, or in other words, a cytosine immediately followed by a guanine. These CpG dinucleotides are under-represented in the genome, occurring at only about 20% of the frequency expected assuming random distribution. In some regions, called CpG islands, the frequency of CpG dinucleotides is only 65% of the expected frequency (Takai and Jones, 2002). These stretches of 500–1000 base pairs typically overlap the promoter or exon 1 region of genes, and there are estimated to be 30,000 CpG islands in the human genome (Lander et al., 2001). CpGs in islands are predominantly unmethylated, while CpGs outside of islands are typically methylated.

The methylation status of a CpG island is normally correlated with the chromatin structure and expression levels of nearby genes (Stirzaker et al., 2004). CpG islands associated with actively transcribed genes are typically unmethylated. When a CpG island is methylated, methyl-CpG-binding domain (MBD) proteins recognize the methylated CpG and recruit the necessary factors for chromatin condensation and gene inactivation. This DNA methylation state is maintained during cell division by a family of enzymes called DNA methyltransferases (DNMTs). DNMT1 is thought to be responsible for maintaining methylation patterns through cell divisions, and DNMT3b is the primary enzyme involved in *de novo* methylation (Lopatina et al., 2002). Mutations in one of the DNMT genes, *DNMT3B*, are responsible for the rare genetic disorder ICF syndrome, which is characterized by severe immunodeficiency and DNA hypomethylation (Hansen et al., 1999). Mice lacking any of the DNMTs die either *in utero* or soon after birth (Okano et al., 1999).

Although most CpG islands in the human genome are typically unmethylated in healthy cells, methylation of some islands plays a role in several normal physiological processes. In females, CpG islands on one of the X chromosomes become hypermethylated in the process of chromosomal inactivation (Hellman and Chess, 2007; Mohandas et al., 1981). On autosomes, methylation is also important during development for inactivation of maternally- or paternally-derived alleles of certain genes in a process called genomic imprinting. For instance, a region 2 kb upstream

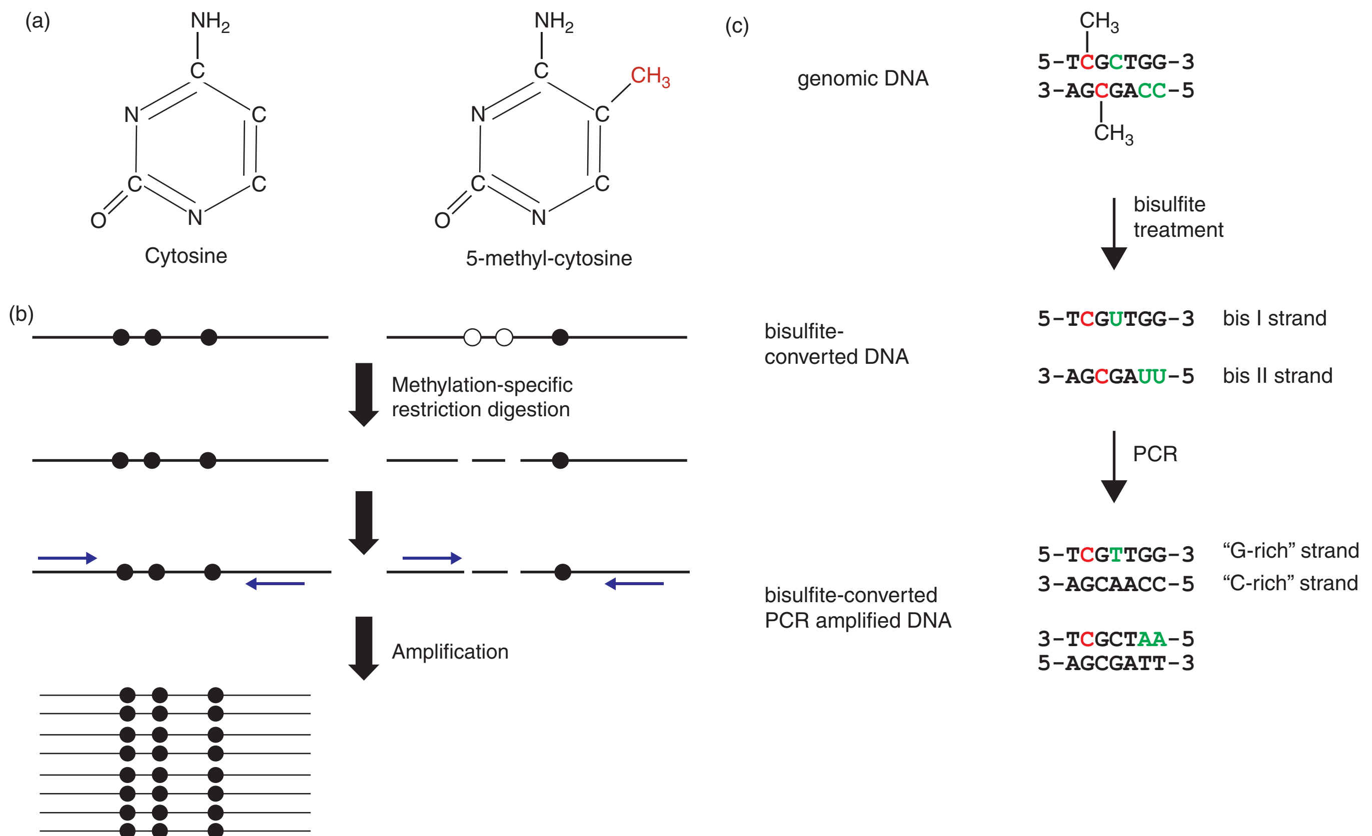

Figure 6.1 Detection of methylated cytosines. (a) Cytosine and 5-methyl-cytosine. (b) Cleavage by some restriction enzymes is blocked by methylation of cytosines in the recognition site. After digestion, various methods can be used to detect the intact methylated DNA, including locus-specific PCR amplification. (c) Genomic DNA is shown at the top with methylated (red) and unmethylated (green) cytosines. The bisulfite treatment converts unmethylated cytosines into uracils. The resulting strands are no longer complementary, and each strand can be amplified by conversion-specific PCR primers.

of the H19 gene for a non-coding RNA is paternally methylated, leading to repressed IGF2 expression (Bartolomei et al., 1993).

During the process of carcinogenesis, two important changes in the methylation pattern of the genome occur. First, sporadic CpGs (outside of CpG islands) become hypomethylated (Ehrlich et al., 1982). This global hypomethylation has been linked to genomic instability, possibly due to mobilization of repetitive elements (Chen et al., 1998; Feinberg, 2004). Meanwhile, some CpG islands, particularly near tumor-suppressor genes, can become hypermethylated during carcinogenesis (Herman and Baylin, 2003; Jones and Baylin, 2002). The hypermethylation is functionally similar to a deletion or mutation and can serve as one method of gene inactivation in Knudson's classic two-hit hypothesis (Jones and Laird, 1999). Different combinations of aberrantly methylated genes are found in nearly all types of cancer (Costello et al., 2000).

TECHNOLOGY TO ASSESS DNA METHYLATION

Cytosine methylation has minimal impact on both thermodynamics and kinetics of common DNA polymerases and can, therefore, not be directly detected by any amplification or hybridization-based methods. Instead, there are three basic principles that can be employed to distinguish differentially methylated DNA sequences: (i) methylation-specific restriction enzymes (Figure 6.1b), (ii) methylation-specific antibodies and proteins, and (iii) methylation-specific bisulfite modification (Figure 6.1c). All existing methods for discovering and evaluating DNA methylation markers are based on one or more of these principles.

Methylation-sensitive restriction enzymes, which typically digest unmethylated but not methylated DNA, have been in use for many years (Bird and Southern, 1978). The recognition sites contain one or more CpG sites. Sometimes cleavage is blocked completely by methylation of the CpG site, but more often the rate of cleavage is affected. Therefore, these methods must be optimized for complete and specific digestion. More recently, restriction enzymes have been introduced that specifically digest methylated DNA (Krueger et al., 1995). Methods based on restriction enzymes are limited to CpGs that are present within a restriction site.

The second major category of DNA methylation methodology relies on naturally occurring proteins whose activity requires methylation detection. Methylation-specific antibodies

have been generated that specifically bind to DNA containing methylated cytosines (Gebhard et al., 2006). In addition, methyl-binding proteins, which play an integral part in bridging DNA methylation information with cellular function, have been successfully used to separate differentially methylated DNA fractions (Cross et al., 1994).

Methylation analysis methods based on bisulfite conversion of sample DNA rely on the unique property of inorganic bisulfite to transform unmethylated cytosine to uracil (Figure 6.1) without affecting methylated cytosines (Frommer et al., 1992). Thus, the bisulfite reaction converts the epigenetic methylation information into sequence information, which can be analyzed by common molecular biology methods, most notably PCR. By converting most of the cytosines to uracils, bisulfite conversion of DNA has the effect of reducing the complexity of the genome, thereby making primer design and multiplexing more challenging. In addition, the chemical reaction can cause DNA damage if sub-optimal conditions are used (Grunau et al., 2001). Despite these caveats, bisulfite-based methods are extremely powerful for sensitive and quantitative analysis of DNA methylation at one or many CpG sites.

Methods for Methylation Marker Discovery

The human genome contains tens of thousands of CpG islands associated with individual genes and their activity. The number of individual methylation positions that could be aberrantly methylated in diseased states is several orders of magnitude higher. Several genome-wide discovery methods to identify differentially methylated regions associated with the specific diagnostic question have been developed. Many of these methods are based on digestion of sample DNA with a methylation-sensitive restriction enzyme. The individual discovery techniques differ in their methods for detection of these restriction cuts, but they include techniques such as linker ligation combined with subtractive hybridization (MCA; Toyota et al., 1999), arbitrarily primed PCR (AP-PCR; Liang et al., 2002), array hybridization (Differential methylation hybridization, DMH; Huang et al., 1999), and two-dimensional gel electrophoresis (RLGS; Costello et al., 2002; Hatada et al., 1991).

These methylation marker discovery methods use methylation-sensitive restriction enzymes to differentiate two classes of samples, such as a DNA from samples of responders to a drug and DNA from non-responders. For a thorough analysis, the entire marker discovery process often involves multiple comparisons. Furthermore, the throughput is low enough that only a few samples can reasonably be processed. Using pooled DNA from multiple patients reduces the likelihood of identifying polymorphic differences associated with individual patients, and it allows for the enrichment of methylation differences associated with disease, which is essential for identification of markers with high prevalence for screening applications.

One approach that is becoming more commonly used is array-based discovery of aberrant methylation (Fukasawa et al., 2006; Hayashi et al., 2007; Taylor et al., 2007). In DMH, originally used for the identification of epigenetic alterations in breast and ovarian cancer (Huang et al., 1999; Yan et al., 2001), genomic DNA is digested by a methylation-insensitive restriction enzyme and then linkers are ligated to the fragments. These products are then digested with a methylation-sensitive restriction enzyme and finally amplified by PCR via the linker sequence. Amplificates are only generated from methylated templates that are not digested by the methylation-sensitive restriction enzymes. The PCR products can be labeled with fluorescent dyes and hybridized to a CpG-island microarray. A recent paper describes the combination of a modified and optimized pre-chip DMH workflow and a custom-made oligonucleotide array representing approximately 50,000 regions of the human genome (Lewin et al., 2007). The advantages of DMH are its reproducibility, speed, and throughput (allowing the option of analyzing individual samples instead of pools). The readout of the microarray not only identifies the differentially methylated sequence, but also provides semi-quantitative methylation values.

Recently, the Human Epigenome Project, a large-scale effort to identify, catalog, and interpret genome-wide DNA methylation patterns of all human genes in all major tissues, has been initiated by The Wellcome Trust Sanger Institute (Cambridge, UK), the Centre National de Génotypage (Paris, France), and Epigenomics AG (Berlin, Germany) (Table 6.1). Based on public versions of the sequence of the human genome established by the Human Genome Project, the Human Epigenome Project will systematically uncover the epigenetic information layer that is still hidden to a large extent. A second Human Epigenome Project was recently proposed by an international group of 40 scientists (Esteller, 2006; Jones and Martienssen, 2005) (Table 6.1).

Methods for Analyzing Markers in Tissue Samples

Methylation analysis in tissues is often not limited by the quantity of sample material available, but the quality of the material, particularly formalin-fixed and paraffin-embedded samples, can be an issue (Schuster, 2004). The isolated DNA is usually damaged to some extent depending on the fixation procedure. In addition, the proportion of the tissue type with aberrant methylation (i.e., the percent tumor) can vary from sample to sample. Laser capture microdissection (LCM), which is used to isolate the tissue type of interest, helps overcome this issue.

There are very different levels at which DNA methylation can be assessed (Figure 6.2) (Laird, 2003), ranging from genome-wide to a particular locus or CpG. The "methylation content" of a cell population corresponds to the overall proportion of methylated cytosines within the entire genome. In contrast, the "methylation level" designates the percentage of methylated DNA strands at one genomic locus, while the "methylation pattern" describes the individual methylation status of a specific set of CpG positions on one DNA strand within a region of interest. Tissue testing is best performed using marker information contained in the "methylation level".

In principle, the methylation level of a DNA sample can be measured in a straightforward manner after bisulfite treatment because the methylation ratio at the CpG site of interest is

translated into an allele ratio. However, in most cases not enough DNA will be available for direct analysis. The bisulfite-treated DNA can be amplified without disturbing this allele ratio using conventional PCR with the primers designed to avoid CpG sites. After amplification, the product can be analyzed using any of a number of analysis methods typically used for the quantification of allele ratios. In MS-SNuPE (Methylation-Specific Single Nucleotide Primer Extension), extension primers

designed to hybridize just upstream of a CpG site are extended by one nucleotide in a methylation-specific manner. Detection and quantification based on HPLC (El-Maarri et al., 2002) and incorporation of radioactivity have been described (Gonzalgo et al., 1997). Another example is pyrosequencing, in which the sequential incorporation of additional bases into the extension primer is translated into a light flash of the same intensity (Colella et al., 2003). Alternatively, hybridization of methylation-specific probes to amplified bisulfite-treated DNA has been combined with different readout systems, including microarrays (Adorjan et al., 2003) and real-time PCR (Quantitative MethyLight; Eads et al., 2000). All of the methods mentioned measure relative levels of methylation, but can be used to quantify DNA methylation levels when they are appropriately calibrated on mixtures of methylated and unmethylated DNA templates.

The methods described in the previous paragraph use an unbiased amplification of bisulfite-treated DNA for measuring methylation levels. Methylation in tissues can also be estimated using various forms of methylation-specific amplification. The most commonly used method in methylation research is methylation-specific PCR (MSP) or the real-time version, MethyLight (Eads et al., 2000). These methods use primers designed for a certain methylation pattern of bisulfite-converted DNA. MethyLight technology is a combination of methylation-specific primers and a methylation-specific real-time PCR probe (Figure 6.3). Since these methods only amplify and detect the methylated portion of the DNA sample, they can only provide qualitative methylation pattern information. In combination with an estimation of total DNA amount, which can be measured for instance by a control real-time PCR assay, methylation-specific assays can be used to estimate relative methylation pattern levels (Ogino et al., 2006a).

For tissue-based analyses, a quantitative methylation assay is likely to be important, because in many cases the required information will depend not on the presence or absence of methylation but on the level of methylation. Responders to a certain drug, for instance, might have fewer inactivated copies of a gene than non-responders. In some instances, the methylation difference could be quite subtle, and it is not clear which of the methods will provide the level of precision required.

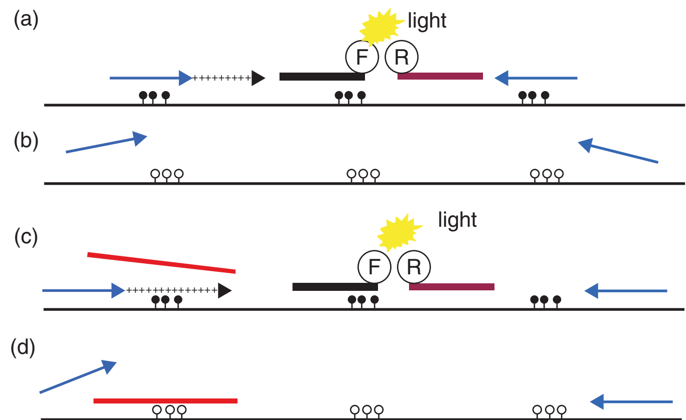

Figure 6.3 Sensitive real-time PCR assays for methylation detection MethyLight assays (a, b) have two methylation-specific primers that bind only to the methylated (a) but not the unmethylated (b) versions of their binding sites. If both primer binding sites are methylated, PCR products are formed and will be detected by methylation-specific real-time PCR probes (a). In contrast, HM assays (c, d) use primers that amplify all methylation states. The methylation specificity of the priming is provided by the blocker oligonucleotide, which prevents the primer from binding to unmethylated DNA (d). Therefore, only methylated DNA is amplified and will be detected by a methylation-specific fluorescent probe (c). Filled circles indicate methylated CpGs, and open circles indicate unmethylated CpGs.

Methods for Analyzing Markers in Disease Screening Samples

The samples of choice for early detection or screening are body fluids that can be obtained by non-invasive procedures. Serum and plasma are optimal targets for methylation marker analyses, but investigators have also analyzed methylation in urine (Hoque et al., 2005), sputum, bronchial lavage, ductal lavage, ejaculate, and other "remote samples" (reviewed in Laird, 2003). In healthy individuals, only small amounts of circulating DNA are observed in plasma and serum, whereas high amounts have been described in patients with various conditions. The main sources of circulating DNA are thought to be apoptotic or necrotic cell death (Holdenrieder et al., 2001). DNA is released from degrading cells after nuclease cleavage of the chromatin between the nucleosomes. Therefore, the tumor- or disease-derived DNA fragments can be as short as the smallest nucleosomal fragment, approximately 180 base pairs (Cottrell and Laird, 2003; Jahr et al., 2001).

In contrast to tissue-based applications, methylation markers for screening must fulfill additional biological requirements. Even if the majority of free DNA in blood is derived from cancer cells, a significant amount of DNA from other cell types, particularly leukocytes, will be present. Therefore, the marker must be methylated in a high percentage of tumor cells and relatively unmethylated in leukocytes and other tissues contributing background DNA. Qualitative markers, which are methylated only in tumor-derived DNA, are well suited for screening applications.

The clinical sensitivity (proportion of diseased people testing positive) and specificity (proportion of healthy individuals testing negative) of the marker is not only dependent on its biological properties, but also on the analytical performance of the assay. The challenge for the final diagnostic assay is a high analytical sensitivity (detecting small amounts of methylated tumor DNA) at a maximum specificity (no detection of unmethylated DNA). In practice, methylation assays suitable for screening must be capable of detecting a few copies of the methylated marker DNA in a background of 1–10 thousand-fold excess unmethylated DNA. In addition, the DNA extraction method must be optimized for high recovery yield, particularly of short DNA fragments found in plasma or serum. Bisulfite treatment is known to cause damage to the DNA, but milder treatment

conditions can be used without risk of incomplete conversion of the DNA (Berlin et al., 2005).

MethyLight may be an assay that is suitable for detection of disease in remote samples. In contrast to MSP, MethyLight minimize false-positive results caused by possible mis-priming of the methylation-specific primer, as the methylation status of the amplificates are analyzed on a second level by the methylation-specific fluorescent probe. MethyLight has been successfully used for various applications, but primers and probes must be carefully designed in order to ensure sensitive and specific detection.

HeavyMethyl (HM) technology is another way to achieve methylation-specific priming, and, like MSP, can be combined with a probe for real-time detection (Cottrell et al., 2004). HM assays combine methylation-non-specific primers and a non-extendable 3′-modified blocker oligonucleotide. The blocker binds to unmethylated DNA, preventing the primers from accessing the priming site (Figure 6.3). The blocker does not bind to the methylated version, allowing the primers to access the priming sites. A methylation-specific fluorescent probe is used to ensure specificity and allow for methylation quantification. HM assays typically have a limit of detection of 25–50 pg of methylated DNA and can detect this methylated DNA in a background of 50 ng of unmethylated DNA. Although HM design requires more effort compared to a MethyLight assay, the HM assay has advantages. Unmethylated template that is amplified unintentionally will be targeted by the blocker in the next cycle. Therefore, the analytical specificity of HM assays is very high.

CLINICAL IMPACT OF DNA METHYLATION ANALYSIS

Cancer has been viewed as an accumulation of chromosomal aberrations and therefore been called a "genetic disease". However, it has become clear over the last two decades that epigenetic changes play a crucial role in carcinogenesis. Research on DNA methylation in cancer has been expanding rapidly, and for this reason, in the following sections, we will rely on examples from oncology to demonstrate how methylation profiles can be applied for basic disease research, early detection, disease stratification, treatment response prediction, and drug target identification.

While attention has focused on methylation in carcinogenesis, a similar groundswell of research is emerging on methylation in other diseases, especially autoimmune and cardiovascular conditions (see Table 6.2). For example, aberrantly hypomethylated DNA in circulation in systemic lupus erythematosus might induce an immune response due to its similarity to unmethylated microbial DNAs (Januchowski et al., 2004). Further contributions of defective methylation to lupus pathogenesis could be due to transcription of endogenous retroviruses (Okada et al., 2002) or the increase in the expression of certain genes related to autoreactivity (Richardson, 2002). In cardiovascular disease, DNA methylation is associated with atherosclerosis pathogenesis in two ways: First, the decrease in essential factors (e.g., folate and vitamin D) for the synthesis of *S*-adenosyl methionine (the main methyl group donor in the methylation reactions) leads to global DNA hypomethylation and coexisting hyperhomocystinemia (Zaina et al., 2005). Second, Lund et al. (2004) provided evidence that methylation profiles are early markers of the disease in a mouse model. Taken together, these data reinforce the notion that methylation profiles can be highly valuable to study the pathogenesis of a variety of conditions (Table 6.2).

Impact of Methylation Research on Basic Disease Understanding

Researchers have spent many years studying the role of permanent alterations in DNA sequence, such as mutations, deletions, and insertions, in carcinogenesis. Cancer has long been thought of as a disease that arises after accumulation of mutational events in growth control genes. In recent years, RNA expression profiling has been used to examine the functional consequences of these sequence alterations, as outlined in other chapters in this book. There is now overwhelming evidence that epigenetic modification can also control RNA and protein levels. As the methylation analysis toolbox expands, we are gaining more insight into how alterations in these patterns of methylation influence disease.

As an example, methylation analysis has provided a new molecular understanding of colon cancer. Colon cancer develops in a well-described pathway from normal epithelium, to aberrant crypts, to adenomas, then to adenocarcinoma, each with specific histological features and molecular alterations. The first alterations to be studied were sequences changes: for instance, *APC* mutations have been implicated in the formation of adenomas (Powell et al., 1992) and *TP53* mutations have been implicated in the transition from adenoma to adenocarcinoma (Baker et al., 1990).

More recently, the role of aberrant methylation events of genes in these same pathways has been elucidated. For example, a hereditary form of colon cancer is commonly caused by mutations in the *MLH1* gene, but this same gene can induce sporadic forms of the disease when it is aberrantly methylated (Cunningham et al., 1998). Some colon cancers are characterized by microsatellite instability (MSI), and the majority of these tumors have methylated *MLH1* alleles. Furthermore, research on methylation in colon cancer has established that tumors can not only be divided based on microsatellite stability status, but also on their CpG island methylator phenotype (CIMP) status (Toyota et al., 1999). Colon tumors, particularly those with MSI, have a bimodal distribution based on the methylation status of multiple genes. Those tumors with multiple methylated genes (CIMP+) are more likely to have *BRAF* mutations and wild-type *KRAS* (Ogino et al., 2006a, b). Clearly, a complete understanding of the pathogenesis of colon cancer requires knowledge of both genetic and epigenetic events.

Methylation Markers for Early Detection and Diagnosis

Early detection is an effective success factor in the fight against any type of cancer. Aberrant DNA methylation patterns show

TABLE 6.2 Examples of DNA methylation in human disease

Disease/Disorder	Phenotype	Mechanism	Genes involved	Reference
Cancer	Tumorigenesis; Increased cell division; metastasis	Hypermethylation	Tumor-suppressor genes	Jones and Baylin, 2002; Herman and Baylin, 2003
		Hypomethylation	Global	Ehrlich et al., 1982
		Loss of imprinting	Insulin-like grow factor 2 (IGF2), GTP-binding RAS-like 3 (DIRAS3), mesoderm-specific transcript homolog (MEST)	Feinberg, 2007
		Heritable germline hypermethylation	Mut L Homolog 1 (MLH1)	Hitchins et al., 2007
Beckwith–Wiedemann syndrome	Embryonal tumors; omphalocele; macroglossia (large tongue); gigantism	Disruption of an imprinting locus	11p15 (IGF2, H19 ncRNA, cyclin-dependent kinase inhibitor 1C (CDKN1C), pleckstrin homology-like domain, family A, member 2 (PHLDA2), solute carrier family 22, member 1 (SLC22A1), potassium voltage-gated channel (KCNQ1))	Weksberg et al., 2003
Prader–Willi syndrome	Developmental delay; obesity; genital hypoplasia; distinct facial features	Disruption of an imprinting locus	15q11-13 (small nuclear ribonucleoprotein polypeptide N (SNRPN), ncRNAs)	Nicholls and Knepper, 2001
Angelman syndrome	Developmental delay; ataxia; microcephaly; distinct facial features	Disruption of an imprinting locus	15q11-13 (Ubiquitin E3 ligase (UBE3A))	Nicholls and Knepper, 2001
Pseudohypoparathyroidism	Hypoparathyroidism without sensitivity to parathyroid hormone	Disruption of an imprinting locus	20q13 (GNAS complex locus (GNAS1))	Bastepe et al., 2001
Immunodeficiency/centromeric instability/facial anomalies (ICF syndrome)	Immunodeficiency; chromosomal breakage; facial defects	Mutations	DNA Methyltransferase 3b (DNMT3b)	Hansen et al., 1999
Rett syndrome	Motor abnormalities; ataxia; hand-wringing; poor verbal skills	Mutations	Methyl-CpG-binding protein 2 (MeCP2)	Amir et al., 1999
Systemic Lupus Erythematosus	Autoimmune disorder; inflammation; tissue damage	Hypomethylation	global, perforin (PRF1), CD70, integrin, alpha L (ITGAL)	Januchowski et al., 2004
Atherosclerosis	Thickening and hardening of arterial walls	Hypermethylation	Estrogen receptor, Monocarboxylate Transporter 3 (SLC16A3)	Kim et al., 2007; Zhu et al., 2005
Schizophrenia	Hallucinations; delusions	Hypomethylation	Global	Shimabukuro et al., 2006
		Hypermethylation	Reelin (RELN)	Grayson et al., 2005
Endometriosis	Growth of endometrial cells outside of the uterus	Hypermethylation	Homeobox A10 (HOXA10)	Wu et al., 2005
Fragile X syndrome	Mental retardation; autism; large ears; macroorchidism	Hypermethylation of an expanded trinucleotide repeat	Fragile X mental retardation 1 (FMR1)	Oberle et al., 1991

promise as biomarkers for early detection of cancer for several reasons: Tumor-specific methylation changes occur early in tumorigenesis, appear to be stable, provide an amplifiable signal, and can be assayed with high analytical sensitivity. DNA methylation patterns characteristic of tumor cells have been found for many types of cancer in several types of body fluids (Laird, 2003).

DNA methylation changes occur frequently in colon cancer and can be present early in malignant transformation (Grady, 2005). Feasibility studies have shown that tumor-derived methylated DNA markers can be detected in serum, plasma, and stool (reviewed in Laird, 2003). These studies analyzed a limited number of patient samples, and larger clinical studies will be necessary to assess the quality of these markers for a screening approach.

Prostate-specific antigen (PSA) based screening has resulted in detection of many cases of prostate cancer, but, due to the low specificity of this assay, its usefulness for prostate cancer screening is no longer certain. DNA methylation markers may improve screening and diagnosis of prostate cancer considerably in the future. *GSTP1*, encoding glutathione *S*-transferase P1, is the best-characterized methylation marker for prostate cancer. Methylation of *GSTP1* in prostate cancer has been consistently reported with a frequency of about 70–90% (reviewed in Henrique and Jeronimo, 2004). Interestingly, *GSTP1* methylation is also reported in some high-grade prostatic intraepithelial neoplasia (PIN) lesions, a precursor to prostate cancer, indicating that *GSTP1* hypermethylation is an early event in prostate cancer development (Henrique et al., 2006). Several groups have demonstrated the feasibility of using *GSTP1* methylation and other methylation markers to detect prostate cancer in bodily fluids. For example, Hoque et al. (2005) analyzed a panel of nine genes in urine sediments from 52 cancer patients and 91 controls using MethyLight assays. A panel containing *GSTP1* and three other genes (*CDKN2A*, *ARF*, and *MGMT*) detected the prostate cancer cases with 87% sensitivity and 100% specificity.

Recently, Lofton-Day et al. (2006) conducted a study to identify and validate DNA methylation-based markers for colorectal cancer using plasma samples. At a set specificity of 95%, the lead methylation marker (Septin 9) showed in several studies sensitivity values of 51, 65, and 50%, respectively. In total, approximately 2000 samples were tested, including over 600 plasma samples from colorectal cancer patients, 600 with related non-malignant diseases, and over 600 normal controls from an age-matched, colonoscopy-verified healthy population. Importantly, early-stage cancers were identified with the same sensitivity as later stage cancers (Lofton-Day et al., 2006). The test was able to detect colorectal cancers regardless of their location, addressing a critical medical need and shortfall of the existing fecal occult blood tests. Once a methylation-based screening test is developed, its use can potentially be extended to monitoring for disease recurrence after treatment, similar to the role of PSA for prostate cancer.

Methylation Markers for Disease Prognosis

Molecular classification holds great promise for assessment of optimal treatment options. DNA methylation markers have been reported as both prognostic and predictive markers, indicating the aggressiveness of tumors and the responsiveness to certain drug regimens, respectively. For example, prognostic markers for breast cancer are required to determine which patients can be spared from aggressive therapy due to very good prognosis. Recently, several reports have been published exploring the prognostic relevance of DNA methylation at the promoter of the *PLAU* gene, which codes for the matrix remodeling enzyme urokinase-type plasminogen activator (uPA) (Guo et al., 2002; Pakneshan et al., 2004; Xing and Rabbani, 1999). Interestingly, *PLAU*-promoter DNA methylation was negatively associated with tumor grade; grade 1 tumors were frequently methylated and grade 3 tumors were unmethylated. These findings are consistent with results from large studies that have demonstrated that protein expression in serum of uPA and its cell surface receptor uPAR are important determinants of distant spread of breast cancer (Look et al., 2002).

Shinozaki et al. (2005) found that in a panel of 151 primary breast tumors, hypermethylation of the *CDH1* gene was significantly associated with lymphovascular invasion, infiltrating ductal histology, and lack of estrogen receptor expression. On the other hand, *RASSF1A* and *RARB* hypermethylation were significantly more common in estrogen receptor-positive and human epidermal growth factor receptor 2-positive tumors, respectively. Other genes that have been associated with prognosis in breast cancer and which appear to be regulated via DNA methylation are *CDH3* (Paredes et al., 2005), the tuberous sclerosis (TSC) genes *TSC1* and *TSC2* (Jiang et al., 2005), and *LATS1*/*LATS2*, tumor-suppressor genes that have been implicated in the regulation of the cell cycle (Takahashi et al., 2005).

We have recently identified a methylation marker, *PITX2*, which predicts outcome in hormone receptor-positive, node-negative breast cancer patients treated with tamoxifen monotherapy (Maier et al., 2004, 2007). The marker was originally identified and validated in two independent cohorts of patients treated with adjuvant tamoxifen monotherapy. The findings were then validated in an independent study analyzing paraffin-embedded tumors of 422 node-negative patients treated with tamoxifen only after surgery. In the group with low *PITX2* methylation, 94% of the patients were metastasis-free after 10 years, compared to only 84% in the group with high *PITX2* methylation. In a multivariate model, *PITX2* methylation added significant information to conventional factors such as tumor size, grade, and age (Harbeck et al., 2005). Analysis of *PITX2* methylation in a large cohort of patients not receiving adjuvant therapy confirmed that *PITX2* methylation is a prognostic marker associated with tumor aggressiveness (Martens et al., 2005). These results provide substantial evidence that *PITX2* DNA methylation is suitable for routine clinical use in order to predict outcome in node-negative, tamoxifen-treated patients, and to identify low-risk patients who can be spared the burden of additional cytotoxic therapy.

Methylation Markers for Treatment Response Prediction

A number of studies have provided evidence that specific methylation changes are associated with responses to a variety of cancer

therapeutic agents currently used in the clinics (reviewed in Maier et al., 2005). These alterations in methylation patterns could serve as predictive markers of drug response and be used by clinicians and patients to support treatment selection. Furthermore, methylation markers could be developed together with a novel drug during clinical trials in order to better select the patients who are likely to respond. The inclusion of predictive markers in clinical trials is becoming increasingly important as more targeted therapies are being tested.

Many anti-cancer therapies disturb DNA integrity and thus interfere with DNA synthesis and successful cellular replication, ultimately inducing cell death. Tumor response to DNA damaging agents is closely linked to expression of several DNA-repair enzymes, many of which are regulated by methylation. Resistance can result from either a gain of methylation event or loss of methylation event. Methylation of *MGMT*, which codes for a DNA-repair enzyme, is associated with response to alkylating agents. In this case, tumor cells rely on the excess *MGMT* product to specifically repair the damage that occurred during therapy with the alkylating agent (Ludlum, 1990). Esteller et al. (2000) investigated the methylation status of the *MGMT* gene in 47 glioma samples from patients treated with the chloroethylating agent carmustine. The *MGMT* promoter region was methylated in 19 (40%) of the samples, 12 (63%) of which were from patients who had a response to carmustine. Of the 28 tumors with unmethylated *MGMT*, only 1 patient (4%) responded to the drug ($p < 0.001$, univariate analysis). Paz and coworkers (2004) found similar results in glioma patients. Balana and colleagues (2003) demonstrated that detection of these treatment response markers might be possible in serum for disease where affected tissue is unavailable.

MLH1 is a mismatch repair enzyme that is activated in response to DNA damage. However, MLH1 expression is not only required to repair the damage, but also seems to be linked to apoptotic signaling: Its activation induces processes leading to programmed cell death. Therefore, in contrast to *MGMT*, methylation of the *MLH1* promoter is associated with resistance to DNA damaging agents, such as temozolomide, dacarbazine, and cisplatin. Expression of *MLH1* increases the effect of the drugs, presumably by acting as a sensor detecting DNA damage caused by the drug, and by activating processes that eventually lead to apoptosis of the cell (Agarwal and Kaye, 2003; Brown et al., 1997; Karran and Bignami, 1994). Other drug classes for which methylation markers were shown to be associated with tumor response in patients or sensitivity of preclinical models are taxanes (*CHFR*, *TRAG3*, *RASSF1*, *BRCA1*), platinum compounds (*ABCB1*, *FANCF*, *RASSF1*), retinoids (*RARB*, *RBP1*), and anti-hormonal therapies (*ESR1*, *ESR2*, *AR*) (Maier et al., 2005).

2009 UPDATE

The field of epigenetics continues to expand rapidly. In early 2008, the National Institutes of Health in the U.S. introduced its Roadmap Epigenomics Initiative program (http://nihroadmap.nih.gov/epigenomics/). The program will create epigenome mapping and data coordination centers, bolster technology development and marker discovery, and drive research on the role of epigenetic regulation in health and disease. Meanwhile, support for a human epigenome project continues to grow internationally (The American Association for Cancer Research Human Epigenome Task Force and European Union, Network of Excellence, Scientific Advisory Board, 2008).

Knowledge of the strengths and limitations of various DNA methylation analysis technologies has become more sophisticated in the past few years, and researchers are beginning to experiment with "next generation" bisulfite sequencing (Taylor et al., 2007; Meissner et al., 2008). This high throughput method is likely to be more quantitative and sensitive than previous methods, and will also give researchers more qualitative information on patterns of CpG methylation across a region of the genome. As genomic methodology expands in many areas, researchers are developing computational approaches to combine information from multiple layers of genomic, epigenomic, and proteomic analyses.

Recent research continues to explore the relationship between DNA methylation and various chromatin alterations. The multiple levels of epigenetic control seem to offer an intricate system for controlling expression in cells such as embryonic stem cells and for priming the cells for response to future events (Ku et al., 2008). As we gain insight into the functioning of this system in normal cells, we are also beginning to understand how aberrant methylation events arise in neoplastic cells (Schlesinger et al., 2007). In fact, some researchers are experimenting with predicting sites of aberrant methylation based on DNA sequence motifs and polycomb binding sites (McCabe et al., 2009).

While our knowledge of DNA methylation events in oncology continues to grow, recent research has begun to elucidate the role of DNA methylation outside of cancer, including mental illness, infertility, and obesity (Houshdaran et al., 2007). For example, Mill et al. (2008) used a combined genome-wide screen and candidate gene approach to find evidence of altered DNA methylation near genes in the glutamatergic and GABAergic neurotransmission pathways in post-mortem brains from individuals with schizophrenia and bipolar disorder.

Recent research has also shown that DNA methylation marks can be long-standing, inherited through several generations, or can be quite dynamic, responding to precisely timed signals. The evidence of epigenetic inheritance comes mostly from studies of the effect of exposure of model organisms to environmental toxins (Nilsson et al., 2008), but epidemiological studies suggest a possible role in humans as well (Kaati et al.,

2007). In contrast, dynamic alterations in methylation of certain genes is involved in memory formation in experiments in which fear conditioning in rats resulted in rapid methylation changes that are reversed within 24 hours (Miller and Sweatt 2007).

Advances in our understanding of the role of DNA methylation in disease are also starting to pay off in clinical practice. The Presept trial, which began enrolling patients in 2008 (http://www.presept.net), is designed to test the promising Septin 9 methylation assay for early detection of colorectal cancer in plasma (Grützmann et al., 2008). Clinical testing for MGMT methylation, a valuable biomarker that predicts response of glioblastomas to radiation therapy and alkylating agents, became available in 2008. In coming years, we expect to see numerous other examples of the clinical benefits of the extensive work being done in the field of epigenetics.

CHAPTER

DNA Microarrays in Biological Discovery and Patient Care

Andrew J. Yee and Sridhar Ramaswamy

INTRODUCTION

While "expression profiling" is now synonymous with DNA microarray technology, expression profiling dates back to the 1970s with techniques such as northern blotting for measuring RNA expression (Alwine et al., 1977). However, only one gene at a time could be queried with these modalities. Later developments enabled analysis of multiple genes (Liang and Pardee, 2003), including differential hybridization (Sargent, 1987), subtractive hybridization (Zimmermann et al., 1980), differential display (Liang and Pardee, 1992), and serial analysis of gene expression (SAGE) (Velculescu et al., 1995). However, these approaches required a significant amount of starting RNA and investment in labor and technical expertise, and were difficult to scale up.

DNA microarrays revolutionized the approach to gene expression profiling. Compared to prior methods, DNA microarrays were both dramatically high throughput and less cumbersome. It should be noted that the concept behind the microarray format was not new, as microarrays were originally developed as a technique for large-scale DNA mapping and sequencing (Hoheisel, 2006). However, changing the support surface from a porous membrane to a solid surface, such as glass, afforded significant improvements (Schena et al., 1998) by increasing reaction kinetics (Southern et al., 1999) and reducing background noise (Cheung et al., 1999).

As an illustration of approaches to define and develop applications of the transcriptome measured in biological samples, here we present specific issues related to the use of DNA microarrays, using applications especially in the context of cancer to illustrate the uses and challenges of gene expression profiling in genomic and personalized medicine.

MICROARRAY TECHNOLOGY

Microarray Platforms

Although the technology for DNA microarrays continues to evolve, the commonly used arrays can be divided into two main categories: (i) oligonucleotide and (ii) spotted or complementary DNA (cDNA) microarrays (see Figure 7.1). Over the years, commercial oligonucleotide platforms have gained in popularity over "homemade" spotted cDNA microarrays as costs have fallen considerably, to the point where commercial microarrays are the *de facto* platform. At the time of this writing, the dominant platforms are produced by Affymetrix and Agilent. For additional details, the reader is referred to a review by Hardiman (2004) and also to reviews collected in a series of *Nature Genetics* supplements (Bowtell, 1999; Cheung

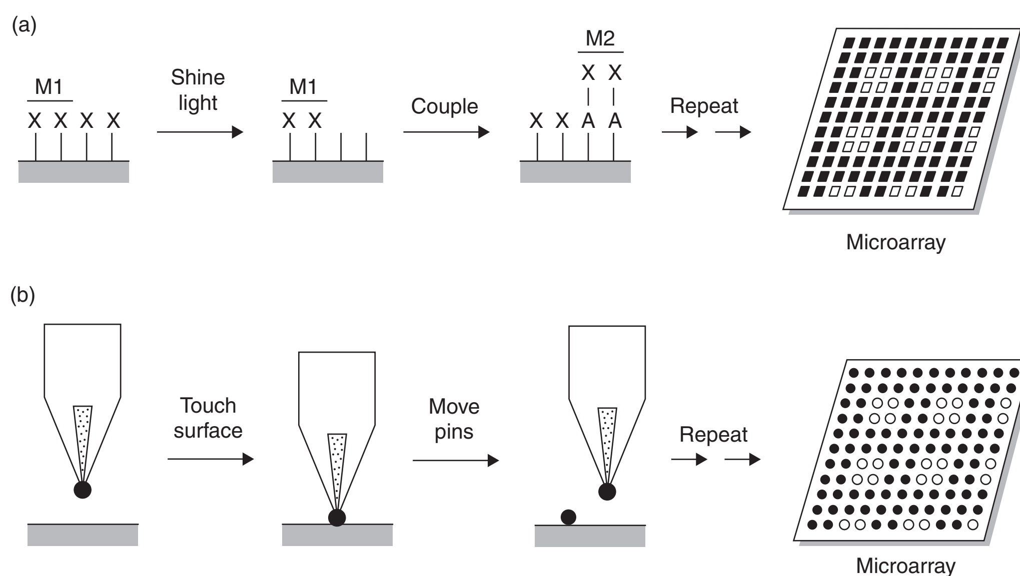

Figure 7.1 Comparison of microarray technologies. (a) Photolithography (as used by Affymetrix): a glass wafer modified with photolabile protecting groups (X) is selectively activated for DNA synthesis by shining light through a photomask (M1). The wafer is then flooded with a photoprotected DNA base (A–X), resulting in spatially defined coupling on the chip surface. A second photomask (M2) is used to deprotect defined regions of the wafer. Repeated deprotection and coupling cycles result in a highly dense microarray. (b) Spotted arrays: the gene of interest is loaded into a spotting pin by capillary action, and a small volume is transferred to a solid surface by physical contact between the pin and the solid substrate. After the first spotting cycle, the pin is washed and a second sample is loaded and deposited to an adjacent location. Robotic control systems and multiplexed printheads allow automated microarray fabrication. Adapted from Schena et al. (1998). (Reprinted with permission from Elsevier).

et al., 1999; Churchill, 2002; Duggan et al., 1999; Holloway et al., 2002; Lipshutz et al., 1999; Southern et al., 1999).

Oligonucleotide Arrays

Oligonucleotide microarrays are created either by *in situ* synthesis or deposition of presynthesized oligonucleotides ranging in size from 25- to 60-mers. Oligonucleotides can be synthesized directly *in situ* using photolithography techniques adapted from the microelectronics industry. The Affymetrix GeneChip platform is the primary example of this method, and because of its popularity, merits further discussion. Emerging from research carried out in the early 1990s (Fodor et al., 1991), this technology combines combinatorial, solid phase DNA synthetic chemistry with the benefits of photolithography. Successive photolithographic masks are used to select regions of the chip surface for exposure to light. Exposure to light deprotects photolabile groups on the nascent oligonucleotides undergoing synthesis. The light-mediated deprotection then allows these specified regions to couple with activated nucleoside monomers using standard DNA phosphoramidite synthetic chemistry. Each cycle thus extends the oligonucleotide by one base (see Figure 7.1).

Over the past 15 years, the feature size of each oligonucleotide probe or feature has been reduced 10-fold, resulting in a 1.6 cm^2 chip with 1.3 million unique features (multiple features are used to measure the expression of a particular gene). The detection sensitivity of these microarrays has been estimated at 1 in 300,000 RNAs (Lockhart et al., 1996). A practical limitation is the efficiency of each synthesis step – about 90–95%. This places a ceiling on *in situ* synthesis of an oligonucleotide to 25-mers. To control for non-specific binding, the probes on the Affymetrix chip are designed in pairs. One sequence is the exact complement of the target transcript, and the other paired sequence differs from the complement typically by one base pair near the middle of the probe. Difference in signal between the two probes can be used to control for non-specific binding and background contributions (Pease et al., 1994); 22 probes are routinely used for each expression measurement. Compared to cDNA arrays (see below), oligonucleotide arrays offer greater specificity and can distinguish single nucleotide polymorphisms (SNPs) and splice variants (Guo et al., 1994); the same technology is used in arrays for measuring DNA copy number and SNP profiling. The current generation of Affymetrix microarrays can measure the expression of over 47,000 transcripts.

Hybridization is detected by using a confocal laser scanning microscope to image the intensity of one color, fluorescently labeled samples. First, experimental mRNA is enzymatically amplified (see below for details of RNA amplification) and then labeled with biotin through the partial substitution of UTP and CTP with biotin-11-UTP and biotin-11-CTP. The labeled mRNA is then hybridized to the microarray and detected by the binding of a fluorescent compound (streptavidin–phycoerythrin) to the biotin-labeled samples. Because of the

robustness and consistency of the manufacturing process, the single-color readout provides an absolute quantitation of mRNA populations (Ishii et al., 2000). In addition, experiments can be compared with samples hybridized to different Affymetrix arrays.

Oligonucleotide microarrays may also be fabricated by using ink-jet printing technology. Nucleotide monomers are printed onto the chip and coupled using phosphoramidite chemistry (Hughes et al., 2001). Agilent has adopted this technology to create a 60-mer oligonucleotide array. Compared to the 25-mer photolithographic chip, a 60-mer array might offer increased sensitivity per probe. In contrast to the Affymetrix platform, there is only one probe per gene in this platform. The longer probes are also more tolerant of mismatches, improving analysis of polymorphic regions.

Spotted, Complementary DNA Microarrays

The first DNA microarrays were developed at Stanford University and based on cDNA samples spotted by a robotic arrayer at defined locations onto glass slides (Schena et al., 1995). These cDNA samples were generally PCR products generated from cDNA libraries or clone collections. The major benefit of spotted arrays is that they can be constructed in-house and tailored to the user's needs. The features are generally 100–300 µm in size and spaced at about the same distance. About 30,000 cDNAs can be spotted onto the surface of a microscope slide (Schulze and Downward, 2001). In the initial report, the sensitivity was estimated at 1 in 50,000 RNAs starting with 5 µg of total RNA (Schena et al., 1995). While spotted arrays offer customizability, they are better suited for smaller-scale experiments, since from a practical perspective managing large clone libraries and creating high-quality arrays consistently can be arduous. In the past, an advantage of spotted arrays was that *a priori* knowledge of the sequence being spotted was not necessary. However, this is less relevant now that complete sequence information for many experimental organisms and humans is readily accessible.

Gene expression using spotted microarrays is determined as a ratio of two samples rather than as an absolute measurement, owing to technical limitations and variability in spot size and probe concentration. Generally, cDNAs derived from experimental and reference RNA samples are labeled with deoxyribonucleotides coupled to different fluorophores (e.g., with Cy3 or Cy5) during first-strand cDNA synthesis. The two different populations are then competitively hybridized to the same array and imaged. While this method accurately compares expression levels between samples, comparing data from different platforms can be difficult, often requiring complex normalization algorithms (Dudley et al., 2002).

Sample Preparation

Tissue Sampling

For biological applications, tissue sampling is an important variable. For example, tumors are heterogeneous mixtures of different cell types, including malignant cells with varying degrees of differentiation, stromal elements, blood vessels, and inflammatory cells. Profiling of this whole sample may dilute out the "signal" profile of cancer cells with extraneous expression "noise" from surrounding tissues. Newer techniques such as laser capture microdissection (LCM) address the challenges of tissue heterogeneity by offering an approach for isolating homogeneous, individual cell populations (Emmert-Buck et al., 1996). While there are other approaches, such as fluorescence-activated cell sorting (FACS) and manual microdissection using micromanipulators (Emmert-Buck et al., 1994), LCM is faster, more versatile, and can be applied to solid tumors directly without the need for disaggregation into a cell suspension. Sgroi et al. (1999) first showed that it was feasible to use LCM to isolate subpopulations of breast cancer cells for expression profiling. Coupled with LCM has been the evolution of methodologies for purifying adequate amounts of high-quality RNA for expression profiling (see below). However, a theoretical limitation of focusing only on individual tissue components such as cancer cells relates to the growing appreciation that interactions with the tumor microenvironment (e.g., with stroma, endothelial, and immune cells) play a critical role in tumor progression. Sampling of "non" cancer cell components thus may be necessary for a profile to adequately reflect *in vivo* biology. An additional consideration is that the actual surgical manipulation itself may affect the expression profiling. Lin et al. (2006) compared expression profiles of prostate cancer from biopsies obtained *in situ* to biopsies obtained from prostates that were surgically removed. They found that 1.5% of measurable genes were altered as a result of the surgery, including transcripts for acute phase response proteins and regulators of cell proliferation.

RNA Isolation

Traditionally, microarray experiments have required roughly 50–200 µg of total RNA (Duggan et al., 1999). However, these quantities are not always easily obtainable, especially with techniques such as LCM. Protocols therefore have been developed for amplifying RNA from much smaller quantities, perhaps even down to the level of a single cell. For example, a single cell contains an estimated 0.1 pg of mRNA or 10 pg of total RNA, requiring an expansion of 10^8–10^9 fold in order to yield adequate amounts for profiling. Two commonly used amplification techniques include *in vivo* transcription and PCR amplification. *In vivo* transcription is a linear amplification approach, first described by Van Gelder et al. (1990). Messenger RNA is converted to double stranded cDNA using an oligo(dT) primer attached to a T7 promoter. T7 polymerase is then used to transcribe complementary copies of the cDNA population. One round of amplification can amplify the starting amount of mRNA by 1000-fold. A second or a third round of amplification can further increase the yield (Baugh et al., 2001). A second approach takes advantage of PCR amplification. PCR-based approaches have several advantages over linear amplification, including speed, cost, and theoretically unlimited degree of amplification. While it has been assumed that exponential amplification may lead to a biased representation of the starting

sample, results from one group suggest that this may not be as problematic as previously suggested (Iscove et al., 2002).

Standardization of Data

Critical to the success of data analysis is standardization of microarray data and annotation of the genes that comprise the microarrays. In 1999, the Microarray Gene Expression Database (MGED) group was created to establish guidelines for the format of microarray data. This led to the development of the Minimal Information About a Microarray Experiment (MIAME) standard (Brazma et al., 2001; Stoeckert et al., 2002). Most major scientific publications require compliance with MIAME standards and submission of data to public repositories.

An additional key factor is the functional annotation of the genes being studied. Biological "knowledge" is intricate, hierarchical, and interrelated. Ontologies are a formalized, standardized means of coding biological knowledge in which concepts are systematically described by both their meaning and their relationship to each other (Bard and Rhee, 2004). Adequate ontologies can thus serve as a common anchor point for systematic integration of data from various microarray sources. An example of commonly used ontology is one devised by the Gene Ontology Consortium (Harris et al., 2004).

DATA ANALYSIS

Gene expression studies pose many challenges for data organization, storage, and analysis (see Chapter 10). In concert with the development of microarray technology has been the evolution of sophisticated statistical methods for analyzing and interpreting highly dense microarray information (Ermolaeva et al., 1998; Quackenbush, 2001). These data can be one's own experimental data or existing data from other investigators' experiments, made available through public databases. Microarray data may be so rich in information that important findings may not be recognized initially, and only better appreciated in retrospect when re-analyzed or combined with newer data. Data analysis methodology is discussed further in Section 2 and has been reviewed also by Allison et al. (2006).

Unsupervised Learning

The computational analysis of gene expression data has largely centered on two approaches: unsupervised and supervised learning (see Figure 7.2). Unsupervised methods include hierarchical and *k*-means clustering (Gaasterland and Bekiranov, 2000). The goal of clustering is to organize genes and samples clusters based on relative similarity (D'Haeseleer, 2005; Eisen et al., 1998). A hierarchy of clusters can be created, which may be visualized as tree diagrams or dendrograms. Unsupervised approaches have the advantage of being unbiased and allow for the identification of structure in a complex dataset without making any *a priori* assumptions. In fact, many of the initial microarray studies on cancer samples utilized unsupervised classification, for example, lymphoma (Alizadeh et al., 2000) and breast cancer (Perou et al., 2000). However, because many different relationships are possible in a complex dataset, the predominant structure uncovered by clustering may not be clearly related to the most clinically or biologically interesting aspect of a dataset.

Supervised Learning

In contrast, supervised learning starts off with a known class distinction and uses this information upfront to select genes whose expression is best associated with this class distinction in a "training dataset" (Golub et al., 1999). This model is then applied to an independent "test" dataset to validate the accuracy of selected gene expression features in classification. Numerous supervised learning algorithms have been applied to gene expression datasets, such as *k*-nearest neighbors, neural networks, or support vector machines (Brown et al., 2000). The accuracy of supervised learning approaches heavily depends on the quality of the initial training data.

Mining

Several tools have been developed for distilling higher-level information from microarray data in order to better appreciate the "forest" among the innumerable "trees" of expression data. Two notable examples include modular analysis and Cancer Outlier Profile Analysis (COPA). Modular analysis examines the coordinated behavior of a set of genes in order to detect significant changes in modules of genes, rather than the individual genes themselves. This offers the ability to extract more "signal" from a given microarray experiment. Indeed, groups of gene expression may be more biologically interpretable and statistically robust than deciphering lists of individual genes. Mootha et al. (2003) used this approach to study changes in gene expression in the muscle of patients with type 2 diabetes. Their group introduced the gene set enrichment analysis (GSEA) and used the Kolmogorov–Smirnov test statistic, a type of non-parametric test statistic that does not make assumptions about population distribution. While the decrease in expression for individual genes was modest, around 20%, it was consistently decreased across a set of genes involved in oxidative phosphorylation, accounting for 89% of 106 genes. Thus, significant changes could be seen when looking at a group of genes, even when the expression of individual genes was not significantly different. GSEA has emerged as a useful tool for identifying biological processes from microarray data and has been refined into a robust method (Subramanian et al., 2005).

Similarly, Segal et al. (2004) created a cancer-focused compendium of expression profiles from 26 studies. They were able to extract 456 modules and found that some modules were unique to a particular type of tumor whereas other modules were shared across a range of conditions, raising the possibility that these modules reflect common tumor progression mechanisms. For example, in acute lymphoblastic leukemia (ALL), a growth-inhibitor module was specifically repressed. On the other hand, a bone osteoblastic module was found across a range of tumor types, suggesting a common mechanism for bone metastasis.

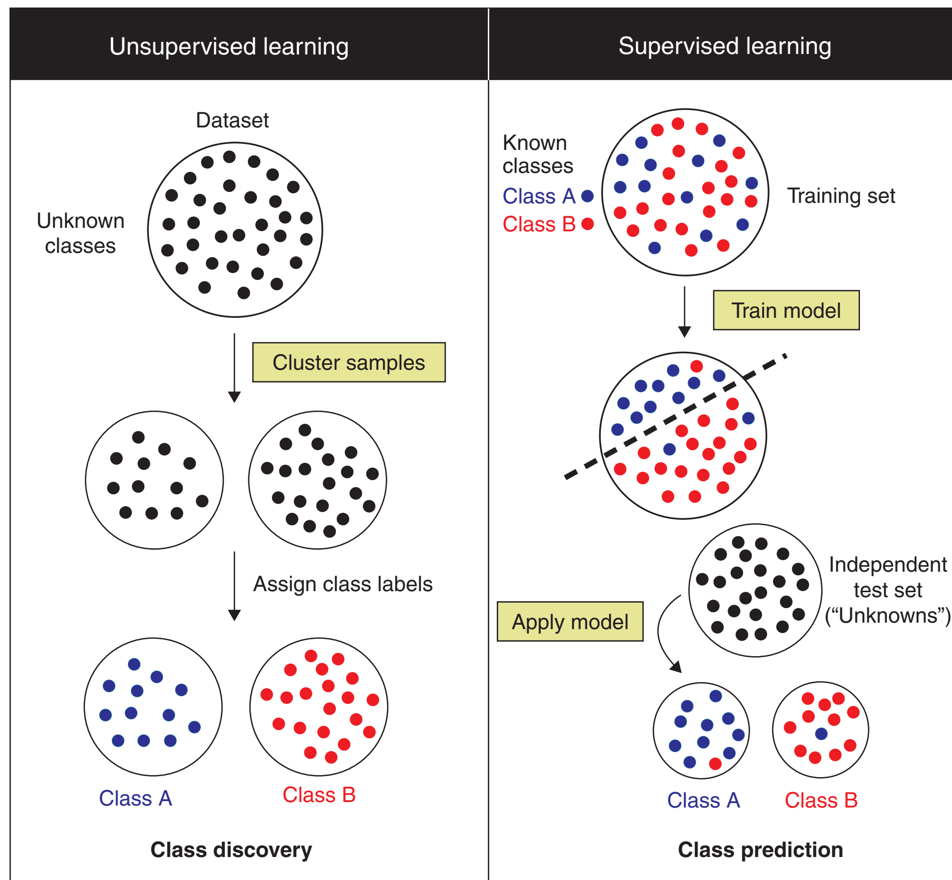

Figure 7.2 Unsupervised versus supervised learning. Unsupervised learning: multiple tumor samples are clustered into groups based on overall similarity of their gene expression profiles. This approach is useful for discovering previously unappreciated relationships. Supervised learning: multiple tumor samples from different known classes are used to train a model capable of classifying unknown samples. This model is then applied to a test set for class label assignment. Adapted from Ramaswamy and Golub (2002). (Reprinted with permission from the American Society of Clinical Oncology).

The COPA method focuses on genes characterized by marked overexpression (Tomlins et al., 2005). This strategy is used in order to efficiently process large amounts of data. COPA was applied to the Oncomine database, a compilation of 132 gene expression datasets representing 10,486 microarray experiments (Rhodes et al., 2004). This approach was instrumental for discovering two transcription factors with outlier profiles, *ERG* and *ETV1*, and subsequently shed light on recurrent gene fusions of the 5′ untranslated region of *TMPRS22* to *ERG* or *ETV1* in prostate cancer tissues. This study was notable for being the first study to identify recurrent gene re-arrangements in an epithelial cancer and suggested a novel mechanism for prostate cancer pathogenesis.

APPLICATIONS

DNA microarrays provide a panoramic, quantitative overview of a sample's expression output. The power of this is obvious, as biological processes generally result from the coordinated interaction of multiple genes.

Research with microarrays in humans can be divided into four categories:

1. normal tissue taxonomy;
2. disease diagnosis and classification;
3. disease prognostication; and
4. dissection of biological mechanisms.

Since the lion's share of research to date has been in cancer biology, in part due to the ready availability of tissue samples procured during routine diagnostic procedures, the following examples will draw largely from this field's literature.

Normal Tissue Taxonomy

Microarrays provide a new way of approaching the same fundamental question posed by Linnaeus in the 18th century: how is *A* different from and similar to *B*? An interesting example of previously unknown molecular heterogeneity was illustrated with human fibroblasts (Chang et al., 2002). Here, the authors demonstrated that the major factor responsible for differences in gene expression was the site of origin of the fibroblast. This

suggests that a detailed positional memory is encoded in a fibroblast's expression profile, and that different fibroblast subsets might be functionally distinct. Prior to the advent of microarray technology, this geographic variation was not appreciated. In addition to topographic location, the effect of aging on fibroblasts can also be measured and classified by expression profiling (Ly et al., 2000). In this study, using an Affymetrix oligonucleotide microarray, the expression profiles of fibroblasts isolated from young, middle-age, and old-age individuals and individuals with progeria were compared. The authors found consistent differences in the expression of genes between these groups in two functional classes: genes involved in cell cycle progression and genes involved in maintenance and remodeling of the extracellular matrix.

Disease Diagnosis and Classification

There have been a multitude of studies using expression profiling for disease diagnosis and classification, most notably in cancer. One seminal study used oligonucleotide microarrays to examine the expression of 6817 human genes in 72 patients with acute leukemia (Golub et al., 1999). Using unsupervised learning, gene expression was able to independently cluster leukemia samples into the known subsets of acute myelogenous leukemia (AML) and ALL (see Figure 7.3). Then, using supervised learning, gene sets that were differentially expressed in AML and ALL were used to correctly classify a group of unknown samples into the correct categories. Significantly, many markers that were both known, such as myeloperoxidase and terminal transferase, and unknown were useful for making this distinction. Although the difference between AML and ALL is often not difficult using modern histopathology, this study provided the first evidence that tumor expression profiles can be used for cancer classification.

Tumor cell lines can also be classified molecularly through expression profiling (Ross et al., 2000). The National Cancer Institute's Developmental Therapeutics Program bank of 60 cancer cell lines (NCI60) was profiled using a spotted cDNA array of 9703 cDNAs. The gene expression patterns observed in these cancer cell lines corresponded to the tissue of origin, which is remarkable since these cell lines have been selected for survival in the host and later in tissue culture. This illustrates a theme that the tissue of origin plays a major role in determining the expression profile. Similarly, a molecular taxonomy of tumor samples from 14 different tumor classes was created using a supervised learning algorithm (Ramaswamy et al., 2001). Some of these samples were from metastatic sites, and interestingly, the majority of them could be categorized from the classification information derived from the primary site, again demonstrating the importance of the tissue of origin in disease.

Breast cancer has been intensively profiled. Perou et al. (2000) reported a molecular classification system based on the expression patterns of 65 breast adenocarcinoma specimens from 42 individuals using a spotted cDNA array. Using an unsupervised method, these breast tumors were categorized into four different subtypes based on their patterns of gene expression. One clinically important subtype was already known (*Erb-B2* or *Her2/neu* overexpressing cancers), and three others were previously unknown: estrogen receptor-positive/luminal-like cancers, basal-like cancers, and normal breast. In addition to this classification system, the authors were able to show the importance of cellular lineage in determining the expression profile. This was illustrated by examining the variation in expression between primary tumors that were biopsied before and after a course of chemotherapy. They also looked at the profiles of two primary lymph node metastasis pairs. The authors found that the paired samples in the same patient were significantly more related to each other than to tumors from other patients, despite intervening chemotherapy or metastatic evolution. These initial observations were subsequently validated in a larger dataset (Sorlie et al., 2001, 2003). Importantly, these molecularly defined subtypes were clinically relevant, as patients with basal-like tumors had a significantly worse prognosis compared to patients with other breast cancer subtypes.

Outside of the realm of cancer, cDNA microarray technology has proved useful for exploring a broad range of diseases such as inflammatory diseases like rheumatoid arthritis and Crohn's disease (Heller et al., 1997), schizophrenia (Mirnics et al., 2000), multiple sclerosis (Lock et al., 2002), and differentiating between ischemic and non-ischemic cardiomyopathy (Kittleson et al., 2004). Microarrays have also been helpful for re-examining basic questions such as aging, as discussed previously (Ly et al., 2000).

Disease Prognosis

A challenge in medicine and especially in oncology is prediction–forecasting which patients will and will not benefit from therapy, particularly when the therapy, such as chemotherapy, has significant risks. DNA microarrays offer the possibility of radically transforming medicine from a traditional one-size-fits-all approach to individualized care. Intuitively, more information, when rich in content and appropriately analyzed, should lead to better prediction models. However, this has not always been borne out with various histopathologic tumor markers (e.g., breast and colon cancer), despite much initial excitement when these markers first became available (Bast et al., 2001). In contrast, there have been several microarray experiments involving different types of cancers that have found that the expression signature can serve as a robust biomarker, better than currently used criteria, for predicting prognosis. A common approach is to identify an expression profile that can subclassify a tumor type and then find correlations between this subclassification and prognosis.

The first such application was described by Alizadeh et al. (2000) in diffuse large B cell lymphoma (DLBCL). These investigators constructed the Lymphochip, a specialized spotted cDNA microarray enriched for genes preferentially expressed in lymphoid cells and for genes with known roles in immunology or cancer. Using this microarray, hierarchical clustering revealed two molecularly distinct forms of DLBCL: germinal center B-like DLBCL and activated B-like DLBCL. These subtypes were not

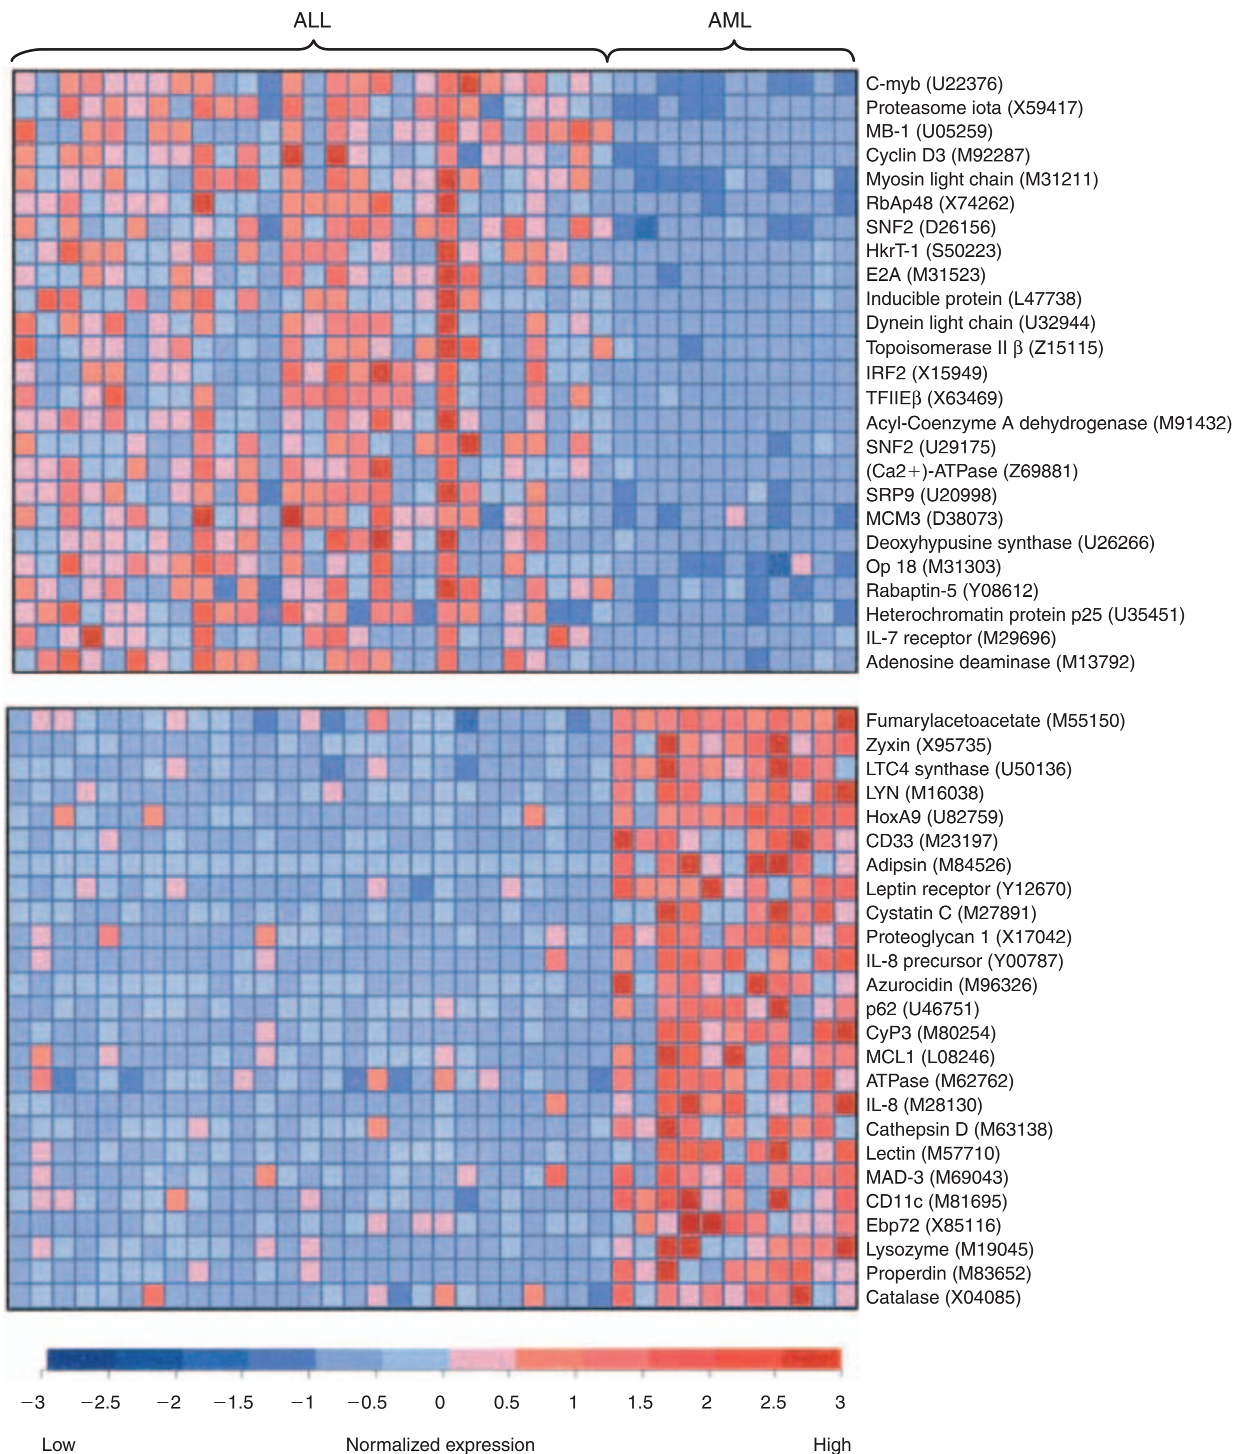

Figure 7.3 Gene expression profiling in acute leukemia. The 50 genes most highly correlated with the distinction between ALL and AML are shown. Each row corresponds to a gene, and each column corresponds to expression levels in different samples. Expression levels greater than the mean are shaded in red, and those below the mean are shaded in blue. The scale indicates SDs above or below the mean. The top panel shows genes highly expressed in ALL; the bottom panel shows genes more highly expressed in AML. Adapted from Golub et al. (1999). (Reprinted with permission from AAAS).

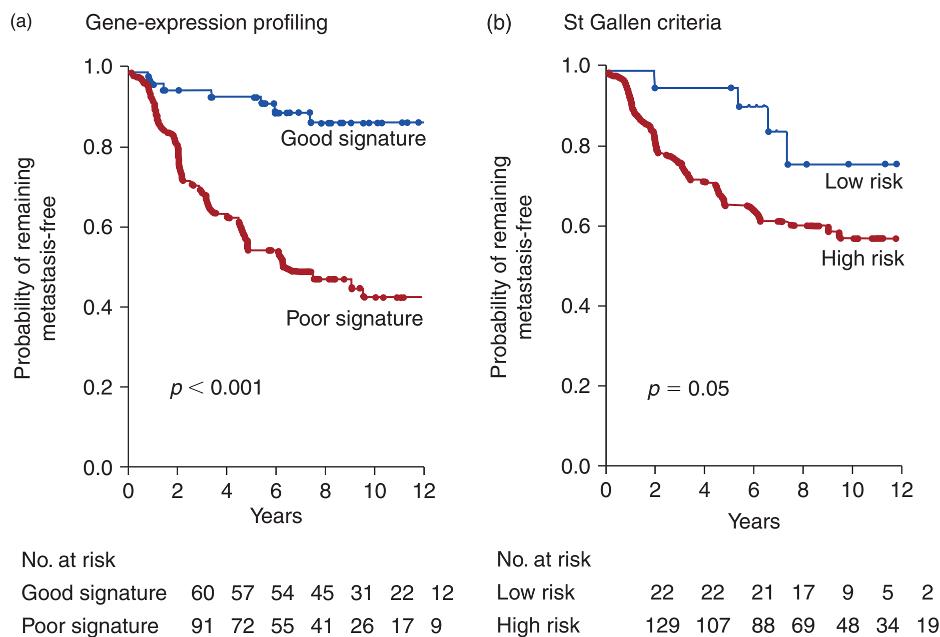

Figure 7.4 Kaplan–Meier analysis of the probability that patients would remain free of distant metastases among 151 patients with lymph node-negative breast cancer by gene expression profiling (a) and by St Gallen clinical criteria (Goldhirsch et al., 2001) (b). Adapted from Van de Vijver et al. (2002). (Copyright © 2002, Massachusetts Medical Society. All rights reserved).

appreciated using traditional histopathology and immunohistochemical techniques, yet nevertheless have clinical significance as patients with germinal center B-like DLBCL had significantly better overall survival when treated with standard chemotherapy. Indeed, as observed with other initial studies in cancer classification, cell lineage was an important determinant of the molecular phenotype. Ultimately, it remains to be seen whether or not molecular phenotyping will supplant traditional diagnostic tools, and this remains an ongoing area of research.

Similar predictive power has been exemplified in microarray studies of breast cancer. Traditional factors for predicting a patient's outcome, such as tumor size, lymph node status, and estrogen receptor status, are imperfect. Van't Veer et al. (2002) used an oligonucleotide microarray to analyze primary tumors from 117 patients with early-stage breast cancer and no lymph node involvement, who received minimal treatment after surgery, to identify a 70-gene expression signature that strongly predicted metastasis. In a subsequent validation study on 295 patients (which included the original cohort of 117 patients), this signature outperformed all currently used clinical predictors and more accurately identified patients at risk for distant metastasis (van de Vijver et al., 2002) (see Figure 7.4). For example, the profile could assign more patients into a low-risk group for metastasis (40%) compared to traditional clinical criteria (15%). These initial findings were subsequently confirmed in an independent group of patients from five European centers (Buyse et al., 2006). Taken together, these results suggested that primary tumor gene expression profiles can be used to molecularly stratify cancer patients according to risk of progression and treatment outcome.

LIMITATIONS AND CHALLENGES

While microarray technology continues to mature, as with any technology, expression profiles must be interpreted in the context of broader biological knowledge. For example, one assumption often made is that gene expression correlates well with protein quantity and therefore protein activity. This view does not take into account additional variables such as mRNA stability, protein degradation, or post-translational modifications that ultimately determine protein activity. Another supposition is that mRNA expression levels correlate well with biological activity. In contrast, small differences in expression may have a dramatic biological effect. For example, the expression level of transcription factors is often quite low even in tissues where these factors play active roles. Finally, expression profiles are not fixed; they may vary dramatically in different physiological contexts (King and Sinha, 2001).

Validation with Non-microarray Technologies

Gene expression data generated from microarray experiments can be credentialed using other methods of expression measurement such as northern blotting (Taniguchi et al., 2001), real-time PCR (Dallas et al., 2005). These studies and others demonstrate that genes found to be expressed with current generation microarrays can be consistently verified. Microarray data can also be verified at the protein expression level. A particularly useful high-throughput technology for validation using immunohistochemistry involves tissue microarrays (Hans et al., 2004).

Reproducibility of Microarray Data

An ongoing concern since the inception of the DNA microarray has been its technical reproducibility (Marshall, 2004). For a general review of these initial concerns, the interested reader is referred to a review by Chuaqui et al. (2002). While initial studies raised concerns about the reproducibility of microarray data (e.g., Tan et al. [2003]), subsequent studies have found that reproducibility is better than initially described (Bammler et al., 2005; Irizarry et al., 2005; Larkin et al., 2005). Recently, the MicroArray Quality Control (MAQC) project involved 137 participants from 51 academic, government, and commercial institutions to assess the performance of seven microarray platforms of two commercially available RNA samples (Shi et al., 2006). Reassuringly, the MAQC project showed high intra-platform consistency across test sites as well as a high level of inter-platform concordance in terms of identifying differentially expressed genes in a common set of biological samples.

FUTURE DIRECTIONS

Newer Platform Technologies

Alternatives to conventional microarray platforms are emerging. One notable example is a bead-based platform developed by Illumina, the BeadChip. This uses randomly assembled arrays of 50-mer coated 3-μm beads in order to create an extremely dense platform that is denser than spotted arrays or photolithographically made arrays (Gunderson et al., 2004). Whereas in conventional arrays, the sequence and location of each probe is known beforehand, the identity (and the corresponding probe sequence) of the beads is decoded after deposition. A DNA-based decoding algorithm is used to identify each bead. Compared to conventional platforms, the main advantage of this platform is lower per-sample cost.

A different type of platform departing from conventional technology is the CombiMatrix platform. This platform synthesizes oligonucleotides *in situ* on a semiconductor chip using routine phosphoramidite chemistry under electrochemical control (Liu et al., 2006). Each feature on the chip is digitally addressed and controlled. When activated, an electrochemical reaction generating acid occurs, ultimately leading to oligonucleotide synthesis *in situ*. The main advantage of this technology is flexibility. Custom microarrays can be created on demand with less labor, whereas technologies with "fixed" content such as the Affymetrix chip require a significant investment of resources to create a new chip (e.g., creation of a new photolithographic mask).

Formalin-Fixed, Paraffin-Embedded Samples

Traditionally, obtaining RNA from human tissues for expression profiling has required that specimens be snap-frozen in liquid nitrogen within a half hour of resection and stored at −80°C or colder to minimize RNA degradation. Samples need to be processed quickly because changes in some mRNA species have been noted even a few minutes after manipulation and devascularization of a tissue (Huang et al., 2001). However, clinical specimens are generally fixed in formalin and embedded in paraffin for routine histopathologic analysis, which causes significant RNA degradation. Only a fraction of the RNA from fixed specimens, roughly 3%, is intact enough for cDNA synthesis, posing a major barrier to obtaining expression profiles from clinical specimens (Godfrey et al., 2000; Masuda et al., 1999).

A method to maneuver around this degradation obstacle is the cDNA-mediated, annealing, selection, extension, and ligation (DASL) assay. This assay is a technology that combines the advantages of microarray-based gene expression profiling with multiplexed quantitative PCR (Fan et al., 2004). An upstream and downstream pair of oligonucleotides is designed to amplify a cDNA of interest. Each pair of oligonucleotides incorporates a universal primer sequence for PCR as well as a specific address sequence that hybridizes to a capture sequence on an array. With this methodology, cancer-specific expression profiles were generated with as little as 50 ng of total RNA from formalin-fixed tissues stored over a decade (Bibikova et al., 2004). Approaches such as the DASL assay thus have the potential to capitalize on the vast supply of archived, paraffin-embedded samples from large clinical trials or population-based cohort studies to advance expression profiling efforts.

Functional Genomics

A goal of functional genomics is to assign biological meaning to genes on a genome-wide level (Steinmetz and Davis, 2004). As illustrated by the examples described earlier, expression profiling has proved useful for assigning functional groups to genes in model organisms such as yeast (Hughes et al., 2000) and for uncovering a role for metastasis with *RhoC* (Clark et al., 2000). Expression profiling has also been used to decipher regulatory networks of transcription by discovering common sequence motifs in upstream regions of genes that have similar expression profiles (Pilpel et al., 2001). These studies, though, have been mainly been done in yeast and await application in more complex systems such as humans.

A new opportunity in functional genomics is to integrate expression profiling with RNA interference (RNAi) technologies now that genome-wide RNA interference libraries are coming to fruition (Moffat et al., 2006). One can imagine using RNAi libraries to systematically knock down individual genes and the comparing the resulting expression phenotypes. One can then look for similarities and differences between expression profiles as a starting point for inferring the function of the genes that have been ablated by RNAi.

Profiling the Transcriptome

Expression profiling has also been used to explore the transcriptome. The transcriptome represents the complete set of all the transcribed elements of the genome in contrast to the collection of transcripts that are only translated into proteins. There is a burgeoning interest in the function of the non-coding part of the transcriptome as the number of actual genes transcribed into

proteins has been substantially revised downward and increasing numbers of non-coding transcripts have been discovered. Key to their detection has been tiling microarrays, specifically those developed by Affymetrix with photolithographic technology. Rather than only using probes for known exons, tiling arrays probe across the entire genome in an unbiased fashion. Cheng et al. (2005) used a 25-mer oligonucleotide-based array spaced every 5 bp to examine ten human chromosomes. They discovered that interestingly, of all the transcribed sequences, 19% were polyadenylated, 44% were not polyadenylated, and 37% were both polyadenylated and not polyadenylated. Additionally, about 10% of the genome was transcribed as polyadenylated transcripts, compared to 1–2% of the genome corresponding to exons. These findings suggest that the expressed genome may be orders of magnitude larger than previously appreciated.

Part of the transcriptome also includes small (roughly 22 nucleotide) non-coding microRNAs (miRNAs). These miRNAs play an important role in regulating gene expression by either degrading mRNA or inhibiting its translation (Bartel, 2004). In cancer, for example, Lu et al. (2005) used a new bead-based profiling system to quantify miRNA expression because of the short size of the miRNAs. This used oligonucleotide capture probes that were coupled to beads, which in turn were differentially impregnated with variable degrees of a fluorescent mixture. Flow cytometry was then used to quantitate the beads and therefore the associated miRNA. Expression profiling of the miRNA population of various malignant and normal tissues revealed an unusually large degree of diversity of miRNA expression across cancers. Furthermore, miRNA signatures could be used to classify poorly differentiated cancers, which have traditionally been difficult to classify using standard mRNA-based profiling strategies. The interested reader is referred to a recent review by Calin and Croce (2006).

Clinical Translation

Expression Profiling as a Biomarker

The ability of expression signatures of tumor samples to predict prognosis has immediate potential clinical translation. A key lesson from these early clinical microarray studies is that appropriate sample size and careful experimental design are necessary for identifying signatures that can serve as robust biomarkers (Michiels et al., 2005; Ntzani and Ioannidis, 2003; Simon et al., 2003). However, reassuringly, a recent study of prognostic breast cancer signatures showed that four out of five reported gene signatures had significant concordance in predicting breast cancer outcome, indicating that these signatures were tracking similar biological behaviors (Fan et al., 2006), pointing to the evolving sophistication of clinically oriented profiling efforts.

The clinical application of expression profiles is most mature in breast cancer, owing to the extensive microarray data already available, and has recently been reviewed (Sotiriou and Piccart, 2007). The 70-gene-expression signature originally formulated by Van't Veer et al. (2002) has been commercialized into the MammaPrint assay for clinical use. This assay serves as the basis of the MINDACT (Microarray In Node negative Disease may Avoid ChemoTherapy) clinical trial, which aims to determine whether the expression signature can be used for making clinical decisions (Novak, 2006). It will test the question of whether or not patients with tumors that have high risk features by clinical criteria – individuals who are routinely recommended adjuvant chemotherapy – but with a low-risk molecular prognosis as determined by MammaPrint, can defer chemotherapy without affecting metastasis-free survival. In other words, it will test if the molecular prognosis generated by MammaPrint can outperform clinical criteria.

An alternative to using existing signatures is to adapt the expression profile into a RT-PCR-based assay. Compared to DNA microarray technology, RT-PCR has the potential to be less technically challenging, more cost-effective, and more easily integrated into routine clinical practice. Genomic Health International has developed the Oncotype assay which is currently available for clinical use (Paik et al., 2004). The Oncotype assay is an RT-PCR assay based on a 21-gene signature (including five control genes) derived from 250 candidate genes selected from the published microarray literature. Rather than using fresh frozen tissues, the researchers were able to exploit archived, paraffin-embedded tissues using RT-PCR as their profiling method (Cronin et al., 2004). They systematically quantified the expression of these 250 candidate genes across three historical groups of breast cancer patients. From this data, they derived a gene expression-based recurrence score for predicting breast cancer recurrence that was more powerful than standard histopathologic criteria. The reproducibility of the score was robust and was subsequently validated in a large, population-based study (Habel et al., 2006). Furthermore, Oncotype had the potential to identify patients who may be able to defer adjuvant chemotherapy treatment. Patients with low and intermediate recurrence score tumors did not appear to derive a significant benefit from chemotherapy (Paik et al., 2006). An advantage of using this RT-PCR-based approach is that it can be applied to tumor samples that have been collected and processed in routine fashion; no special handling (e.g., freezing tissues in liquid nitrogen) is required. Other examples of adapting expression profiling to an RT-PCR assay include a two-gene breast cancer signature (Ma et al., 2003) and a six-gene signature predicting survival in DLBCL (Lossos et al., 2004).

In the future, one of the challenges for translational research will be the integration of expression profiling with routine histopathology in clinical practice. As can be seen with the 21-gene breast cancer signature, expression profiling in this application offers the advantage of reproducibility and minimizes human error and variability with pathological interpretation. However, cost continues to be a major limitation to widespread adoption of profiling technologies. An ongoing prospective study, similar in concept to MINDACT, is the TAILORx (Trial Assigning Individualized Options for Treatment) trial in North America, which will help answer the question of how to integrate microarray technology (i.e., Oncotype DX) into clinical practice for patients with breast cancer. TAILORx is examining whether chemotherapy is required for the intermediate-risk group defined by Oncotype's recurrence score (Paik, 2007).

Drug Development

DNA microarrays have also facilitated drug target discovery and prediction of drug response. For general reviews, the reader is referred to a recent one by Stoughton and Friend (2005). Using the NCI60 cancer cell line panel, Scherf et al. (2000) constructed a database that correlated gene expression and drug activity patterns. They were able to find relationships between gene expression and drugs such as 5-fluorouracil and L-asparaginase. Gunther et al. (2003) employed a similar strategy with primary human neuronal precursor cells and various psychotropic drugs. Potti et al. (2006) have expanded on this approach by using the expression profiles of sensitive and resistant cancer cell lines for six different chemotherapy drugs to predict response to neoadjuvant chemotherapy for breast cancer.

Stegmaier et al. (2004) have developed a high-throughput approach to drug discovery using expression profiling: gene expression-based high-throughput screening (GE-HTS). These authors were interested in compounds that could terminally differentiate AML cells. To discover these compounds, they used 5-gene-expression signature of the differentiated neutrophil and leukemic states as a surrogate. With an RT-PCR-based readout of these five genes, they then screened a small molecule library to identify drugs that could induce differentiation of leukemic blasts and discovered an epidermal growth factor receptor kinase inhibitor with this property (Stegmaier et al., 2005). Remarkably, GE-HTS discovered this potential therapeutic without prior detailed biological knowledge.

A related approach to screening small molecules has been implemented through The Connectivity Map, an *in silico* tool recently developed at the Broad Institute that uses expression profiling to systematically discover functional connections among diseases, genetic perturbations, and drug actions (Lamb et al., 2006). Lamb et al. first created a reference collection of gene expression profiles from cultured human cancer cells treated with small molecules. They then developed pattern-matching software to mine these data. The Connectivity Map has been used to perform *in silico* discoveries of rapamycin as a new approach for treating glucocorticoid-resistant ALL (Wei et al., 2006) and the inhibition of HSP90 as a novel mechanism for inhibition of androgen receptor signaling in prostate cancer (Hieronymus et al., 2006).

2009 UPDATE

Expression profiling using microarray technology is now a standard tool in biological and medical discovery. At the technical level, recent years have seen dramatic advances in the ability to efficiently perform deep, comprehensive sequencing (Shendure and Ji, 2008).

The power of this next generation of sequencing has recently been applied to expression profiling (Wang et al., 2009). This approach, known as “RNA-seq”, typically starts with the conversion of RNA samples to cDNA fragments. These cDNA fragments are then sequenced in a massively parallel, high-throughput manner using platforms from companies such as Applied Biosystems and Illumina to obtain short sequences at great sampling depth. There are several significant advantages to evaluating RNA expression at the individual RNA level instead of the relative amounts measured by hybridization from traditional microarrays. These include lower background signal and significantly improved dynamic range (generally five orders of magnitude, which is three orders higher than microarrays). This is especially useful for quantifying genes expressed at very low or very high levels. Starting requirements for RNA are also lower for RNA-seq than for conventional microarrays. RNA-seq is beginning to be used for exploring basic biological questions, for example, characterizing mouse embryonic stem cells (Cloonan et al., 2008) and discovering new splice events, additional promoters, and untranscribed regions in the mouse transcriptome (Mortazavi et al., 2008).

There continues to be a proliferation of expression profiling data in translational and clinical research. Novel insights from basic cancer biology are being explored through microarrays in clinical settings, for example, profiles of breast cancer “stem cells” (Liu et al., 2007) and profiling of the stroma in diffuse large B-cell lymphoma (Lenz et al., 2008). Application to standard formalin-fixed, paraffin-embedded clinical specimens for microarray analysis is expanding with improving methods, for example, obtaining gene expression in hepatocellular carcinoma (Hoshida et al., 2008). Using microarray data for clinical decision making continues to be challenging. It is furthest along in breast cancer, where the Oncotype DX assay has been recently incorporated into the American Society of Clinical Oncology recommendations for use of tumor markers (Harris et al., 2007). It is gaining increasing use in the clinic for identifying patients with node-negative, estrogen-receptor positive breast cancer who may derive the most benefit from tamoxifen, sparing them from the potential toxicities of adjuvant chemotherapy. Results from the ongoing Trial Assigning IndividuaLized Options for Treatment (Rx) (TAILORx) trial will be key to determining how to effectively incorporate expression profiling information into the treatment of early stage breast cancer (Sparano, 2006).

Looking towards the future, at the time of this writing, there is excitement surrounding the application of RNA-seq technology to more clinically focused questions. Indeed, one example illustrating the power of deep sequencing, in general, was in the genomic analysis of a patient with cytogenetically normal, acute myeloid leukemia (Ley et al., 2008). In the months ahead, we anticipate that RNA-seq will change the landscape of expression profiling.

CHAPTER

Proteomics: The Deciphering of the Functional Genome

Li-Rong Yu, Nicolas A. Stewart and Timothy D. Veenstra

INTRODUCTION

The continuing development of novel analytical technologies and instrumentation has brought a dramatic new dimension to how biological research can be pursued. This new dimension has enabled discovery-driven research to be conducted at par with hypothesis-driven research. In a hypothesis-driven approach, the understanding of a particular biological entity – whether it be a cell, gene, or protein – is used to develop studies that are designed to answer a specific question about a single gene, transcript, or protein, for example. Hypothesis-driven studies utilize technologies that focus on one specific entity per experiment. Discovery-driven studies, however, are designed around broad questions and focus on global characteristics of a cell or organism. These studies utilize advanced technologies that are able to gather information on thousands of different genes, transcripts, proteins, and metabolites in a relatively rapid and comprehensive fashion.

While these globally directed studies have seemingly been thrust upon the scientific community overnight, in reality it has taken decades of technological and instrumental development to bring this field of science to fruition. The first giant step in discovery-driven science is the completion of the Human Genome Project. This monumental effort could only have been accomplished with the many developments in cloning, amplification, and high-throughput gene sequencing (Yager et al., 1991). The analysis of thousands of gene transcripts using mRNA arrays has been made possible by the ability to synthesize mRNA probes and coupling them to solid surfaces (Gilham, 1970). Shortly after the development of these genome – and transcriptome-scanning technologies, many scientists shifted their focus onto proteins. Proteomics – the analysis of the entire protein complement of a cell, tissue, or organism under a specific, defined set of conditions – in its present state has also been dependent on decades of technological and instrumental developments. These developments have included advances in mass spectrometry (MS) technology, protein fractionation techniques, and bioinformatics, to name a few.

One of the difficult challenges in proteomics is the uncertainty of its complexity. Let us assume that as many as 15,000 genes are expressed within a given human cell at any single time. Let us then assume that these genes give rise, on average, to four different mRNA transcripts each, or 60,000 different transcripts in total. This estimate is very conservative given the presence of splice variants, single nucleotide polymorphisms, etc. that can arise from expressed genes. Now consider all of the events that can happen to a single transcript during and after translation into a mature protein. The protein can be processed from a pre-protein into a mature protein. The most common event that happens to change a protein is post-translational modification. There are over 300 known modifications, however; some of the more common are (in no particular order) phosphorylation, glycosylation, methylation, and acetylation. A single protein that may have four potential phosphorylation sites will, in itself, give rise to 16 different isoforms ranging from all the sites phosphorylated to none of them being phosphorylated. If each of the 60,000

Essentials of Genomic and Personalized Medicine

possible protein products contained only four possible sites of modification, these would give rise to as many as 960,000 different proteins. Obviously, these numbers are extremely conservative and suggest that the human proteome is likely to contain well over 1,000,000 distinct species. This number is well beyond the current capacity of state-of-the-art technologies, resulting in a consistent undersampling of the proteome regardless of the analysis method chosen. It is this uncertainty in the overall measurement that results in the question that hovers around many global proteomic studies: "Was the protein absent in the sample or did we simply fail to detect it?"

GEL-BASED AND SOLUTION-BASED PROTEOMICS

Proteomics relies on three basic technological cornerstones: a method to fractionate complex protein or peptide mixtures, MS to acquire the data necessary to identify individual proteins, and bioinformatics to analyze and assemble the MS data. While the MS and bioinformatic components are somewhat similar in most applications, there are two very distinct methods to separate out complex protein samples in proteomics. The mere mention of the word "proteomics" conjures up an image of stained protein spots that have been fractionated by two-dimensional polyacrylamide gel electrophoresis (2D-PAGE). This separation technology, which was developed over 30 years ago, is still the most common separation technique used in proteomics today (O'Farrell, 1975). Advances have been made in this technology that enables thousands of proteins to be resolved in a single gel.

While the primary role of 2D-PAGE is to separate complex mixtures of proteins, it also allows a means to compare the relative abundances of proteins from different proteomes. In a typical 2D-PAGE-based study, the proteomes from two distinct cell populations (e.g., control versus treated cells) are extracted and fractionated on separate gels (Figure 8.1) (Van den Bergh and Arckens, 2005). Since most proteins are colorless, the separated proteins need to be visualized (Westermeier and Marouga, 2005). This visualization is routinely accomplished using colorimetric stains, such as coomassie blue or silver stain. The resulting images are typically quite complex; therefore the spots observed on both gels are aligned so that the relative staining intensity of individual proteins can be compared between gels. Protein spots that are stained more intensely on one gel compared to the other are excised from the gel. The protein within the gel is then enzymatically digested by introducing trypsin into the gel piece. The resultant tryptic peptides are extracted from the gel and analyzed by MS or tandem MS (MS/MS) to acquire the raw data necessary to identify the protein(s) within the gel spot. This identification is accomplished using software designed to compare this type of data against databases containing large amounts of genomic or protein sequence information.

While 2D-PAGE fractionation has been the subject of many different criticisms over the years, it still remains a cornerstone technology in proteomics (Van den Bergh and Arckens, 2005). Many of the criticisms, such as its inability to resolve membrane proteins and gel-to-gel irreproducibility have been addressed through the development of better reagents, equipment, and gel alignment software. For instance, over the past several of years, 2D-DIGE reagents have been developed that allow comparative proteomes to be labeled with different fluorophores (i.e., Cy2, Cy3, and Cy5) (Hoorn et al., 2006). This differential labeling allows for the relative abundance of proteins from different proteomes to be compared by their combination prior to their run on a single gel, obviating the separation irreproducibility that can be observed between gels.

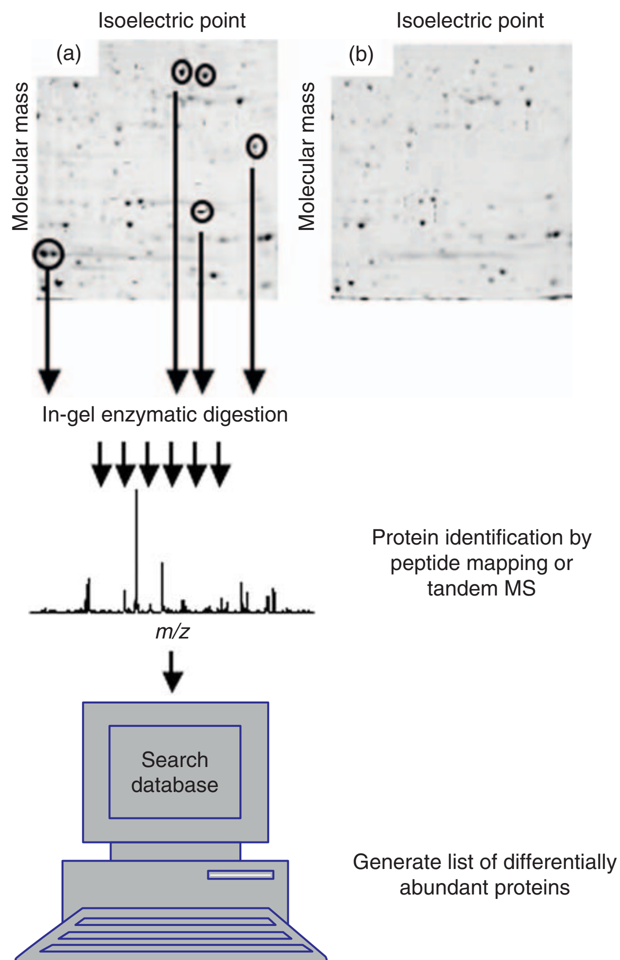

Figure 8.1 Quantitative proteomics using two-dimensional polyacrylamide gel electrophoresis (2D-PAGE). In this method, comparative proteome samples are separated on distinct 2D-PAGE gels. After staining, protein spots that are more abundant on one gel compared to the other are excised from the gel. The protein(s) within the gel is then subjected to in-gel tryptic digestion and the resultant peptides are extracted and analyzed by mass spectrometry (MS). The MS data are then searched against the appropriate database to identify the protein(s) with the gel spot.

No single chromatographic or electrophoretic procedure, including 2D-PAGE, can completely resolve a mixture as complex as that of a proteome. As a complement to 2D-PAGE methods,

solution-based chromatographic techniques have been developed that permit direct on-line MS analysis of proteomes (Issaq et al., 2005). Analogous to 2D-PAGE, these solution-based methods typically use at least two different fractionation schemes to separate peptides/proteins prior to their entering the mass spectrometer. While many different combinations have been proposed, the most effective and popular has been the use of strong cation exchange (SCX) followed by reversed-phase high-performance liquid chromatography (RPLC). John Yates III first demonstrated the effectiveness of combining this multidimensional separation with MS (Washburn et al., 2001). This method, termed "MudPIT" (multidimensional protein identification technology), has shown the capability of identifying thousands of proteins per proteome study. In this scheme, the proteins extracted from a cell lysate are first digested into peptides. There are two major advantages in working with peptides instead of proteins. Peptides are more soluble and easier to separate than intact proteins, especially hydrophobic and membrane proteins, and peptides are more amenable to identification by MS than are proteins (as described in more detail later). The challenge with this strategy is that the number of species that have to be resolved has dramatically increased. The digestate is initially separated by SCX and fractions collected off this column are then loaded onto a RP column that is coupled directly on-line with the mass spectrometer. The mass spectrometer can then dynamically select and acquire the data necessary to identify peptides as they elute from the RP column.

A limitation of MudPIT when compared to 2D-PAGE is in its inability to directly measure the relative abundance of proteins in different proteome samples. To meet this need, many different approaches have been developed, all of which use the data provided by the mass spectrometer for quantitation (Ong and Mann, 2005). Many of the methods rely on the use of differential stable-isotope labeling (Julka and Regnier, 2005). Analogous to DIGE, which uses differently fluorescent molecules with identical electrophoretic properties, stable-isotope labeling of proteomes uses chemically identical reagents that differ in their isotope content (i.e., mass). For example, the most popular labeling method termed isotope-coded affinity tags (ICAT) utilizes thiol-modifying reagents that differ in their carbon-13 (^{13}C) content (Gygi et al., 1999). In this procedure, one proteome sample is labeled with the "light" ICAT reagent while a comparative sample is labeled with the "heavy" ICAT reagent that contains nine ^{13}C atoms in place of nine ^{12}C atoms found in the "light" version (Figure 8.2). The label is attached to the proteins after they have been separately extracted from the samples to be compared. Once the two samples are differentially modified, they can be combined. The proteins are digested into peptides and the modified peptides are extracted by virtue of a biotin tag that is present at the termini of the ICAT reagents. This enriched peptide mixture is finally analyzed using MudPIT and the relative abundance and identity of the peptides are determined from measurements provided by the mass spectrometer. While ICAT illustrates a post-extraction/chemical modification method, stable-isotope labeling can also be performed at the metabolic level by culturing cells in growth media that is highly enriched

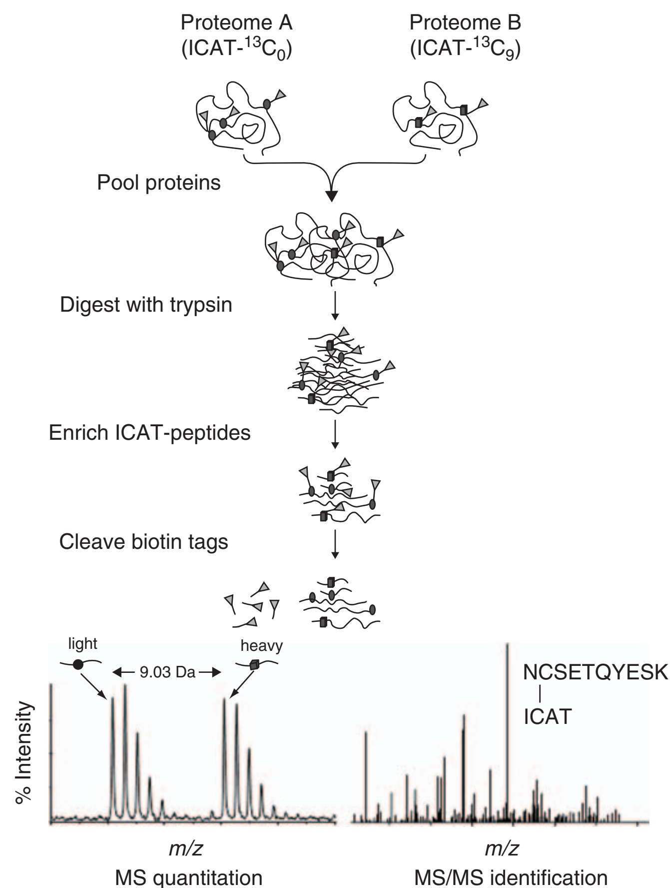

Figure 8.2 Quantitative proteomics using isotope-coded affinity tags (ICAT). In this method, comparative proteome samples are labeled with chemically identical reagents that differ only by their carbon isotope content (i.e., $^{12}C_9$ for the light reagent and $^{13}C_9$ for the heavy reagent). After the proteins are modified, the proteome samples are combined and digested into tryptic peptides. The ICAT-modified peptides are extracted using avidin chromatography by virtue of the biotin moiety on the terminus of the ICAT reagents. After removal of the biotin portion, these ICAT-peptides are analyzed by reversed-phase liquid chromatography coupled directly on-line with a mass spectrometer. The mass spectrometer is operated in a data-dependent tandem mass spectrometry (MS/MS) mode, enabling the relative quantitation of the peptide in the two samples to be measured in the MS mode as well as its identity be discerned from the data acquired by MS/MS.

in a particular heavy isotope (e.g., ^{15}N in place of ^{14}N) or a "heavy" amino acid (e.g., $^{13}C_6$-lysine) (Ong et al., 2003). A list of various sample preparation used in proteomics today, along with their advantages and disadvantages is provided in Table 8.1.

MASS SPECTROMETRY

While high-resolution separations are critical for complex protein mixture analysis, MS is inarguably the technology that

TABLE 8.1 List of advantages and disadvantages of popular sample preparation methods used in proteomics

Method	Advantages	Disadvantages
2D-PAGE	• Staining provides relative quantitation • Only sequence proteins of interest	• Laborious • Limited sensitivity • Irreproducibility a factor
2D-DIGE	• Can compare multiple proteomes on single gel • Reproducible separation	• Laborious • Requires fluorescent scanner
MudPIT	• Highly sensitive • Broad proteome coverage • High throughput	• Limited individual protein coverage • Unable to target specific proteins Lacks inherent ability for quantitative comparison
ICAT	• Reduces complexity prior to MS analysis	• Low throughput • Limited to a binary comparison • Unable to target specific proteins
iTRAQ	• Allows 4 samples to be simultaneously compared	• Low throughput • Unable to target specific proteins

has driven the proteomics revolution. Although, it has been around for approximately a century, MS has gained increased prominence with the development of techniques to rapidly identify proteins. There are many different reasons that have propelled the MS to its prominent position within the field of proteomics. Among these are the sensitivity afforded using MS, allowing proteins and peptides present in the low femtomole (fmol, 10^{-15} mol) to high attomole (amol, 10^{-18} mol) range to be successfully identified. The mass measurement accuracy available using current MS technology, which can routinely be in the range of 1–5 ppm, also increases the confidence in the identification provided by the bioinformatic search of the raw data.

While these and other technology specifications have been important, the development of MS/MS (McLafferty, 1981) and the coupling of on-line protein/peptide separations with MS (Henion, 1978) have been the key determinants that have enabled proteomics. Tandem MS allows tryptic peptides obtained from an enzymatic digestion of a complex proteome mixture, to be fragmented in such a way that sufficient sequence information can be obtained for its unambiguously identification. While proteins are typically identified through MS/MS identification of their peptide surrogates, methods to characterize intact proteins by MS/MS are becoming more and more popular. The coupling of on-line separations, most commonly RPLC, has enabled complex mixtures to be fractionation prior to MS analysis so that thousands of peptides can be identified within a few hours, as shown in Figure 8.3 (Washburn et al., 2001). The throughput by which proteins in complex mixtures are identified by LC-MS is unparalleled using any other technology: a critical parameter for discovery science in which large amounts of data are collected in order to find the important factors.

There are many different types of commercially available mass spectrometers, and it can be confusing as to which type is most suitable for a specific application. For instance, ion-trap mass spectrometers equipped with electrospray ionization (ESI) sources are the "work-horse" instruments for the characterization of complex proteomes when solution-based separations are used. Time of flight (TOF) instruments are popular for identifying proteins separated using 2D-PAGE, primarily because of their speed and mass accuracy. The choice of what instrument to be utilized needs to be weighed against the type of research that is being focused on.

How is MS able to identify so many peptides in a complex mixture? A schematic of the process is shown in Figure 8.3. The mass spectrometer is operated in what is referred to as a "data-dependent" mode of operation. In this mode, the instrument takes a series of "snapshots" of peptides eluting from a LC column into the mass analyzer. This scan is referred to as the MS scan. In between these snapshots, a series of MS/MS scans of peptides that are isolated within the instrument for CID are acquired. The instrument selects peptides for MS/MS analysis based on their intensity in the preceding MS scan. A data-dependent experiment can perform 10 MS/MS scans between every MS scan. The mass spectrometer continues this cycle of MS scan followed by ten MS/MS scans throughout the entire LC/MS/MS experiment. Depending on the length of the LC separation, upwards of 7000 MS/MS sequencing attempts are made on peptides eluting from the column into the mass spectrometer. Bioinformatic analysis will result in 10–25% (i.e., 700–1750) of these sequencing attempts resulting in successful peptide identifications. A list of popular mass analyzers used in proteomics and their performance characteristics is given in Table 8.2.

BIOINFORMATICS

Probably no area of proteomics evolves faster than bioinformatics. Proteomics is critically dependent on bioinformatics to process the raw mass spectral data into protein data. While routinely used by every proteomic laboratory, the most critical software programs are those that take peptide mapping and/or tandem MS results and determine the protein or peptide sequence that most closely matches the experimental data. The two most popular software packages for matching experimental MS data to peptide/protein sequences are MASCOT

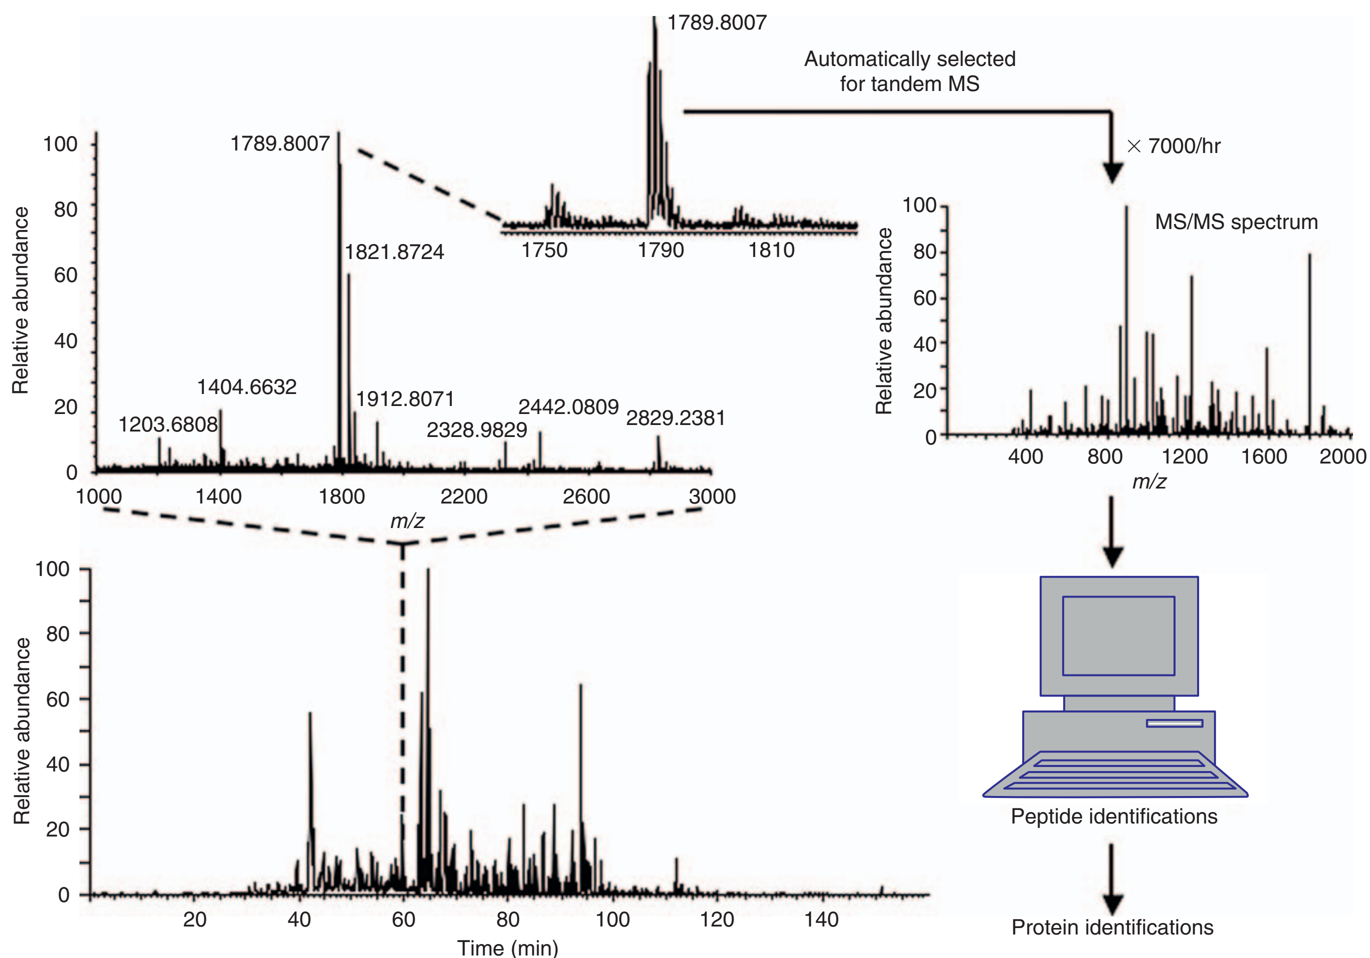

Figure 8.3 Principles of data-dependent tandem mass spectrometry (MS/MS). In data-dependent MS/MS, the mass spectrometer conducts an MS scan to record peptide masses that can be detected during a reversed-phase liquid chromatography (RPLC)-MS analysis of a complex proteome sample. The mass spectrometer isolates the peptide producing the most intense signal (i.e., *m/z* 1789.8007) and subjects it to collisional induced dissociation (CID). The resultant fragment ions are detected by the mass spectrometer and are subsequently used to identify the peptide in a bioinformatic analysis of the data. The mass spectrometer then isolates the next most intense peptide and collects its MS/MS spectrum. Linear ion-trap mass spectrometers may sequentially select on the order of 10 peptides for CID prior to recording the next MS scan. In the following MS scan, the instrument looks for new peptides that may have eluted from the LC column and selects these for CID and possible identification.

Table 8.2 Performance characteristics of various mass analyzers commonly used in proteomic research

Analyzer	Sensitivity	Resolution	Mass accuracy
Ion-trap	Good	Low	Low
Linear ion-trap	Excellent	Low	Low
Triple-quadrupole	Good	Good	Good
TOF	Good	High	High
FTICR	Excellent	High	High

(Lubec et al., 2005) and SEQUEST (Yates et al., 1995). As with most software algorithms, they both do what can also be done manually but at a much faster speed. For instance, SEQUEST is capable of transforming thousands of raw tandem MS files into potential peptide identifications within minutes, whereas manually assigning a single raw file would take on the order of hours. These software algorithms are also capable of identifying modified peptides when the mass added to the peptide as a result of some covalent modification (e.g., phosphorylation) is known. While not in widespread distribution, software packages, such as Scoring ALgorithm for Spectral Analysis (SALSA) developed by Daniel Leibler, provides a means of identifying unanticipated modifications, by identifying spectra that display characteristic

product ions, neutral or charged losses of groups of signals that are indicative of a particular modification (Hansen et al., 2001). Taken together, these varieties of software packages have been critical to the enabling of data analysis on the scale needed for discovery-driven proteomic studies.

Throughout this chapter, the theme has been to use proteomic technologies to measure the relative abundances of proteins in different samples. Software has been developed to do this both at the gel-staining level and the mass spectral data level (i.e., when stable-isotope labeling quantitation is employed). Where the major lack has been is how this relative abundance data is presented. It is still typically displayed as lists of proteins with their relative abundance between two samples being given as a fold-difference. Unfortunately, with the ability to generate abundance data for thousands of proteins, these lists become an "unsolvable puzzle" when trying to identify major effects on a cell's proteome as a result of a specific treatment. Recently, software packages such as Ingenuity™ have been developed to distill abundance data into annotated protein pathways enabling the probability that any specific signaling pathway has been affected can be statistically measured (www.ingenuity.com/products/pathways_analysis.html). Software packages such as these also allow transcriptomic and proteomic data to be directly compared at both the single biomolecule and pathway levels.

IMPACT OF PROTEOMICS ON UNDERSTANDING DISEASES

It is impossible to find a common characteristic that threads every disease together. One prevalent characteristic, primarily in the area of cancer, is that the earlier it is detected the better the chance of survival. To detect cancer at earlier stages is going to require novel biomarkers that possess high sensitivity and specificity. This need has driven much of the proteomic research over the past 3–5 years. Much of the search for novel biomarkers falls within discovery-driven research, and therefore MS has played a major role. The aim, in most studies, is to leverage the ability of MS to identify proteins in biological samples from patients with specific cancers and compare that to lists of proteins identified in the same sample types obtained from healthy-matched controls. Proteins that are found to be more prevalent in samples from disease-afflicted patients are considered as potential biomarkers.

While on the surface the premise sounds simple enough, in reality there are several daunting challenges, both technological and physiological. Even with the speed at which MS is capable of identifying proteins, it still undersamples any complex proteome mixture. When such entities as post-translational modifications and splice variants are taken into account, it is impossible to know exactly the number of distinct proteins within a cell or biofluid proteome. Therefore, when a protein is detected in a diseased sample but not in a matched control, there is always that uncertainty as to whether the protein is not really present or it just was not detected in the present experiment. As is commonly quoted in science, "the absence of evidence is not the evidence of absence". On the physiological side, the fact that the proteome of any cell or biofluid is dynamic results in a constantly changing background that occurs both between different patients and within the same patient. For instance, the serum proteome of an individual is different before and after lunch. Compound this with the genetic and lifestyle variability that is observed between different patients and it is easy to grasp how difficult it is to confidently identify a disease-specific change in a protein in this shifting matrix.

Regardless, the promise of technologies such as MS that can scan proteomes at levels never before possible propels investigators to search for new diagnostic markers. While the success in discovering new markers has been limited, they do however exist. For instance, a biomarker for the bladder disorder interstitial cystitis (IC) was found using a combination of protein fractionation and MS techniques (Keay et al., 2004). Previous to this report, no useful diagnostic marker for this disorder existed and patients were typically diagnosed by the exclusion of other maladies. This study resulted in the discovery of a novel nine-residue sialoglycopeptide that was shown to be present only in the supernatant of cultured bladder epithelial cells obtained from patients with IC and not in healthy controls or patients with bacterial cystitis.

One of the more intriguing MS-based proteomic techniques to identify signatures of diseases in blood involves the detection of peptides that signify exo- and endo-protease activities (Villanueva et al., 2006). In this study, low molecular weight peptides were extracted from serum and analyzed using matrix-assisted laser desorption ionization (MALDI) TOF MS. The study showed that a subset of the serum peptides were able to provide a signature allowing patients with three types of solid tumors to be classified separately from controls without cancer. Sixty-one of the signature peptides were identified and shown to fall into several tight clusters (Villanueva et al., 2006). Most of the identified peptides were generated by cancer-type specific exopeptidase activities that enabled highly accurate classification of a set of prostate cancer samples used to validate the markers. While this method does not identify a novel diagnostic or therapeutic protein marker, it does use MS to reveal a cancer-specific activity found within serum of cancer-affected patients.

2009 UPDATE

As any useful field of science does, mass spectrometry (MS)-based proteomics has continued to evolve in capabilities and direction. While many of the fundamental aims of MS-based proteomics – such as identifying differentially abundant proteins between different systems – remain, the instrumental capabilities available to achieve these aims have increased in the recent past. In addition, many novel experimental approaches have been designed to better interrogate specific proteins and post-translational modifications.

The complexity of the proteome, even from a simple organism, is such that fractionation remains critical prior to MS analysis. Two-dimensional polyacrylamide gel electrophoresis (2D-PAGE) (O'Farrell, 1975) remains a cornerstone separation method with the use of 2D-DIGE (differential in-gel electrophoresis) becoming increasingly popular due to its comparative reproducibility, quantitative capability, and ease of use (Hoorn et al., 2006). Multidimensional protein identification technology (popularly known as MudPIT) continues to dominate the separation of complex proteomes in cases where investigators wish to avoid the use of gels (Washburn et al., 2001). This combination of strong cation exchange and reversed phase liquid chromatography (LC), combined with the continuing development of mass spectrometers with higher sensitivity and faster duty cycles, has enabled laboratories to routinely identify >5,000 proteins within complex proteomes.

The chief development in mass spectrometry technology in the recent past is the Orbitrap mass spectrometer with electron transfer dissociation (ETD) (McAlister et al., 2007). This instrument combines high sensitivity, mass accuracy, and resolution in an ion-trap configuration that uses ETD to fragment proteins and peptides. Conventional fragmentation methods, such as collisional induced dissociation (CID), are most effective when dealing with small peptides with molecular masses in the range of 500-3500. ETD has the ability to effectively fragment much larger peptides, thereby enabling top-down approaches in which peptide and intact proteins with molecular masses up to 20,000 can be effectively identified. Post-translation modifications are also preserved during fragmentation using ETD enabling phosphorylation sites, in particular, to be more effectively characterized.

Quantitative proteomics, in which global differences in protein abundances are measured, continues to be an important area in proteomics in both cell biology and biomarker discovery. While this area has been dominated by the use of stable-isotope labeling approaches (e.g. ICAT, iTRAQ, etc.), recent developments in label-free quantitation are changing the way quantitation is conducted (Du et al., 2008). Label-free methods rely on the measured intensity of a peptide ion and compare this to its intensity as recorded within other samples. Theoretically, quantitative proteomics methods enable cross comparison of a large number of samples, instead of the small number enabled by isotope-labeling approaches. In addition, label-free methods are higher throughput and require fewer sample manipulation steps. Some of the difficulties in routine application of these methods, however, have centered on correct matching of peptides from run-to-run due to variation in LC separations of the mixtures prior to MS analysis.

While MS-based proteomics has probably not yet had the impact on understanding human diseases that was anticipated, the progress has still been substantial. Many investigators are now using multiple-reaction monitoring (MRM) of specific peptides within very biofluid samples to quantitate the absolute abundance of proteins in clinical samples (Issaq and Veenstra, 2008). This method combined with development of MS technology continues to push proteomics closer to routine use within clinical laboratories, where its impact on public health will be substantial.

CHAPTER

Comprehensive Metabolic Analysis for Understanding of Disease

Christopher B. Newgard, Robert D. Stevens, Brett R. Wenner, Shawn C. Burgess, Olga Ilkayeva, Michael J. Muehlbauer, A. Dean Sherry and James R. Bain

INTRODUCTION

Despite decades of research, the molecular etiology of chronic and indolent diseases and conditions such as diabetes, obesity, cancer, and cardiovascular disease remains obscure, in part because they represent slowly developing phenotypes caused by the interplay of a complex mixture of genetic and environmental effectors. For similar reasons, it has been very difficult to detect and diagnose these diseases at a stage that allows sufficient time for effective intervention. Comprehensive measurement of intermediary metabolites and changes in metabolic activity (metabolic flux) could lead to improved detection and understanding of these diseases.

As will be discussed in this chapter, instrumentation for measurement of large groups of intermediary metabolites as well as computational methods for analyzing such data are emerging. This surge in development of "metabolomics" technologies confers a number of potential advantages to scientists interested in disease research. First, it is estimated that human beings contain approximately 5000 discrete small molecule metabolites, far less than the estimate of 25,000 genes and >100,000 proteins. Thus, metabolomics may ultimately be the most tractable of the "omics" sciences. Second, metabolomics measures changes in metabolic or chemical milieu that are downstream of genomic and proteomic alterations, therefore potentially providing the most integrated picture of biological status. Third, identification of metabolic fingerprints for specific diseases may have particular practical utility for development of therapies, because metabolic changes immediately suggest enzymatic drug targets. And fourth, metabolomics is likely to be a powerful and precise tool for discerning mechanisms of action and possible toxicological effects of drug therapies.

The purpose of this chapter is to describe current methodologies for metabolic profiling and flux analysis and to provide selected examples of insights into biological and disease mechanisms gained from these approaches. Studies involving integration of metabolomics with genomic and transcriptomic profiling methods are just beginning to emerge, and early examples of this exciting area will also be highlighted. It is important

to emphasize from the outset that metabolic profiling tools are in a rapid phase of development, such that our description of currently useful methods will likely represent a "snapshot in time" that will evolve rapidly over the next several years.

CURRENT METABOLOMICS PLATFORMS: BASIC TOOLS AND GENERAL FEATURES

As described in other chapters in this volume, genome-wide analysis of genetic variation ("genomics") and surveys of changes in mRNA abundance by microarray technologies ("transcriptomics") are examples of robust and relatively mature technologies for investigation of mechanisms underlying biological variability. For example, mRNA profiling has developed to a point that microarray cores have become common in both the academic and private sectors, with many thousands of RNA profiling experiments performed on a yearly basis. This is not yet the case for laboratories that focus on comprehensive metabolic analysis. One reason for this is the complexity inherent in attempting to measure small molecule metabolites (intermediary metabolites as discussed in this chapter are defined as non-peptidic and with a molecular weight of <3000) in a quantitatively rigorous fashion. Underlying issues include the variable lability of metabolites (e.g., amino acids are often quite stable, whereas organic acid or lipid species can be quite labile), the chemical diversity of different metabolite classes, problems encountered in efficient extraction of metabolites from different biological matrices (e.g., tissues, blood, urine, etc.), and the wide dynamic concentration range of metabolite species (ranging from sub-nanomolar to milimolar). Thus, it is not surprising that there is currently no single technology for measurement of all of the metabolites in the "metabolome". This means that the small number of existing laboratories that engage in comprehensive metabolic analysis have usually been constructed on an "*ad hoc*" basis, often driven by the direct technical experience and/or scientific goals and philosophies of the founding scientists. This leads to varying choices in instrument platforms, and places an even greater burden on individual laboratories for rigor in quantitative analysis, since standardized methods do not yet exist for the majority of analytes.

The two major instrument platforms for measuring metabolite levels in biological samples are nuclear magnetic resonance (NMR) and mass spectrometry (MS) (Dettmer et al., 2007; German et al., 2005; Hollywood et al., 2006; Lindon et al., 2007; Watson, 2006). Both technologies can also be used for metabolic flux analysis following provision of stable isotope-labeled metabolic fuels (e.g., U-^{13}C glucose) to cells and organisms, as discussed later. In general, when applying these technologies to assays of metabolite levels, research groups in the field tend to fall into two camps that adopt either "unbiased"/"top-down" approaches or "targeted"/"bottom-up" methods as their core technologies. Unbiased profiling involves use of either NMR

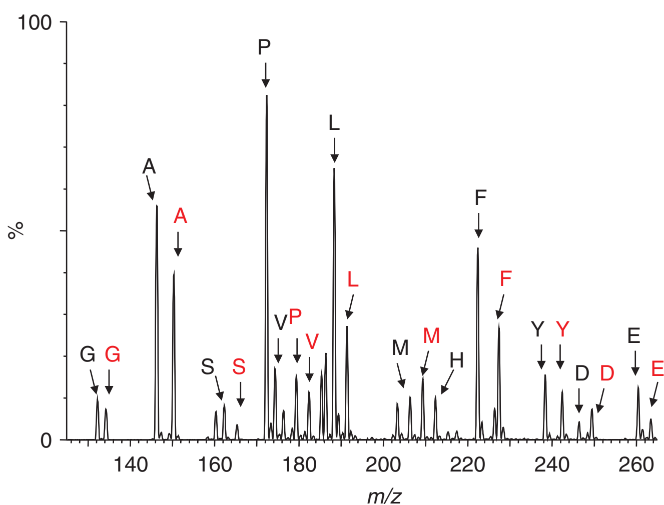

Figure 9.1 Tandem mass spectrum of butyl esters of acidic and neutral amino acids in serum. Data were obtained using a neutral loss of 102 Da scan function. The figure illustrates the use of internal standards for "targeted" quantitative profiling of metabolites. Each amino acid in serum (shown by black letters) is measured against its own stable-isotope-labeled internal standard (shown in red letters). G, glycine, A, alanine, S, serine, P, proline, V, valine, L, leucine, M, methionine, H, histidine, F, phenylalanine, Y, tyrosine, D, aspartate, E, glutamate.

or MS for measurement of as many metabolites as possible in a biological specimen simultaneously, regardless of the chemical class of the metabolites. When applied to unbiased profiling, both NMR and MS have advantages and limitations, as discussed below, and neither technology can presently be used for surveying all of the metabolites in a sample in a quantitative fashion. In contrast, targeted profiling focuses on quantification of discrete clusters of chemically related metabolites ("modules") using various combinations of chromatographic separations technologies and MS instruments that are most compatible with the analyte class. For example, electrospray ionization (ESI) and tandem mass spectrometry (MS/MS) are used for quantitative measurements of multiple amino acids and urea cycle intermediates or acylcarnitines (byproducts of mitochondrial oxidation of fatty acids, amino acids and glucose) of varying chain length and degree of saturation, whereas gas chromatography-MS (GC-MS) is used routinely for measurement of multiple species of free fatty acids and organic acids.

For each separate module, accurate quantification of the analytes is facilitated by addition of a cocktail of stable isotope labeled standards to the biological sample prior to the extraction and derivatization steps that may be necessary for the particular MS approach (see below and example shown in Figure 9.1). Ideally, each unknown analyte will be paired with its labeled cognate (usually an M+3 heavy isotope, e.g., methionine

with methyl-D_3 methionine, pyruvate with $^{13}C_3$-pyruvate, etc.) to control for differences in analyte loss during chemical extraction and/or derivatization of individual analyte species and to compensate for ionization suppression effects. In practice, the limited range of stable isotope-labeled metabolites available from commercial suppliers and their relatively high cost constitute a current impediment to more broad-scale development and deployment of these technologies. To overcome this problem in the future, it may be necessary for metabolomics core laboratories to import chemical synthesis capabilities for production of comprehensive libraries of internal standards.

Table 9.1 provides a summary of various MS-based metabolic profiling technologies that are currently used for measurement of different metabolite classes.

COMPARISON OF NMR AND MS TECHNOLOGIES FOR UNBIASED METABOLIC PROFILING

Nuclear magnetic resonance spectroscopy is theoretically an excellent tool for unbiased metabolic profiling of all small

molecule metabolites, since the method is based on detection of any molecules that contain carbon or hydrogen (German et al., 2005; Lindon et al., 2007). Moreover, the method is non-destructive, in that analyses can be conducted directly in bodily fluids, cells, and even in intact tissues without the need for chemical extraction or derivatization of the individual analytes. These advantages are off-set by significant technical challenges, including poor sensitivity (it is generally not possible to detect metabolites at sub-micromolar levels with NMR) and the difficulty of deconvoluting spectra of complex metabolite mixtures such as typically found in biological matrices like plasma, urine, or tissue extracts. When NMR is applied to such samples, all metabolites within the detection limits of the technology resolve as hundreds to thousands of proton magnetic resonance peaks. The complexity of these data and the absence of comprehensive libraries of NMR spectra make it very difficult to assign the different resonances to specific metabolites. Thus, although NMR spectra are rich with information, the full harvesting of these datasets is not yet possible. Instead, peaks within NMR datasets are often treated as independent statistical variables, and the data analyzed by methods such as principal components analysis (PCA) to identify clusters of resonances that characterize different biological or disease states.

Mass spectrometry has the immediate advantage of much higher sensitivity compared to NMR, and the most advanced MS platforms such as Fourier transform ion cyclotron mass spectrometers (FT-ICR-MS) have the capacity to detect metabolites at concentrations as low as the femtomole range (Dettmer et al., 2007). Moreover, modern MS platforms have very high-mass resolution (>100,000), can resolve literally thousands of individual small molecules without the need for chromatography, and can achieve mass accuracies of <1 ppm. Seemingly, current MS platforms could therefore provide a means of circumventing problems encountered when using NMR methods for unbiased metabolic profiling of complex biological matrices, as described earlier. In practice, however, MS techniques usually require a sample extraction step that can cause metabolite losses. Moreover, different kinds of MS instruments use varying methods for the generation and detection of ions, and in concert, different kinds of metabolites have discrete ionization properties and are therefore variably resolved and detected in instruments that rely on mass and charge for analyte separation (Dettmer et al., 2007). Thus, while several current MS instrument platforms can be used for resolution and detection of large numbers of metabolites (e.g., high-performance liquid chromatography-MS, Q-TOF-MS, and FT-ICR-MS), the variable lability, solubility, recovery, and ionization of the different analyte species, coupled with the lack of broad-coverage spectral libraries makes these unbiased methods inherently non-quantitative and useful mainly for detecting gross changes in spectral peaks in samples of different biological origin. Similar to NMR, masses in these complex MS spectra are often not assigned to a specific analyte, and the data are instead analyzed by PCA or other multi-factorial statistical tools. However, an advantage of MS-based unbiased profiling methods is that when specific peaks or clusters of peaks consistently differentiate biological states (e.g., a metastatic tumor from a benign tumor), their detection by high-resolution MS platforms provides an immediate clue for analyte identification by providing an accurate mass estimate of the analyte. These mass estimates can be used to query databases such as KEGG, HMP, and ChemSpider for chemical formulae that match the estimated mass, thereby usually providing a strong starting point for identifying the analyte, and ultimately facilitating a return to more mechanistically oriented studies. The number of possible formulae is also significantly reduced by high-mass accuracy; for example, the number of possibilities for a mass ~500 at a mass accuracy 5 ppm with an elemental palate CHNOS is ~23. A mass accuracy of 2 ppm would reduce the number to 10 and an accuracy of 1 ppm would yield only 4 possibilities.

MS METHODS FOR TARGETED METABOLIC PROFILING

For scientists with core interests in biological mechanisms rather than biomarkers, knowledge about the identity of metabolites being surveyed and their exact concentration greatly enhances the value of the datasets. This means that some metabolic profiling laboratories are built in a bottom-up fashion, with emphasis on targeted and quantitative MS-based analyses. Although these approaches tend to utilize simpler tools such as ESI-MS/MS and GC-MS, significant challenges must still be overcome in building rigorous and fully vetted analysis modules for groups of metabolites. For example, GC-MS, when coupled with the use of stable isotope standards, can provide sufficient chromatographic resolution and analyte-specific detection to allow quantification of groups of metabolites in a class (e.g., fatty acids of different change length and degree of saturation or organic acids/TCA cycle intermediates). However, because the chromatography is performed in the gas phase at high-temperature, analytes must be volatile and have sufficient thermal stability to survive the analysis. To help stabilize the analytes under study, reactive carboxyl, sulfhydryl, amine, or hydroxyl groups are derivatized by akylation, oximation, acylation, or silylation (Dettmer et al., 2007; German et al., 2005). These methods, while effective, add complexity beyond that already introduced by sample extraction to the analytical procedures, and can result in batch-to-batch variation if not properly controlled. Similarly, analysis of acylcarnitines or amino acids/urea cycle intermediates by ESI-MS/MS requires different derivatization steps for each module – for example, treatment with acidic methanol for acylcarnitines and n-butanol for amino acids/urea cycle intermediates (Haqq et al., 2005). Nevertheless, with care, these modules can provide quantitative data for highly informative clusters of analytes (e.g., fatty acids, fatty acylCoAs, and acylcarnitines of different chain length and degree of saturation, amino acids/urea

cycle intermediates, and organic acids), with coefficients of variation in replicate assays in the range of 10%.

EXAMPLES OF NMR-BASED METABOLIC PROFILING IN DISEASE RESEARCH

The most common application of ^{1}H-NMR-based metabolic profiling in mammals and humans to date has been for evaluation of toxic effects of xenobiotic drugs. Work in this area has been reviewed by others (Lindon et al., 2007), so we focus instead on newer applications in the realm of disease research.

Coronary artery disease (CAD) is the leading cause of death in the United States and, in concert with the epidemic of obesity and diabetes, is rapidly becoming the leading cause of death in many developing countries. The genetic predilection of CAD is well established; family history has repeatedly been shown to be a robust, independent risk factor for CAD. Many of the commonly accepted risk factors for CAD are metabolic, such as lipid abnormalities and diabetes, making this disease a particularly logical target for comprehensive metabolic profiling technologies. Indeed, ^{1}H NMR was recently reported to detect metabolic profiles that predicted the presence and severity of CAD (Brindle et al., 2002). The study involved comparison of a relatively small group of patients with triple vessel coronary heart disease ($n = 36$) to angiographically normal subjects ($n = 30$). Partial least squares-discriminant analysis was used to identify peaks in the major lipid regions of the spectra that appeared to provide separation between the groups. The specific lipid species involved were not identified by this analysis, although it was suggested that choline-containing metabolites were particularly diagnostic. However, a subsequent study using very similar techniques demonstrated that the predictive value of the NMR-based metabolic profiles was weak when other factors such as gender and use of medical interventions such as statins were taken into account (Kirschenlohr et al., 2006). This second group of authors demonstrated that the ^{1}H NMR technique could identify male versus female subjects with 100% accuracy, but was much less able to identify statin users or subjects with CAD, despite expectations of substantial changes in lipid profile in the former group. This study makes it clear that ^{1}H NMR is currently not a substitute for the more invasive procedure of angiography in detection of CAD.

An intriguing and more promising recent application of ^{1}H NMR-based metabolic analysis has been to study the influence of intestinal bacteria (microbiota) on pathophysiologic outcomes of high-fat (HF) feeding (Dumas et al., 2006). This involved feeding of a HF diet to a mouse strain (129S6) known to be susceptible to HF-induced hepatic steatosis and insulin resistance, and for comparison, to a strain (BALBc) with relative resistance to these effects of diet. Metabolic profiling of plasma and urine samples revealed low circulating levels of plasma phosphatidylcholine (PChol) and high levels of methylamines in urine in the 129S6 strain. Since the conversion of choline to methylamines is accomplished by gut microbiota rather than mammalian enzymes (Zeisel et al., 1983), and choline deficient diets are associated with hepatic steatosis (Buchman et al., 1995), the authors propose that the increased propensity of the 129S6 strain for hepatic steatosis and insulin resistance could be due to a reduced PC pool necessary for the assembly of VLDL particles, leading to deposition of triglycerides in liver. As with its application to diagnosis of CAD, the value of NMR for detecting the contributions of bacterial metabolism to whole animal metabolic profiles and disease development remains to be confirmed or refuted by an independent study. However, in this instance, other studies suggest that this could indeed be an important pathway. Thus, treatment of germ-free mice with microbiota from the cecum of conventionally raised animals produced an increase in body fat content and appearance of insulin resistance within 14 days of transfer (Backhed et al. 2004). In addition, more recent studies have revealed that genetically obese rodents or obese humans have changes in relative abundance of two main intestinal bacterial groups, the Bacteroidetes and the Firmicutes, relative to lean controls, and that the "obese microbiome" has an increased capacity to harvest energy from the diet (Turnbaugh et al., 2006). The mechanism by which the obese microbiome influences peripheral metabolism of the host seems to involve changes in circulating levels of fasting-induced adipose factor (FIAF), a circulating lipoprotein lipase inhibitor, as well as changes in activity of the important metabolic regulatory proteins PGC-1α and 5′ AMP-activated kinase (AMPK) in skeletal muscle and liver (Backhed et al., 2007). An intriguing area for future study is to attempt to define metabolic profiles for specific gastrointestinal bacteria such that their relative contributions to changes in overall metabolic profile can be monitored and fully understood in the context of fuel homeostasis in the host.

EXAMPLES OF TARGETED MS-BASED METABOLIC PROFILING FOR UNDERSTANDING OF DISEASE MECHANISMS

Development of Tools

The past decade has seen a rapid increase in the use of MS-based analysis platforms for metabolic profiling. Many of the early applications of MS technologies were in the area of plant biology (Fiehn et al., 2000) or for detecting inborn errors of metabolism in newborn children (Frazier et al., 2006; Shekhawat et al., 2005). Application of tandem mass spectrometry (MS/MS) to newborn screening has allowed detection of more than 40 different genetic diseases of lipid and amino acid metabolism. In newborn screening, less emphasis is placed on absolute quantification of multiple analytes in a module, since the screen only requires detection of changes in a single

or discrete cluster of analytes with respect to established laboratory norms. For example, a defect in HMG-CoA lyase results in large and specific increases in C5-OH-carnitine and methylglutaryl-carnitine species detected by MS/MS, whereas defects in long-chain L-3-hydroxyacyl CoA dehydrogenase (LCHAD) or mitochondrial trifunctional protein (MTP) are associated with increases in C16-OH and C18-OH-carnitine metabolites (Shekhawat et al., 2005). Similarly, defects in amino acid catabolizing enzymes such as phenylalaine hydroxylase to cause phenylketonuria, or the branched-chain α-ketoacid dehydrogenase complex to cause Maple Syrup urine disease are readily detected by dramatic increases in phenylalanine or branched-chain amino acid (BCCA) levels, respectively.

In more recent years, many of the MS-based targeted metabolic profiling techniques developed for diagnosing inborn errors of metabolism have been adopted and refined for studies of metabolic regulatory mechanisms, disease detection, and mechanisms of disease pathogenesis. Selective examples, meant to be illustrative rather than comprehensive, are provided.

One approach has been to combine several targeted MS-based assay modules as an assemblage of tools that can report on several critical metabolic pathways (An et al., 2004; Haqq et al., 2005; Koves et al., 2008). Using a combination of GC/MS and MS/MS, we are currently able to perform quantitative analysis of approximately 150 metabolites in six groups:

1. free fatty acids of varying chain length and degrees of saturation;
2. total fatty acids (free+esterified);
3. acylcarnitines (representing products of mitochondrial fatty acid, amino acid, and glucose oxidation);
4. acyl CoAs of varying chain length and degree of saturation;
5. organic acids (TCA cycle intermediates and related metabolites); and
6. amino acids, including urea cycle intermediates.

Although the total number of analytes measured with these tools is small relative to estimates of 5000 total metabolites in the "metabolome", they are nevertheless highly useful for understanding changes in metabolic fuel selection under different physiologic and pathophysiologic circumstances. Moreover, expansion of the platform to include a broader range of analytes of interest in disease pathogenesis would appear possible in the near term, via adoption of published methods for analysis of sphingolipids (including ceramides), phospholipids, and prostaglandins and their metabolites (eicosanoids) (Dettmer et al., 2007; Han and Gross, 2005; Merrill et al., 2005; Watson, 2006). However, the reader should appreciate that development of new modules is not a trivial or inexpensive undertaking, as it requires acquisition or synthesis of stable isotope-labeled internal standards to cover most if not all of the individual analytes in the module, development of extraction procedures that are efficient for multiple analytes in a class, and demonstration of quantitative reproducibility of the method. The advantage gained is that such tools can be applied to understanding of metabolic regulatory mechanisms in isolated cells, animal models of disease, and human disease states, as summarized in the following specific examples.

Metabolic Profiling for Studies of Metabolic Regulatory and Signaling Mechanisms in Cultured Cells

An example of integration of NMR- and MS-based tools for understanding of metabolic regulation and signaling mechanisms comes from recent work on the process of glucose-stimulated insulin secretion (GSIS) in pancreatic islet β-cells (Boucher et al., 2004; Jensen et al., 2006; Joseph et al., 2006; Joseph et al., 2007; Lu et al., 2002; Ronnebaum et al., 2006; Ronnebaum et al., 2008). Stimulation of islet β-cells with glucose causes increases in insulin secretion within seconds to minutes, and this response is mediated by signals that are generated by β-cell glucose metabolism. A commonly accepted idea is that increases in the rate of glucose metabolism in β-cells leads to increases in ATP:ADP ratio, which causes inhibition of ATP-sensitive K^+ channels (K_{ATP} channels), membrane depolarization, and activation of voltage-gated calcium channels. The resulting influx of extracellular Ca^{2+} is then thought to stimulate exocytosis of insulin containing secretory granules. However, this model clearly does not provide a complete description of signals that regulate GSIS, since pharmacologic or molecular inhibition of K_{ATP}-channel activity does not abrograte glucose regulation of insulin secretion (Henquin et al., 2003; Nenquin et al., 2004).

To investigate non-K_{ATP}-channel related signals for GSIS, a set of insulinoma (INS-1)-derived cell lines with varying capacities for GSIS were developed (Hohmeier et al., 2000). Application of ^{13}C NMR-based isotopomer analysis and MS-based profiling of intermediary metabolites led to the discovery of a critical link between pyruvate carboxylase (PC)-mediated pyruvate exchange with TCA cycle intermediates ("pyruvate cycling") and GSIS, and demonstration that these pathways are dysregulated in lipid-cultured and dysfunctional β-cells (Boucher et al., 2004; Jensen et al., 2006; Joseph et al., 2006; Joseph et al., 2007; Lu et al., 2002; Ronnebaum et al., 2006). More recent studies have focused on identification of the specific pyruvate cycling pathways that may be involved in generation of signals for insulin secretion. One important pathway appears to involve export of citrate and/or isocitrate from the mitochondria via the citrate/isocitrate carrier (CIC), and subsequent conversion of isocitrate to α-ketoglutarate (α-KG) by the cytosolic NAPD-dependent isoform of isocitrate dehydrogenase (ICDc) (Joseph et al., 2006; Ronnebaum et al., 2006). siRNA-mediated suppression of CIC or ICDc cause substantial impairment of GSIS in both insulinoma cell lines and primary rat islets. These studies suggest that a metabolic byproduct of pyruvate/isocitrate cycling may be an important amplifying signal for control of GSIS. Possible mediators that are under investigation include NADPH, α-KG or its metabolites, or GTP generated by the succinyl CoA dehydrogenase reaction, all of which are direct or downstream products of the ICDc reaction.

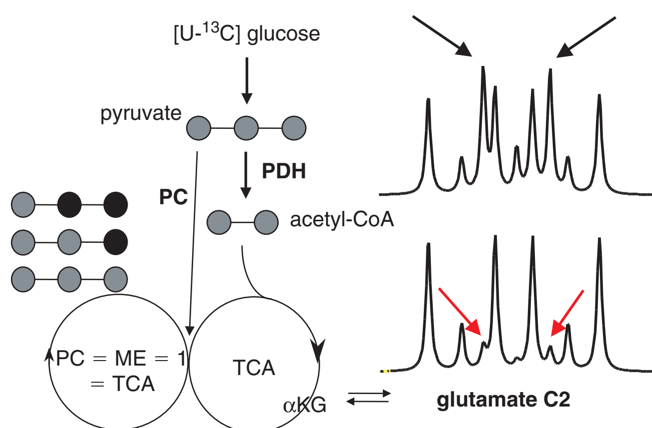

Figure 9.2 Use of ^{13}C NMR for measurement of metabolic flux in cells. To measure flux of pyruvate into the TCA cycle via the oxidative enzyme pyruvate dehydrogenase (PDH) versus the anaplerotic enzyme pyruvate carboxylase (PC), [U-^{13}C] glucose is administered to cells in culture. After 3 hours of incubation, cells are extracted and the NMR spectra of different carbons of glutamate are obtained. If all of the ^{13}C-labeled glucose is converted to pyruvate to enter the TCA cycle through PDH, the spectrum of carbon 2 of glutamate will appear as shown at the bottom right of the figure. In contrast, if the labeled pyruvate enters the TCA cycle both through PDH and PC in equal proportions, the glutamate C2 spectrum will appear as shown at the top right of the figure. Arrows show significant difference in peak height in the two spectra. The change in the spectra under these two scenarios occurs because pyruvate that enters the TCA cycle via PC can engage in pyruvate recycling pathways that results in dilution of ^{13}C (black circles) with natural abundance ^{12}C (gray circles), thus changing the pool of glutatmate mass isotopomers. Spectra of other glutamate carbons are obtained in the same fashion, and the aggregate data are deconvoluted to derive estimates of flux through PDH versus PC (Boucher et al., 2004; Lu et al., 2002; Sherry et al., 2004).

In the foregoing studies, measurement of pyruvate cycling flux was accomplished by incubation of β-cells in low (3 mM) or high (12 mM) concentrations of U-^{13}C glucose for several hours, followed by extraction of cells and analysis of the glutamate spectrum by NMR (see e.g., Figure 9.2). Specific resonances for each of the carbons of glutamate are affected by the population of mass isotopomers (glutamate with varying mixtures of ^{13}C and ^{12}C at each of the 5 carbons of the molecule), and this information can be used to calculate flux through the oxidative (PDH) and anaplerotic (PC) entry points of the tricarboxylic acid (TCA) cycle (Boucher et al., 2004; Lu et al., 2002; Sherry et al., 2004). When coupled to measurements of oxygen consumption (respiration), these rates can be expressed in absolute rather than relative terms (Boucher et al., 2004; Sherry et al., 2004). These methods revealed that the capacity for GSIS in variously glucose responsive INS-1-derived cell lines was tightly correlated with PC-catalyzed pyruvate cycling activity, but not PDH-catalyzed glucose oxidation.

To gain deeper understanding of the specific pyruvate cycling pathway involved in GSIS, these NMR-based methods of flux anlaysis were combined with MS/MS and GC/MS methods for profiling of acylcarnitines and organic acids, respectively. These experiments revealed that siRNA-mediated suppression of PC activity has little influence on pyruvate cycling rates or GSIS due to a compensatory rise in C2-acylcarnitine, which reflects the acetyl CoA pool; acetyl CoA is an allosteric activator of PC, which offsets the decrease in PC protein. These studies therefore uncovered a compensatory mechanism for preservation of pyruvate cycling activity and GSIS even when PC levels are reduced (Jensen et al., 2006). In another study, organic acid profiling was used to show that suppression of CIC caused a fall in cytosolic citrate levels, as would be expected if a major pathway for export of citrate from the mitochondria to the cytosol is blocked (Joseph et al., 2006). Finally, suppression of ICDc caused a decrease in pyruvate cycling flux, as measured by NMR, coupled with a rise in lactate levels measured by GC/MS, suggesting that in the face of suppressed pyruvate cycling activity, pyruvate is converted to lactate by default (Ronnebaum et al., 2006). These examples illustrate two important application of MS-based metabolic profiling in cellular research: (1) use in validation of specific genetic engineering or pharmacologic manipulations of cellular systems; (2) integration with flux analysis to provide a complete picture of changes in metabolic pathways under varying experimental conditions.

Application of MS-Based Metabolic Profiling for Understanding of Human Disease Pathogenesis

Targeted MS-based metabolic profiling has also been increasingly applied to studies of human diseases and conditions. Specific examples of applications to the areas of obesity and cardiovascular disease (CAD) are discussed here, but these tools are also being applied to diverse areas such as cancer (Fan et al., 2006) and mental disorders (Kaddurah-Daouk et al., 2007).

It has been appreciated for many years that obesity is associated with impaired metabolic regulation, including development of insulin resistance in muscle, liver, and adipose tissue, as well as loss of mass and function of pancreatic islet β-cells (Muoio and Newgard, 2008). However, the specific mechanisms that link overnutrition and obesity to global metabolic dysfunction remain incompletely defined. We recently completed a metabolic analysis of 74 obese (median BMI of 36.6 kg/m^2) and 67 lean (median BMI of 23.2 kg/m^2) human subjects using the MS-based metabolic, hormonal and physiologic profiling tools described earlier (Haqq et al., 2005; Newgard et al., 2008). PCA was used to detect a metabolic signature comprised of changes in amino acid, acylcarnitine, and organic acid metabolites that suggests that pathways of BCAA catabolism are overloaded in obese humans. To test the significance of this for development of obesity-related disease, we fed normal rats on HF, high-fat with supplemented BCAA (HF/BCAA) or standard chow (SC) diets. Despite a low rate of body weight gain equivalent to the SC group, HF/BCAA rats were equally insulin resistant as HF rats, demonstrating a contribution of BCAA to development of

insulin resistance independent of body weight. However, the effects of BCAA on body weight and insulin sensitivity seem to require the presence of fat, since animals fed on SC diet with supplemented BCAA gain weight normally and have normal insulin sensitivity. These findings demonstrate a synergistic interaction of dietary protein and fat in the development of insulin resistance, and provide a demonstration of how broad-based metabolic profiling tools can identify unanticipated contributions of dietary and metabolic factors to disease development.

MS-based metabolic profiling has also been applied to cardiovascular disease. In one study, liquid chromatography/triple quadrupole high-sensitivity MS analysis was applied to plasma samples of 18 subjects with exercise-inducible ischemia compared to 18 normal controls (Sabatine et al., 2005). Blood samples were taken immediately before and immediately after exercise, and levels of 173 known and several more minor intermediary metabolites were measured. A number of metabolites were found to be discordant between the two groups, including lactate, byproducts of AMP metabolism, metabolites of the citric acid cycle, and several of the unknowns. Using the six most discordantly regulated metabolites, a metabolic ischemia risk score was created and found to be statistically correlated to the probability of ischemia. However, it should be noted that the number of subjects was quite small in this study, necessitating follow up studies that either confirm or refute these interesting initial findings.

In another recent study, MS/MS and GC/MS-based profiling of fatty acids, acylcarnitines, and amino acids was performed on plasma samples from 117 subjects from eight multiplex families with familial early-onset CAD (Shah et al., 2008). Using SOLAR and adjusting for variables such as diabetes, hypertension, dyslipidemia, body-mass-index (BMI), age and sex, high heritabilities were found for several amino acids (arginine, glutamate, alanine, ornithine, valine, leucine/isoleucine, h^2 0.50–0.85, $P = 0.00004 - 7.2 \times 10^{-15}$), free fatty acids (arachidonic, linoleic, h^2 0.57–0.59, $P = 0.0004 - 0.00005$), and acylcarnitines (h^2 0.54–0.86, $P = 0.002 - 0.0000002$). Moreover, PCA was used to identify several metabolite clusters, with several of these factors found to be highly heritable. Interestingly, GENECARD families showed two distinct metabolite profiles, tracking with their clinical characteristics and reflective of factors identified from PCA, suggesting different genetic backgrounds and consequent variation in control of key metabolic pathways that converge on CAD. However, once again, the utility of these profiles for predicting CAD in other high-risk families or in the general population will require further study.

2009 UPDATE

Since the original publication of this chapter, a number of interesting advances have been made in the area of application of metabolomics tools to understanding of disease mechanisms and susceptibility.

Integration of metabolomics tools with other forms of "omics" technologies is at a very early stage, but has great potential in chronic disease research. As an example, diabetes-resistant B6-ob/ob and diabetes-susceptible BTBR-ob/ob mice were crossed to create an F2 cohort that was analyzed by microarray analysis and targeted mass spectrometry-based metabolic profiling (Ferrara et al., 2008). Application of advanced computational methods defined correlations and inferred causality between metabolite and transcript levels (Chaibub Neto et al., 2008; Ferrara et al., 2008) and unveiled a novel network by which the amino acid glutamine controls expression of the key gluconeogenic enzyme phosphoenolpyruvate carboxykinase (PEPCK). These studies show how integration of transcriptomics and metabolomics can lead to identification of novel pathways for diabetes pathogenesis.

Metabolomics has also recently been integrated with genotyping for understanding the biochemical impact of common genetic polymorphisms (Geiger et al., 2008). These authors performed ESI-MS/MS to measure 363 metabolites in serum of 284 male participants in the KORA study (a general population study from Germany). Significant associations were observed between frequent single nucleotide polymorphisms (SNPs) and changes in specific metabolites. Moreover, polymorphisms in four specific genes encoding metabolic enzymes (FADS1, LIPC, SCAD, and MCAD) were linked to perturbations in the metabolic pathways in which the enzymes are known to reside. The authors suggest that the combination of genotyping and metabolic phenotyping may provide new roadmaps for application of personalized medicine.

Other studies have recently emerged in the realm of applying metabolomics to better understand metabolic lesions in heart failure and myocardial infarction (MI). In one study, LC-MS-based profiling of approximately 200 metabolites was performed on subjects undergoing planned MI via alcohol-mediated septal ablation, or on subjects with spontaneous MI or undergoing elective coronary angiography as positive and negative controls, respectively (Lewis et al., 2008). Five metabolites were altered in both spontaneous and planned MI, and this metabolic signature may become useful for early detection of myocardial injury with further validation.

A second study applied targeted ESI-MS to measure 63 metabolites in arterial and coronary sinus blood obtained during cardiac surgery, before and after ischemia/reperfusion (I/R) (Turer et al., 2009). This work demonstrates that the preexisting ventricular state [left ventricular dysfunction (LVD), coronary artery disease, or neither condition] is associated with clear differences in myocardial fuel uptake, both at baseline and following I/R. In particular, LVD was associated with global

suppression of metabolic fuel intake (glucose, fatty acid, and amino acids) and limited myocardial metabolic reserve and flexibility following I/R. Moreover, altered metabolic profiles following I/R were associated with postoperative hemodynamic course. These findings help to focus future studies on optimal design of perioperative treatment regimens based on the particular form of cardiovascular disease and the metabolic status of the heart.

CHAPTER

Bioinformatic and Computational Analysis for Genomic Medicine

Atul J. Butte

INTRODUCTION

The past 10 years have seen development and deployment of a variety of measurement tools in molecular science that enable the large-scale parallel quantitative assessment of molecular state. The premier example of such measurement tools is the RNA expression detection microarray, which provides quantitative measurements of expression of over 40,000 unique RNAs within cells (Chee et al., 1996; DeRisi et al., 1996). Yet, as illustrated in previous chapters in this volume, microarrays represent just one of at least 30 or so measurement or experimental modalities available to investigators in molecular biology and genomics, including metabolite quantification (Edwards et al., 2001), DNA polymorphism measurements (Johnson et al., 2001), protein quantification (Espina et al., 2003; Ghaemmaghami et al., 2003; Gygi et al., 1999; Liotta et al., 2003), protein activity (Hestvik et al., 2003), protein interactions with small molecules (Jessani et al., 2002) and DNA (Lee et al., 2002; Odom et al., 2004; Ren et al., 2000; Wang et al., 2001; Weinmann et al., 2002), and many others. Though these molecular technologies are commonly described as being "high-throughput" or "genome-wide" in nature, we will use the term *high-bandwidth* to describe them in this chapter. An analogy explains our reasoning: *high-bandwidth* is to a *supermarket*, which serves a large variety of different foods irrespective of speed, while *high-throughput* is to a *fast-food restaurant*, serving a few types of foods quickly. *Genome-wide* technologies are biased towards genes, while we are covering measurements of many other types besides genes.

The service role for bioinformatics in research using these new tools is undeniable. Each of these high-bandwidth modalities yields a sizeable amount of raw data, so distilling these raw data and filtering out measurement noise through the proper use of bioinformatics methods is crucial. Bioinformatics clearly plays a role in the storage, retrieval, and sharing of these measurements from local and international repositories and in relating these measurements to clinical outcomes. However, what we will argue in this chapter is that the role for bioinformatics in genomic and personalized medicine is well beyond that of providing a service and lies more broadly in enabling new and interesting questions to be asked in biomedical, translational, and clinical research.

In this chapter, we will present several examples that illustrate how the use of specific bioinformatics methods has enabled a revolution of discovery in medical diagnostics, prognostics, therapeutics, anatomy, and nosology. We will then review a few specific analytic methods and standardized vocabularies useful in studying and identifying high-bandwidth measurements for genomic and personalized medicine. After covering a few freely available software tools valuable for conducting analyzes, we will end with some thoughts about where the future discoveries in genomic medicine, enabled by bioinformatics, may come from.

VIGNETTES: HOW SPECIFIC BIOINFORMATICS METHODS CAN CHANGE THE PRACTICE OF MEDICINE

While many high-bandwidth measurement technologies have been used to enable basic discoveries in the life sciences, certainly the most intriguing and provocative use of these measurement modalities has been in enabling novel types of medical discoveries. Here, we will present case examples of how these discoveries were enabled by bioinformatics techniques and have demonstrably altered our abilities in four distinct areas of medicine: diagnosis, therapeutics, histopathology, and nosology (Table 10.1). For these vignettes, we will particularly focus on the use of microarrays, as this is currently the most commonly used high-bandwidth measurement modality.

Diagnosis

Diagnosis is a process in which a physician, when presented with a patient holding a chief complaint, gathers information through questioning, history taking, physical examination, and testing, compares the results of those queries with patterns established for known diseases, and assigns the disease with the highest likelihood. High-bandwidth testing in molecular biology has impacted every step of the diagnostic process. For example, those being evaluated for a disease may not yet even have a complaint, as DNA polymorphisms are discovered and used to predict future disease (Kohane et al., 2006). Medical history taking becomes problematic when considering the genetic context of a patient, which is increasingly known; for example, many infants now have one or more genes sequenced at birth as part of state-mandated newborn screening (Khoury et al., 2003). History taking has potential to become even more convoluted as more adults have genes (and even whole genomes) sequenced. The bioinformatics challenge in storing, providing, and teaching patients and parents how to use this type of medical information, while protecting against others finding this information, has only just started to be addressed (Adida and Kohane, 2006; 2004; Centers for Disease Control and Prevention, 2004; Henneman et al., 2006; Roche and Annas, 2001, 2006).

The nature of the physical examination itself has changed. Positive and negative physical findings (e.g., *acanthosis nigricans*, or darkening of the skin of the neck) are traditionally considered as probes into the process of disease (e.g., type 2 diabetes mellitus). With the democratization of genomics throughout all fields of medicine, physical findings can now be viewed collectively as phenotype and as a probe into the inner workings of the genome (Freimer and Sabatti, 2003). Two different diseases with similar sets of physical findings may indeed appear quite similar when viewed from the perspective of genes and gene products (Brunner and van Driel, 2004).

But certainly the greatest impact on diagnosis from high-bandwidth molecular testing has been felt on our ability to redefine our patterns of disease using these new measurements. One

TABLE 10.1 Bioinformatics techniques have demonstrably altered our abilities in four distinct areas of medicine

Area of the practice of medicine	Example of bioinformatics altering practice
Diagnosis	
Chief complaint	Predicting future disease from polymorphisms before complaint
Medical history	Genetic screening at birth should become part of a patient's life-long electronic medical record
Medical record keeping	Patient-owned Internet-based genomic records
Physical examination	Findings collectively viewed as phenotype and matched against patterns
Differential diagnosis	Molecular measurements can be compared against case-examples
Disease sub-type	Hierarchical clustering to determine novel subtypes from molecular measurements
Therapeutics	
Finding novel effects for existing drugs	Linking drug effects to molecular measurements
Side effects	Predicting drug adverse effect from pre-clinical molecular measurements
Finding novel therapies for untreatable conditions	Matching molecular profiles of disease with molecular profiles of drug effect
Histopathology	
Metastasis of unknown origin	Matching molecular measurements from metastasis with profiles of known primary cancers
Pathological mechanism of action of disease	Identifying differentially expressed genes and linking back to known biological pathways
Nosology	
Finding differences between diseases	Principal components of variance of disease sample microarrays
Finding similarities between diseases	Common signatures across microarray measurements of disease
Linking cellular models to human diseases	Comparing cellular and disease microarray measurements

of the earliest examples of this impact was in the work of Golub and colleagues published in 1999 (Golub et al., 1999). Acute lymphomas were first divided into acute lymphoblastic leukemia (ALL) and acute myeloid leukemia (AML) in the 1960s based on histochemical testing, and more recently by antibody-based testing against cell-surface molecules, but there was no single established test to make this diagnosis. Golub was the first to show that gene expression microarrays could be used to measure gene expression levels from samples from acute lymphomas, and using a bioinformatics technique known as *supervised machine learning*, trained a prediction system to find and use those genes that uniquely distinguished ALL from AML (Figure 10.1). He then used this predictor to accurately classify additional new leukemia cases. Many others have used alternative computational and bioinformatics techniques to build predictors since this landmark study, while many additional diagnostic dilemmas have similarly

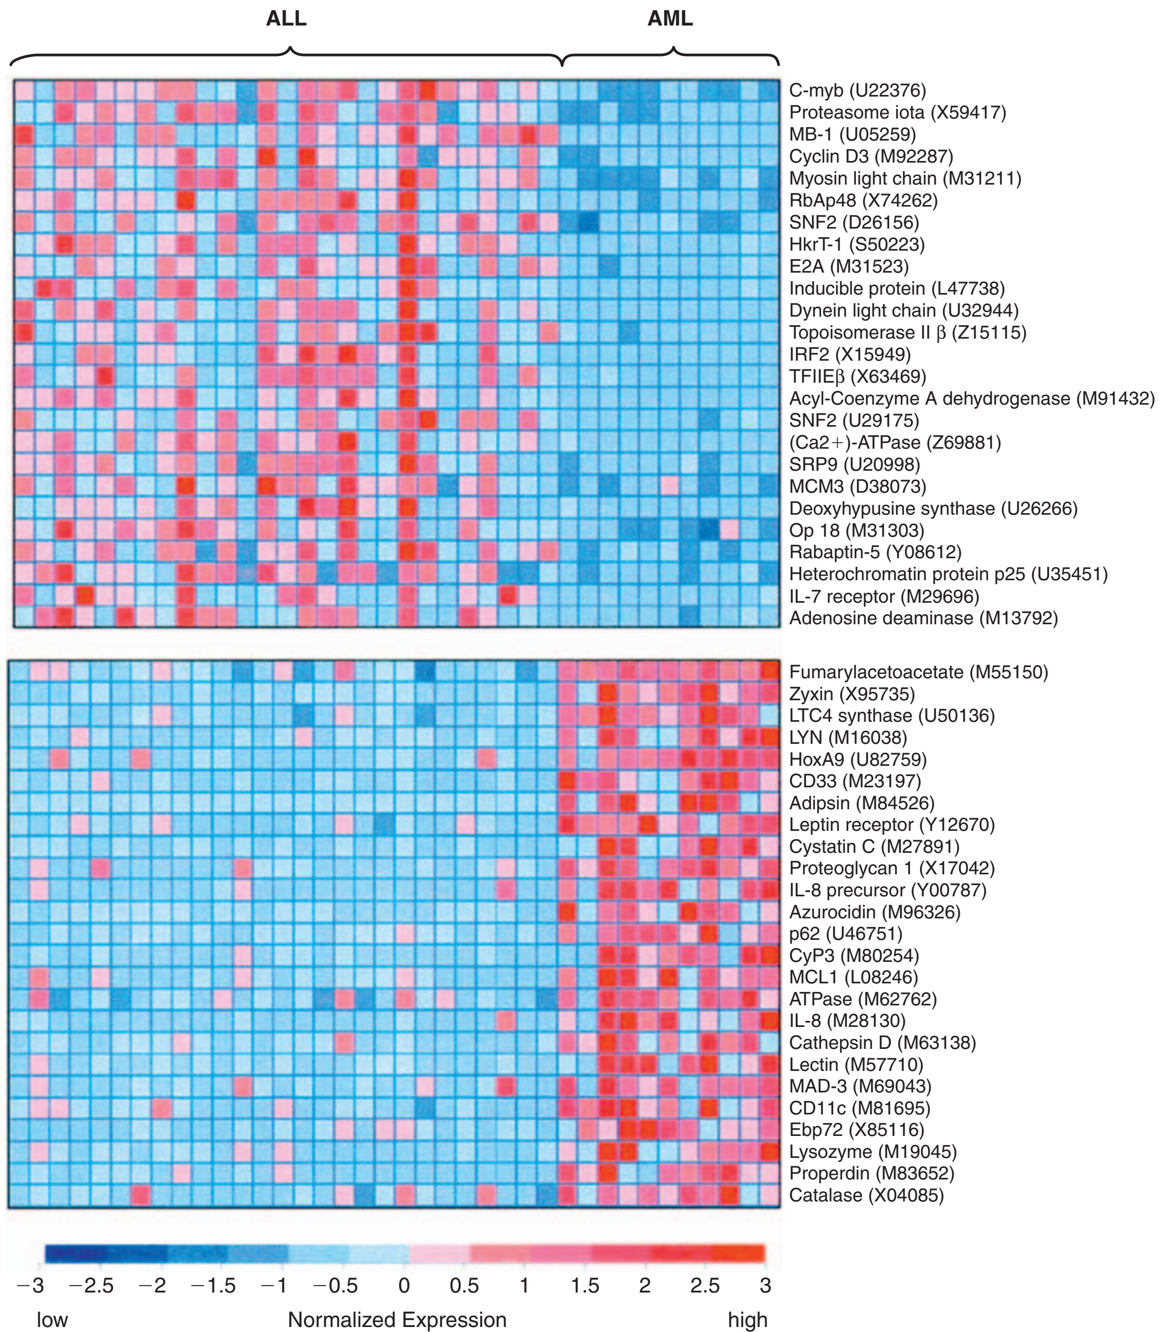

Figure 10.1 Todd Golub and colleagues measured genome-wide expression levels in samples from patients with ALL and AML. The top 50 genes distinguishing ALL and AML are displayed, with genes elevated in expression shown in pink, and genes decreased in expression shown in blue. From Golub et al., 1999 *Science* 286:531. Reprinted by permission from AAAS.

been addressed using gene expression microarrays, including melanoma (Bittner et al., 2000) and prostate cancer (Singh et al., 2002). Other types of high-bandwidth modalities have been used to assist in other diagnostic questions, including proteomics (Petricoin et al., 2002; Robinson et al., 2002) and metabolomics (Clayton et al., 2006) (see also Chapters 8 and 9).

While enabling physicians to make more efficient and accurate decisions between diseases itself is remarkable, the potential for high-bandwidth molecular testing in diagnosis is even greater. Beyond just improving on older tests for established diagnostic dilemmas, high-bandwidth studies have also been used to redefine and even divide diagnoses into novel sub-types. The earliest example of this was in the work of Alizadeh and colleagues in 2000 (Alizadeh et al., 2000). Alizadeh used gene expression microarrays to measure gene expression in samples from patients diagnosed with diffuse large B-cell lymphoma, a cancer of B-lymphocytes. This type of cancer was previously divided into low-, intermediate-, and high-grade categories based on growth pattern and immunohistochemistry. After applying a bioinformatics technique called *hierarchical clustering* (described later in this chapter) to the microarray data, Alizadeh discovered that the patient samples of B-cell lymphoma could be divided into an equal split of two sub-types (Figure 10.2). Most importantly, patients with these two different sub-types of lymphoma retrospectively demonstrated significant differences in survival by *Kaplan–Meier analysis*. This was a landmark study because it showed how high-bandwidth molecular measurements could provide a next level of resolution to resolve sub-types of disease not otherwise discernable by physicians. This type of study has been replicated for other types of cancers, including lung cancer (Bhattacharjee et al., 2001) and breast cancer (Sorlie et al., 2001), has been replicated using other types of measurements, including proteomics (Welsh et al., 2003), and is starting to enter clinical trials (Potti et al., 2006).

Therapeutics

Bioinformatics, coupled with the exponential growth in data collected using high-bandwidth measurement modalities, has the potential to revolutionize the way patients are treated with pharmaceuticals. Much has already been written on how high-bandwidth measurements have generally altered the process of drug discovery (Debouck and Goodfellow, 1999). Here, we will cover specific case examples on how the conceptualization of pharmacology can be radically changed through development and use of biomedical informatics methods.

In 2000, Butte and colleagues focused on generating hypotheses of functional relationships between pairs of genes and pharmaceuticals, with the hope that specific genes could be found that altered a cancer's ability to respond to specific drugs. To do this, they started with two databases, both related to the NCI60, a standardized set of 60 human cancer cell lines used by the National Cancer Institute Developmental Therapeutics Program (Weinstein et al., 1997). One database contained the baseline microarray measurements of the expression level of 6701 genes measured in these cell lines. The other database contained a set of drug susceptibility measurements for the same cell lines, across

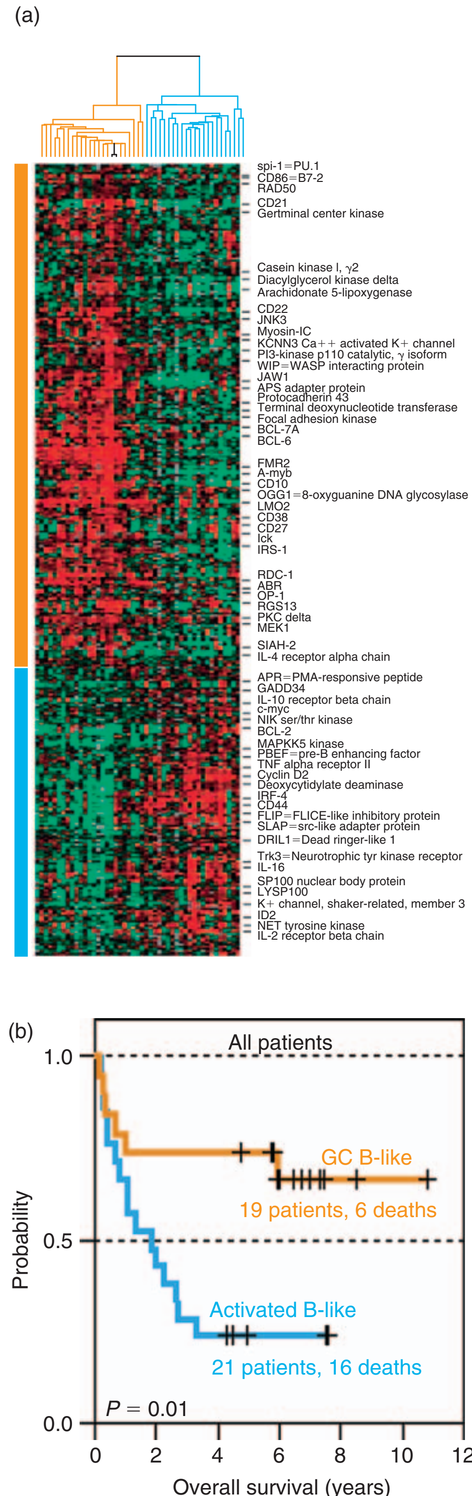

Figure 10.2 (a) Ash Alizadeh and colleagues measured genome-wide expression levels in samples from patients with diffuse large B-cell lymphoma and found samples clustered into two sub-types based on expression patterns. (b) Patients in these two sub-types have a significant difference in survival (Alizadeh et al., 2000). Reprinted by permission from Macmillan Publishers Ltd: *Nature* 403:503, copyright 2000.

nearly 5000 anti-cancer agents. They then used a database technique known as *join* to combine these two databases through the cell lines in common. After joining the two tables, they searched for baseline RNA expression levels in the cell lines that correlated with the inhibition of growth of these same cell lines by thousands of anti-cancer agents. They found only one network containing an association between a gene expression and a measure of anti-cancer agent susceptibility (Figure 10.3). The association suggested that increased expression of lymphocyte cytosolic protein-1 (*LCP1*) is associated with increased susceptibility to the anti-cancer agent NSC 624044, a thiazolidine carboxylic acid derivative. Though a specific role for *LCP1* in tumorogenicity had been postulated and though other thiazolidine carboxylic acid derivatives were known to inhibit tumor cell growth, there was no known relationship between this specific anti-cancer agent and gene in the biomedical literature. The significance of this work was that drug efficacy measurements could be joined to microarray measurements and potentially other types of genomic measurements, enabling the discovery of hidden associations between drugs and genes.

Fliri and colleagues joined databases in a similar manner in 2005, but instead of joining using cell lines, they used the drugs themselves (Fliri et al., 2005). Specifically, they took a database of known side-effects of drugs and joined it to a database of ligand binding assay results as measured in the presence of those same drugs. With this method, they were able to show that drugs with similar side-effect profiles actually had similar ligand-binding assays. The significance of this finding is that pre-clinical studies, such as ligand-binding assays and others, could be used to predict clinical side-effects, which, when severe enough, can lead to withdrawal of a drug from the market.

Lamb and colleagues in 2006 built a database from microarrays measured across the genome after the application of 164 different small molecules to a breast cancer cell line (Lamb et al., 2006). They then queried this database of drug responses using responses measured from other experiments for which a detailed

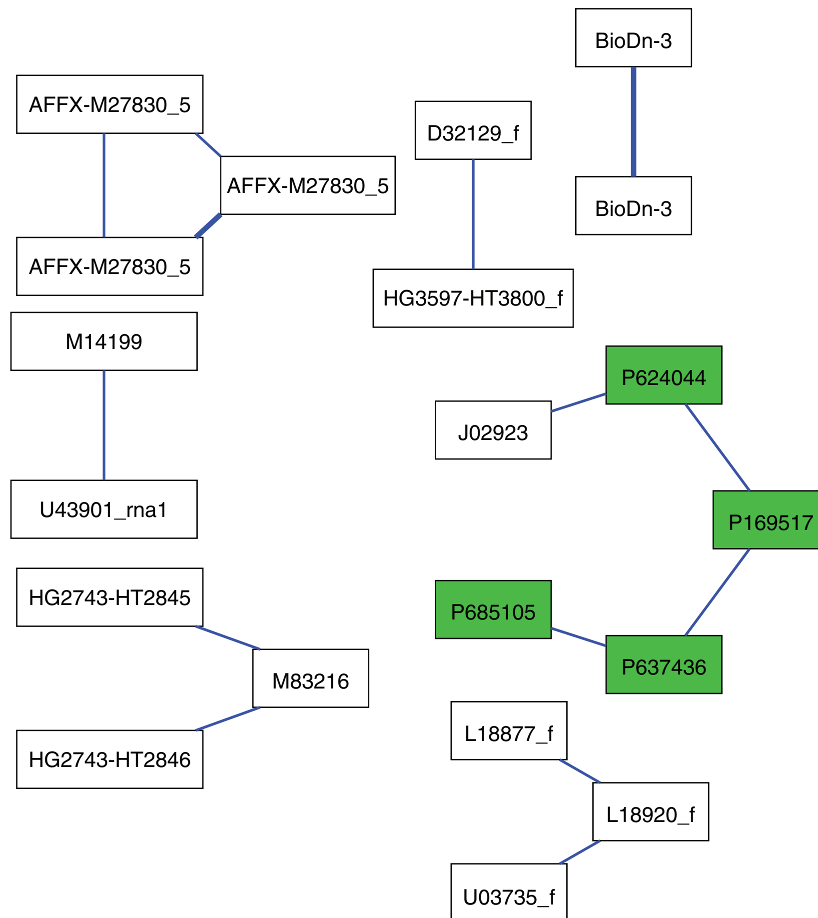

Figure 10.3 Relevance networks calculated by joining drug activity data with gene microarray measurements. White rectangles indicate genes, and green rectangles indicate anti-cancer agents. The only discovered network involving both genes and drugs is shown in the middle. The activity of four anti-cancer agents against multiple cancer cell lines correlates with the expression pattern of a single gene across those same cancer cell lines. *J02923* indicates the gene *LCP1*, while drug identifiers correspond to National Cancer Institute NSC identifiers (Butte et al., 2000).

mechanism had not been known, using a measure of similarity known as a *Kolmogorov-Smirnov statistic* (Figure 10.4). For example, when queried with the gene expression differences between dexamethasone-treatable and dexamethasone-resistant ALL, they found that the genome-wide difference between these two types of leukemia most closely matched that of the genome-wide response to the drug sirolimus. The significance of this approach is that existing drugs could be associated with unexplained disease-related processes, and might even be used to treat those diseases. But most importantly, this work highlights the importance of building structured searchable repositories of experimental data.

Histopathology

Histopathology is the study of diseased tissue by sectioning, staining, and multi-resolution microscopy. Given high-bandwidth measurements from samples of potentially diseased tissue, bioinformatics methods can be applied to determine whether such samples do quantitatively resemble a disease (van de Rijn and Gilks, 2004). For example, Ramaswamy and colleagues tackled the problem of finding the original source of a cancer, given just a metastatic sample (Ramaswamy et al., 2001). They used a method called *support vector machines*, each of which was designed to recognize one specific type of cancer (Figure 10.5). This work was significant in that it was one of the first to show how multiple types of cancers could be distinguished using high-bandwidth measurements, and that unknown samples could be accurately assigned a primary diagnosis. Similar work has been published using alternative bioinformatics methods (Su et al., 2001).

Fibroblasts are cells in the connective tissue that create much of the extracellular matrix between tissues and proliferate during wound healing. Though fibroblasts from different parts of the body may have similar properties and resemble each other under a microscope, Chang and colleagues demonstrated that when fibroblasts are considered by high-bandwidth measurements of gene expression, significant differences between fibroblasts are seen depending on where in the body they were originally obtained. In other words, cells that appear exactly the same by microscope appear quite differently by microarray, consistent with their original source (Chang et al., 2002).

Microarrays have also been used to uncover histopathological findings that might have otherwise been missed. Sarwal and colleagues used microarrays to study the process of acute rejection after kidney transplantation (Sarwal et al., 2003). After *hierarchically clustering* their samples, they noticed a set of B-cell specific genes that corresponded to one sub-type of acute rejection. This was particularly interesting because B-cells had not previously been thought to be involved in acute rejection. Staining for a B-cell specific cell surface protein showed large aggregations of B-cells in samples of acute rejection. The significance of this finding was the realization that while histochemistry can offer a broad survey of the cellular makeup in a sample, these cells will still remain invisible unless illuminated with the right stain. The proper stain can be found using gene expression microarrays coupled with the right bioinformatics techniques, especially the prior annotation of genes as being specific for a certain cell type.

Nosology

In the mid 1700s, Carl Linnaeus promoted the binomial nomenclature to classify living things into a hierarchy, or taxonomy. Though we still organize species into taxonomies based on anatomic and physiological similarities, our modern-day use of DNA sequencing and genome sequence has enabled the reorganization of the position of species within established taxonomical trees.

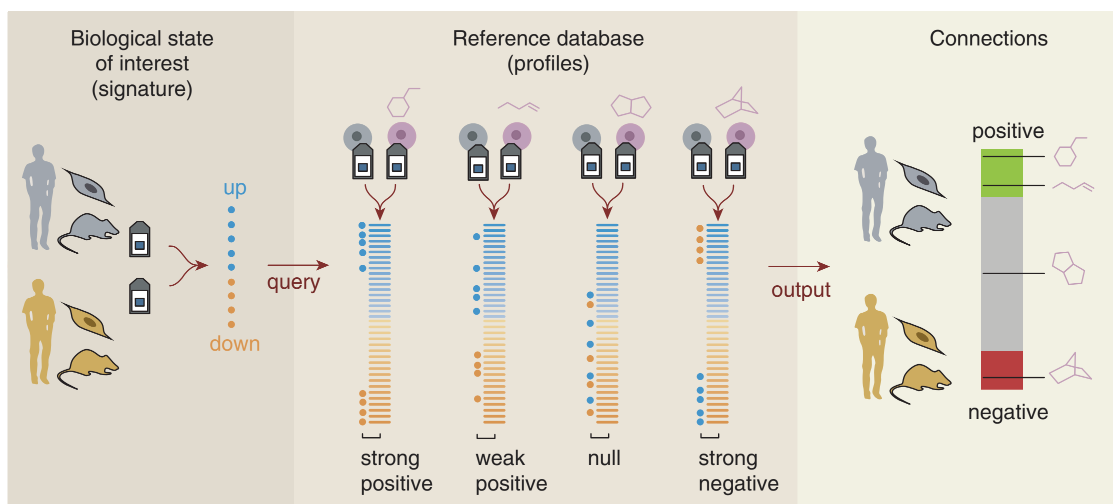

Figure 10.4 A reference database of high-bandwidth molecular measurements can be made after the application of various drugs, then queried with an unknown biological response, yielding those drugs sharing a similar response. From Lamb et al., 2006, *Science* 313:1929. Reprinted by permission from AAAS.

This is because DNA sequence similarity analysis provides a quantitative measurement of how different two species are (Baldauf et al., 2000). Linnaeus was also a co-founder of systematic nosology, or the classification of disease, for which he is not as well known (Linnâe and Schrèoder, 1763). Genomic data and bioinformatics methods have now advanced to the point that we can begin to modernize the classification of disease itself, similar to how DNA sequencing has modernized taxonomy.

Crescenzi and Giuliani were one of the first to demonstrate this principle in 2001 (Crescenzi and Giuliani, 2001). They gathered samples representative of 60 cancer cell lines and used a statistical method known as *principal components analysis* to find combinations of genes that capture the significance variance across cancers. They then showed how analyzes using just the top five principal components could reproduce the findings from the entire dataset. In other words, Crescenzi and Giuliani were able to show that when measured using high-bandwidth measurements, the 60 varied types of cancers differed in only a few ways that could be modeled.

Instead of modeling the significant differences between cancers, Rhodes and colleagues searched for commonalities in 2004 (Rhodes et al., 2004). After collecting 40 published microarray datasets totaling more than 3700 samples of cancer, Rhodes determined a genome-wide signature representative of neoplastic transformation. As expected, most of the genes in this cancer signature were known to participate in the cell cycle, the biological process involved in cell replication. A similar study by Bild and colleagues found commonly deregulated biological pathways across cancers that correspond with worsening survival (Bild et al., 2006). This type of work is significant because it suggests that a quantitative classification of cancers, or one based on actual measurements, might be more useful than the traditional anatomic or even histopathological classification of cancer (Figure 10.6).

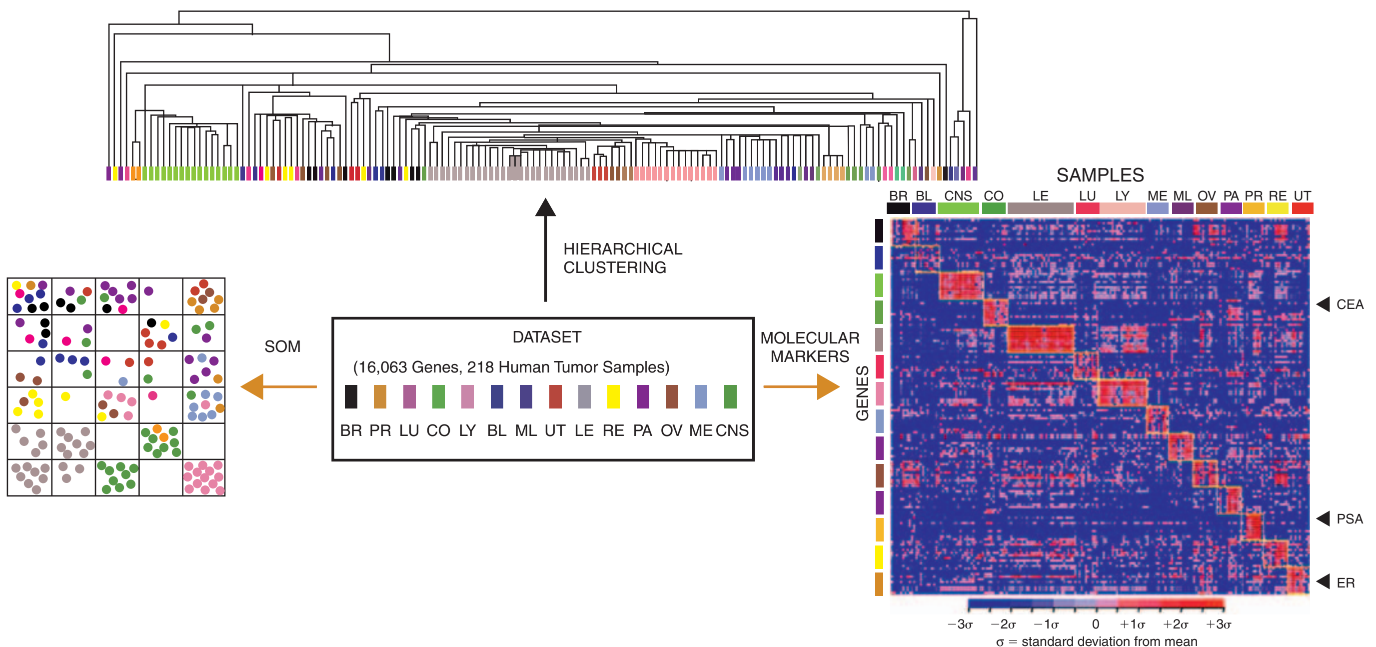

Figure 10.5 Over 200 samples of 14 different types of tumors were clustered to indicate similarities in tumor types and then classified to find genes uniquely implicating each type of tumor (Ramaswamy et al., 2001).

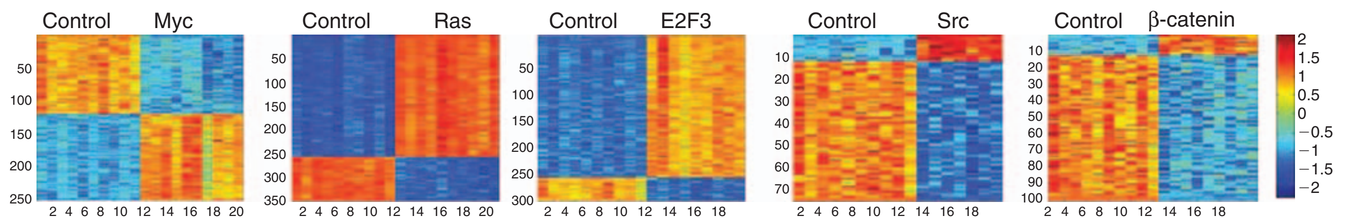

Figure 10.6 Cells made to over-express particular oncogenes were measured using gene expression microarrays, and a "signature" or pattern of gene expression changes for each oncogene was then computed and used to probe samples of cancer (Bild et al., 2006). Reprinted by permission from Macmillan Publishers Ltd: *Nature* 439:353, copyright 2006.

ANALYTIC METHODS

The field of computer science involved in the search for patterns and the induction of rules from data is called *machine learning*. Current methodologies to analyze high-bandwidth measurements can broadly be divided into two categories: *supervised machine learning* approaches, or analysis to determine genes or proteins that fit a predetermined pattern; and *unsupervised machine learning* approaches, or analysis to characterize of the components of a dataset, without the *a priori* input or knowledge of a right answer (Butte, 2002).

Supervised machine learning methods are commonly used to find those individual or sets of measured elements with measurements that (1) are significantly different between defined groups of samples, and (2) accurately predict a characteristic of the sample. An example of an application of a supervised machine learning method is the vignette described above in which Golub and colleagues found genes that distinguish ALL and AML.

There are many published supervised methods that find measured elements that accurately predict characteristics of samples, such as distinguishing one type of disease from another, or a malignant disease from a benign one (Dudoit et al., 2002). There are methods that find individual measured elements, such as the nearest-neighbor approach (Golub et al., 1999), and those that find sets of multiple elements, such as decision trees (Quinlan, 1992), neural networks (Rumelhart et al., 1986), and support vector machines (Brown et al., 2000; Chow et al., 2001; Furey et al., 2000).

Unsupervised machine learning methods are used to find internal structure or relationships within a dataset, instead of trying to determine how best to predict a "correct" answer. Two of the example vignettes provided above – in which Crescenzi determined those genes that best explained the differences between cancers and in which Alizadeh found sub-types of B-cell lymphoma – are good examples of the use of unsupervised machine learning methods.

Within unsupervised learning, there are three classes of techniques, including (1) measured element discovery, or finding elements (e.g., genes) with interesting properties without specifically searching for a specific predefined pattern, such as by principal component analysis (Alter et al., 2000; Fiehn et al., 2000; Hilsenbeck et al., 1999; Raychaudhuri et al., 2000; Wen et al., 1998); (2) cluster discovery, or finding groups of measured features or samples with similar patterns, such as by nearest-neighbor clustering (Ben-Dor et al., 2000; Golub et al., 1999), self-organizing maps (Tamayo et al., 1999; Toronen et al., 1999), k-means clustering, and one and two-dimensional hierarchical clustering (Eisen et al., 1998; Ross et al., 2000); and (3) network discovery, or finding graphs representing associations between measured elements, such as by using Boolean networks (Liang et al., 1998; Szallasi and Liang, 1998; Wuensche, 1998), Bayesian networks (Friedman et al., 2000), and relevance networks (Butte and Kohane, 1999; Butte and Kohane, 2000; Butte et al., 2000).

Several recent articles have reviewed many of the available methods (Butte, 2002; Quackenbush, 2004, 2006). Here we will consider two of the most commonly used supervised and unsupervised methods used in those publications with the greatest impact for medicine.

Case-Control Studies

The majority of experiments performed using high-bandwidth measurements still typically use only a handful of cases in two or three conditions, and the experimenter typically has the goal of finding those measured elements (e.g., genes) that are significantly different between these groups. Significance has and continues to be evaluated in a multitude of different methods, including parametric (Tusher et al., 2001), non-parametric (Butte et al., 2001), Bayesian (Baldi and Long, 2001), and many others. Analysis of variance has been used for measurements from samples with multiple characteristics (Pavlidis and Noble, 2001). Signal processing (Butte et al., 2002), trend detection (Tseng et al., 2005), Bayesian (Ramoni et al., 2002), non-parametric (Reis et al., 2001), and many other methods have been used for measurements from samples across time (Simon et al., 2005).

The challenge in using any of these methods across the set of measured elements (e.g., genes) is compensating for the high number of measurements made. For example, even a standard t-test could be used on every gene measured in two sets of microarrays from two conditions. The null hypothesis for a particular gene would be that the gene expression level is not significantly different across the two conditions, and a p-value can be calculated to assess the ability to reject that null hypothesis for each gene. But in such a case, it would be incorrect to use the "standard" threshold of $p \leq 0.05$ to determine those genes that are significantly different. Traditionally, such a threshold indicates the likelihood of calling a truly negative finding positive, otherwise known as the *false positive rate* or a type 1 error in statistics. For a single test, a 5% false positive rate may not be unreasonable, but when multiplied across 40,000 transcripts, such a false positive rate would be expected to yield 2000 falsely positive genes, too many to validate.

With high-bandwidth measurements, one is typically more interested in the *false discovery rate*, rather than the false positive rate. The false discovery rate is the expected proportion of accepted type 1 errors within a list of tested hypotheses, and controls for the number of tests being made. A false discovery rate can actually be calculated for every measured element. In essence, such a rate would indicate the likelihood of false discoveries if that element were considered positive. In practice, this is called the q-value for that element (Storey and Tibshirani, 2003). Those elements with low p-values also have low q-values.

Though q-values and false discovery rates are gaining in popularity, it is important to note that there have been many other proposed methods to compensate for multiple-hypothesis testing (Dudoit et al., 2003b).

Sub-Type Discovery

The discovery of disease sub-types using high-bandwidth measurements has been the prime motivator for personalized disease

therapeutics, where a sample of disease from an individual could be potentially measured and the most appropriate set of therapies potentially prescribed.

Typically, the discovery of sub-types involves a two-step process. First, an unsupervised machine learning method is applied yielding subsets of samples (e.g., patients) with similar measurements. Many choices are available in this step, including the specific clustering method used (e.g., hierarchical clustering (Eisen et al., 1998), self-organizing maps (Tamayo et al., 1999), or others), the mathematical definition of similarity used (e.g., Pearson correlation coefficient, Spearman rank correlation, Euclidean distance, or others), and the threshold similarity at which clusters are demarcated.

While this first step will yield potential sub-types of disease, the utility of these sub-types still needs to be determined. Typically, utility is defined using a marker of clinical outcome, such as survival, disease-free survival, or response duration. The two or more sub-types of disease identified in the first step are then tested statistically against the marker, using a Kaplan–Meier estimator or Cox Proportional Hazards Model.

The most important point to note with these types of analyzes is the censored nature of the samples. A particular patient that is lost to follow-up can only "contribute" his or her survival up to the length of follow-up. Recent methodological work has provided numerous new methods that combine both of these steps, enabling the single-step discovery of sets of measured elements (e.g., genes) that best discriminate for censored survival or other outcomes (Bair and Tibshirani, 2004; Nguyen and Rocke, 2002; Park et al., 2002).

WHERE DATA FOR STUDIES MAY BE FOUND

Corresponding with the successful application of high-bandwidth molecular measurement modalities, the amount of data in international repositories has grown exponentially, because top-tier journals require the public availability of such data and because of increased calls for transparency of raw data in publications (Nature, 2002; Ball et al., 2004; Perou, 2001). For example, the Gene Expression Omnibus (GEO) is an international repository for gene expression data, developed and maintained by the National Library of Medicine (Wheeler et al., 2004). As of this writing, GEO holds 103,000 samples (i.e., microarrays) from over 4300 experiments involving 189 species, across over 2100 types of microarrays, with 2.6 billion individual gene measurements (Figure 10.7). More impressively, GEO has been gaining data at 300% per year.

GEO is not the only international repository for microarray data. ArrayExpress is a similar database of gene expression measurements supported by the European Bioinformatics Institute (EBI) (Parkinson et al., 2005). As of this writing, ArrayExpress contains 42,424 samples from 1437 experiments. The Stanford Microarray Database (SMD) was the first international repository

Figure 10.7 Screen shot of the home page for the National Center for Biotechnology Information (NCBI) Gene Expression Omnibus (GEO).

for microarray data (Ball et al., 2005). As of this writing, SMD holds 61,573 samples involving 37 species, with a total of 1.84 billion individual gene measurements. It is not clear how much overlap there is in experiments with GEO, but it is likely that over 150,000 unique samples are available for study.

Recently, international repositories for proteomic experimental datasets have been instituted (Prince et al., 2004). PeptideAtlas, supported by the Institute for Systems Biology (ISB), is an example of one such repository (Desiere et al., 2006; Deutsch et al., 2005). As of this writing, PeptideAtlas holds the raw and processed mass spectra for 76 experiments. The Proteomics Identifications Database (PRIDE), supported by EBI, currently holds data from over 1655 experiments (Jones et al., 2006).

Though GEO, ArrayExpress, SMD, and PeptideAtlas are already incredible resources for gene expression measurements, these measurements are poorly indexed. Even for microarray data stored in standardized formats like MIAME and MAGE-ML (Brazma et al., 2001; Spellman et al., 2002), the contextual annotations needed to determine relevance of a dataset are unfortunately still represented by unstructured narrative text. Determining the phenotypes, diseases, and environmental contexts studied by these experiments is no longer a tractable manual process. Most repository websites provide only a free-text based search facility for experimental annotations.

A case example demonstrates the significance of the problem. At the time of this writing, searching on the NCBI GEO website yields 27 datasets annotated with the term "breast cancer." However, a search for "breast tumor" yields only 8 datasets. A search for the plural, "breast tumors," yields 9 datasets, while a search for "breast carcinoma" yields only 6 datasets. Breast cancer is one of the most important cancers affecting women, but searching for existing microarray datasets relevant to this important disease yields arbitrary results and is fraught with false negatives. The basic problem is that data in these repositories are not consistently annotated with terms from a standardized vocabulary. While some initial work has been done in re-annotating these datasets using a standardized vocabulary (Butte and Kohane, 2006), investigators interested in finding relevant data will have to try multiple terms to comprehensively find data.

Another caveat is that much of the most relevant clinical data associated with high-bandwidth measurements may not be stored in international repositories. For example, a dataset of microarray measurements on patients with varying lengths of survival after cancer diagnosis may be available in GEO, but the survival times may not be. Such clinical data may be available on an investigator's laboratory website or in an associated publication, but is often not publicly available at all.

BIOINFORMATICS VOCABULARIES AND ONTOLOGIES

A cell biologist interested in finding clinical samples relevant to a disease being studied in the lab will not find those samples unless she can "speak the same language" as the pathologists storing and indexing the samples. A physician interested in learning more about genes that are significantly different in his experiments will not be able to learn more about the pathways implicated by those genes, unless he can "speak the same language" as those geneticists providing annotative information for those genes. In the application of bioinformatics to genomic and personalized medicine, it is often the case that shifting focus like this crucially depends on the use of a standardized vocabulary. The formal modeling and representation of concepts of knowledge, the terms and other attributes used to describe these concepts, and the relationships of these concepts, is called a *ontology*. The importance of using proper ontologies in biomedical research has been described in recent publications (Blake, 2004; Soldatova and King, 2005). Here, we will describe some of the more commonly used ontologies used in the research of genomic medicine (Table 10.2).

Clinical vocabularies

The largest disease ontology (or nosology) in use today is the Systemized Nomenclature of Medicine-Clinical Term (SNOMED-CT) ontology. SNOMED-CT has a lineage spanning 75 years and is used by pathologists world-wide (Chute, 2000). SNOMED-CT has over 340,000 biomedical concepts in 18 hierarchies with 1.3 million relationships that classify diseases based on syndromic and pathophysiological mechanisms (Cho et al., 1998). For example, relations in SNOMED-CT assert that *clear cell carcinoma of the kidney* is a *malignant tumor of the kidney* (i.e., a type of tumor of a particular organ) and separately is also

TABLE 10.2 Some of the ontologies and vocabularies in use in bioinformatics

Ontology and vocabulary	Use
Systemized Nomenclature of Medicine-Clinical Term (SNOMED-CT)	Pathological based classification of disease
International Classification of Diseases (ICD) with Clinical Modification	Diagnosis codes for billing, public health, and epidemiology
Gene Ontology (GO)	Molecular functions, biological processes, and cellular components of proteins
Open Biomedical Ontologies (OBO)	Includes Gene Ontology and many other ontologies describing cell types and anatomy
InterDom	Protein–protein interactions
InterPro	Protein domains
Unified Medical Language System (UMLS)	Unified compendium of 140 biomedical vocabularies

a *malignant neoplasm of the retroperitoneum* (i.e., a type of tumor in a particular anatomical location).

Another disease classification more familiar to physicians is the International Classification of Diseases (ICD) with Clinical Modification, a nosology with origins in the 1850s. ICD-9-CM has nearly 7000 codes, while ICD-10-CM has over 14,000 codes to describe causes of morbidity and mortality (World Health Organization, 2005). Both ICD-9-CM and ICD-10-CM are in use by various health care providers, the US Federal Government, and the World Health Organization. Though most health care institutions in the United States use ICD-9, ICD-10 was recently approved for use by the US Congress. To continue the example above, relations in ICD-9-CM assert that a *malignant neoplasm of the kidney* is a *malignant neoplasm of the genitourinary organs*. Importantly, however, the limited resolution in ICD-9-CM does not permit the specific diagnosis of *clear cell carcinoma of the kidney*.

There are several important differences between the SNOMED-CT and the ICD nosologies. As shown above, SNOMED-CT has greater expressiveness than ICD to represent diseases. SNOMED provides a rich set of relationships between medical concepts. ICD provides only a hierarchical relationship between concepts.

Despite their differences, it is important to note that both SNOMED-CT and ICD are viewed as administrative nosologies, typically used for billing, reporting, electronic medical records, and decision support systems. However, important sources of stored tissues in medical institutions, such as frozen tissue banks, may only be accessible through SNOMED or ICD codes, and these coding systems commonly serve as an index into these repositories.

Genomic Ontologies

The Gene Ontology (GO) is a taxonomy that is used to describe the normal *molecular* function of proteins, the *cellular components* in which proteins operate, and the larger *biological processes* in which they participate (Ashburner et al., 2000). At the time of this writing, GO currently holds 7470 molecular functions, 1823 cellular components, and 12,250 biological processes. Over 186,000 genes across a variety of species have been assigned to one or more GO categories, but this essentially translates to one-third of human genes having some coded function.

The easiest way to find the GO classification for a gene is to execute a query using Entrez Gene. For example, a query for the gene coding for the insulin receptor (INSR) yields 13 molecular functions (e.g., *phosphoinositide 3-kinase binding*), 7 biological processes (e.g., *carbohydrate metabolism*), and 2 cellular components. It is important to note that an actual publication detailing the evidence for each annotation is available for many GO annotations, and these publications can be easily referenced. It is also important to note that the GO annotations for genes can change quickly, as both the annotations for genes and GO itself continue to be "works in progress."

The GO is actually one of 61 ontologies in the set known as Open Biomedical Ontologies (OBO) (Mungall, 2004). These ontologies are open, in the sense that they can be freely downloaded and used without constraints. Other ontologies in OBO include ontologies to describe the gross anatomy of flies, worms, and mice, cell types, and functional portions of proteins, as well as ontologies to describe cancers and other concepts related to humans.

Other vocabularies used for gene and protein annotation include InterDom (Ng et al., 2003), InterPro (Mulder et al., 2003), and PRINTS (Attwood et al., 2003) for protein domains, and other gene identifiers include the stable NCBI Gene identifier (Wheeler et al., 2006) and the unstable NCBI UniGene identifier (Wheeler et al., 2000).

Unified Medical Language System

The Unified Medical Language System (UMLS) is the largest available compendium of biomedical vocabularies, containing 140 biomedical vocabularies with over 1.2 million concepts and 41 million relations between concepts (Bodenreider, 2004; Butte and Kohane, 2006). UMLS already unifies vocabularies used extensively in molecular biology and genomics, such as the Medical Subject Headings (MeSH), NCBI Taxonomy, and the GO, with medical vocabularies including the International Classification of Diseases and SNOMED Clinical Terms (Ashburner et al., 2000; ICD, 2003; Wheeler et al., 2004). The UMLS is a unified vocabulary, which means that concepts listed in multiple vocabularies are brought together. For example, the concept of *fever*, which holds the UMLS concept unique identifier of *C0015967*, is represented in 78 component vocabularies, such as *D005334* in MeSH, *386661006* and *50177009* in SNOMED-CT, *780.6* in ICD-9-CM, *10016558* in the Medical Dictionary for Regulatory Activities Terminology (MedDRA), *X25* in Perioperative Nursing DataSet, *GO:0001660* in GO, and *U001776* in the Library of Congress Subject Headings. Each of these individual codes represents the same concept, and thus have been unified to a single biomedical concept in UMLS.

Because of its ability to span nearly every other relevant vocabulary, UMLS best serves as a bridging vocabulary, providing terms commonly used by both physicians as well as molecular biologists. Given the support for UMLS and its component vocabularies shown by the National Library of Medicine and the US Department of Health and Human Services, it is likely that terms and concepts from UMLS will constitute important portions of the future electronic health records of patients in the United States (see also Chapter 12). As samples from patients continue to be valuable for study using high-bandwidth measurements, tapping into the medical records associated with these samples will only grow in importance and UMLS can help enable these secondary research uses of medical records.

FREELY AVAILABLE BIOINFORMATICS TOOLS

There is an incredible preponderance of software tools freely available for research in bioinformatics. As an example, as of this writing, over 300 articles are published each year specifically describing bioinformatics software tools in the journals *BMC Bioinformatics*, *Bioinformatics*, *Nucleic Acids Research*, and *Genome Biology*. The vast majority of these are freely available for

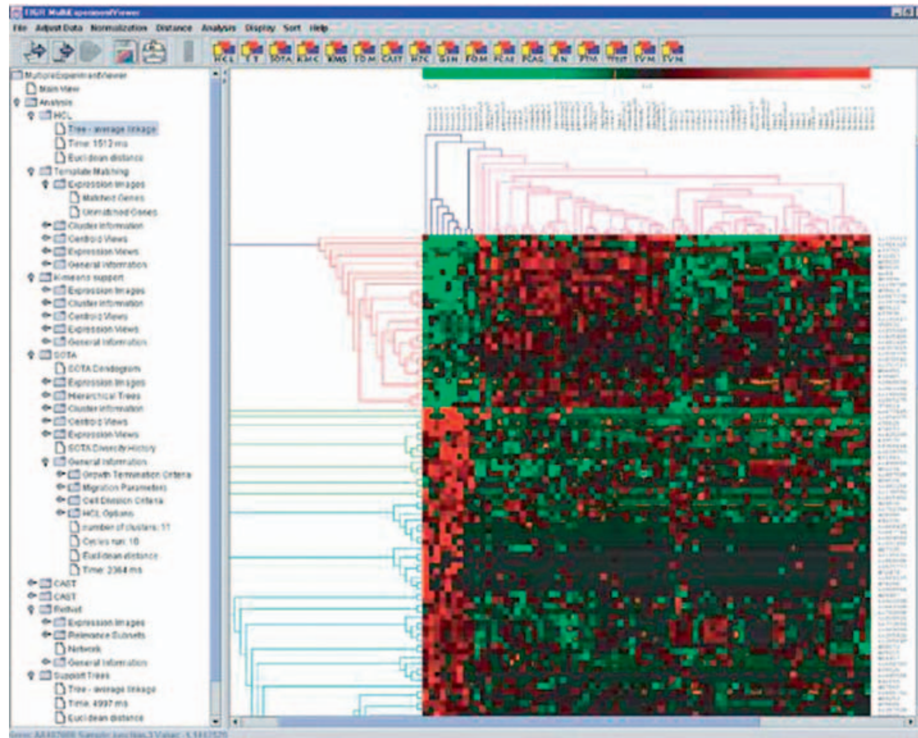

Figure 10.8 Screen shot of the MeV (Saeed et al., 2006). Reprinted from Methods in Enzymology, Volume 411, Saeed, A.I., Bhagabati, N.K., Braisted, J.C., Liang, W., Sharov, V., Howe, E.A., Li, J., "TM4 microarray software suite", 134–93, copyright 2006, with permission from Elsevier.

researchers. Describing all of the available free tools is clearly intractable, though a recent book and paper serve as nice collections of most of the commonly used tools (Dudoit et al., 2003a; Parmigiani, 2003). Here instead, we will arbitrarily focus on a few important tools useful in the study of genomic and personalized medicine, dividing our set into two groups: those useful in the analysis of high-bandwidth data and those useful in the interpretation of results.

Analytic Tools

The Multiexperiment Viewer (MeV) is an easy-to-use analytic tool initially developed at the Institute for Genomic Research and currently maintained at the Dana Farber Cancer Institute (Saeed et al., 2006). It specifically supports 17 tools for the analysis of gene expression microarrays, and presents these tools using easy-to-use on screen buttons (Figure 10.8). It runs under the Macintosh, Windows, and Linux operating systems, and the programming source code is available and can be modified by bioinformatics programmers. At the time of this writing, MeV has been cited by nearly 200 publications and has been extensively documented.

GenePattern is a sophisticated analytic tool developed and maintained by the Broad Institute (Reich et al., 2006). GenePattern supports the analysis of multiple types of high-bandwidth measurements, including gene expression microarrays, proteomics, and single nucleotide polymorphisms (SNP). Each analytic and visualization tool is contained within a module, which can be chained together to represent a reproducible pipeline for analysis (Figure 10.9). GenePattern runs under the Macintosh, Windows, and Linux operating systems. GenePattern is well-documented and supported, and as of this writing, approximately 30 papers have cited its use.

GenePattern clearly excels in its advanced features. One particularly useful feature of GenePattern is that it offers a modular architecture allowing users to plug in new analytic tools or visualization methods as they become available. These tools can be created to interface with other bioinformatics analytic tools, including Matlab and R and Bioconductor (described below). GenePattern can distribute the work required for an analysis onto a parallel computer cluster, which, if available, can speed the time required to complete an analysis. In addition, GenePattern supports the output of measurements into the standardized formats necessary for submission to international repositories, a step that is increasingly required before a top-tier journal accepts a manuscript.

At the opposite extreme of user-friendliness lies the statistical computing and graphics environment known as R (R Development Core Team, 2004). Based on the S statistical computing environment developed by Bell Labs in the late 1970s, R is the most flexible of the tools listed here. R is almost essentially "command line" driven, in that commands to execute statistical and visualization tools are typed and interpreted serially, but most users write scripts and sophisticated programs that can be run to generate the appropriate output and figures. There is essentially no user-interface (i.e., menus and windows) that can be used to perform analyzes; getting up-to-speed with R involves climbing a steep learning curve.

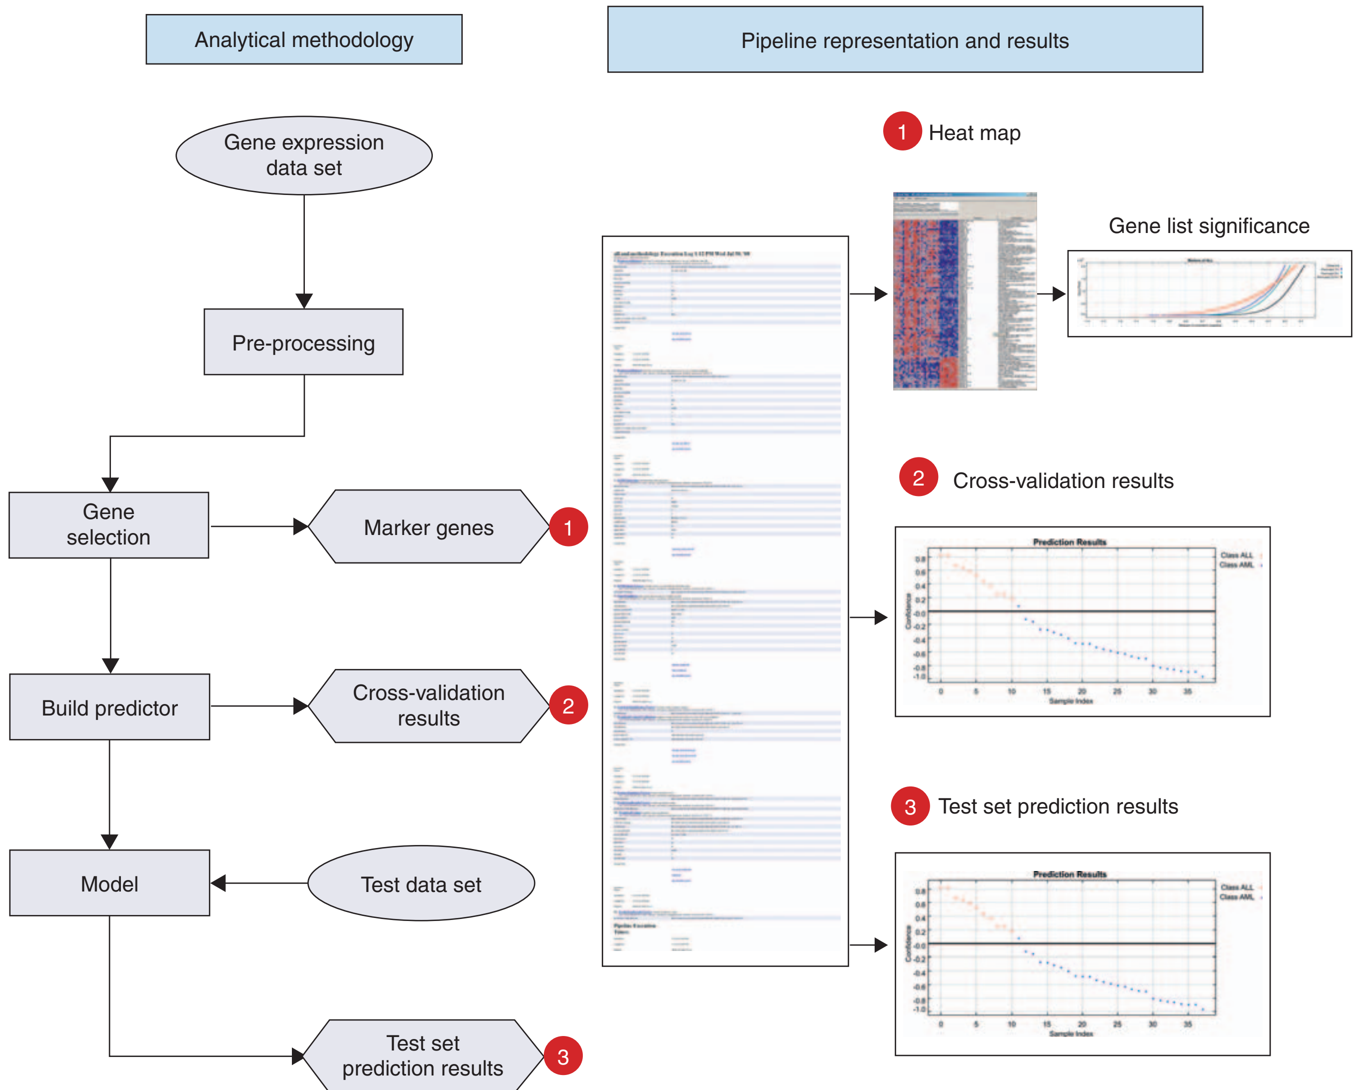

Figure 10.9 The conceptual analytic "pipeline" needed to analyze high-bandwidth molecular data is represented on the left, while its computational equivalent is represented on the right. Using GenePattern, these steps can be coded and documented, yielding reproducible research results (Reich et al., 2006). Reprinted by permission from Macmillan Publishers Ltd, *Nature Genetics* 38, 500, copyright 2006.

Despite the severe user-interface handicaps, the most important advantage of R is its community of users. Because of its designed similarity to S, users of R can benefit from decades of developed analytic tools (some statistical tool plug-ins for R and S available on the Internet date back to the late 1980s). The most important set of plug-in tools for research in genomic medicine are those contained in the Bioconductor package, which offers tools for reading microarray data, processing raw data files, common supervised and unsupervised machine learning methods, and visualization methods (Gentleman et al., 2004).

More than 50 books have been written that explain both commonly-used and cutting-edge statistical techniques using R (and S), including a few specifically for bioinformatics and Bioconductor (Gentleman et al., 2004; Parmigiani, 2003). R runs under the Macintosh, Windows, and Linux operating systems and its source code is available.

Intepretation

After several analyses, it quickly becomes obvious that the rate-limiting step in experiments involving high-bandwidth measurements is neither the handling of the biological samples nor the actual statistical or numerical work, but instead the post-analytic work in determining what the results actually mean. First, detailed names and knowledge might not yet exist for genes and proteins that have been found to be significantly involved in an experiment, even though these elements may have already been measured for many years. This complicates the interpretation of results. The official gene name, predicted

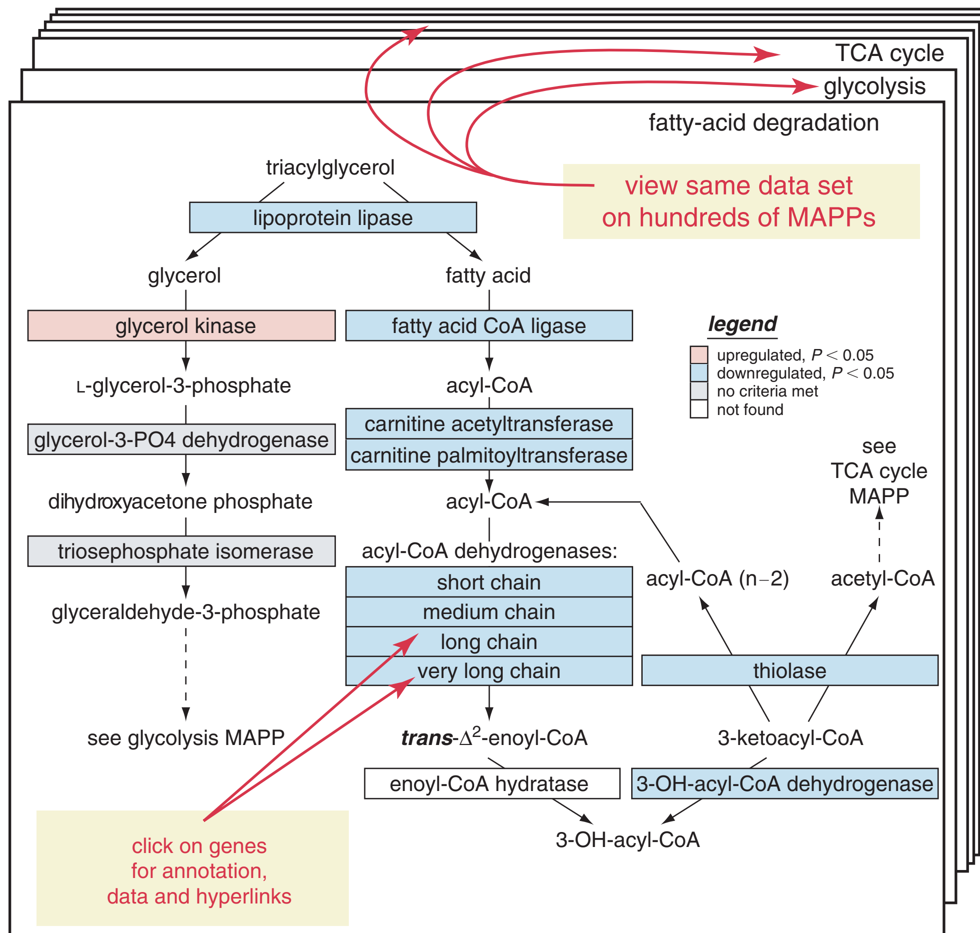

Figure 10.10 GenMAPP has the ability to color-code proteins participating in biological pathways based on measurements (Dahlquist et al., 2002). Reprinted by permission from Macmillan Publishers Ltd, *Nature Genetics* 31, 19, copyright 2002.

protein domains, or GO classification may become available for a gene or protein as early as tomorrow, or as late as years from now. Operationally, this means that one is never done analyzing a set of microarray data. One has to develop the infrastructure to constantly reinvestigate genes and proteins from analyzes performed in the past. It may be next week, for example, that new knowledge about a protein that was significantly implicated in an analysis performed three months ago gets published, finally leading to a novel and important finding.

The challenges in determining the proper analytic methods to use are usually only a short-term difficulty, and typically after the "functional genomics pipeline" has been established, the rate-limiting step shifts to the post-analytic challenges (Kohane et al., 2002). In the future, truly demonstrating a "return on investment" from high-bandwidth molecular measurements depends on taking findings past the measurement stage and integrating them with the rest of the research pipeline, including interpretation and validation. The list of elements resulting from an analysis should not be viewed as an end in itself; its real value only increases as that list moves through biological validation, ranging from the numerical verification of measurement levels with alternative techniques, to the ascertainment of the meaning of the results, such as finding common mechanisms or biological pathways involving the genes or proteins. While tools that link measurement elements back to known biological pathways are still in their infancy, some have been shown to be quite useful.

GenMAPP is a software tool that can visualize of high-bandwidth molecular measurements using pre-drawn diagrams illustrating biological pathways (Dahlquist et al., 2002). Though GenMAPP comes with nearly a thousand useful biological pathways across numerous species, GenMAPP also comes with an editor enabling a biologist or bioinformatician to draw any new pathway (Figure 10.10). Because of this, the GenMAPP user base has developed into a large community of users who share pathways. GenMAPP runs only under the Windows operating system. At the time of this writing, GenMAPP has been cited by nearly 600 publications and has been extensively documented.

The Kyoto Encyclopedia of Genes and Genomes (KEGG) is an extensive web-based database of biological pathways and functions under development for more than a decade (Kanehisa, 1997). Similar to GenMAPP, KEGG offers tools that can color-code diagrams of biological pathways based on quantitative measurements, instead using a web-based interface (Figure 10.11). KEGG offers more than 42,000 biological pathways for nearly 500 species.

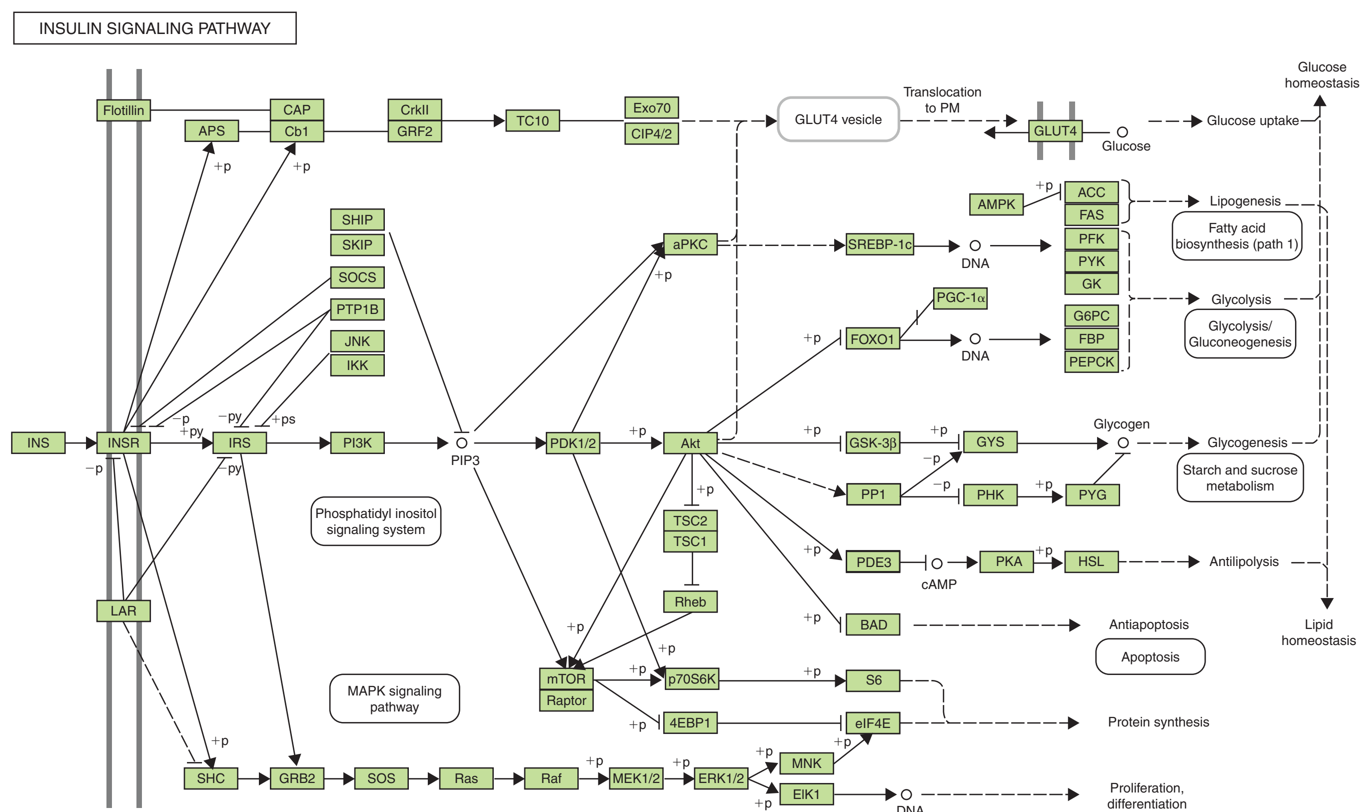

Figure 10.11 The insulin signaling pathway, as represented in KEGG as of this writing. A click on any protein yields additional data about that protein.

Beyond biological pathways, KEGG also provides knowledge on ligands, metabolites, small-molecule drugs, and diseases. At the time of this writing, KEGG has been cited by nearly 1000 publications.

Other free web-based resources available to study genes by known function and protein domains include Entrez Gene and GeneCards (Safran et al., 2002; Wheeler et al., 2006).

2009 UPDATE

There has been astounding growth in biomedical databases over the past two years. The January issue of *Nucleic Acids Research*, in which significant biomedical databases are listed annually, reached 1170 databases in 2009, demonstrating a 16% increase from the previous year (Galperin and Cochrane, 2009). New databases this year include those containing microRNA and their binding sites as well as data and genomes of pathogens causing infectious diseases in humans, including Giardia and Plasmodium.

Individual databases have also demonstrated growth. The NCBI Gene Expression Omnibus, an international repository for gene expression microarray data, has (as of this writing) over 278,000 microarrays from 11,000 experiments, demonstrating 1.4× growth over the past year (Sayers et al., 2009). The EBI ArrayExpress database holds another 100,000 microarrays from 3400 experiments (Parkinson et al., 2009). Even greater growth has been seen in proteomics databases; the EBI PRIDE holds nearly 9000 samples yielding over 17 million mass spectra, showing 6.7-fold growth in the past year. In most cases, the data from these sources are easily and quickly downloaded.

The most significant new source of data is from genome-wide association studies (GWAS) (McCarthy et al., 2008). As of this writing, the NHGRI-curated database at http://genome.gov/gwastudies lists 245 GWAS publications. Typically the list of SNPs with significant association is publicly available for many of these, while the raw genotyping measurements are available for fewer. Genotype and phenotype data on GWAS funded by the United States. NIH are held at the NCBI Database of Genotypes and Phenotypes (dbGAP). As of this writing, dbGAP has grown to include 35 studies (up from 14 one year prior), with nearly 90,000 human samples with genetics and phenotyping. The Framingham Heart Study itself contributes 102 separate substudies. Compared to gene

expression microarray and proteomics data, data on genetics are not as easily downloaded; access to genetics data sometimes requires pre-approval from both local and repository Institutional Review Boards (IRB). Most available genetics data are in the form of measurements from SNP assays, where between 50,000 and 2 million SNPs are measured across individuals. Expectations are high that over the coming years, more genetics data will instead come from high-throughput sequencing, as the capabilities of pyrosequencing, single molecule sequencing, and other technologies develop (Schuster, 2008). However, worries about the re-identifiability of individual study participants from publicly-available GWAS data have led to increased vigilance and regulation to the accessibility of this data (Homer et al., 2008).

Clinical data, including those from electronic health records (see Chapter 12), are just starting to be used in large-scale genetics experiments. A recent GWAS for genetic variants influencing the maintenance dose of warfarin, a commonly-used anti-coagulant, used electronic medical records on bleeding events as part of the phenotyping (Rieder et al., 2005). This type of approach is being built into the research infrastructure at particular medical institutions, where DNA biobanks are linked to phenotypic information from electronic medical records (Roden et al., 2008). As more academic research centers are enabled to build such infrastructures through the NIH Roadmap Institutional Clinical and Translational Science Awards (CTSA), we can expect to see more studies bridging the methodologies clinical informatics and bioinformatics (National Institutes of Health, 2005).

CHAPTER

Systems Biology and Systems Medicine

Nathan D. Price, Lucas B. Edelman, Inyoul Lee, Hyuntae Yoo, Daehee Hwang, George Carlson, David J. Galas, James R. Heath and Leroy Hood

INTRODUCTION

A new approach to biology, which we call *systems biology*, has emerged over the past 10 years or so – an approach that looks at biology as an informational science, studies biological systems as a whole, and recognizes that biological information in living systems is captured, transmitted, modulated, and integrated by biological networks that pass this information to molecular machines for execution. This approach differs from early "systems approaches to biology" in that it attempts both a bottom-up approach (from large molecular datasets) and a top-down approach (from computational modeling and simulations) where there is an attempt to trace complex observations of phenotype back to the digital core encoded in the genome.

New measurement and visualization technologies, together with powerful computational and modeling tools, have transformed systems biology by making it possible for the first time to execute the five uniquely defining features of contemporary systems biology:

1. measurements of the various types of biological information that are global or comprehensive to the greatest extent possible (e.g., measure the digital code of all genes or, for example, the concentrations of all mRNAs, all proteins, all metabolites, etc.);
2. the different levels of information (DNA, RNA, protein, etc.) must be integrated to understand or capture how the environment has modified the basic digital information of the genome at each level of the biological information hierarchy (DNA, RNA, proteins, interactions, biological networks, cells, individuals and ecologies) and thereby to induce biological responses;
3. all biological systems (e.g., networks) must be studied dynamically as they capture, transmit, integrate and utilize the biological information necessary for the execution the two most fundamental responses of living organisms – development or physiological responses to the organism's environment;
4. all measurements must be quantitatively determined to the greatest extent possible; and
5. the global and dynamic data from the variety of information hierarchies must be integrated and modeled.

These models essentially create hypotheses about biological functions and mechanisms of disease that can then be tested experimentally by systems perturbations – the enumeration of new datasets, their integration, modifications of models, in an iterative manner, until the working models reflect the reality of the experimental data. Once the models accurately fit the biological systems measurements, they can then be used to predict the results of perturbing the system in new ways (e.g., for designing treatment strategies or for identifying likely underlying causes for disease).

The information revolution in biology will enable systems medicine to emerge in the next 10 years. Key to this transformation will be harnessing computationally the vast amount of biological information becoming available through rapid

Essentials of Genomic and Personalized Medicine

advancement in measurement, visualization and computational technologies. Two fundamental types of biological information, the digital information of the genome and interacting information from the environment, are integrated together to specify the five fundamental mechanisms of life – evolution, development, physiological responses, aging and the onset and progression of disease (Hood et al., 2004). Advances in high-throughput DNA sequencing will enable each person's genome to be sequenced rapidly and at a reasonable cost, providing digital information for each person and making possible the prediction of increasingly accurate probabilistic health futures. Also, the advance of high-throughput measurement technologies will enable the assessment of dynamic environmental information emerging from the integration of genome and environmental information from each individual, as reflected, for example, by the changing levels of proteins in the blood – thus providing a real time (current) health assessment of the individual. These technologies will generate tremendously large, dynamical datasets about health states and hence about the states of relevant biological networks of the individual patients. This detailed information will arise through the use of perturbation experiments coupled with global experimental technologies, and progress in systems biology research is increasingly elucidating the functions and structures of these networks.

A systems approach to medicine argues that disease arises from disease-perturbed biological networks and that the dynamically changing, altered patterns of gene expression that are controlled by these perturbed networks give rise to the disease manifestations. Here, we present a systems view of biology and disease together with a discussion of some recent advances in state-of-the-art *in vitro* and *in vivo* diagnostics technologies, and we suggest how, as these technologies mature, they will move us towards a future of predictive, personalized, preventive, and participatory medicine (*P4 medicine*) (Hood et al., 2004).

SYSTEMS SCIENCE IN BIOLOGY AND MEDICINE

Systems Biology

How do systems approaches to biology and medicine lead to a revolutionary view of medicine? We present this systems view in some detail, because an understanding of P4 medicine and its implications for society are predicated upon understanding these systems principles. Two primary domains of biological information lend themselves readily to such systems-level analysis: the static, digital information of the genome, and the dynamic information arising from environmental interactions with the subcellular, cellular, and tissue levels of organization (Hood et al., 2004). Digital genome information encodes two types of biological networks – *protein interactions* and *gene regulatory networks*. Protein networks transmit and use biological information for development, physiology and metabolism. Gene regulatory networks – transcription factors, their regulatory binding sites and the small RNAs that regulate networks of other transcription factors and other RNAs interacting with one another – receive information from signal-transduction networks, integrate and modulate it, and convey the processed information to networks of genes or molecular machines that execute developmental and physiological functions. In biological systems, these two types of networks are closely integrated. The organization of these networks can be inferred from various types of measurements including, for example, global measurements of dynamically changing levels of mRNAs and proteins during developmental and physiological responses, as well as large-scale measurements of protein–protein and protein–DNA interactions. There are multiple hierarchical levels of organization and information (for example, DNA, RNA and protein networks, cellular and metabolic networks, and organization and responses of organ systems). To understand biological systems, information must be gathered from as many information levels as possible and integrated into models that generate hypotheses about how biology works. Let us now consider the logic of systems approaches to medicine.

Systems Medicine

The central premise of systems medicine is that disease-perturbed networks alter patterns of expression in genes and proteins – and that these altered patterns encode the dynamic pathophysiology of the disease and necessarily results in altered molecular fingerprints that can be detected clinically. Through advances in measurement technologies and computational analysis tools for tissue and blood analyses, we will be able to read these signals to make a multitude of diagnoses to distinguish health from disease and to determine the nature of any pathology. Multi-parameter analyses of biological information will be key to tracking these altered patterns in disease-perturbed networks. Diagnostic methods of the past have been pauci-parameter in nature – usually measuring just a single parameter relevant to a specific disease state (e.g., PSA levels to assess prostate health), and so our ability to track health and disease has been limited. Current and emerging technologies are creating a transition into a new era of predictive, preventative, and personalized medicine. A causal disease perturbation could be the result of specific, disease-causing DNA mutations, pathogenic organisms, or other pathological environmental factors such as toxins. Molecular fingerprints of pathological processes can take on many molecular forms, including the analyses of proteins (Wang et al., 2005a, b), DNA (Papadopoulou et al., 2006), RNA (Scherzer et al., 2007), and metabolites (Solanky et al., 2003), as well as informative, post-translational modifications to these molecules such as protein phosphorylation.

Signals related to health and disease can be found in multiple sites. For instance, many bodily fluids such as the blood, urine, saliva, cerebral spinal fluid and so forth can be sampled to identify evidence of perturbed molecular fingerprints reflecting the altered expression patterns of genes and proteins in disease-perturbed biological networks. Of these, the blood is likely the most information rich organ (or fluid) in that it bathes all of the tissues in the body, and it is easily accessible for diagnostic procedures. In addition to the biomolecules secreted into the blood

from cells and tissues throughout the body, the transcriptomes and proteomes of cells circulating in the blood (e.g., white blood cells) are also potentially an abundant source of biomedically important information (Buttner et al., 2007). Thus, the amount of information available in the blood about health and disease is enormous if we learn to read and interpret the molecular signals.

These dynamically changing, disease-perturbed networks lead to two important conclusions. First, some significant network nodal points change before the related clinical or histological changes are evident. Therefore, labeled biomarkers that are specific for the changing nodes or the biological processes they regulate could be used for *in vivo* imaging diagnostics even before symptoms arise, as has already been shown in patients (Golub et al., 1999; Quackenbush, 2006; Ramaswamy et al., 2001; Wang et al., 2005a, b). Alternatively, if some of these altered nodes encode secreted proteins, they could provide readily accessible *in vitro* diagnostic blood markers for early disease detection. Second, many of the sub-networks of proteins that change during the onset of disease affect changes in phenotypic traits that are consistent with the pathology of the disease.

About 900 perturbed mRNAs appear to encode the core prion-disease response, and, during the progression of the prion-disease process, several hundred undergo significant gene expression changes well before the clinical signs of prion disease. Many of these potential early disease "sentinels" are predicted to be secreted into the blood and therefore represent potential protein biomarkers for early disease diagnosis through blood protein analysis. One interesting new diagnostic method evaluates relative expression reversals in protein concentrations or gene expression levels. This procedure eliminates the need for data normalization or the establishment of population-wide thresholds. This approach has been successfully used to identify robust and accurate classifiers for prostate cancer (Xu et al., 2005), sarcomas (Price et al., 2007), and a variety of other cancers (Tan et al., 2005), as well as to predict treatment outcomes in breast cancer (Ma et al., 2004), demonstrating the efficacy of even relatively low-order systems analysis in medicine.

Another key issue that needs to be addressed is how to best decouple two primary dimensions of disease information: namely, disease stratification (e.g., which type of prostate cancer is present) and disease progression (e.g., stage of development of a particular prostate cancer stratification in time). Molecular signature changes can indicate the presence of different diseases (stratification) as well as their stage (progression). Thus, a key challenge in future will be to develop analysis tools that will enable us to differentiate the location of the physiologic state in regards to both of these critical clinical dimensions.

MULTI-PARAMETER BLOOD-BOURNE BIOMARKERS

In principle, it is clear how blood samples containing secreted molecules from all of the tissues in the body can be used as a window into health or disease states (Anderson and Anderson, 2002; Fujii et al., 2004; Hood et al., 2004; Lathrop et al., 2003; Lee et al., 2006). In practice, however, the task of identifying markers of disease states in the vast array of secreted proteins can seem daunting. There are millions of different proteins present in the blood and they are expressed at levels that probably differ by 12 orders of magnitude (10^{12}). Thus, there are indeed very significant challenges associated with defining relevant biomarkers in the plasma proteome, as is evidenced by the paucity of blood protein markers found thus far, despite significant efforts (Wilson, 2006). This fact highlights the need to develop well-founded systems approaches to diagnostics in order to hasten the identification of such markers and to harness the tremendous information potential of the blood. While the potential information available to diagnose heath and disease is enormous, it is also true that the challenges of separating signal from background noise (biological or measurement noise) are also very significant. Sources of noise include error in measurements, polymorphisms in the population, environmental variations, stochastic variations, as well as signal dilution through mixing and other processes of molecule transport. Thus, enhancing signal while reducing noise will be a primary theme of research in predictive medicine for the foreseeable future.

An important strategy for dealing with noise arising from genetic polymorphisms and health histories in the population are through dynamic, subtractive analyses carried out in the individual patient. In other words, measurements taken from individual patients at different time points (longitudinal data) can be used to perform subtractive analyses where only the differences observed are considered. Thus, each patient becomes their own control, which eliminates many of the sources of noise. Eventually, it will be important for each patient to have biannual blood analyses taken so that changes can be observed relative to the background of what is normal *in each individual* rather than relative to the population at large. Such databases of measurements will be essential to enabling personalized and predictive medicine. Using each patient as their own control is one of the essential features of the emerging personalized medicine.

Organ-Specific Blood Protein Fingerprints

We discuss the organ-specific blood protein fingerprint approach to diagnostics because it lies at the very heart of the predictive medicine that will emerge over the next 10 years. Our feeling is that this will be one of the central data gathering strategies for predictive and personalized medicine and, accordingly, we will discuss it in detail. The idea is that disease arises from dynamically changing disease-perturbed networks, that the diseased organs will secrete proteins into the blood, and that if these proteins are encoded by disease-perturbed networks their levels of expression in the blood will be altered in a manner that reflects the specific nature of the disease. Indeed, this idea is the basis for the very broad range of blood biomarker studies that are being carried out by many scientific centers (Anderson and Anderson, 2002; Fujii et al., 2004; Hood et al., 2004; Lathrop et al., 2003; Lee et al., 2006). The major difficulty with this simple view is that if you identify multiple blood proteins whose changes are specific for a

particular disease state (as compared against normal controls) and then examine the same blood markers for that disease in bloods drawn from individuals, with say 10 other pathologies, these marker proteins can change in unpredictable ways since multiple organs control the expression of most blood proteins and these organs respond differently to various environmental signals. The important point is that if a marker protein synthesized in five organs changes in the blood, we cannot be certain which organ(s) is the origin of the change. While that marker may sample a biological network relevant to disease diagnosis, since its origin is not clear its use as a disease biomarker may raise more questions than it answers. The solution to this dilemma is clear – employ organ-specific blood protein biomarkers whose changes must therefore reflect changes only in the organ itself. If enough of these organ-specific blood proteins are sampled, they will represent a survey of many different biological networks in the organ of interest and will provide sufficient diagnostic information for any disease. Eventually, correlation of these organ-specific biomarkers with more general biomarkers may prove to be the best long-term strategy for developing diagnostic fingerprints.

We have several lines of preliminary evidence that suggest this organ-specific blood protein approach will be effective. In prostate cancer, for example, there are disease-mediated altered patterns of mRNA and protein expression in the prostate. Some of these genes are expressed primarily in the prostate (organ-specific products) and some of these organ-specific proteins are secreted into the blood, where they collectively constitute a protein molecular fingerprint comprised of say 100 or more proteins whose relative concentration levels probably report the status of the biological networks in the prostate gland. We have demonstrated that changes in the blood concentrations of several of these prostate-specific blood proteins reflect the various stages of prostate cancer and, as discussed above, various brain-specific blood proteins also reflect the progression of prion disease in mice. We propose that the distinct expression levels of the individual proteins in each fingerprint represent a multi-parameter (and therefore potentially information-rich) diagnostic indicator reflecting the dynamic behavior of, for example, the disease-perturbed networks from which they arise. The analysis of 50 or so organ-specific proteins should allow us to both stratify diseases in the organ as well as determine their stage of progression. We have identified tens to hundreds of organ-specific transcripts in each of the 40 or so organs that we have examined in mouse and human.

We can envision a time over the next 5–10 years when 50 or so organ-specific blood proteins will be identified for each of the 50 or so major organs and tissues in humans – so that computational analyses of the relative concentrations of the protein components in these organ-specific fingerprints will enable blood to become the primary window into health and disease. When we analyze data from these blood indicators, we also may be in a position to identify the dynamically changing disease-perturbed network(s). The analysis of these dynamic networks will allow us to study in detail the pathophysiology of the disease response and hence be in a position to think of new approaches to therapy and prevention. To generate the ability to assess simultaneously all 50 organ blood protein fingerprints in patients, we ultimately need to develop the microfluidic or nanotechnology tools for making perhaps 2500 rapid protein measurements (e.g., 50 proteins from each of 50 human organs) from a droplet of blood. Nanotechnology is necessary because only this severe miniaturization can allow the necessary thousands of measurements from a single drop of blood. In order to reach this stage we will also have to create the appropriate computational tools to capture, store, analyze, integrate, model, and visualize the information arising from this approach.

EMERGING *IN VIVO* AND *IN VITRO* TECHNOLOGIES

In vitro Measurement Technologies

P4 medicine will require that *in vitro* measurements of thousands of blood proteins be executed rapidly, automatically and inexpensively on small blood samples. This will require miniaturization, parallelization, integration and automation of tissue and blood purification and measurement technologies. In short, it will require making *in vitro* measurements inexpensively – perhaps for a penny or less per protein measured. This need for inexpensive *in vitro* measurements is driving the development of integrated microfluidics and nanotechnologies for *in vitro* diagnostics. We further argue that the complex changes in these protein levels must be analyzed computationally to search for the patterns that correlate with particular diseases – and indeed to stratify each disease as well as determine its stage of progression.

To meet the expanding requirements of systems medicine, *in vitro* measurements of cells, proteins, mRNAs, etc., whether for fundamental biological studies or for pathological analysis, must not just be inexpensive, but must also be sensitive, quantitative, rapid, and executed on very small quantities of tissues, cells, serum, etc. We are working towards developing chip platforms that can take a few microliters (a finger prick) of blood, separate the plasma from the serum, and then measure on the order of 100 or more proteins and/or mRNAs quantitatively, with high sensitivity and specificity, and in a few minutes time. We can envision a time 5–10 years hence when small hand-held devices will be able to make these 2500 measurements from a fraction of a droplet of blood, send them *via* wireless to a server for analysis and consequently inform the patient and physician as to the status of the patient. While many fundamental scientific challenges remain to be solved before this goal is achieved, none of those challenges appears insurmountable at this point.

One will also be able to use the blood cells as powerful diagnostic markers – either of infectious diseases or of genetic diseases. Microfluidic cell-sorting technologies for being able to sort blood cells into their 10 or so individual types for analysis are now available. Even more important is the emergence of

single-cell analytic tools where DNA, mRNAs or small RNAs, proteins and even metabolites can be analyzed rapidly from individual cells. The cells can also be perturbed with appropriate environmental stimuli to identify defects. It is possible that an appropriate analysis of immune cells (both innate and adaptive) from the blood will reveal important information about past antigenic history of the individual as well as current state of immunological responsiveness. Similarly, analysis of rare blood cells such as circulating cancer cells may also be utilized to guide therapies.

Another type of *in vitro* measurement will be a determination of the complete genome sequence of individuals with a nanotechnology approach to sequencing single strands of DNA on a massively parallel basis (billions of DNA strands simultaneously). A device like this will emerge over the next 5–10 years and will allow millions, if not billions, of individual human genome sequences to be determined rapidly, inexpensively and in a massively parallel manner. The 2500 organ-specific blood marker measurements and the complete individual human genome sequences will be the heart of the predictive and personalized medicine that will emerge over the next 10 years or so.

While transcriptomic approaches have proven useful for identifying informative molecular signatures for a number of diseases (Quackenbush, 2006), high-throughput proteomic characterizations have lagged behind. The reason for this difference is clearly the more difficult challenge of measuring proteins compared to mRNA transcripts. Emerging proteomics technologies hold the promise of greatly improving our ability to make detailed disease assessments using protein-based molecular signatures. One key advantage of protein signatures relative to gene expression is that the proteins found in the blood and other accessible bodily fluids exhibit slower degradation rates than their mRNA counterparts – and of course proteins are the direct agents mediating the disease process itself. Thus, protein concentration signatures represent an important class of molecular signature for disease diagnosis.

The Imaging of Proteomics and Blood Protein Biomarkers

The blood is an ideal organ for identifying biomarkers because it interacts with virtually every organ and major tissue type in the body, and each secretes proteins into the blood. Moreover, the blood is easily accessible for diagnostic studies – and presumably the analysis of changes in protein levels or protein modifications that could serve as surrogates or reflections of health and disease. As noted earlier, the blood is an enormously complex organ; it contains hundreds of thousands to millions of proteins whose concentrations range over 12 orders of magnitude. Since there is for proteins no equivalent to the polymerase chain reaction (PCR) amplification procedure, only the more abundant proteins can be seen by conventional protein analysis studies. It should also be pointed out that many different features of proteins ultimately must be characterized or quantified: identification, quantification, chemical modifications, alternative mRNA splicing products, cellular localizations, three-dimensional structures (and their dynamics), as well as their functions. We here are only concerned with the quantification and identification of proteins.

There are two general approaches to the analysis of protein mixtures. In one case protein-capture agents such as antibodies are used – and with appropriate controls these approaches can quantify the levels of proteins. These techniques include Western blot analyses, ELISA assays, surface plasmon resonance and protein chips. A second approach is to use mass spectrometry. Since proteins have large masses that are difficult to analyze accurately by mass spectrometry, most proteins are analyzed after converting them into tryptic peptides (or other proteolytic fragments) whose masses are far smaller and hence more easily analyzed. Because blood is such a complex mixture, proteins of interest are often enriched by some type of fractional procedure (charge, hydrophobility, size and/or the presence of modifications such as glycosylation or phosphorylation), before (or after) their conversion into peptides and analysis by mass spectrometry. Isotopically labeled and synthesized peptides may be used to identify and quantify (relative or absolute) the same peptides from unknown samples (and hence one obtains a proxy for the quantification of their corresponding proteins) very effectively by mass spectrometry.

We discuss below examples of some of these techniques.

Antibody Microarrays Using Surface Plasmon Resonance Imaging (SPRI)

Protein chip methods hold great potential for broad quantitative screens of proteins, and a variety of techniques have been developed based on antibody binding (Haab et al., 2001; Olle et al., 2005; Song et al., 2007). Various types of antibody arrays have been used for biomarker discovery and protein profiling of serum from patients with prostate, lung, pancreas, and bladder cancer (Gao et al., 2005; Miller et al., 2003; Orchekowski et al., 2005; Sanchez-Carbayo et al., 2006). One emerging approach with tremendous promise is SPRI (Hu et al., 2007; Huber and Mueller, 2006; Koga et al., 2006), which enables real-time, label-free measurement of protein expression by large numbers of different antibodies. SPR-based chips have a detection sensitivity of 10–100 times less than ELISA (Hu et al., 2007), but have a spatial resolution down to approximately 4 μm (Lyon et al., 1998). It is thus possible to print up to 800 unique antibodies on Lumera Nanocapture Gold™ microarray slides and monitor the abundance of the target proteins in real time (Hu et al., 2007), even in complex samples such as blood, because the same slide can be regenerated for reuse many times in 10 minutes or less (Z. Hu, C. Lausted, unpublished observations). We are in the process of automating the sample introduction procedures using microfluidic chips, which means that SPRI has the capacity necessary to screen rapidly through tens to hundreds of patient samples. Thus, this approach holds tremendous promise to be able to screen through large numbers of proteins, including secreted proteins and cell-surface markers and not only measure their presence,

but also abundance and the dynamics of their binding. The limitation of this technique is its dependence on the affinity and specificity of the antibodies it employs for detection – cross-reactivities in complex protein mixtures (such as blood) can pose significant problems.

DNA-Encoded Antibody Libraries (DEAL)

One recently developed technique that offers great potential for detailed analyses is DEAL. The primary advantage of DEAL is that it uses a single, robust chemistry – that of DNA hybridization – to spatially localize and detect proteins, mRNAs, and cells, all in a multiplexed fashion. Antibodies are typically too fragile to survive the fabrication procedures associated with assembling robust microfluidics chips, but DNA oligomers are significantly more robust. DEAL thus enables the detection of panels of protein biomarkers within a microfluidics environment and from very small quantities of biological material (100 nanoliters or so) (Yang et al., 2006). This amount of plasma can be readily separated from whole blood on-chip, thus allowing for the measurement of serum biomarkers from a finger-prick of whole blood. In addition, within the environment of flowing microfluidics, the rate-limiting step in performing a surface immunoassay is the kinetics of the binding of the analyte to the surface-bound capture agent (Zimmermann et al., 2005). Thus, DEAL-based immunoassays can be executed very rapidly.

The versatility of DEAL also enables multiplexed cell sorting and localization, followed by few- or single-cell measurements of protein, RNA, and other biomolecules (Bailey et al., 2007). DEAL can be engineered into a highly sensitive and very rapid measurement technique, with a reported detection limit of 10 fM for the protein IL-2, 150 times more sensitive than the corresponding commercial ELISA assay. This sensitivity can be applied to the isolation of rare cells based on combinations of cell-surface markers, enabling the isolation and addressing of individual cancer stem cells. DEAL can also be used to make single-cell measurements of secreted proteins from each of these isolated single cells. Thus, DEAL offers superb sensitivity and the ability to perform spatially multiplexed detection for characterization of rare cell types, such as circulating cancer cells or cancer stem cells. These advantages still face the inherent limitations of antibodies, so the development of new approaches to generating protein-capture agents is a critical part of future development of comprehensive blood diagnostics.

Mass Spectrometry-based Techniques

Isotopic Tagging for Relative and Absolute Quantification (iTRAQ) of Proteins Analyzed by Mass Spectrometry

Stable isotope labeling enables the quantitative analysis of protein concentrations through mass spectrometry (MS). One state-of-the-art technique for quantitative MS is iTRAQ (Ross et al., 2004), which uses stable isotope labeling of proteolytic peptides. This technique modifies primary amino acid groups of peptides by linking a mass balance group, and a reporter group by forming an amide bond. When MS/MS is used for analysis with iTRAQ-tagged peptides, the mass balancing carbonyl moiety is released as a neutral fragment generating 4–8 distinct sets of peptides whose relative abundances can be determined quantitatively. Because eight different iTRAQ reagents are currently available, comparative analysis of a set of two to eight samples is feasible within a single MS/MS run (Hu et al., 2007). The, iTRAQ technology represents the state-of-the-art in quantitative proteomics and represents a promising technology for using proteomics to differentiate key differences in protein networks.

Glycopeptide Capture – Front-End Enrichment of Blood Proteins Containing Sugar Residues

Mass spectrometry-based methods will allow for the identification of proteins spanning approximately three orders of magnitude in concentration from a given sample. Therefore, methods that can select specified fractions of the proteome are important for simplifying the sample sufficiently to identify the proteins of interest. One recently developed approach is the shotgun glycopeptides capture approach (Sun et al., 2007). This approach selects for N-linked or O-linked glycosylated peptides by selectively coupling these peptides to beads – allowing the uncoupled peptides to be washed away – then the glycosylated peptides are be released and analyzed by mass spectrometry. Both secreted and cell-surface proteins are enriched for glycopeptides compared with their nuclear and cytoplasmic counterparts. Thus, this approach can be used to, for example, identify candidates for unique cell-surface markers to make identifications of clinically relevant cellular subpopulations.

In Vivo Molecular Diagnostics

As it relates to personalized and predictive medicine, *in vivo* molecular diagnostics will also require the development of a diverse library of molecular imaging probes. These modular tools can be used to:

1. identify the specific location of disease-perturbed networks in patients;
2. link *in vivo* molecular measurements in diseased tissue in patients to *in vitro* measurements;
3. rapidly assess the efficacy of personalized therapeutics; and
4. validate that a drug is hitting its target and inducing the desired pharmacological outcome.

Although there are many *in vivo* imaging modalities, perhaps the best current method from the point of view of personalized and predictive medicine in patients is positron emission tomography (PET) molecular imaging (Czernin and Phelps, 2002). For PET, trace quantities of radiolabeled molecular probes are injected into the patient. As the probes circulate through the body and its various organ systems, they interact with target proteins to provide imaging assays for, as examples, the rate of metabolic processes, the concentration of receptors in signal transduction, enzyme activity, DNA-replication rates, hormone status, pharmacokinetics, and pharmacodynamics.

COMPUTATIONAL AND MATHEMATICAL CHALLENGES IN SYSTEMS MEDICINE

Molecular Signature Classifiers

Computational methods are needed to reduce the high degree of data dimensionality associated with global datasets to identify molecular signatures that can be used for disease diagnosis. Despite notable and significant challenges that remain (Dupuy and Simon, 2007; Simon, 2005), computational analyses to identify molecular signatures from global gene expression datasets that can be used for diagnosis and treatment selection (Quackenbush, 2006) is an area of research that has shown significant promise. These studies typically involve the collection of samples from two or more classes (e.g., cancer versus normal, or responsive versus non-responsive to treatment) and the use of a set of data on which to train the classifier and another set on which to test. In the absence of a true test set, re-sampling methods (such as cross-validation) are generally used to estimate likely performance of the classifier on future data. The ability to generate an accurate classifier is a function of factors such as: (1) the size of the training set relative to the number of features, (2) the computational method used, and (3) the inherent distinctness of the selected phenotypes. Typically, the number of samples is far less than the number of transcripts, and consequently over-fitting is a significant problem. This leads to the need for computational methods that avoid over-fitting when selecting a classifier.

A variety of methods have been applied to disease diagnoses, including approaches based on support vector machines (Furey et al., 2000; Ramaswamy et al., 2001) and relative expression reversals (Geman et al., 2004; Price et al., 2007; Tan et al., 2005; Xu et al., 2005), among many others. Application of these methods has perhaps been applied most extensively to the study of cancer, leading to the discovery of molecular classifiers of varying degrees of accuracy to identify prognostic signatures for breast cancer (Adler and Chang, 2006; Buyse et al., 2006; Dai et al., 2005; Foekens et al., 2006; Glinsky et al., 2004a, b; Goncalves et al., 2006; Ivshina et al., 2006; Liu et al., 2007; Ma et al., 2004; Nuyten et al., 2006; Park et al., 2007; Pawitan et al., 2005; Thomassen et al., 2007; van 't Veer et al., 2002; van de Vijver et al., 2002; Wang et al., 2005a, b; Weigelt et al., 2005), ovarian cancer (De Cecco et al., 2004; Smith, 2002; Spentzos et al., 2004), colon cancer (Barrier et al., 2006; Giacomini et al., 2005), prostate cancer (Dhanasekaran et al., 2001; Glinsky et al., 2004a, b; Halvorsen et al., 2005; Lin et al., 2005; Luo et al., 2002; Singh et al., 2002; Xu et al., 2005), and brain cancer (Fuller et al., 2005; Kim et al., 2002), among others.

Biological Networks and the Interactome

Among the most promising opportunities presented by systems biology is the integrated assessment of multiple biological parameters to magnify our understanding of complex developmental or pathological states. The interaction among all individual biomolecules in complex regulatory, signal transduction, and feedback networks present in eukaryotic organisms forms the theoretical framework for this higher-order analysis and is referred to as the *interactome*. These dynamic associations include protein–protein interactions, transcriptional regulation, and post-transcriptional gene silencing by short-interfering RNA and microRNA (miRNA) (Ruvkun, 2001). Multiple high-throughput methods have been developed to characterize the interaction between proteins, including the yeast-two-hybrid system (Ito et al., 2001) and surface plasmon resonance (Usui-Aoki et al., 2005). These methods are to determining interactome interactions what microarray studies are to determining relative mRNA concentrations.

2009 UPDATE

An area of intense interest and progress during 2008 has been multiparameter blood-borne biomarkers. An important advance for making multiple protein measurements with high sensitivity in blood was the reported development of an integrated blood barcode chip (Fan et al., 2008). This microfluidic system has the ability to sensitively sample a large panel of protein biomarkers over a wide range of concentrations, a key challenge for the complex proteome in blood. This device holds the promise of inexpensive, highly sensitive measurements from just a pinprick droplet of blood.

In addition to protein biomarkers, a number of findings were made regarding other important possible sources of diagnostic information from the blood to guide systems medicine. One intriguing finding showed that when glioblastoma tumor cells release microvesicles, they are taken up by normal host cells and also ultimately appear in the blood (Skog et al., 2008). This study also showed that the tumor-specific EGFRvIII mutation was detected in serum microvesicles in a subset of patients. Such mutation-specific findings are critical to guide individualized therapies. In another study, it was found that miRNAs not only hold promise as tissue-based biomarkers, but that they also exist in stable forms in human plasma – as was demonstrated in a study of prostate cancer (Mitchell et al., 2008).

Outside of blood, markers in other accessible bodily fluids as well as tissue markers continued to show promises. For example, analysis of the average concentration over 24 h of certain metabolites found in urine was shown to reliably differentiate a number of different phenotypes, including blood pressure linked to coronary heart disease and stroke (Holmes et al., 2008). At the tissue level, a large study involving over 1000 patients showed that the use of panels of molecular markers

conclusively improved diagnosis substantially beyond diagnoses based on accepted risk factors, even in elderly patients (Zethelius et al., 2008). Gene expression and genetic profiles were also used to stratify breast cancer tumors, including cancer cells with stem-cell like properties (Shipitsin et al., 2007), a highly important cell population based on their demonstrated ability to regenerate tumors.

Progress was also made on deciphering protein networks of importance to systems medicine. For example, the proteome-wide mapping of interactions between hepatitis C virus and human proteins was performed (de Chassey et al., 2008). Close to 500 interactions were reported, which were enriched for highly interconnected proteins and that were related to cellular pathways targeted by the hepatitis C virus. Another important advance for uncovering the human proteome interaction network was the development of a novel analytical process for identifying human protein complexes (Glatter et al., 2009). This method was developed to improve upon current methods that are impeded because of low throughput, sensitivity, and robustness of existing procedures (Glatter et al., 2009). With this new method, the experimental identification of the human proteome interaction network should accelerate.

An example of a model for systems medicine can be found from the study of prion disease in mice (Hwang et al., 2009). Here the dynamic onset of the infectious prion disease in eight different inbred strain/prion strain combinations was studied at the level of mRNA in the brain (the affected organ) and showed that a series of interlocking protein networks that surround the prion protein are significantly perturbed across the 150-day span from disease initiation to death. It was shown that differential networks could be derived from comparisons of mRNA-expression patterns in normal and diseased brains at each of eight to ten time points after infection. The initial network changes occur well before the clinical signs of the disease can be detected and predict later widespread histopathological events. By subtractive analyses using various of the inbred mouse strain/prions strain combination and the application of powerful new statistical methods, a core of 333 changing mRNA transcripts were identified that mapped to four biological networks (prion replication and accumulation, astrocyte and microglial activation, bouton and axon degeneration, and nerve-cell death) that appear to encode the core prion-disease response. About two-thirds of these transcripts encoded and explained most of the known aspects of the pathophysiology of the disease and about one-third encoded aspects of the disease here-to-fore unknown. The dynamics of these four biological networks also suggested new approaches to therapy for prion disease. This study demonstrates the power of the systems approach to medicine in unraveling the complexities of disease mechanisms (Hwang et al., 2009).

Finally, high-throughput sequencing of individual human tumor samples is beginning to yield important information into human cancer that will enhance systems medicine going forward. Importantly, genomic sequencing studies perform unbiased genomic analyses that are uncovering novel mutations that are prevalent in tumors but were previously unknown, as was done for glioblastoma multiform (Parsons et al. 2008) as well as breast and colorectal cancers (Wood et al., 2007). In a study of 24 pancreatic cancers, it was found that they contain an average of 63 genetic alterations each (Jones et al., 2008). These mutations were found to define a core set of 12 signaling pathways whose dysregulation help explain the major features of pancreatic tumorigenesis (Jones et al., 2008).

Taken together, progress on many fronts continues to use systems approaches to drive toward a future of personalized, predictive, preventative, and participatory (P4) medicine.

CHAPTER

Electronic Medical Records in Genomic Medicine Practice and Research

Glenn S. Gerhard, Robert D. Langer, David J. Carey and Walter F. Stewart

INTRODUCTION

The implementation of electronic medical records (EMRs) is expected to substantially improve the quality and efficiency of health care and provide an important vehicle to advance patient-centered personalized care, the *sine quo non* of genomic medicine. In the United States, the use of EMRs in care delivery is expanding rapidly, especially among large integrated health delivery systems. The amount of clinically relevant genomic data and the number of resources devoted to research on genomic medicine are increasing in parallel. However, relatively few publications have yet addressed the use of EMRs in genomic medicine, although the need for such integration has been clearly established (Martin-Sanchez et al., 2004).

In this chapter, the role of EMRs in the practice of genomic medicine and their use for genomic research will be considered. The need for digital approaches to storing, processing, and using information is driven by the growing density of genomic data, whether derived from gene expression profiling, single nucleotide polymorphism (SNP) genotyping, or DNA sequencing, and from the pace of discovery. Moreover, the complexity of clinical decision-making will change commensurately as genetic data relevant to diagnosis and therapeutic interventions increases. Historically, the disciplines of medical (or clinical) informatics and biological informatics (or bioinformatics) have both evolved to address the needs of genomic medicine practice and research (Maojo and Kulikowski, 2003). Differences between the two communities have resulted in an attempt to integrate the approaches (Altman, 2000), with some proposing that health care organizations should be more proactive in collaborating with other public and private sector organizations in the development of an EMR containing both clinical and genomic data (Groen et al., 2005). These are laudable goals, but most of the work published thus far has come from those who have focused on the manipulation and analysis of genomic data for the clinical setting. However, the major factors driving the development of EMRs, such as quality measures, efficiency, and reimbursement, are not directly related to genomic medicine.

This chapter is written from the perspective of those involved in the use of EMRs in large integrated delivery systems that make use of data and populations for research. While the US health system is fragmented, the large health systems that are adopting EMRs are becoming increasingly integrated, especially in adopting and implementing practice standards (Orlova et al., 2005). A significant window of opportunity thus exists to incorporate various aspects of genomic medicine into the development of these emerging systems. The data relevant to genomic medicine are highly diverse and applicable to essentially all medical specialties. As a result, multiple approaches and solutions will likely need to be developed for the myriad of needs in genomic medicine research and practice (Stein, 2003; Sujansky, 2001).

EMRs AND GENOMIC MEDICINE CLINICAL PRACTICE

The EMR is a longitudinal electronic record of patient health information generated by encounters in any care delivery setting, encompassing patient demographics, progress notes, problem lists, medications, vital signs, past medical history, immunizations, laboratory data, and radiology reports. The EMR substitutes for traditional paper-based "charts". The EMR has the ability to generate a complete record of a clinical patient encounter, as well as supporting other care-related activities directly or indirectly, such as evidence-based decision support, quality management, and outcomes reporting. It may also be part of a solution to addressing a decades old problem of decreasing the long lag time that exists before evidence-based medical knowledge is routinely used in clinical care (Stewart et al., 2007). This may be of tremendous importance for the rapid progress being made in genomic medicine. In this section, the integration and use of genomics data in EMRs for the clinical practice of genomic medicine is discussed.

Example of an EMR

The Geisinger Clinic, a large integrated health system in northeastern and central Pennsylvania, initiated installation of an EMR (i.e., EpicCare) in 1996, which was completed (i.e., completely paperless operations) in all community practice sites and specialty clinics by 2001. The EMR contains patient information from a variety of sources that is routinely integrated into a common database and includes age, sex, height, weight, and other demographics; lifestyle data (e.g., smoking, alcohol, etc.); clinical measures (e.g., BP, pulmonary function, cardiac information); digital imaging (MRI, CT, X-ray); all orders (i.e., labs, prescriptions, imaging, procedures) that require at least one clinical indication (i.e., ICD-9 code); clinical notes, which are increasingly created using smart-sets, or structured protocols; and laboratory measures (including results of genetic and molecular tests). Patients have on-line access to their EMR in the EpiCare system through the My Geisinger Internet portal. With My Geisinger patients can securely access their EMR, schedule visits, and email their doctor. Such web-based communications represent future opportunities for genomic medicine research. To date, the Geisinger clinic EMR database contains information on more than 2.2 million patients.

Integration of Genomic Medicine Data into the EMR

EMRs make use of relational database structures and utilities to access and display data to facilitate medical care and clinical decision-making. Although most observers and users consider the EMR to be a single application, in reality there are multiple data feeds from disparate sources that comprise the EMR. Some data sources, for example laboratory information systems, are usually integrated with the main EMR application, while others, such as radiology, histopathology, and molecular data are incompletely integrated or are resident in entirely separate databases. Genomic data currently used for clinical practice are often generated by hospital, reference, or specialty laboratories that produce a wide variety of reporting formats, data types, and nomenclature (Ogino et al., 2007). Integration of these data into the EMR thus requires the ability to assemble the different data sources into an accessible format. Customized systems are sometimes developed in-house using on-site information technology expertise that are motivated by institution- and/or laboratory-specific needs and allow for flexibility and control over how the software evolves. However, the tendency is to invest significant resources into these in-house solutions, which sometimes underestimate the effort needed and fail to meet the intended goals. The choice of integration architecture and format for data representation are thus significant decisions and have a number of important issues associated with them (Haas et al., 2001).

The disparate sources that generate genomic data often report text-based data that are distributed through laboratory information systems into the EMR. These text results are commonly discrete, that is genotype A or genotype B, rather than continuous, although quantitative results are also produced, such as the number of trinucleotide repeats in the gene (*FMR1*) responsible for many cases of fragile X syndrome (Murray et al., 1997). Genomics results may also be reported in unique formats developed by diagnostic companies in niche markets. The disparate nature of the data and data sources further complicates the growing trend of integrating genomics data with other laboratory and/or clinically relevant data to generate a comprehensive clinical report. For example, cytogenetic and molecular remissions are recommended in reporting standards for acute myelogenous leukemia (Cheson et al., 2003). With the tendency of health care organizations towards the delivery of care in a service line structure and/or disease-specific care model (e.g., heart hospitals, neuroscience centers, etc.), more comprehensive and integrated reporting of genomic medicine results will likely be needed. This will apply to both genomic and other types of data-intensive results, such as proteomic and metabalomic data (Table 12.1).

Currently most genomic data generated for clinical care are in the form of a discrete result. However, as the cost of full DNA sequencing continues to decline (Bennett et al., 2005), it is likely that discrete and highly relevant-specific results will be provided along with a large amount of DNA sequence data that has no known clinical significance (Mitchell and Mitchell, 2007). Ultimately, complete genome sequencing may become the most cost effective means of identifying sequence variants (Hutchison, 2007). It would not be unexpected in the future if DNA sequence determination became the standard of care for every patient, even though most of the sequence data may not be relevant to clinical decisions. Prior to that, many smaller iterations of DNA sequence data will be determined, for example, comprehensive mutation detection for *BRCA1* and *BRCA2* (Myriad Genetics, Salt Lake City, Utah, "BRAC Analysis for *BRCA1* and *BRCA2*, Breast and Ovarian Cancer, Comprehensive Analysis"). In this analysis, full sequence determination in both forward and reverse directions of approximately 5400 base pairs comprising 22 coding exons and approximately 750 adjacent base pairs in the non-coding intervening sequences (introns) of the *BRCA1*

TABLE 12.1 Examples of genomic and other related data types potentially relevant for inclusion in the EMR

- DNA sequence data
- Single nucleotide polymorphism (i.e., SNP) genotypes
- Multiple nucleotide polymorphism (e.g., insertion, deletion, repeat) genotypes
- Cell and/or tissue-specific microarray gene expression profiles
- Proteomic (e.g., mass spectroscopy) profiles
- Glycomic (i.e., carbohydrate) structural data
- Lipomic (i.e., lipid) profiles
- Metabolic phenotypes

gene is made. For *BRCA2*, full sequence determination in both forward and reverse directions of approximately 10,200 base pairs comprising 26 coding exons and approximately 900 adjacent base pairs in the non-coding intervening sequence (intron) is performed. Similar sequence analysis is offered for several other gene or genes that are associated with specific inherited cancer syndromes. Such testing generates an enormous amount of extra information that is not currently clinically relevant. However, as new discoveries are eventually translated into practice, ready access to relevant DNA data on patients may become necessary.

How to maintain such dense sequencing data is thus an important decision (Mitchell and Mitchell, 2007). For example, placing every base sequenced into the patient's medical record may clutter the record with predominantly clinically insignificant data. Alternatively, only bases that differ from reference data may need to be tracked. Reference data may change, which may alter the interpretation of patient data. The American College of Medical Genetics (ACMG) has previously recommended a minimum amount of information for inclusion in DNA sequencing reports (ACMG, 2000). Important considerations include reporting of all of the bases sequenced, as well as linked sequence reference data. Such recommendations are likely to evolve as more clinical experience is acquired with sequence data.

Family History Data

An integral component of genomic medicine is the application of family history to clinical care. Interest in collecting family history data as a routine part of care delivery is growing, as knowledge advances in linking family history of disease to patient risk. Many common diseases, such as coronary heart disease, diabetes, several types of cancer, osteoporosis, and asthma, are known to occur more frequently in some families than in others; thus the identification of at-risk individuals is important for high quality medical care. Family history data are also necessary for research aimed at identifying environmental and/or genetic factors that may underlie these common diseases (Hopper et al., (2005)). However, the acquisition of such data by most physicians is inadequate, in part because tools do not exist for efficient, reliable, and valid collection and analysis of such data (Guttmacher et al., 2004). Structured family history data are almost universally absent in current EMRs.

The need for the development of better family history tools has been highlighted by projects at the Centers for Disease Control (CDC) and by the US Surgeon General's Family History Initiative (Wolpert, 2005). However, these efforts have not directly addressed the integration of tools into the real-world scenario of busy physicians and a multiplicity of health record systems, and do not provide an adequate breadth of data capture necessary for research. Various paper family history tools are available, as are various computer-based tools for drawing pedigrees (Trager et al., 2007). Several EMRs incorporate free text documentation of family history, while others allow for the development of family history templates and support checklists for taking and documenting family history. However, currently available tools are inadequate for many situations, especially primary care (Rich et al., 2004). The need for new tools is therefore apparent, and several characteristics of the ideal family history tool have been suggested, including patient-completed (e.g., paper, desktop, telephone, or web input), adapted to patient age, gender, ethnicity, common conditions, elicits-patient specific concerns, brief, understandable, easy to use, compatible with multiple clinical applications (e.g., paper, EMR, personal digital assistant), contains clinical decision support, and prioritizes based on clinical significance (Rich et al., 2004). No such electronic family history tools have yet been developed, despite the availability of suitable technologies.

EMRs, Genomic Medicine, and Clinical Decision Support

Genomic medicine is accelerating the growth of medical knowledge. In contrast, the means by which knowledge is translated into clinical practice have not evolved to keep up with the accelerating growth. Translation of knowledge into practice relies on a century-old tradition, the direct education of clinicians, an approach that was useful when knowledge was relatively limited. Today, it is not possible for most physicians to stay abreast of medical knowledge, especially genomics, and provide state-of-the-art care. The nuances in clinical decision-making in genomic medicine already render many care scenarios complex. Access to an EMR and the ongoing codification of medical knowledge (i.e., Clinical Practice Guidelines or CPGs) will be essential to addressing this growing translation gap.

CPGs greatly facilitate, but are not sufficient for translating knowledge to practice. Almost 2000 active CPGs exist in the US National Guideline Clearinghouse (Kozma, 2006) and an individual CPG may encompass dozens to hundreds of clinical recommendations. These recommendations will rapidly expand in the era of genomic medicine, and thus codification of knowledge will be essential to increasing its access. EMRs offer a platform to translate codified knowledge into real-time actionable processes. Genomic data will need to be accessed with other patient data located in disparate locations within the EMR and evaluated in relation to a rule set. Real-time actionable recommendations will need to be created and be supported by an integrated and intuitive visual display of information, such as a set of orders or recommendations for the physician or other care provider.

An example of clinical decision-making using an EMR potentially relevant to genomic medicine is a process with a specific focus on cardiovascular risk management in primary care being developed at the Geisinger Health System. The process involves a decision support rules "engine", external to the EMR, in which patient data such as labs, questionnaire data for phenotyping, and other clinical measures (Figure 12.1) are extracted in real time and evaluated in relation to clinical rules. The process can be used to generate a span of outputs including orders, clinical notes, and medication lists, etc. (Figure 12.2). The current model involves rules for smoking cessation, control of LDL, control of blood pressure, and management of other cardiovascular risk factors. Together, the combination of rules for different risk factors translates into more than 100,000 possible ordersets. The process itself demonstrates that it is technically feasible to develop and implement a comprehensive set of rules for state-of-the-art management of a clinical condition. Genetic variants reported to predispose to coronary heart disease (Samani et al., 2007) may impact this process and could greatly increase the number of ordersets.

Figure 12.1 Screenshot of EMR (Epic Systems, Corporation, Verona, WI). The software uses a tab-based design for access to medical record information including encounters, clinic notes, lab and imaging results, orders, medications, and procedures. These data can be extracted and used to automatically generate orders or recommendations, such as laboratory tests or imaging procedures for health maintenance or disease management.

Figure 12.2 Screenshot of EMR (Epic Systems, Corporation, Verona, WI). Examples of output from problem list, immunizations, allergies, medications, and health maintenance fields.

EMRs AND GENOMIC MEDICINE RESEARCH

The EMR offers an exciting opportunity for genomic medicine research, both as a tool and as a data resource. It also represents an economically efficient means of obtaining phenotypic data and biosamples for generating genotypic data. Initial large-scale efforts to use genomic and clinical information for research, for example, deCode Genetics in Iceland, required the conversion of medical information from paper records into an electronic format (Hoffman, 2007). Even current large-scale efforts, such as the UK BioBank (Ollier et al., 2005), are based upon a mix of paper and electronic sources. The EMR thus represents a potentially large increase in efficiency for obtaining phenotypic data, and as described below, can also be an extremely efficient tool for patient recruitment and biosample acquisition.

EMRs and Genome-Wide Association Studies

The continued acceleration in genotyping technologies has enabled a dramatic increase in the use of genome-wide association studies (GWAS) to identify genetic variants underlying a variety of clinical phenotypes. However, the very large sample sizes and the logistics of collecting phenotype data and biological samples often require multi-center studies with coordinating centers and are very costly and time consuming to complete. Moreover, multiple replication studies are essential to verify initial GWAS findings. The long time period and substantial costs in initiating population-based studies limits the scope of such approaches.

As an alternative, biorepositories are being developed to provide the resources necessary for GWAS. In Iceland (Hakonarson et al., 2003), the United Kingdom (Ollier et al., 2005), and elsewhere (Austin et al., 2003a), efforts are being made to link biobanking activities to national health records. In the United States, however, there are challenges with devising a national biobanking strategy (Austin et al., 2003b; Hsieh, 2004; McCarty et al., 2007; Sanner and Frazier, 2007). The US population is very heterogeneous, highly mobile, and health care is highly fragmented. Information on patients is highly dispersed and not in an easily accessible form. Hence, GWAS and related validation studies are largely conducted in conventional single project formats (i.e., *de novo* data collection), where there is a long lead-time between data acquisition and analysis.

In the United States, integrated delivery systems that use EMRs may be critical to addressing logistical challenges to conducting large-scale GWAS studies. While health care in the United States is highly fragmented, approximately 10% of care is provided by integrated delivery systems. Nationwide, these systems are undergoing a quiet revolution through the introduction of EMRs. Efforts to standardize data elements for research purposes and data sharing are being pursued by the larger systems (Hornbrook et al., 2005). There may be substantial opportunities to accelerate genomics research in the United States by leveraging the growing number of systems that are both adopting EMRs and creating biorepositories. However, there are many unanswered questions regarding whether such resources can be effectively used for genomics research. At the individual system level, there are questions regarding the quality, specificity, and completeness of data for phenotyping. In addition, little is known about system-level challenges that influence the quality and completeness of data captured during clinical encounters (e.g., impacts upon workflow, technical, and business priorities). Moreover, in some systems, even if quality data are available, there may be substantial technical, ethical, or policy barriers that limit access or use. Finally, GWAS and follow-up replication studies will require collaboration of multiple systems to achieve sample sizes that are sufficiently large, but there are enormous data quality, technical, and policy challenges to pooling data across institutions.

Using the EMR to Access Populations for GWAS

Case-control studies and family based studies have been the two primary designs for GWAS, but the economic efficiencies of the case-control format conducted within health systems are significant. Patient populations and inherent selection bias also impact GWAS, which may vary substantially depending on the source (e.g., primary care, specialty care, outpatient, inpatient). Primary care populations tend to be similar to general population samples with the exception that younger individuals (especially males) and individuals from lower middle-income strata (i.e., not eligible for Medicaid and no access to health care benefits through work) are under-represented. Selection bias inherent to specialty care samples depends on the extent to which there are competing providers in the same market and whether a provider has local, regional, national, or international reach. Selection bias increases directly in relation to market reach. These potential biases will be reflected in clinical data available in EMRs, depending upon where and when the system was installed.

Genetic heterogeneity in a population may also arise due to population structure and recent admixture and may confound the results of genetic association studies in unrelated individuals, leading to a potential excess of both false positive and false negative results (Ziv and Burchard, 2003). The degree of confounding is dependent in part on how genetically different the subgroups are within the population. For example, among many contemporary populations, recent admixture between two or more genetically distinct subgroups has added to the genetic complexity. In the United States, this complexity is particularly pertinent for admixed populations such as Latino- and African-Americans (Parra et al., 1998). Within indigenous continental population groups, European subpopulations appear to be the most similar to each other (Bowcock et al., 1994; Mountain and Cavalli-Sforza, 1997). The ability of an EMR to distinguish among ethnicities within its patient base may impact the usability of the data for GWAS.

The Geisinger MyCode Biorepository

The creation of biorepositories that are closely linked with EMRs may be an extremely efficient approach to genomic medicine research, especially for GWAS that require DNA samples from large populations with corresponding robust phenotypic data. The challenges to establishing such biorepositories involve complex institutional, legal, and social issues that also must be addressed. However, the EMR opens new opportunities to address these concerns, such as patients' safety, rights, informed consent, and privacy.

The Geisinger Clinic MyCode biorepository project is perhaps the first large-scale biobanking initiative built around an EMR. In this project, the EMR is used as a tool for identifying and recruiting patients, obtaining blood samples, and retrieving phenotype data. The primary goal of the MyCode project is to bank blood/serum/DNA samples from patients on a large-scale coupled with access to their EMR data. MyCode was initiated in 2007 to leverage the resources of the Geisinger Health System, an integrated delivery system offering healthcare services to residents of 31 of Pennsylvania's 67 counties, with a significant presence in central and northeastern Pennsylvania between Pittsburgh and Philadelphia. Census data indicate that in most counties, the out-migration rate is less than 1% per year, thus providing an extremely attractive population for longitudinal studies. The population within the Geisinger Clinic catchment area is relatively homogeneous. Based on available historical, demographic, and self-reported ethnicity data, the Geisinger population is almost entirely Caucasian of mixed European ancestry, with only small contributions from other continental population groups, such as African, Asian, or Latino. The relatively lower degree of genetic variation among European subpopulations, and the length of time for intermingling of European subgroups in Pennsylvania, also serves to minimize population stratification. Such a population straddles genetically homogeneous populations such as Iceland or Finland with strong founder effects, and admixed populations, now present in many urban areas.

The MyCode patient recruitment process (Figure 12.3) begins with a search of the EMR for patients scheduled to visit an outpatient or designated specialty clinic in which a consenter will be stationed. Eligible patients are identified through a daily EMR report, while consent status (e.g., consent/did not consent/ not interested) is verified in the patient's EMR to prevent unnecessary requests for participation at future appointments. Patients are invited to participate in MyCode through direct interaction with a project consenter. After consent, a standing order for the additional MyCode blood draw is placed in

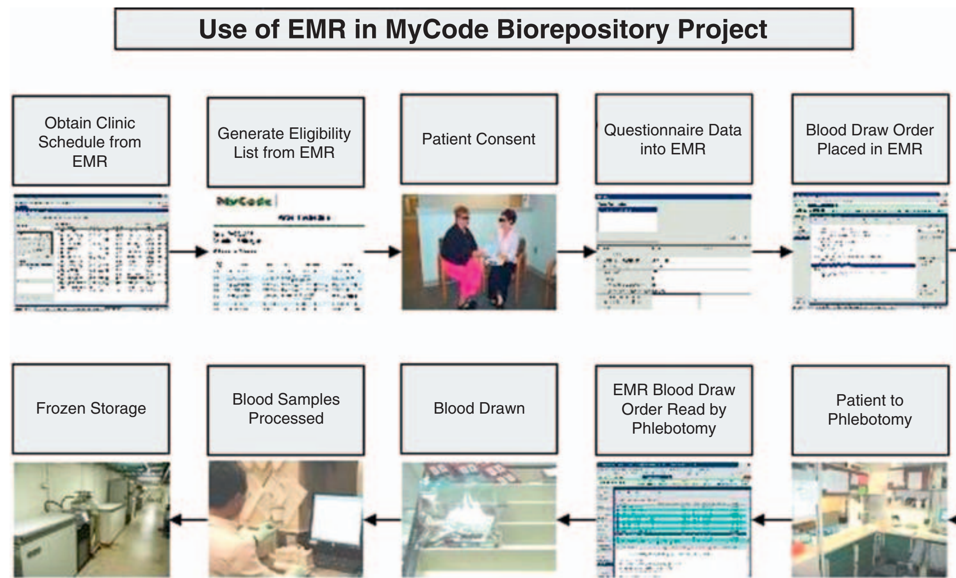

Figure 12.3 Use of the EMR in the MyCode Biorepository Project. The EMR functions as a tool at multiple points in the patient recruitment and consenting processes, and for acquisition of blood samples. The EMR also serves as the repository for phenotype data.

the EMR such that it is appended to the new order for blood work ordered by a physician at a future visit. With this strategy, blood is not specifically drawn for research which has resulted in high patient participation rates, as has been found in other studies (Sanner and Frazier, 2007). The sample collection process is highly efficient because it leverages the EMR (i.e., maintaining a standing order with an automatic protocol to activate the order), the laboratory infrastructure (e.g., standard protocols for phlebotomy, data systems, transportation of blood samples to a central location, etc.), and a passive low cost means of obtaining samples. Blood samples are transported from clinics across the Geisinger coverage region using the existing Geisinger Lab courier service to a central research laboratory that processes the samples for the MyCode biorepository. The EMR serves as the electronic enabler of the entire MyCode process.

The approach to creating the MyCode biorepository mitigates several methodological challenges with GWAS, including possible genotype errors, phenotype misclassification, and selection bias. While genotyping platforms are robust, DNA quality can affect genotyping results. Frozen blood and/or DNA are collected using the same protocol and processed using the same methodology. Errors in labeling patient samples are minimal, since an integrated clinical lab quality protocol is used for tracking samples from the point of phlebotomy to freezer storage. Phenotype misclassification is minimized through the use of careful case and control definition. Selection bias is minimized through the selection of cases and controls from the same population base.

Example of EMR Data Extraction

The EMR is a powerful and convenient source of phenotypic data for GWAS and genomic medicine research. A reference dataset has been created with a record for each patient in the Geisinger EMR population that includes demographics, physical measurements, personal medical history, health behaviors, laboratory tests, surgical and medical procedures, and medications prescribed. The dataset was developed to reflect the top 80% of elements most likely to be used for standard research purposes. Core data were extracted from the EMR using imbedded routines (known as Clarity), provided by the software vendor. Clarity tables can be manipulated using standard queries in SQL applications. The Clarity tables containing the specific elements in the data dictionary for a particular domain (e.g., physical measurements, or endocrine-related lab) are identified, and those fields are extracted into a text file. Typically, all instances of an element are pulled (e.g., the dataset contains all blood pressure measurements, or all glucose lab for a patient), not just the most recent or the first. The text file is read into SAS/STAT software (SAS Institute Inc., Cary, NC) and mapped to pre-defined fields. The resulting files are documented, cleaned and stored on a dedicated directory controlled by the biostatistics team. Analysis files are created by merging the appropriate data and applying any algorithms necessary for derived values.

As an example, this extraction of core data from the EMR can be used to obtain body mass index (BMI) data on over 270,000 adults (Table 12.2). Analyses were limited to adult patients 20 years of age and older. The mean and median BMIs were 28.4 and 27.2, respectively. Slightly over 30% of patients had a BMI ≤25 while 7.8% had a BMI of 40+. Patients with a BMI of 40+ were three times more likely to be female and more likely to be between 40 and 59 years of age (i.e., with 46.2% versus 29.6%) compared to those with a BMI ≤25. The relatively smaller proportion above age 60 and the gender bias may suggest a survival effect for this subgroup.

TABLE 12.2 Percent of adult patients by BMI and specific phenotypes

Phenotype	BMI Category			
	≤25 n = 80,861	>25, <30 n = 85,626	>30, <40 n = 83,298	40+ n = 21,187
Male	31.2	46.2	42.2	27.9
Female	68.8	53.8	57.8	72.1
Age <40	45.4	28.2	25.1	30.2
Age 40–59	29.6	36.5	40.7	46.2
Age 60+	25.0	35.3	34.2	23.6
Diagnosis of HTN	39.5	59.9	72.2	78.5
Diagnosis of LoHDL	18.8	28.2	39.8	47.8
Diagnosis of T2D	7.8	12.8	21.1	32.1
Diagnosis of HTN and LoHDL	13.3	23.4	34.4	42.5
Diagnosis of HTN and T2D	6.2	11.1	19.0	29.0
Diagnosis of LoHDL and T2D	5.3	9.0	15.3	23.6
Diagnosis of HTN, LoHDL, and T2D	4.9	8.3	14.4	22.2
No Diagnosis of HTN, LoHDL, or T2D	35.4	20.2	11.0	6.1

The prevalence of Type II diabetes (T2D), hypertension (HTN), and low HDL levels (LoHDL), and combinations of these, for each BMI subgroup was also determined. A patient was defined as having T2D or HTN if the condition was on the EMR Problem List (i.e., ICD-9 linked searchable fields) or if they had two encounters within 24 months where the condition(s) were listed as a reason for visit. HTN was also designated if there was any record of diastolic blood pressure of 90 mm Hg or more, or a systolic blood pressure of 140 mm Hg or more, or if the patient was taking an antihypertensive medication. T2D was designated if any of the following conditions were true: a random blood sugar of 200 or more, a hemoglobin A1C of 7% or higher, or if there was a prescription for insulin or an oral hypoglycemic medication. LoHDL was designated if the patient was male and had an HDL ≤35 or was female with an HDL ≤45 mg/dl. In general, prevalence of HTN, LoHDL, and T2D increase substantially in relation to BMI category. A diagnosis of all three conditions was found for 22.2% of those with a BMI of 40+, more than four times higher than the prevalence among those with normal BMI. In contrast, fully 35.4% of individuals with a BMI ≤25 had one of these conditions (as opposed to only 6.1% of patients with a BMI of 40+).

2009 UPDATE

The use of EMR data for genomic medicine research and practice is still in its early stages, but it is expanding rapidly and is evolving as a major platform to enable genomic medicine research. Our group published the first genomics paper based upon a comprehensive database of phenotypic information derived from an electronic medical record (Wood et al., 2008), supporting the feasibility of this approach and providing an initial example of an EMR-based genomic medicine research study. An important issue for such studies, as was emphasized, is the quality of the data, which may be influenced by practice variation among staff and clinicians (Yamada, 2008). Despite the potential disadvantages, the economic and temporal efficiency at which genotype–phenotype associations and replication studies can be performed with existing databases derived from EMRs coupled with biobanked blood/DNA samples is very promising.

Such promise has led to the initiation of large-scale biobanks at several health care organizations with long-standing electronic health records, similar to the Geisinger MyCode biorepository project described in this chapter. These projects plan to exploit the phenotypic information contained in electronic health records, but vary in their specific approaches. In one case, an "opt-out" model is used for patient consenting that is allowed for a de-identified mirror image of the EMR, a "synthetic derivative", to be linked to DNA extracted from leftover blood clinical samples (Roden et al., 2008). Algorithms for sample handling and procedures for de-identification were developed and validated in order to ensure acceptable error

rates. A strong advantage of this approach is the high rate of sample acquisition from the "opt out" consenting approach. In another large-scale biobanking effort, DNA samples will be sought from a patient population consisting of diverse social and genetic backgrounds (Nature News, 2009). Other projects have also been announced, so the next several years should see a blossoming of biorepositories in the United States and elsewhere.

The US National Institutes of Health has also realized the potential value of EMRs and has funded the electronic medical records and genomics (eMERGE) network (https://www.mc.vanderbilt.edu/victr/dcc/projects/acc/index.php/Main_Page), a five-member consortium formed to develop, disseminate, and apply approaches that combine DNA biorepositories with EMR systems for large-scale, high-throughput genetic research. The eMERGE network is designed to address whether EMRs can serve as resources for complex genomic analysis of disease susceptibility and therapeutic outcomes across diverse patient populations. In addition, the consortium will also address social and ethical issues, such as privacy and confidentiality. Issues involving the confidentiality, privacy, and security of EMR data for genomic studies have been addressed by others as well (Castle and DeBusk, 2008; McGuire et al., 2008).

Progress has also been made on the use of EMRs to collect family history data. The US Surgeon General's tool, "My Family Health Portrait" (https://familyhistory.hhs.gov), was re-issued with interoperability in an EMR environment using existing standards including the HL7 Family History Model, LOINC, SNOMED-CT, and HL7 Vocabulary. In addition, the tool includes information from the minimum core dataset for family health history as recommended by the American Health Information Community (Feero et al., 2008). At Geisinger, a pilot project was initiated to use the EMR web-portal, MyGeisinger, to collect family history information. A novel aspect of this approach is the automatic generation of an email alert message to a provider for patients indicating they have relevant family members with histories of premature heart attack, colon cancer, and breast cancer. The use of the EMR allows for the collection of actionable information relevant to preventative genomic medicine.

RECOMMENDED RESOURCES

James M. Walker (Editor), Eric J. Bieber (Editor), Frank Richards (Editor), *Implementing an Electronic Health Record System* (Health Informatics) Publisher: Springer 2004.

Implementing an Electronic Health Record System addresses the range of issues and opportunities that implementing an electronic health records system (EHR) poses for any size of medical organization-from the small one-man operation to a large healthcare system. The book is divided into sections on preparation, support, implementation and a summary and prospects section, enabling the clinician to define the framework necessary to implement and evaluate a clinically effective EHR system. With the increasing involvement of clinicians in the day-to-day running of the practice, interest is now focused on EHR as a key area for improving clinical efficiency. This book uniquely provides the guidance a clinical team needs to plan and execute an effective EHR system within any clinical setting.

CHAPTER

Online Health Information Retrieval by Consumers

Mark S. Boguski

INTRODUCTION

In an age of personalized medicine, nothing represents the *zeitgeist* more than individual consumers using the Internet and World Wide Web to seek medical and health information. According to surveys by the Jupiter organization and Harris Interactive, 71% of people who use the Internet also used it to seek health information in 2007, and this percentage, which represents an estimated 160 million people in the United States, had increased by 37% since 2005 (Anonymous, 2007b; Levy, 2007).

Consumers perform health information search (HIS) and retrieval (HIR) for themselves as well as for friends and family. Studies have shown that most of these consumers do not later discuss the information with a health-care provider and that, for many people, the Internet may be the primary or even sole source of health information. (Fox and Fallows, 2003). Seventy percent of people who obtain health information online say that it has influenced a decision about their treatment.

Clearly, it is important for health care professionals to understand how their patients find health information and the pitfalls associated with this activity. Indeed, given the challenges that consumers face in obtaining quality health care information from Internet sources, health-care providers will increasingly be in a position where they have to act as reviewers of information and as educators of patients who bring this information to their attention.

CHARACTERISTICS OF CONSUMER SEARCHES FOR HEALTH INFORMATION

A 2007 study by the Pew Internet & American Life Project (Fox, 2006) showed that the top 10 reasons American adults search online for health information are:

- a specific disease or medical condition;
- a particular medical treatment or procedure;
- diet, nutrition and supplements;
- exercise or fitness;
- prescription and non-prescription drugs;
- a particular doctor or hospital;
- alternative medicine or treatments;
- health insurance;
- mental health issues and
- environmental health hazards.

Zeng and Tse (Zeng and Tse, 2006) reported that, in performing searches, consumers use query terms that consist of "every-day language, technical terms (with or without knowledge of the underlying concepts) and various explanatory models, all influenced by psychosocial and cultural variations..." According to Lorence and Spink (Lorence and Spink, 2004), lay terminology is only partly effective in retrieving useful health

Copyright © 2010, Elsevier Inc.
All rights reserved.

information and often produces irrelevant or misleading information because, as reported by Zeng et al. (Zeng et al., 2006), "… the terms and concepts used by consumers often do not accurately reflect their information needs and therefore do not constitute effective queries."

Problems with such *consumer health vocabularies* may occur at various levels (Zeng et al., 2002):

- *Lexical* (form-level) mismatches (e.g., misspellings)
- *Semantic* misunderstanding (e.g., incomplete or misinterpretation of abbreviations or acronyms, over-generalization, redundancy)
- Misleading mental models, conceptual models that consumers employ either incorrectly and/or in a manner different than health care professionals.

Form-level (lexical) mismatches need no further explanation, as examples are easy to imagine. In the case of semantic mismatches, searches with general search engines may yield a large amount of irrelevant information. Consider the abbreviation "MS", which a consumer might use to mean *multiple sclerosis* but could also be interpreted to mean *Microsoft*, *mass spectrometry* or the state of *Mississippi* (Romacker et al., 2006). In another example, "CHF" would be interpreted as *congestive heart failure* by a physician whereas an international banker would interpret CHF as a unit of currency, the Swiss franc.

Other groups (Tse and Soergel, 2003) have similarly characterized problems with consumer health vocabularies on multiple levels, namely:

- *Shared forms/different concepts* (e.g., the phrase "the results of the [diagnostic] test were negative" could mean "unfavorable" in the mind of a patient but is usually a positive step forward in the mind of a physician.)
- *Different forms/shared concepts* (e.g., "blood cancer" is a lay term that a physician might refer to as a "hematologic malignancy." Likewise when a physician refers to "metastatic disease", the patient would say "the cancer has spread.")
- *Different forms/different concepts* (e.g., "Miracle cure" rather than a "statistically unlikely" or "idiopathic" remission of a disease, emergence from coma, etc.).

The most challenging HIS/HIR problems of all undoubtedly arise at the conceptual level because it is intimately tied to an individual's level of *health literacy* (McCray, 2005). Concept-level mismatches might include notions outside the framework of mainstream medicine such as homeopathy, acupuncture and other alternative medicine concepts. Another example is when a patient may focus on a body part (anatomical location) or symptom when a clinician might view the same problem in terms of pathophysiology or from a sub-specialty perspective. Even mainstream medical concepts are subject to significant cultural influences (Payer, 1996).

There have been a number of attempts and exploratory studies to map lay terminology to *controlled vocabularies* in a number of formal coding systems and comprehensive collections of medical terms such as *CTP, SNOMED, MeSH, ICD-9* and the *UMLS Metathesaurus* (Shortliffe et al., 2003). Furthermore, *ontologies* have been employed to perform *semantic* expansion on queries that may be too general or simplistic (see (Spasic et al., 2005) and below). The idea is to take queries consisting of consumer health terms and to translate or reformulate them into professional terms and qualifiers with the aim of improving query meaning, *precision* and *recall*. So far such experiments have met with only minor or mixed success (Plovnick and Zeng, 2004; Zeng et al., 2006). There is also the challenge of "back translating" from professional to consumer language the results of a search using a *reverse medical dictionary*. (See also Chapter 10.)

Two additional reasons for suboptimal performance of consumer HIS/HIR is short query length and low complexity. Consumer HIS/HIR queries tend to be very short and too general to be effective. Indeed one study found that 63% of consumer queries consisted of only a single word and only 10% contained more than two words (Zeng et al., 2002). Also, consumers are generally unaware of *stop words* that add little or nothing to search performance. Thus, limited knowledge of both medical vocabulary and query string search principles contributes to the construction of simplistic, ineffective queries. Another important aspect is the inability or unwillingness to construct complex queries (such as Boolean combinations of terms) even when such "advanced search" options are provided via simple check boxes. Users seem to prefer (or at least have become accustomed to) search and retrieval as an iterative process during which their goals are refined, focused or revised again and again (Fredin and Prabu, 1998) until either a satisfactory answer is obtained or they abandon the effort altogether due to frustration or fatigue. A precise, unambiguous and well-formed query would ideally produce the answer(s) one is looking for in the first iteration. This ideal assumes that the information sources containing the information exist and are accessible.

WHAT AND WHERE ARE CONSUMERS SEARCHING?

Equally important to how searches are formulated by consumers are the sources of the information that are being searched. As an editorial in the *British Medical Journal* put it: "…the internet has vastly increased the availability of information, but often what it offers is untailored, incomplete, irrelevant, and plain wrong" (Jones, 2003) although actual cases of harm have been difficult to document (Crocco et al., 2002). Online health information is problematic as it encompasses everything from evidence-based, peer-reviewed content in professional journals to advertiser-sponsored content and personal testimonials (Table 13.1). A consumer's online HIS/HIR experience may even be greatly influenced by non-substantive characteristics of a site such as an attractive and professional-looking appearance even though the quality of the underlying information is unknown.

Sixty-six percent of consumer HIS/HIR begin with a general search engine such as Google or Yahoo! (Fox, 2006), and the rest will start with one of a number of emerging or established

specialty sites that are surveyed in Table 13.1. These sites fall into four general categories (online libraries, e-magazines, search and social networking) that largely reflect their historical origins and/or stages of development. Although a complete description of the origins and development of these sites is beyond the scope of this chapter, one pioneering organization deserves special mention.

Online medical libraries date back to mid-1960s, when the US National Library of Medicine (NLM) experimented with teletypewriter machines and satellite communications (Schoolman and Lindberg, 1988). Searches at this time were not interactive but rather conducted by "batch processing." In the early 1970s, interactive searches of NLM's MEDLINE became possible through dedicated remote terminals in 10 regional and 14 large academic medical libraries (Atlas, 2000). During this era, users of these systems were trained librarians who learned specific query commands and retrieval protocols. It was not until after the advent of personal computers that online search of the medical literature became accessible to consumers. In 1986 a computer application named "Grateful Med," that ran on IBM-compatible DOS computers was produced by NLM, was distributed at a cost of $9.95 through the National Technical Information Service of the US Department of Commerce (Schoolman and Lindberg, 1988). Using Grateful Med and a 300 bits-per-second modem, users could use dial-up telephone lines to NLM computers and receive literature citations. The current descendents of these pioneering efforts are PubMed (Wheeler et al., 2007) for the professional literature and MedlinePlus (Miller et al., 2004) for consumer information.

The Dot-com era from 1995 to 2001 (2007) was characterized by experimentation with new sites and services, including commercial entities supported by sponsored advertising. Compared with online "libraries," which maintained content and user interfaces more oriented toward health care professions than consumers, Dot-com era sites introduced magazine-type articles and layouts focused on non-professional users, enabled by the development of web browsers such as NCSA Mosaic (later named Netscape Navigator (2007)). Somewhat prior to this, sites providing comprehensive ("horizontal") Internet search were mainly being used by academic researchers and computer professionals (e.g., (Boguski and Ouellette, 1995)). But gradually, at first, search engines of the time (e.g., AltaVista (2007)) began to index content that expanded into the consumer realm. The ascendance of horizontal Internet search by companies like Yahoo! (2007) and Google (2007) has recently led to the emergence of several start-up companies applying a similar approach to deep *vertical* (specialized) health care content on the web (Table 13.1). The latest experimentation with consumer-oriented, medically-oriented websites involves social-networking, following the example of more horizontal (although demographically differentiated) social-networking communities and sites (e.g., MySpace (2007) and Facebook (2007)).

In July 14, 2007 article in the *Wall Street Journal*, Borzo reported running a variety of searches on several vertical health sites and noted that many features were not self-evident and required repeated experimentation to uncover. Borzo's overall conclusion from this limited, non-scientific study was that conducting a useful search requires the consumer to run multiple queries on several sites and to then compare the results and reach their own consensus on the adequacy and usefulness of the retrieved information. These observations are consistent with more formal research (Fox, 2006). Borzo did not examine, however, the underlying sourcing and quality of the information. When one examines this aspect, a perplexing assortment of both public and propriety

information from both consumer-oriented sources as well as sources designed for medical professionals is revealed (Table 13.2).

Only a tiny fraction of Internet health information sites publish any sourcing and date-stamped information or other information quality indicators (Anonymous, 2007). Published guidelines for quality assurance and quality control are rare and consumers are left to evaluate the quality of the information based on whether or not they consider the site to be a trusted "brand." Given this situation, and the difficulty non-professionals have in constructing effective queries (see previous section), the best advice on Internet HIS/HIR that one can give to the consumer at the present time is to validate their findings with a health care professional. The US National Library of Medicine provides information for consumers to finding health information and includes a "Guide to Healthy Web Surfing" at their MedlinePlus site (Table 13.1).

PERSONALIZED GENOMICS FOR CONSUMERS

Personalized genomics involving DNA polymorphism scans (e.g., see (Weber, 2006)) is currently in a tumultuous gestational stage that will ultimately lead to a new way to teach and practice medicine (Childs et al., 2005 (see Chapter 1).) Consider the following examples:

- A father uses commodity DNA sequencing technologies and publicly-available medical databases to investigate the elusive cause of his daughter's genetic illness (Maher, 2007).
- A controversial scientist publishes his autobiography which is partially based on the complete sequence of his own genome (Venter, 2007).
- A Harvard geneticist launches a *Personal Genome Project* (Table 13.3) to encourage medical altruism and self-knowledge, makes his own biological material available for study and encourages others to volunteer to do likewise (Church, 2005).
- Several start-up companies (one of which is backed by Google) form to provide genotyping services as direct-to-consumer (DTC) businesses (Winslow, 2007) and Table 13.3.
- The cover story of *WIRED* magazine asserts that "a new $1000 DNA test can tell how you'll live – and die" (Goetz, 2007).

The ethical, legal and social issues arising in this milieu certainly signify a brave new world well beyond the scope of this chapter. But what are the medical issues? Kohane and colleagues (Kohane et al., 2006) consider the situation "a threat to genomic medicine" because the volume and complexity of genotypes

Table 13.3 Selected Sites of Interest for Personal Genomics*

Site	Services Offered	Cost
Not-for-Profit		
www.MyDaughtersDNA.org	"a forum for those searching for explanations and the help of the interested community of geneticists, patients, physicians, scientists and family members"	Not applicable
Personal Genome Project www.pgen.us	"focuses on the practical issues of recruiting and informing volunteers… a test bed for personalized medicine and new ways of interfacing with the research subjects"	Not applicable
Commercial Businesses		
23andMe Personal Genome Service www.23andme.com	"personal insight into ancestry, genealogy, and inherited traits"	Not available
Navigenics www.navigenics.com	"a personalized genetic analysis that, combined with relevant health and wellness information, enables a far more personalized health strategy for each individual"	$2500
deCODE genetics www.decode.com	"Subscribers … can take their genome and examine it in the context of the literature"	$985 (Introductory, promotional price)

*Information current as of November 16, 2007.

and their statistical, phenotypic associations will undoubtedly lead to a plethora of incidental, "abnormal" findings that will be pursued at great cost but little benefit by the patients and their physicians. A person's genotype will become an "incidentalome" – analogous to the *incidentalomas* (Mirilas and Skandalakis, 2002) recognized by a previous generation of physicians but unbelievably more complex. Kohane and colleagues call for several key actions including the creation of information systems for "estimating and explaining the risks associated with various incidental genomic findings" (Kohane et al., 2006). They envisioned such systems as being used by medical professionals "…in the clinic and at the bedside." However, it is likely that consumer versions will lead the way as patients "surf the web" trying to understand the implications of their genotypes and manage their personal health accordingly. Dr. Google has office hours 24/7.

2009 UPDATE

A New York Times' article by Tara Parker-Pope entitled *You're sick. Now what? Knowledge is power*, discusses the use of the Internet by consumers seeking health information (Parker-Pope, 2008). In this article, Dr. Marisa Weiss, founder of breastcancer.org, states: "I don't think people have a choice – it's mandatory…The time you have to spend with your doctor is getting progressively shorter, yet there's so much more to talk about. You have to prepare for this important meeting." This situation represents a great potential for enhancing the value of clinical encounters between patients and providers and improving the overall efficiency of the healthcare system, provided that the central challenge of locating and retrieving reliable and personalized health information can be met.

The sources that consumers might consult in preparation for important meetings with their physicians remain highly variable and are rapidly changing. For example, of the new health search portals listed in Tables 13.1 and 13.2, the *MammaHealth* search service is no longer available, *MedStory* has not developed further, and *Kosmix* has split its health coverage into an odd assortment of subcategories such as Health Law, Fashion Health and films, magazines, and even rock bands that have the term "health" in their titles. The general search engines, particularly Google and Microsoft Live Search, have improved their medical search algorithms using a mechanism for query refinement (see Table 13.4) and by apparently "hard-coding" some links to credible, authoritative sources.

Treatment Information

Information on drugs and other treatments from the US Food and Drug Administration (FDA) has historically been designed not for patients but for "learned intermediaries," that is physicians and other healthcare professionals (Goetz and Growden, 2008). Recent studies by the Institute of Medicine (IOM) of the US National Academy of Sciences, however, have stressed the need to "help the public get the accurate, science-based

TABLE 13.4 Results from query term "diabetes"

Google

information they need to use medicines and foods to improve their health" and specifically recommended "that Congress enact legislation to establish a new FDA advisory committee on communication with patients and consumers" (Baciu et al., 2007). Moreover, the same report noted that "patients historically have been left out of the loop in much of the communication…" and also noted "…a shift in the formerly passive role of the patient…" A separate but related study from the IOM reported that "patients often leave the doctor's office with very little information about what drugs they are taking, what they are used for, and how they should be taken," and "few patients are given any sort of printed material about their medications" (Hernandez, 2007).

As a partial solution to these problems, the National Library of Medicine, working with the FDA, provides two web pages (dailymed.nlm.nih.gov/dailymed/about.cfm and www.nlm.nih.gov/medlineplus/druginformation.html), but these sites are extremely limited in their search capabilities, permitting only browsing or alphabetical searching by the first letter of a drug's name.

Personally Controlled Electronic Health Records

Within the past two years, Microsoft Corporation (Lohr, 2007), Google (Lohr, 2008), and a consortium of major employers called Dossia (McWilliams, 2007) have launched services to provide portable, electronic, personally controlled health records (PCHR) to consumers. With the motivation to reduce the risk of medical errors and spare the expense of missing records and unnecessary treatment (Goetz, 2007), it is hoped that doctors and medical practices will be largely converted to these from paper records by 2014, although this goal may be a bit too optimistic (Steenhuysen, 2008).

Electronic health records have the potential to permit consumers to customize or personalize their medical Internet search activities, in much the same manner in which online travel agencies such as *Orbitz* can tailor their products and services to individuals based on voluntarily submitted personal preferences.

Clinical and Recreational Genomics

In September 2008, the personal genotyping company 23andMe lowered its price for a genome-wide, single nucleotide polymorphism (SNP) scan from $999 to $399 and held a marketing event (dubbed "spit party" in reference to its saliva sample collection procedure) that was reported in the *Style Section* of the *New York Times* (Salkin, 2008). In this article, Dr. Alan Guttmacher, acting Director of the US National Human Genome Research Institute, has quoted a saying: "People think if you have the money to spend on this, why not by a test instead of a model train for Christmas." DTC genomics has leaped far outside the domain of learned intermediaries and it will undoubtedly be some years before the medical profession can catch up by assimilating genomics into medical education, training, and practice (Boguski, 2008). In the meantime, it's *caveat emptor* for consumers. Kaye (2008) discusses many of the important ethical, social, and legal implications of DTC genomics and its regulation.

The principal consumer genomics companies, 23andMe, deCODEme and Navigenics, currently genotype approximately 500,000 to 1,000,000 SNPs and report associations of up to 100 diseases and conditions ("traits," "characteristics"). 23andMe and deCODEme use the Illumina human 1M duo bead chip platform for their assays (www.illumina.com), whereas Navigenics uses the Affymetrix Gnome-wide SNP Array 6.0 technology (www.affymetrix.com). Thirty of these diseases or conditions are common to either two or all three of the companies (Tables 13.5 and 13.6). Each company has its own heuristic methods for determining and reporting risks of disease associated with these polymorphisms (e.g., relative risk, lifetime risk); the associations themselves are derived from published literature.

A number of people (including this author) have had themselves genotyped by all three of these companies in order to compare and contrast their services and features, and to assess the consistency of results. Davies (2008) had himself genotyped by the three major companies and also a fourth company, SeqWright (www.seqwright.com), that entered this marketplace in January 2008 and, like Navigenics, uses the 500,000 SNP Affymetrix GeneChip platform. Davies reported general agreement among results obtained from the different companies, but also noted some disagreements or discrepancies and their possible causes. A detailed analysis of my experiences is in preparation, but a preliminary account is available as a "Grand Rounds" presentation (Boguski, 2009).

TABLE 13.5 Disease Markers Detected by 23andMe, deCODEme and Navigenics

Diseases covered by all three companies[a]	SNP associations[b]
Age-related macular degeneration	rs1061147, rs547154, rs3750847
Atrial fibrillation	
Breast cancer	rs1219648, rs3803662
Celiac disease	rs2187668
Colorectal cancer	rs2187668
Crohn's disease	rs2066844, rs2066845, rs2066847, rs11209026, rs2241880, rs7714584, rs3197999, rs11190140, rs17234657, rs1893217, rs11805303, rs10210302, rs10761659
Glaucoma	
Heart attack	rs2383207
Lung cancer	rs8034191
Multiple sclerosis	rs6897932, rs3135388
Obesity	rs3751812
Prostate cancer	rs1447295, rs6983267, rs10505483, rs1859962, rs4430796
Psoriasis	rs10484554, rs3212227, rs11209026
Restless leg syndrome	rs3923809
Rheumatoid arthritis	rs6457617, rs11203366, rs2476601, rs3890745, rs2327832, rs3761847
Type 2 diabetes	rs7903146, rs1801282, rs5219, rs4402960, rs1111875, rs4712523, rs13266634, rs10012946, rs2383208

TABLE 13.6 Conditions Detected by Personal Genomics Companies

Diseases and other phenotypes covered by two out of three companies	SNP associations
Abdominal aortic aneurysm	
Alcohol flush reaction	rs671
Alzheimer's disease	
Asthma	
Bitter taste perception	rs713598
Intracranial aneurysm	
Lactose intolerance	rs4988235
Lupus (systemic lupus erythematosis)	rs9888739, rs7574865, rs2187668, rs10488631
Nicotine dependence	
Osteoarthritis	
Peripheral arterial disease	
Type 1 diabetes	rs3129934, rs3087243, rs1990760, rs3741208, rs1893217, rs2476601, rs3184504, rs725613
Venous thromboembolism	rs6025, i3002432

[a]Information current as of January 15, 2009.
[b]SNPs included in table are from the 23andMe website, specifically those pages that are accessible without a subscription. SNPs are referenced by their dbSNP ("rs") numbers – unique identifiers that can be used to locate extensive information about SNPs and their associations at www.ncbi.nlm.nih.gov/projects/SNP/. SNPedia (www.snpedia.com) is another useful resource.

As described earlier, the consumer genotyping companies report on up to 100 diseases and conditions that have been linked to genetic polymorphisms in published, genome-wide association studies (GWAS). However, there are many more than 100 published GWAS associations, and each company selects those it will report on according to their own criteria. For example, Davies describes the "decision heuristic" used by Navigenics to select diseases that it will cover (Davies, 2008). However, each of the companies also makes the primary genotype data available, and one company, SNPedia, has developed a software tool they call *Promethease* which allows one to generate their own reports based upon the primary data (Cariaso and Lennon, 2009).

Over the next several years, the technology platforms for personal genomics are expected to shift from SNP genotyping to complete DNA sequencing as so-called "Next Generation Sequencing" technologies continue to advance toward the "$1000 genome" (Mardis, 2006; Pollack, 2008).

CHAPTER

Translational Genomics: From Discovery to Clinical Practice

Geoffrey S. Ginsburg

INTRODUCTION

The use of genomic technologies to improve medical decision-making so as to achieve the goal of personalized medicine is poised to transform health care (Ginsburg and McCarthy, 2001; Ginsburg et al., 2005; Snyderman and Williams, 2003; Willard et al., 2005). New knowledge from the study of genomes and their by-products now has permitted the development of predictors of disease predisposition ("who is at risk"), prognosis ("who to treat") and therapeutic response ("how to treat") in individual patients and thus provides an opportunity to employ these predictors in present day practice. Many of these opportunities are highlighted in this book in which an astounding number of genome-based discoveries are defined with the potential to fundamentally alter how medicine is practiced in cardiovascular disease, oncology, metabolic disease, neuropsychiatric disorders, infectious disease and diseases with a basic inflammatory component.

The rate of genome-based discovery is stunning. However, despite the vast amount of genomic information now in the scientific literature, the translation of basic scientific findings from the genome and its derivative products, RNA and protein, to daily use in medical practice has been slow (Graham et al., 2006; Sung et al., 2003). It now takes an average of 17 years for 14% of scientific discoveries to enter day-to-day practice (Westfall et al., 2007). For genomic discoveries, the path is undoubtedly more complex.

The research paradigm for translational genomics is inconsistent and nonsystematic; multiple, and in some cases non-linear, pathways to translation of genomics to clinical medicine exist. For example, diagnostic companies have traditionally "cherry-picked" a narrow repertoire of new genomics-based molecular diagnostics from academic laboratories and the literature. The pharmaceutical industry has developed "targeted therapies" such as trastuzamab, imatinib and erlotinib that use molecular diagnostic tests – some of which are based on genetic variation (Lynch et al., 2004) – to identify individual patients who are likely to benefit from the drug. The lack of a clear system of regulatory oversight of genetic and genomic tests has led to gaps and ambiguity in the pathways of translation, an area that the US Secretary's Advisory Committee on Genetics, Health and Society has recently addressed (SACGHS, 2007). Personal genomics and direct-to-consumer avenues are being opened to bring genomics directly to the public, thus circumventing the traditional health care delivery and regulatory channels (Feero et al., 2008; Hunter et al., 2008; Janssens et al., 2008; McGuire et al., 2007).

These issues speak to the need for a comprehensive agenda for translational research to move human genome discoveries into health practice. This chapter will focus on paradigms

for translational genomics to human health as well as the various opportunities, challenges, and strategies that will enable the effective translation of human genome information to clinically relevant actions and outcomes.

A ROADMAP FOR TRANSLATION

Khoury and colleagues (2007) have developed a framework for the acceleration of human genome discoveries into health care and disease prevention. This is a logical first step in guiding genomic innovation to health care and more widespread use. The framework (Table 14.1) contemplates four phases of translational research from discovery to public health impact. T1 research seeks to move a basic genome-based discovery into a candidate health application (e.g., the association of a gene mutation with a health outcome). This phase of research starts after gene discovery and provides the early evidence that genomic information might support predictive testing, screening, diagnostic, prognostic or pharmacogenomic testing. T1 research will usually take advantage of observational studies or clinical trials where the correlation of the genomic information with health characteristics or outcome can first be made. T2 research assesses the value of a genomic application for health practice, leading to the development of evidence-based guidelines (e.g., prospective or retrospective assessment of the predictive value of the mutation test for the health outcome). This phase of research usually begins after the analytical validity of the test has been established and progresses to establish clinical utility, or impact on clinical decision-making. T3 research examines the pathways for delivery, dissemination, and diffusion of genomic testing into practice (e.g., defining the barriers to the use of the test in relevant populations). Public–private partnerships will usually be required to facilitate T3 research, and this research phase will also involve policy makers, regulatory bodies, professional organizations and insurers. Finally, T4 research assesses the impact on human health (e.g., outcomes studies across a broad and diverse population). This area of research is about the results of the implementation, as opposed to the implementation research itself (T3).

TABLE 14.1 The continuum of translation research in genomic medicine: Types of research

Translation research phase	Notation	Types of research
T1	Discovery to candidate health application	Phases I and II clinical trials; observational studies
T2	Health application to evidence-based practice guidelines	Phase III clinical trials; observational studies; evidence synthesis and guidelines development
T3	Practice guidelines to health practice	Dissemination research; implementation research; diffusion research; Phase IV clinical trials
T4	Practice to population health impact	Outcomes research (included many disciplines); population monitoring of morbidity, mortality, benefits and risk

Adapted from Khoury et al. (2007).

T1 research is illustrated in many of the clinical chapters in this book that highlight genomic discoveries with potential disease relevance. The molecular signatures described by Dave et al. (2006), Bullinger and Valk (2005) and Potti et al. (2006) to stratify and number of cancer phenotypes based on their molecular signature are illustrative. Examples of T2 research are found in Marcom et al. (2008) and Potti et al. (2006), in which a genomic-guided clinical trial design is described that uses a microarray-based molecular profile to assign patients to the various treatment arms in the trial. The clinical outcomes in the trial are dependent on the genomic signatures and the evidence for the genomic application to humans will be determined by these prospective studies. Examples of T3 research are described in Khoury et al. (2007) as surveys of physicians, internists and oncologists on the knowledge of genetic testing for susceptibility for breast and ovarian cancers. This information would provide support for the basis of strategies to enhance the dissemination of innovative genomic tools and information. T4 research is ongoing in areas such as *BRCA1* testing for hereditary breast and ovarian cancers or for HNPCC testing in colon cancer (see Chapters 35 and 36). In these early cases, the value of such testing is being assessed on a population level in terms of survival, quality of life and economic value. We are clearly in the early days of T2–T4 research.

WHERE CAN GENOMICS HAVE IMPACT IN THE CONTINUUM OF HEALTH AND DISEASE?

DNA-based approaches (SNP detection, copy number variation and sequencing) (see Chapters 3–5) can now be used to quantify one's predisposition, susceptibility, and risk for complex diseases. These measures can be made during health and even at birth or at any time point over a person's lifetime, as these "stable" genomic measures do not change from the time of conception. Individual SNPs or multi-SNP panels are emerging from genome-wide approaches that might be used as part of health risk assessment (see e.g.: Bare et al., 2007; Zheng et al., 2008). DNA variation may also provide information about the possibility of being relatively protected from disease development

(Cox et al., 2007), as well as one's sensitivity or resistance to certain medications (Eichelbaum et al., 2006) and ability to metabolize nutrients in our diets (Ordovas and Corella, 2004).

All of this can and probably should be done early in life, such that a strategy to maintain health can be formulated well in advance of the development of potentially detrimental lifestyle habits and exposures. The "dynamic" components of the genome (gene-, protein- and metabolite expression; see Chapter 2) that are responsive to environmental stimuli, lifestyles, diets and pathogens are rapidly improving capabilities to predict and intervene at an individual level. Transcriptional profiles, protein expression and levels of metabolites combined with dynamic imaging modalities should provide more precise ways to screen individuals who are at high risk for developing a disease for its earliest molecular manifestations while the disease is subclinical (Seo and Ginsburg, 2005). This same type of information may also provide a definitive diagnosis and a molecular classification of a disease state that foretells prognosis.

For example, today a *her2/neu*-positive breast cancer ascribes that patient to a more aggressive form of the disease and directs care to a much different course than a *her2/neu* negative cancer (see Chapter 35). Similarly the selection of drugs can be guided both by the patients underlying genetic make up and by the molecular architecture of the disease in the individual (see Chapter 15). The emerging picture is one of applied genomics *throughout* an individual's lifetime, from health through death, that enables assessment of disease predisposition, screening, diagnosis, prognosis, therapeutic selection with precision that until now has been unachievable (Figure 14.1). "Strategic health planning" (see Chapter 17 and Snyderman and Yoediono, 2006) and disease prevention should be possible and will allow a shift in the current paradigm of care from the time when disease is manifest (rightward in Figure 14.1) to proactive personalized predictive care at a more cost-effective time in the disease life cycle (leftward in Figure 14.1).

TRANSLATIONAL GENOMICS: ENABLING COMPETENCIES

The pharmaceutical industry has a clearly defined and decision-gated series of steps to move a potential therapeutic from discovery to the clinic. Translational genomics may also benefit from defining the processes, the key competencies, and capabilities that support the directional movement of genomics from discovery to human health applications (Khoury et al., 2007). Figure 14.2 is a potential (and admittedly simplified) schema for moving genomic discoveries from bench to bedside from the perspective of needed and enabling capabilities and competencies. Academic centers, industry and government research groups right benefit from developing organizing principles to move a potential genomic discovery into practice through a variety of stages similar to what the pharmaceutical industry has done for drug development candidates. Below and in the ensuing chapters, we will consider these capabilities in greater detail.

Centralized Biobanking and Biorepositories

Biobanks – centralized, institutional repositories for biological samples – are among the most important enabling resources in

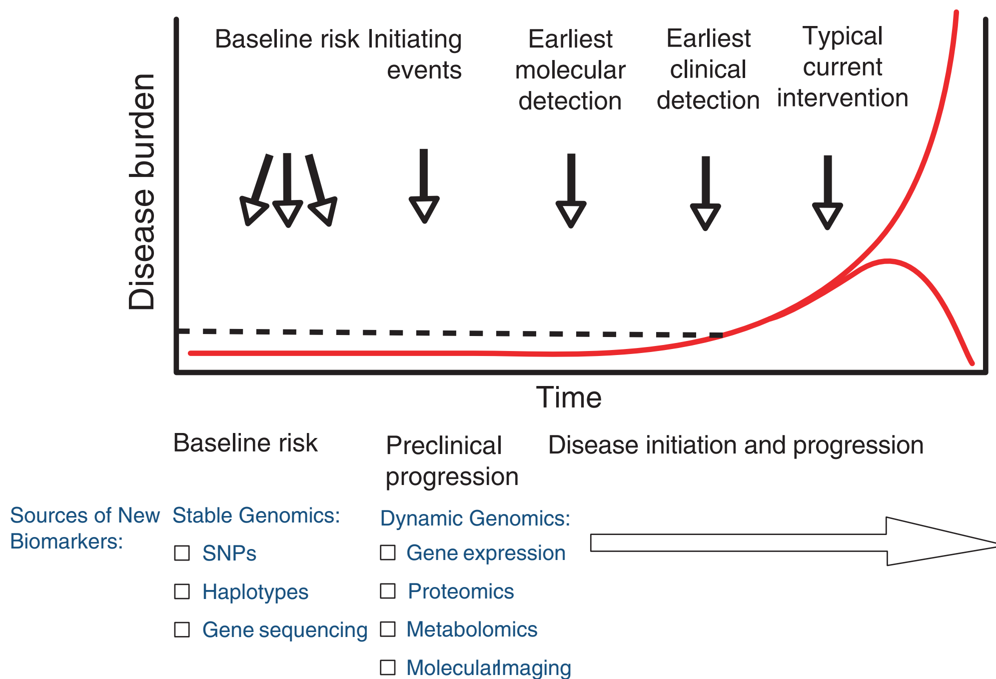

Figure 14.1 Use of genomic markers predict, prognose, diagnose, treat and monitor health and disease (adapted from Snyderman and Yoediono, 2006).

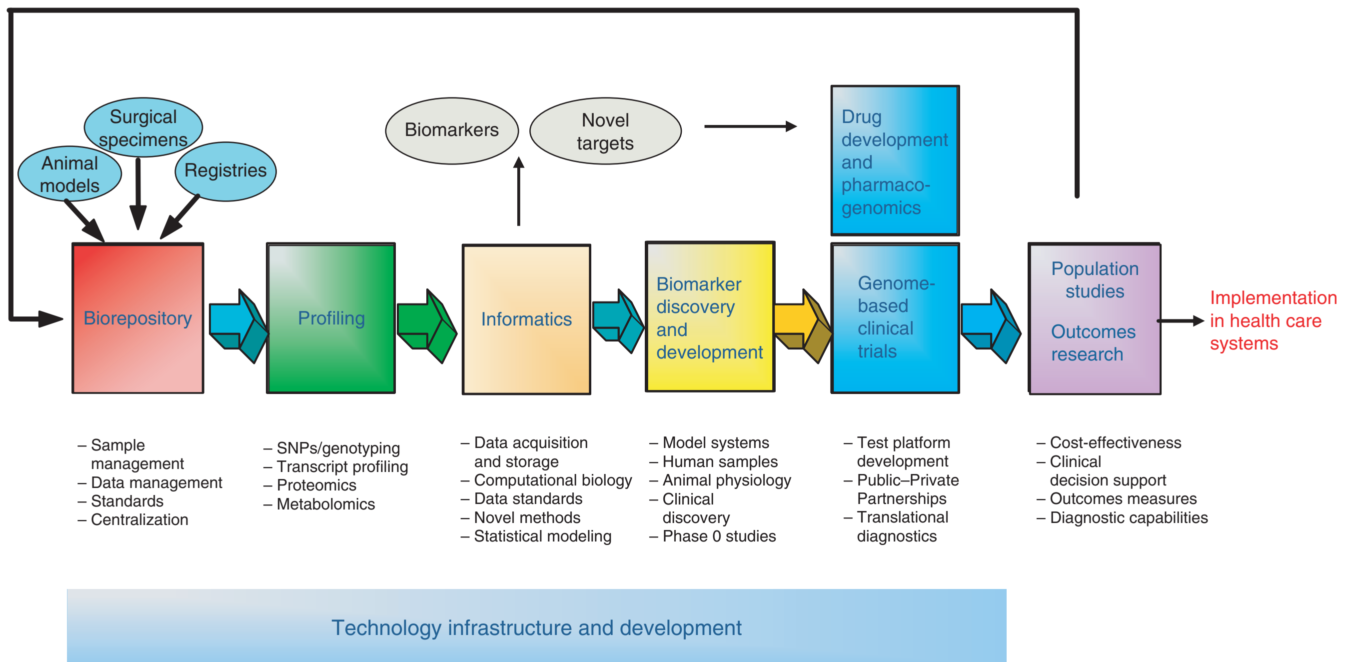

Figure 14.2 Enabling capabilities and competencies to translation genomic-based discoveries into health care applications. Based on Willard et al., 2005.

support of genomic medicine (Ginsburg et al., 2008). The study of complex diseases has been greatly facilitated by the availability of well-annotated DNA, blood and tissue specimens for high-throughput genomic analyses. Scale and scope characterize biobanks today from previous tissue repositories in Departments of Pathology or held by individual investigators. Today biobanks manage hundreds of thousands to millions of samples and require robotics and advanced informatics tools. Key capabilities for efficient and effective biobanking include centralized sample and data management systems and clearly define standards for handling of samples and their associated data. Equally important is the ability of biobanks to provide support for longitudinal studies enabling sample and data capturing in the entire disease cycle from pre-disease onset, to disease diagnosis, and clinical outcomes.

Several existing and developing biobanking models highlight developing trends in biobanking organization and management. The Singapore experience is particularly instructive in that the establishment of a national biobank was coupled with simultaneous development of the entire biomedical research infrastructure at an accelerated pace. Key considerations involve professional acceptance, custodianship, security and access. Data privacy for subjects is of paramount importance and applications of informatics technologies may provide the requisite security. Once properly implemented, biobanks may not only accelerate medical research but also contribute to public health.

Genomic "Profiling"

There are many sources of genomic data (see Chapters 3–9) that can now be applied to an integrated view of genomic epidemiology. A competency in genomic profiling technologies is clearly needed to optimize the value of clinical samples and data to develop novel predictive models of disease states and outcomes. The information provided by today's clinical and biochemical markers of disease falls well short of an adequately describing disease complexity and heterogeneity (West et al., 2006). The advent of the full complement of technologies spawned by the Human Genome Project capable of interrogating complex diseases such as cancer, cardiovascular disease, obesity and diabetes mellitus provides opportunities for acquiring quantitative data that can match the complexity of the disease. Genomic technologies can now potentially capture data that do provide this complexity, identifying discrete subsets of disease that have not been previously recognized. Profiles and patterns that identify new subclasses of tumors, such as the distinction between acute myeloid leukemia and acute myeloid leukemia (Bullinger and Valk, 2005), or Burkitt's lymphoma from diffuse B cell lymphomas (Dave et al., 2006), without prior knowledge of the classes. More recently several genomic signatures that go beyond disease classification have been discovered and validated that predict prognosis and response to therapy for many solid tumors and hematologic malignancies (Potti et al., 2006; Staudt, 2003). Not far behind, although lacking the throughput of RNA expression analyses, are whole-proteome analyses of tissue homogenates or serum using surface-enhanced laser desorption ionization–time-of-flight or liquid chromatograph/mass spectrometry/mass spectrometer technologies (Caprioli, 2005; see Chapter 8).

The capability to discern structure in this data – in the form of patterns of gene, protein, or metabolite expression that provide

snapshots of gene activity in a cell or tissue sample at a given instant of time that can then be used to describe a phenotype – is transforming biology from an observational molecular science to a data-intensive quantitative genomic science. The dimension and complexity of such data provide opportunities for uncovering patterns and trends that can distinguish subtle phenotypes in ways that traditional methods cannot (West et al., 2006). In an integrated view of genomic epidemiology, all of these sources of data will be used to develop signatures and models that classify disease and predict outcomes (Figure 14.3). To fully realize the clinical potential of genome-scale information requires a dramatic shift in the way complex, large-scale data are captures, viewed, analyzed and used.

Data Acquisition, Standards and Bioinformatics

All of the exciting medical, biological and technological advances described in this book are limited by requirements for intensive data acquisition, storage and computational capacity. Individuals with skills in this arena are in critically short supply. Informatics is a fundamental competency for the era of genomic medicine. Unless the nomenclature of the current "Tower of Babel" is improved, we will miss the opportunity for applying our newfound knowledge, because these measurements will not be compatible when attempts are made to aggregate them. Currently, most data collection efforts are relatively isolated and many different groups are working on controlled vocabularies and data standards (Hanauer et al., 2007).

In addition to nomenclature standards that allow observations to be compared across observers, the methods for exchanging data must be standardized (see Chapter 12 and Klein, 2002). Health Level Seven has essentially solved this problem for common laboratory measurements that can be measured as a number or coded output. Unfortunately, such standards are only now emerging for clinical data, and considerable variation exists in the purposes, stated or perceived, for this effort, including better individual patient care, quality measurement, research and improved administrative efficiency and billing. An effective and unifying cross-platform system will be needed that will allow collaborations among industry, academia, the NIH and other partners (see below).

There are fundamental "bioinformatics blocks" in translation of genomics that must be overcome (see Chapters 10, 12, and 13). First, there is an enormous amount of data at the level of fundamental biological measurements. Second, at the level of the patient in the intact health care system, a major challenge exists in integrating disparate electronic health records (EHRs). Third, there are further challenges in integrating research, clinical and demographic/societal data into a common format. And lastly, there must be ways to link the clinical and molecular information, so that analyses that yield both cross-sectional and longitudinal patterns relevant to disease sub-classification can be carried out in a reproducible fashion.

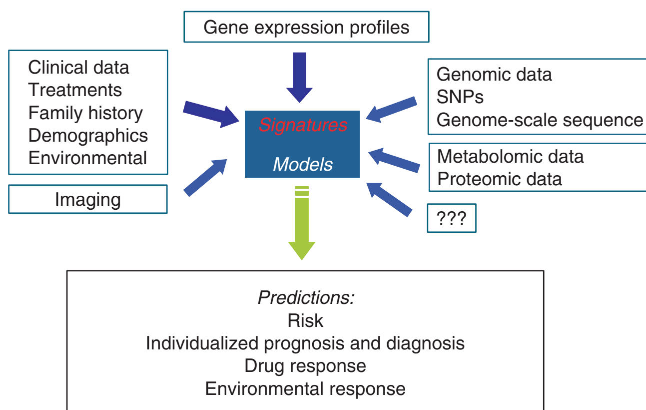

Figure 14.3 Integration of clinical, genomic, imaging, and other data to develop signatures and models to predict disease and response to drugs and environmental stimuli.

Biomarker Discovery and Development

The discovery and development of physiologic and disease biomarkers has provided a valuable set of tools to assess disease outcomes (Downing, 2000; Goodsaid et al., 2008). Biomarker research has also greatly improved our knowledge and understanding of mechanisms of etiology and disease pathogenesis. This will require access to robust model systems, human samples and exquisitely curated phenotypic data. Indeed, a genomic signature that characterizes a disease subset also provides a wealth of biological information through the members of genes, gene transcripts or proteins that constitute such a signature, either as markers of disease or as target for potential therapeutics. This approach has been particularly well developed in cancer research, although the driving concept of the gene–environment interaction has been widely applied in medical research.

Genome-Based Clinical Trials

Fundamental to defining the clinical validity and clinical utility of genomic biomarkers is the genomics-based clinical trial (see e.g., Marcom et al., 2008). In this setting, genetic and genomic biomarkers are fundamental to the trial design and the selection of patients for the trial (inclusion criteria) or for assignment to a specific experimental arm of the study. The basic principles of experimental design can also be applied to genomic studies. The task is to design a study in as economical a way as possible and simultaneously to optimize the information content of the experimental data. Clinical studies that serve to enrich a trial with a particular genomic biomarker or to test that a particular genomic subset of patients respond to therapy are required to advance translational genomics. Often these studies will both "validate" the biomarker – showing that it indeed identifies the relevant group of patients – and at the same time show its clinical utility – that the patient group selected by the biomarker indeed responds differently to the intervention in the trial. Key to enabling genome-based clinical trials is the interface between

discovery genomics with the platforms for developing a genomic assay that is ready for clinical use. In many cases, this will require key public–private partnerships to facilitate the transition from discovery research to human applications. In addition, there are several open issues in the design of genomic studies that need further investigation, such as selection bias at the patient recruitment level, tissue specimen sampling procedures, assays, and time point selection; in addition lack of calibration, poor reproducibility of molecular signatures across different studies and technical variation between different chip technologies also are in need of greater study as these novel study designs are developed.

Integration of Genomics into Drug Discovery and Development

Currently, the pharmaceutical industry is facing challenges in terms of the low number of new chemical entities (NCEs) that are approved each year, despite soaring research and development (R&D) costs. A main cause for low pharmaceutical productivity is pipeline attrition due to failure of NCEs to demonstrate efficacy or the emergence of safety issues during or after development. In parallel to genomic-guided clinical trials, pharmaceutical studies that use biomarkers for trial enrichment or for pharmacogenomics will be another pathway for genomics to reach the clinic in the form or diagnostic/therapeutic combinations. The practice of genomics and related technologies in transforming drug discovery and development has provided sophisticated and novel new approaches for target identification, target validation, the drug screening process and the understanding of the mechanism of action of targets and drugs (Stoughton and Friend, 2005). In drug development, the process by which new drugs are tested in model organisms and in humans, genomics has provided a means to understand heterogeneous disease populations at the gene level. This has enabled the selection of subjects for clinical trials with more homogeneous disease characteristics, thereby enabling a much better assessment of drug activity. In addition, the understanding of drug metabolism on a genetic level has offered a means to provide drugs with a better safety profile for certain patient populations.

Pharmacogenetics and Pharmacogenomics

The impact of the genome on our ability to predict drug response is one of the most promising and fertile areas of genomic and personalized medicine (see Chapter 15). *Pharmacogenetics* is the study of genetic variation that ultimately gives rise to the variable responses in individuals to any given drug treatment. More recently, pharmacogenetics has provided an explanation as to why certain individuals do not respond, or respond differently to a given drug treatment. *Pharmacogenomics* utilizes genomic technology to understand the effects of all relevant genes on the behavior of a drug or conversely the effect of a drug on gene expression. Pharmacogenomics, like pharmacogenetics, has rapidly embraced genomic technologies to identify molecular patterns of response, drug disposition and drug targets, yielding molecular biomarkers of drug response both of which have great potential to positively affect the area of medicine. Grossman and Goldstein (Chapter 15) outline the scope of study designs for pharmacogenomics studies, depending on specific features related to the study population, underlying disease, phenotypes of interest (i.e., drug efficacy, safety and dosing) and drug compound being tested. Considerations related to the realization of a valid genetic effect into an acceptable diagnostic kit are reviewed, providing analytical tools objectively evaluating the validity, utility and cost-effectiveness, as well as ethical properties, associated with a specific drug application.

Translational Diagnostics

Translational diagnostics is “the subfield of translational medicine concerned with diagnostic methods and information.” Many of the translational issues affecting genomics as whole also affect this area of innovation. These include communication and education of researchers, institutional support for translational research activities, the regulatory environment, cost and reimbursement issues, the need for bioinformatics and complex data handling capabilities, intellectual property and licensing protection and the willingness to embrace new paradigms for diagnostic and therapeutic strategies (Horig and Pullman, 2004; Horig et al., 2005; Humes, 2005; Marincola, 2003; Sonntag, 2005).

Integration of Genomic Testing into Clinical Practice

A final hurdle that genome-based medicine faces is the integration of testing into day-to-day clinical practice. Despite the optimism that genomic testing might bring to improving the practice of medicine, there are barriers that must be overcome for their seamless integration into clinical practice. The incorporation of genetics and genomics into patient management guidelines has largely failed to occur thus far, perhaps because researchers, diagnostic firms and the regulatory authorities are still seeking to establish methodologies by which to judge their effectiveness because practicing clinicians and guideline writers are still working to understand how such new tests fit into current models of care and risk assessment, and because payers are just beginning to foresee new pressures to cover the additional costs. Indeed, population studies and outcome studies will be critical for this final phase of clinical uptake, implementation into guidelines and into reimbursement strategies.

To address some of these issues, a framework has been proposed to assist in genetic testing evaluation, consisting of six areas (Table 14.2): technical and operational excellence, diagnostic capability, impact on diagnostics and/or prognostics, impact on therapeutic strategy, cost-effectiveness and health outcomes (Douglas and Ginsburg, 2008). It is clear that the physician community faces many of the same issues the payer and diagnostics groups do as well. Therefore, it makes sense to consider developing the partnerships that bring the stakeholders together to jointly address these translational obstacles.

TABLE 14.2 Framework for evaluating genetic tests*

Technical capability and operational excellence	● development of analytic standards ● computational capabilities to acquire, store and analyze large datasets
Diagnostic capability	● define the clinical situation(s) that may be informed by genomic data ● validation of genomic associations or predictors in distinct and separately ascertained cohorts
Impact on diagnostics and/or prognostics	● development of clinical decision support platforms and "just-in–time" solutions in the practice environment ● linkage to authoritative knowledge sources
Impact on therapeutic strategy	● evaluate genomic testing in the context of physicians' confidence in decision-making ● develop educational strategies with test implementation ● assess physician behavior
Cost-effectiveness	● assessment of system wide costs resultant health care utilization and outcomes ● assess patient, provider, payer and government perspectives
Health outcomes	● incorporation into guidelines driven by the evidence base ● carry out prospective randomized trials of usual care versus genomics guided care ● development of an educational strategy aimed at the patient

*Modified from Douglas and Ginsburg (2008).

DEVELOPING ENVIRONMENTS THAT FOSTER TRANSLATIONAL GENOMICS TO HEALTH APPLICATIONS

It is clear that academicians and industry scientists are on convergent paths to personalized medicine using genomic technologies and information. Specialized centers for genomic and personalized medicine in academic health systems can be instrumental in integrating, facilitating and catalyzing the needs of both the academic and industry stakeholders by providing:

- Access to patients, patient data, and molecular and biological data that drive the development and exploration of genomic information and its link to clinical outcomes.
- The scientific foundation for novel biomarker discovery for both disease and drug response based on mechanism.
- An environment for innovation that fuels the development of novel translational strategies.
- A vehicle for aligning the efficiency and quality metrics of patient care with the goals of personalized medicine.
- The infrastructure for the types of public–private partnerships required for executing genomic assay-guided clinical trials, and, finally,
- A place to engage in a dialog and research on the key issues challenging the translation of genomics into personalized health care (Haga and Willard, 2006): education, facilitating clinical trials, information systems and integration into practice.

To bring about the transformation in health care promised by the genome sequence and its derivatives will require assembling diverse stakeholders focused on the application and translation of genomics with a goal of improving the health of individuals and driving efficiency in health care. Specialized centers housing basic genome science laboratories, clinical researchers, informaticians, clinicians, health policy makers and in partnership with industry (pharmaceutical and diagnostic companies), and with health systems that will enable the scientific output of the genome to cross the chasm between bench and bedside.

Just a few years ago, academic medical centers alone were the primary mechanism to foster translational research and facilitate collaboration between researchers and clinicians. In the United States, the key ingredients for this effort are in place through the NIH Roadmap and the Clinical and Translational Science Awards (NIH, 2007). This NIH initiative will eventually fund up to 60 academic health centers and their associated clinical practice partners, with significant infrastructure capability in most of the areas above. These large centers are being bolstered by multiple grants and contracts that are intended to provide avenues for innovative approaches to scientific problems ranging from biomedical informatics to community-based research networks. Similar programs are under way in Canada, the United Kingdom, Singapore, Germany and other countries.

In particular, it will be important for governmental and foundational funding agencies to anticipate the critical imperative for interdisciplinary work (Figure 14.4). Academic health systems will need to consciously steer faculty activities in this direction to reap the benefits of the enormous societal investment in the biomedical enterprise that has made this clinical scientific revolution possible. Industry will need to engage earlier in the discovery process and assist in guiding the research agenda.

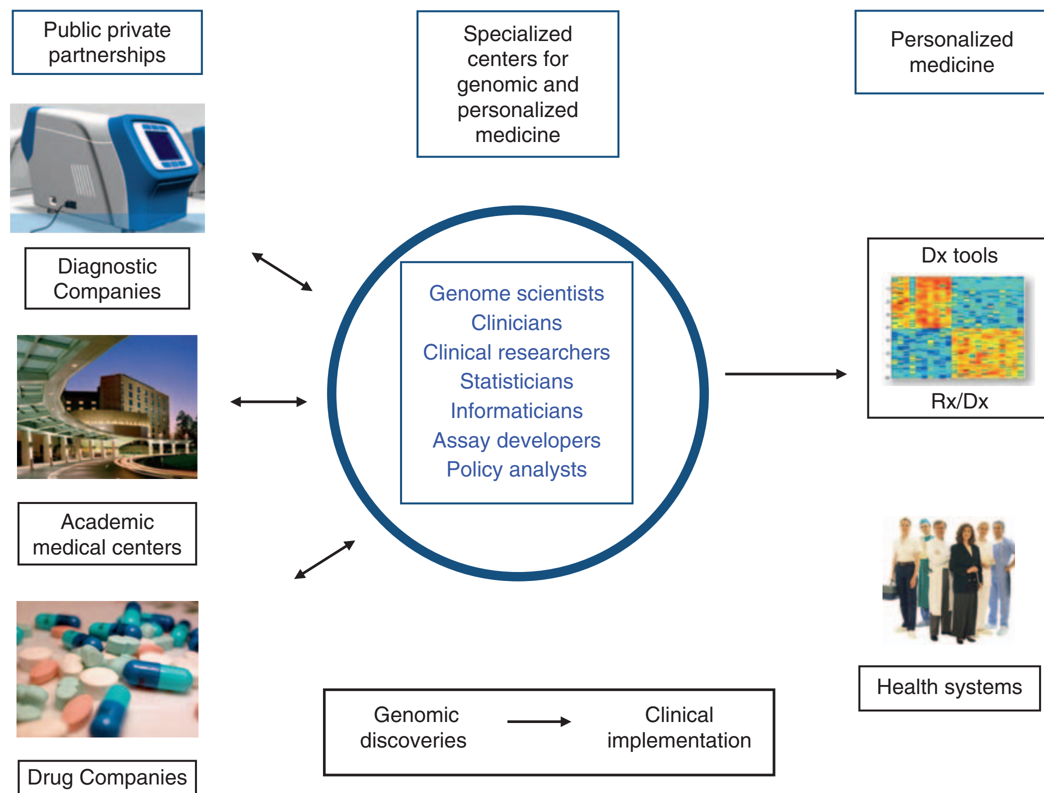

Figure 14.4 A framework for an organization to translate genomics to personalized medicine through public–private partnership and academic health centers.

Regulatory agencies and payers will need to prepare for this fundamental shift in the basis for assessing diagnostic and therapeutic technologies and their reimbursement. Effective planning for this coming shift in the way human disease and its prevention and treatment are viewed through the genomic lens, particularly the systems aspects of creating interdisciplinary hubs for the development of translational genomics, will result not only in an advanced clinical scientific discipline, but improved health for people worldwide.

2009 UPDATE

There continue to be significant advances in translational genomics. Progress has been made in developing the infrastructure that supports developing and disseminating genome information, the informatics tools for clinical use of this information, as well as the definition and development of the evidence required for clinical adoption. Indeed the labels of more therapies are including genetic and genomic information to facilitate prescribing by physicians – a major advance for pharmacogenetics. Personal genomics represents a new and potentially disruptive innovation in translating genomics, and the stakeholder community is developing guidance as to how best to use this information in the care of patients.

Tools and Catalogs of Genome Information

The toolbox for achieving the goals of genomic and personalized medicine is becoming increasingly high throughput and low cost. In April 2008, the sequencing of the genome of Nobel scientist James Watson was completed (http://jimwatsonsequence.cshl.edu/cgi-perl/gbrowse/jwsequence/). It took 13 years and $3B to complete the first draft sequence of the human genome; however, Watson's sequence of the human genome cost only $1M and took two months to complete. Advances in genomic sequencing are occurring exponentially and the $1000 genome is likely within reach. The NHGRI (US NIH) announced several initiatives aimed at taking full advantage of advanced sequencing technologies – Medical Resequencing (http://www.genome.gov/15014882), 1000 Genomes (http://www.genome.gov/26524516), and the Human Microbiome project (http://nihroadmap.nih.gov/hmp/members.asp) are among them – that will generate large publically accessible databases of human variation in health and disease. In parallel to the acceleration of sequencing technologies, a

number of important public–private partnerships have begun to generate publically available data and frameworks to support large genome-wide association studies.

- The *Genetic Association Information Network* (*GAIN*) (http://www.genome.gov/19518664) was established as a public–private partnership to support genome-wide association studies. The effort has linked comprehensive genotyping data on roughly 2000 participants to their clinical records and deposited the information in the publicly accessible dbGaP (http://www.ncbi.nlm.nih.gov/entrez/query/Gap/gap_tmpl/about.html).
- The *Biomarker Consortium* (http://www.biomarkers-consortium.org/) was set up as an industry–government partnership to discover and develop biomarkers for risk for developing disease, to assist in diagnosis or to guide treatment.
- The NIH launched the *Genes, Environment, and Health Initiative* (http://www.gei.nih.gov/) to develop data on how genetic variation affects an individual's response to environmental factors.
- *The Cancer Genome Atlas* (http://cancergenome.nih.gov/) to explore the entire spectrum of genomic changes involved in human cancer, starting with brain, lung and ovarian cancer. The first results were reported this year for glioblastoma (Cancer Genome Atlas Research Network, 2008) and the first data for ovarian cancer were recently released (http://tcga-data.nci.nih.gov/tcga/homepage.htm).

Developing a Nationwide Biospecimen Repository

There remains a compelling need for centralized biobanks and development of standards of biospecimen banking that are universally accepted and applied (Ginsburg et al., 2008). No organized effort is underway; however, in the United States, the Clinical and Translational Science Awards consortium has initiated several projects to achieve this goal, including one aimed at defining the data standards and IT platform to create a "virtual" national biorepository, as well as a second to articulate the cultural barriers and regulatory best practices. These data will lay the groundwork for a future initiative of national biospecimen banking.

Advances in Health Care Information Technology

Health care information technology (HIT) development is essential to record genetic profiles of disease susceptibility and drug response, to gather evidence for improved outcomes, and to aid in the discovery of new gene-disease associations through formal studies and the collection of data in everyday clinical encounters. HIT systems will also be important in providing clinicians not trained in genomics with critical information and decision-making tools (Kawamoto et al., 2009). Genomic and personalized medicine will require a sound HIT infrastructure to support clinical decisions to deliver full benefit to the patient and to the health system as a whole. This effort remains woefully behind the need. Sobering is a study that reported that only 19% of hospitals and 13% of solo physicians have implemented fully operational EHRs. Large group practices (<50 physicians) are relatively ahead of the curve, with 57% having adopted EHRs, but adoption remains incomplete overall (Jha et al., 2006). Surprisingly, large segments of the health care profession remain primarily on a paper-based system. The reasons for this rest largely on two key issues: the cost of implementing a health care information system and the lack of a uniformly accepted standard in the way data is stored and shared. Interoperable HIT is a goal; how this will be accomplished remains unclear. In the United States, the Obama administration has prioritized nationwide implementation of standardized HIT, and there is reason to hope that a changeover to EHRs will occur within a matter of years with government driving the process.

Where are We Today in Translating Genomics to Health care?

Despite the clear advances in technology that bring genomic information closer to physicians, patients, and the public, looming even closer are issues that are outside of the sphere of the genome sciences and more in the realm of genome policy. Scheuner and colleagues carried out an extensive meta-analysis of 68 studies seeking to integrate genomic medicine to the clinical management of chronic diseases (Scheuner et al., 2008). The study posed the following questions: "What are the outcomes of genomic medicine? What is the current level of consumer understanding about genomic medicine and what information do consumers need before they seek services? How is genomic medicine best delivered? What are the challenges and barriers to integrating genomic medicine into clinical practice?" The authors concluded that gaps in provider and public education, addressing privacy concerns, building an evidence base, and developing the appropriate cost models for genomic medicine in health care delivery will need to be addressed in order to facilitate the translation of genomic innovations into clinical practice. These findings are not surprising given the spectrum genome policy issues that have emerged as the genome sciences have matured (Haga and Willard, 2006); nonetheless, this is the first comprehensive analysis of data on these issues and provides a basis to address them.

Evidence Evaluation

The Evaluation of Genomic Applications in Practice and Prevention (EGAPP) Initiative (http://www.cdc.gov/genomics/gtesting/egapp.htm), established by the US National Office of Public Health Genomics at the Centers for Disease Control and Prevention, supports the development and implementation of a rigorous, evidence-based process for evaluating genetic tests and other genomic applications for clinical and public health practice in the United States. EGAPP recently published its recommendations for the use of CYP450 polymorphisms

in the management of selective serotonin reuptake inhibitors (EGAPP, 2007), gene expression profiles and outcomes in breast cancer (EGAPP 2009a), and UGTA1A testing in colorectal cancer patients treated with irinotecan (EGAPP 2009b).

Building the Evidence: Genome-Based Clinical Trials

Personalized approaches to cancer therapy will likely depend on genomic assays. Full-transcriptome assays using microarrays have the advantage of providing multiple prognostic and predictive signatures in one assay. Duke University's Institute for Genome Sciences & Policy has created a unique clinical infrastructure with the objective of obtaining full genome expression data on cancer samples as a clinical assay for use in a prospective trials (www.genomestohealth.org). One of these trials – "Performance of Genomic Expression Profiles to Direct the Use of Preoperative Chemotherapy for Early Stage Breast Cancer" – is a prospective trial validating genomic signatures for predicting response to doxorubicin (A) or docetaxel (T) treatment in HER2 negative cancers (Marcom et al, 2008). Fresh-frozen cores are reviewed by the study pathologist for tumor content. RNA is then extracted and probe generated to hybridize to an Affymetrix U133Plus2.0 microarray. Microarray data quality is determined using summary metrics for U133Plus2.0 arrays and principal component analysis (PCA) plots. The data is then used for predicting A or T sensitivity. This is an important example of a series of innovative clinical trials underway to develop the prospective evidence in breast, lung, prostate, ovarian, colon, and hematologic malignancies that a genomic signature derived from a patient's tumor can predict prognosis, as well as response and resistance to conventional cytotoxic chemotherapy.

Pharmacogenetics

Information on genetic risk for adverse events is now beginning to appear on drug labels. For example, testing for the HLA-B*5701 allele is recommended for the initiation of abacavir therapy to reduce the risk of hypersensitivity reactions (Mallal et al., 2008). In a randomized control trial, testing for this allele showed a 50% reduction in the risk for hypersensitivity. Testing is also recommended for HLA-B*1502 for Asians who are being prescribed carbamazepine to identify those at high risk for Stevens Johnson syndrome (FDA, 2009). A recent study of warfarin pharmacogenetics found that a clinical/genetics algorithm better predicted maintenance doses compared to a clinical algorithm without genetics, particularly for the outliers (International Warfarin Pharmacogenetics Consortium, 2009). In 2008, the FDA published a comprehensive list of biomarkers on drug labels (http://www.fda.gov/cder/genomics/genomic_biomarkers_table.htm), laying the groundwork for the clinical implementation of pharmacogenetic testing in clinical practice.

Personal Genomics

"The genome is out of the bottle" (Hunter et al., 2008). Direct-to-consumer marketing of personal genomics services has raised concerns about the scientific foundation for such tests. There is a growing need for clarity of the evidence base required for both the clinical validity and utility of personal genomics. A recent NIH/CDC workshop made the following recommendations: (1) develop industry-wide scientific standards, (2) develop a multidisciplinary research agenda, including observational studies and clinical trials, (3) enhance credible knowledge synthesis and information dissemination to both providers and consumers of health cares, (4) link scientific evidence to recommendations for use of personal genomics, and (5) expand the concept of clinical utility to include personal health utility and developing appropriate metrics for evaluation (http://www.scgcorp.com/PersonalGeno2008/agenda.htm).

CHAPTER

Pharmacogenetics and Pharmacogenomics

Iris Grossman and David B. Goldstein

INTRODUCTION

Western medicine has been extremely successful in producing mass pharmaceutical solutions by following the "one-drug-fits-all" paradigm. Indeed, the majority of individuals plotted on a Gaussian distribution show reasonable efficacy and safety profiles, justifying the overall validity of this approach. However, alarming reports are amassing on the frequency and gravity of adverse drug responses, as well as inadequate efficacy, clearly signaling the need to shift from "blockbuster" to more individualized treatment models. The objective of pharmacogenetic research is to identify a genetic marker, or a set of genetic markers, that serve as prognostics for the fashion in which a given person is likely to respond to a given medicine. The appropriate formulation, dose, and regimen are presumed to be predicted, at least partially, by genetic determinants, thus serving as diagnostics that can be tested prior to initiation of drug treatment. In this fashion, treatment would be allocated only, or mainly, to individuals who are expected to benefit from it, thus reducing dramatically the suffering and costs associated with adverse drug reactions (ADRs) and inadequate efficacy. As summarized by Wilkinson, "most major drugs are effective in only 25–60% of patients, and more than two million cases of ADRs occur annually in the US, including 100,000 deaths" (Wilkinson, 2005).

It should be noted that two terms exist in the scientific literature, *pharmacogenetics* and *pharmacogenomics*, each with its own connotation and a range of alternative and poorly defined distinctions. Here, we use the term *pharmacogenetics* (PGx), which has historical priority, according to its broadest meaning – relating heritable variation to inter-individual variation in drug response (Goldstein et al., 2003). It should be mentioned that the term *pharmacogenomics* is often used to describe the study of differential gene-expression profiles in tissues of interest and their relation to drug-response phenotypes. While such expression signatures may be affected by underlying genetic variation, non-inherited environmental determinants play an important role as well. We therefore focus here solely on inherited sequence variation (i.e., single nucleotide polymorphisms, SNPs), insertions–deletions, copy number variations, micro-satellites, *Alu* repeats, and so on) and its association with treatment response end-points. A comprehensive review of gene-expression signatures, their association with response to chemotherapy, and the search for underlying genetic determinants is provided in Nevins and Potti (2007).

The complexity of genetic relationships and its interplay with drug-response phenotypes has been recently acknowledged by the US Food and Drug Administration (FDA) in a rather crude and controversial decision to stratify patients' populations by race in the case of severe heart failure adjunct treatment with BiDil (Meadows, 2005). Although little beneficial effect has been registered in the general population, BiDil treatment showed a dramatic reduction in death and hospitalization in African

Essentials of Genomic and Personalized Medicine

Americans. Indisputably, this stratification criterion is simplistic, biased, and ethically provocative, but it illustrates the concept of inherent differences between individuals in the general population and serves as a bridging step from indiscriminant allocation of therapeutics to genetic-based stratification into risk/benefit subgroups. This example also illustrates the fact that the popular description of PGx as aspiring to "individually tailor" therapy is an exaggeration. The field is *not* centered around each individual specifically, but rather seeks to increase homogeneity among patients to an acceptable efficacy and safety level. In other words, PGx aspires to generate an individualized guide to proper therapeutic option among predictable segments of the patient population (Roses, 2004).

The discipline of PGx is closely tied to human genetics and genomics as a whole, but focuses on specific phenotypes of interest. While disease predisposition research in the realm of non-Mendelian traits is faced with extremely complex etiology, dictated by interplay between various pathways in the human body, it is assumed that pharmacogenetic phenotypes are largely governed by a limited number of molecules (an oligogenic structure), most of which interact with the drug as pharmacokinetic or pharmacodynamic entities. Although genetic factors associated with underlying disease etiology may impact treatment response features, these effects are hypothesized to have relatively modest sizes comparison to genetic variations in molecules that come in physical contact with the drug upon its administration. Moreover, the phenotypic changes that are induced by drugs are clearly and reproducibly caused by treatment exposure, which renders them less difficult to relate to genotype in comparison to studies of other complex traits. Thus, PGx research is equipped with the enormous advantage of being more readily and fruitfully realized in clinical practice. In addition, the (potential) direct application of pharmacogenetic findings in the daily management of disease burden prompts this field to be attractive, not only to academic circles but also to the pharmaceutical industry, patients, health care providers, regulators, and health systems as a whole.

Any treatment for which inter-individual variability is significantly larger than intra-individual diversity indicates an underlying genetic effect associated with response variables. In order to maximize the potential benefit from PGx research, it is helpful to focus and prioritize the analyzed therapies as follows (Table 15.1):

- Chronic disease states: in these cases disease burden on both the patients and health systems translates into compromised patients' quality of life, continuous suffering, low medication adherence rates, polypharmacy, and ultimately considerable care management costs. Therefore, management of chronic diseases comprises an attractive aim for optimization of available treatments and development of new therapeutic solutions (e.g., hypertension, diabetes, asthma, and so on).
- Narrow therapeutic index drugs (i.e., those with little difference between toxic and therapeutic doses) require close and constant dosage adjustment procedures to achieve therapeutic levels and minimize toxicity (usually by repeated measurements of therapeutic drug monitoring (TDM) protocols). Utilization of predictive genetic tests that may identify individuals at risk – either prior to treatment initiation or during the initial dose adjustment period – will save patients' lives, while diminishing substantially the costs of care management (e.g., warfarin, 6-mercaptopurine, and so on).

TABLE 15.1 Circumstances defining high priority targets for pharmacogenetic investigation

Circumstances	Rationale	Examples
The underlying condition being treated is chronic, incurable, and/or recurrent	Arrest the progression of the underlying disease, reduce patients' suffering, and decrease disease management burden on the health system	Epilepsy (Tate et al., 2005) Multiple sclerosis (Grossman et al., 2007)
Current clinical practice of the underlying condition follows a "trial and error" paradigm		Asthma (Weiss et al., 2006) HIV (Telenti and Goldstein, 2006) Hypertension (Arnett et al., 2006)
The studied drug has a narrow therapeutic index	Save patients' lives and decrease hospitalization costs associated with ADRs	Warfarin (Aquilante et al., 2006) TPMP (van den Akker-van Marle et al., 2006)
The studied drug is associated with severe, life-threatening side-effects		Herceptin (Krejsa et al., 2006)
The predictive value and clinical utility of the studied drug are high	Develop accurate and useful clinical diagnostic tools	Abacavir (Warren et al., 2006) TPMT (van den Akker-van Marle et al., 2006)
Rescue drugs post Phase II development	Market drugs to patient subpopulations that are predicted to benefit from the treatment, protecting potential non- or adverse responders	GW320659 (Spraggs et al., 2005)

- Disease states for which current practice follows a "trial-and-error" paradigm due to absence of predictive markers of efficacious and safe treatment regimens often require long adjustment periods, thus resulting in months or even years of incrementing doses and drug switching until a successful course of treatment is identified. Predictive genetic tests may assist in reducing this elongated adjustment period, resulting in increased compliance rates, and reduction of side effects, disease management burden and costs.
- As an integral part of the drug research and development process, rescuing formulations efficacious in subgroups of the patient populations, but failing to exhibit overall benefit in the all-inclusive cohort.

Noteworthy is the fact that most of the current examples in the PGx literature, including those discussed here, investigate marketed drugs retrospectively, when the drug and its clinical responses are available to be studied by academic investigators. A comprehensive review of PGx research along the drug development process with examples from discovery through phase III trials is presented elsewhere (Roses et al., 2006).

PHARMACOGENETIC STUDIES: FROM CONCEPT TO PRACTICE

The Ultimate Goal: Definition of the Key Research Question

A PGx study aims at identifying genetic determinants associated with drug–response features. The latter focus mainly on treatment efficacy, dosing, and safety. The definition of each of these elements is not trivial and is tightly dependent upon the specific parameters of a given dataset: the underlying disease and relevant clinical follow-up measurements dictate the available tests and clinical information that is not only relevant, but also obtainable, especially with respect to retrospective data acquisition. For example, in an investigation of the response to multiple sclerosis, treatment efficacy may be determined by clinical observations evaluated by the Extended Disability Status Scale (Kurtzke, 1983) (EDSS), reduction in relapse rate, severity of relapses, and/or MRI findings estimating T1-weighted hypointense lesions and central nervous system (CNS) atrophy measures (Grossman et al., 2007). Even a phenotype as "simple" as dosing may be regarded by various experts in a host of different ways. For instance, dosing phenotypes relevant to treatment with anti-psychotics for the treatment of schizophrenia are often assessed by "maintenance dose," which may reflect halving the drug dose that was proven effective during the acute phase (Gaszner and Makkos, 2004) or a titration regimen starting from minimum doses determined experimentally up to a recommended target dose on average (Perry and Hradek, 2004). When considering phenotypes of treatment safety recombinant protein therapeutics (including supplements to, or blockers of, endogenous proteins, immunomodulatory molecules and small, highly selective, targeted binding proteins), as opposed to small-molecule drugs, introduce an additional dimension requiring consideration of their potential immunogenicity (Krejsa et al., 2006). Whatever the case may be, the phenotypes to be tested must be determined prior and blinded to acquisition of results and are required to be precise, consistent, obtainable in the current investigation, reproducible and clinically relevant.

Tailor-Design of Your Study by Available Resources and Specific Goals

Researching the genetic determinants underlying a phenotype of interest is a task largely pre-defined by the specific characteristics of the studied phenomena. The investigator has no control over attributes such as phenotype penetrance; frequency of the (unknown) causative polymorphism(s); number of involved and modifier genes; genotype relative risk; phenocopy and genocopy effects; linkage disequilibrium extent between the typed markers and the causative polymorphism(s); and so on. Notwithstanding, an array of tools are available at the disposal of the pharmacogenetic researcher aimed to better the chances of identifying genotype–phenotype associations by sophisticated tailor fitting each individual project (Figure 15.1):

- collection of a large enough sample size as reflected by power estimations (Chapman et al., 2003; Kelly et al., 2005; Singer et al., 2005);
- distinct and precise, yet simple and broad, phenotype definitions;
- skilled marker selection (as detailed later); and
- appropriate choice of study design.

Classic Case–Control Study Design

The classic most "simplistic" study design, which is still considered the basic and fundamental association test pursued in genetic literature, is the case-control study. Originally, this analysis was used for testing significant differences in exposure without attempting to quantify the risk associated with exposure: *Statistically, do more lung cancer patients have a history of smoking than controls?* Rather than *by how many times does smoking increases the risk of lung cancer?* Case-control studies contain only group-level information and may determine the association between potential cause and effect on an *individual* basis. In pharmacogenetic investigations, cases and controls do not refer to health states or existence of drug exposure (affected versus unaffected, treated versus untreated), but rather to subpopulations within a source population of affected *and* treated individuals: positive responders versus non-responders, or patients manifesting ADRs versus safely treated individuals. Investigation of quantitative traits (as opposed to qualitative traits) is traditionally pursued by linear regression methods assuming that the *Y*-axis variable is a continuous measurement (e.g., optimized drug doses prescribed to schizophrenia patients [Grossman et al., 2008]). In order to avoid bias due to confounding effects inherent in the study populations while employing qualitative, as well as quantitative, phenotype definitions, and so as to allow follow-up replication analysis within the total or the remaining trialed population (Figure 15.2), it is

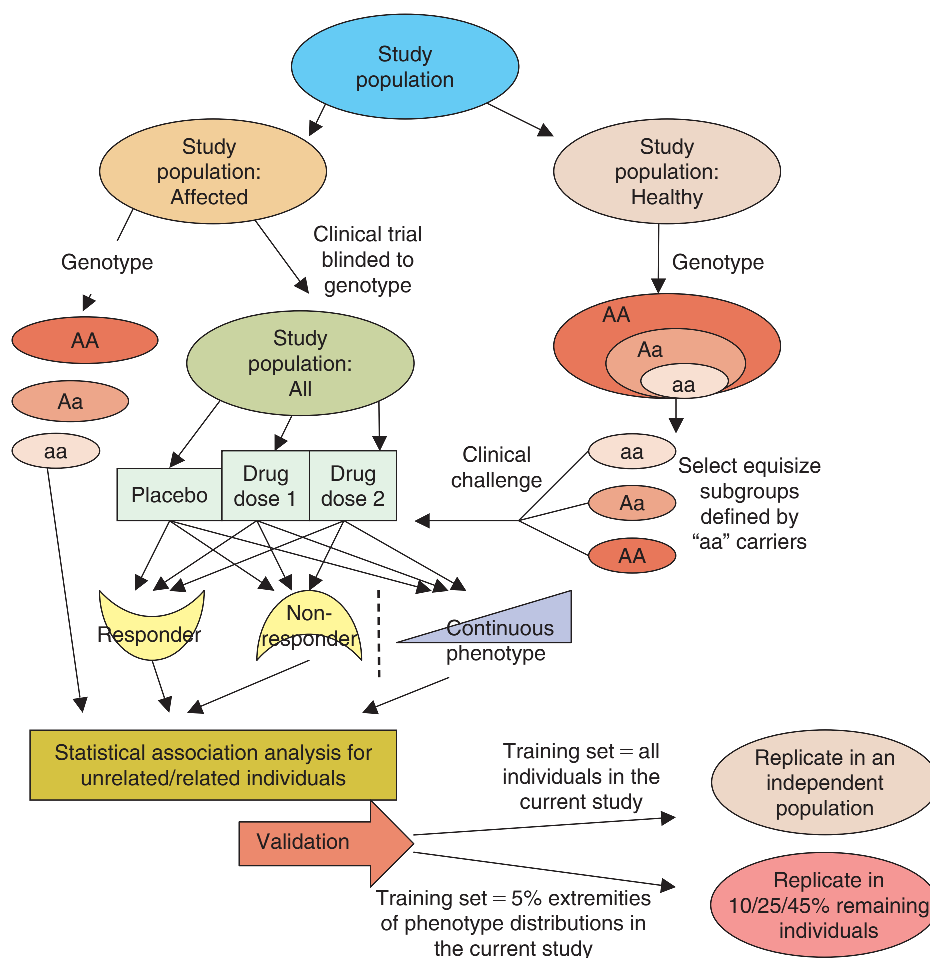

Figure 15.1 Pharmacogenetic study design alternatives in a simplified case, genotyping a single nucleotide polymorphism in a study population. In research settings pharmacogenetic study populations may either be healthy or affected subjects. *A priori* genotyping may be used as inclusion criteria and in several models may be used to reduce study population, when equisize groups of genotype carriers (aa, aA, and AA) are randomized to treatment and subsequent analysis. In clinical trial settings, individuals are randomized to treatment groups (active drug, parallel dose comparison arms, gold standard comparator drug, and/or placebo) blinded to genotype. Only once trial is completed and efficacy and safety end-points are clinically analyzed does statistical analysis take into account genetic underlying effects. Similar approach can be utilized in adaptive trial design for interim analysis. It is expected that some genetic associations will reach statistical significance at random and thus it is vital to validate any association results in either the replication set within the current cohort, or in an independent population.

becoming acceptable to employ case–control designs in which cases are chosen as patients exhibiting the lowest 5% of a phenotype distribution, while controls represent the 95th percentile of this distribution. Contrasting these two subgroups in the initial analysis enables focusing on the most extreme representations of the phenotype of interest with a lenient significance level, accentuating the roles that causative factors (genetic and environmental) play in exhibition of these phenotype states, and expecting most of the findings to reflect false-positive associations. In the second stage, designed to replicate and validate the obtained results, individuals represented by the remainder of the distribution space are split into cases and controls. Analysis can be performed at this level by using a stringent Bonferroni-corrected significance level as a "replication-based analysis" or by combining test statistics from both stages and applying significance level corrected only for the number of markers tested, titled "joint-analysis" (Skol et al., 2006). The above-described alternatives of one-stage versus two-stage association study designs are summarized in Figure 15.2.

Familial Study Design

Familial and twin genetic association studies allow refined elucidation of genetic associations while inherently correcting for environmental effects and risk factors (Endrenyi et al., 1976; O'Reilly et al., 1994). The task of collecting appropriate related cohorts suffering from the same conditions and exposed to the same pharmacological agents is often not trivial (although has been demonstrated to be helpful in the case of nicotine

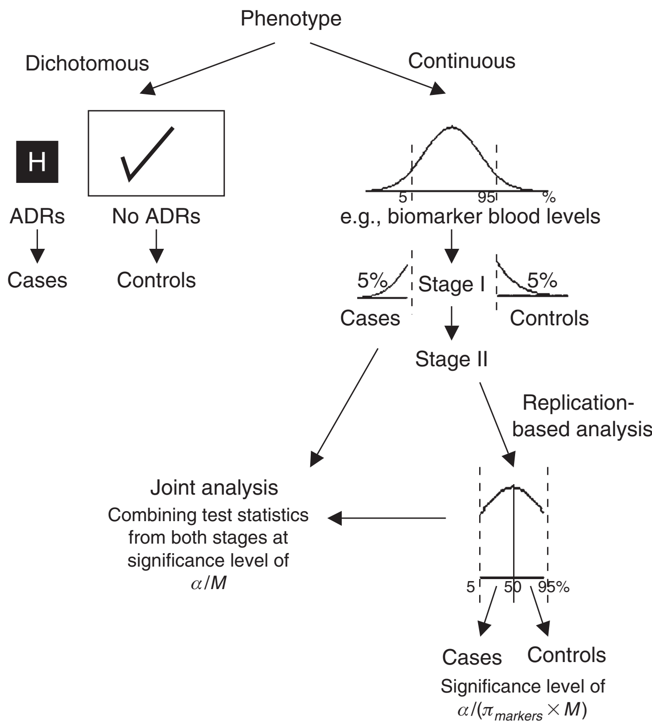

Figure 15.2 One-stage versus two-stage case–control genetic association analyses. The phenotype of interest in pharmacogenetic studies can be categorized as either continuous or dichotomous. When occurrence of adverse drug reactions is analyzed, the natural statistical model calls for a case-control design. However, efficacy end-points tend to display a continuous distribution, such as measurements of biomarker blood levels. A two-stage design would split the study population into (Stage I) a case–control analysis contrasting the 5% extremities of the Normalized distribution; thereafter (Stage II) would employ a replication-based analysis of the remaining 90% of the distribution with adjusted requirements for significance level. A joint analysis will then ensue, combining test statistics from both stages at a corrected significance level (Skol et al., 2006). ADR, adverse drug reaction; α, study false-positive rate (type I error rate); M, number of genotyped markers; $\pi_{markers}$, the proportion of markers found to be associated in Stage I and followed up in Stage II.

metabolism [Swan et al., 2004] and alcohol exposure [Heath and Martin, 1994]). However, implementation of healthy volunteer challenge studies (see later) within related cohorts may be highly effective (Kendler et al., 1988).

Healthy Volunteer Challenge Design

Pharmacogenetic investigations, as opposed to disease predisposition genetic analyses, bear the extraordinary advantage of inducing the phenotype of interest in any given individual – including in healthy volunteers. In other words, in order to study the effects of drug intake in a genetic context, one can either investigate affected individuals prescribed the drug in question for the therapeutic purpose of controlling their condition (the traditional approach) or administer the drug to healthy consenting individuals specifically for the purpose of PGx research. This unique option allows not only the rapid recruitment of study population to be screened for genetic variation but also enables specific tailoring of the study design to address PGx questions, rather than clinical trial end-points.

In practice, researchers assess the impact of pre-selected polymorphisms on the PGx phenotypes (e.g., efficacy, safety, dosing, and pharmacokinetic properties) of the studied drug, by prospective clinical analysis of healthy volunteers chosen conditioned on their genotype profile. In this manner, Kirchheiner et al. (2004) identified a total of 25 healthy males carrying one of three genotypes of interest (*CYP2D6* ultra, extensive, and poor metabolizers) out of more than 1000 healthy volunteers in a PGx study of Mitrazapine and clinically challenged this miniature group of interest for clinical measurements. This cohort size matched power estimates for detecting at least a 1.5-fold effect on drug clearance differences between subgroups. Similar designs have been published for a variety of pharmaceutical applications and bear a great potential for simplification of PGx research in agents with favorable safety profiles.

Placebo and Multiple Dosing Cohort Comparisons

PGx association studies in general, and those of medications for psychiatric and immunological diseases in particular, are characterized by a poor signal-to-noise ratio: approximately one-third of the patients enrolled in efficacy trials may respond to placebo treatment. The placebo "response" in randomized clinical trials includes such statistical artifacts as regression to the mean, drift in measurement of the response over time, and bias of expectations by both patients and evaluators, as well as real effects such as spontaneous recovery, a tendency to seek treatment outside the study, and the response to additional attention and concern involved with participating in clinical trials (Singer et al., 2005). It has been shown that placebo "response" strongly affects statistical power of association studies and that employing a placebo-treated control group in the PGx analysis enables elucidation of specific drug-induced genetic effects, differentiating these from confounding effects related to underlying disease progression and severity (Grossman et al., 2007). Similarly, employment of trial arms administering different drug doses may shed light on the genetic underlying mechanisms and their magnitude (Risner et al., 2006).

MARKER SELECTION – STRATEGY AND APPLICATION

Candidate Genes Strategy Versus Whole-Genome Scans

A comprehensive search for genetic influences on drug response would involve examining all genetic differences in a large number of affected individuals and controls. This will eventually

(and probably not too far ahead) be achievable by complete genome re-sequencing. However, current practice is limited to a systematical test of common genetic variants (those with 2–5% minor allele frequency [MAF] and higher). These variants explain most of the genetic diversity in human populations and may be sampled taking advantage of the genetic property termed linkage disequilibrium (LD) (see also Chapter 4). LD reflects shared ancestry of contemporary chromosomes, measuring the degree of non-random co-occurrence of two (or more) polymorphic sites along a stretch of genomic sequence. Polymorphisms showing a high degree of LD may be considered redundant, eliminating the necessity to type all SNPs in this correlated group. It suffices to genotype a representative SNP and virtually represent the entire variation captured by the whole group, given the LD threshold imposed on the model.

Traditionally, studies of common traits have been studied by two different strategies: family-based linkage studies across the entire genome and population-based association studies of individual candidate genes (usually only a handful). Although there have been notable successes, progress has been slow due to the inherent limitations of both methods: linkage analysis has low power except when a single locus explains a substantial fraction of disease, and association studies of one or a few candidate genes examine only a small fraction of the "universe" of sequence variation in each patient. Progress in technology and the development of sophisticated statistical tools have paved the way toward the application of Whole Genome Association Studies (WGAS) in a population-based cohort (see Chapter 4). This progress makes it possible to study the full scope of possible genetic determinants involved with phenotypes of drug response in a hypothesis-free fashion (i.e., unbiased approach). However, the quest for the Holy Grail, that is, the identification of causal polymorphisms underlining the phenotype of interest, remains a key unanswered question even when interrogating the entire genome.

While many approaches have been suggested in the literature as to how to decipher between true associations and false-positive results, no consensus is likely to be established in the next few years (for recommendations on replication design in large-scale association studies see the NCI-NHGRI Working Group on Replication in Association Studies [2007]). Expert genetic, biological, and pharmaceutical skills will be needed to establish a prioritization scheme by which result interpretation will reflect not only statistical plausibility but also scientific rationale. Independent comparative studies will eventually give rise to the most successful strategies that should be pursued. Hence, the strategy of choice for years to come will progressively rely on a single universal tagging set that will be used in all whole-genome association studies. This would not only ensure comparability for replication efforts within complex traits but also allow direct comparison of the role of the same variants as risk factors for different conditions. Led by this vision, The National Center for Biotechnology Information (NCBI) is currently managing the submission, storage, and access for clinical phenotype measures and associated whole-genome genotype data for several different programs, making this data as widely available to the research community as possible while protecting the privacy of the participants as defined by consent agreements for individual projects.

Application of whole-genome scans for PGx phenotypes is currently being undertaken by various academic and pharmaceutical researchers. One pioneering example depicts a WGAS investigating drug-induced liver injury ADRs and represents the incorporation of PGx in pharmaceutical R&D (Kindmark et al., 2007).

Pharmacokinetics- Versus Pharmacodynamics-Based Gene Selection

Once administered, a drug goes through a series of interactions in the body that are responsible not only for the therapeutic effect conveyed by this agent, but also for side effects and bystander alterations to other compounds processed in conjunction. As a whole, all interactions related to modifications acted upon the drug by the host body are termed "drug pharmacokinetics" and include all aspects of drug absorption, distribution, metabolism, and elimination (ADME). The most prominently studied molecule group within the sphere of pharmacokinetics has indisputably been drug-metabolizing enzymes (DMEs). These enzymes exist in every eukaryotic cell and in most, if not all, prokaryotes and are thought to have evolved in humans to neutralize xenotoxins and/or to control concentrations of signaling molecules in endogenous pathways (Nebert and Dieter, 2000). The fact that modern drugs have been introduced to the *in vivo* environment very recently in evolution uniquely excludes selection forces from having impacted the functional genetic properties of DMEs, thus potentially permitting whopping effects on drug-response phenotypes (Nebert and Dieter, 2000). In the early years of PGx research and up until very recently, genes encoding pharmacokinetic properties of drugs have been the focus of research (for a comprehensive table of drug–drug interactions based on cytochrome P450 enzymatic activity see [Flockhart, 2007]). This has been due to the scientific expectation of marked clinical effects underlined by diminished or absent capacity of the body to obliterate drugs or transform prodrugs into active compounds, but also due to the pragmatic constraint posed by considerable gaps in our understanding of, and technological methods for, investigating genes encoding drug pharmacodynamic features. Pharmacodynamics relates to any modifications acted upon the host body by the drug, that is, drug targets (receptors or enzymes) and their downstream signal pathways.

With the advent of the Human Genome Project, the HapMap project (see below) and incredible progress in genotyping techniques and costs, it is currently feasible to interrogate known functional, as well functionally as-yet-unknown, genetic variants in pharmacodynamic candidate genes. It is now becoming increasingly evident that polymorphisms within genes involved in the pharmacodynamic properties of drugs may in fact be more important and clinically relevant than variants of ADME genes for non-Mendelian drug-response phenotypes. Examples supporting this notion include reports on the relative contribution of variants in the *VKORC1* and *CYP2C9* genes to warfarin

response (Aquilante et al., 2006); *SCN1A* and *CYP2C9* to phenytoin response (Tate et al., 2005); and *5-HTR$_{2A}$* and *CYP2D6* to paroxetine response (Murphy et al., 2003).

Pathway-Based Analyses and Search for Epistatic Associations

Advances in haplotype tagging strategies have made it possible to represent variation in entire pathways relevant to drug response economically. The focus in pathway-based PGx investigation is further facilitated by the accumulation of knowledge regarding pathways relevant to drug response (e.g. PharmGKB Pathways). Although promising, pathway-based analyses face considerable challenges. Most fundamentally, the huge number of tests conducted when analyzing large SNP datasets, multiple phenotype definitions, and application of a diverse spectrum of parametric and non-parametric statistical methodologies pose considerable barriers on power, statistical design, and interpretation. Increasing the population sample size, applying permutation-based multiple correction methods, and seeking independent replication are obvious solutions dealing with these difficulties. A further complication is that all components of all pathways that a drug acts on are rarely understood completely (Need et al., 2005).

As PGx investigations rapidly progress toward a pathway-centered approach, considering dozens and hundreds of genes in each instance, or assigning prior probability scores of whole-genome scans founded on the biological processes involved with a given drug's PGx, it is progressively evident that research should embrace methods that take into account possible interactions between genetic variants along a pathway of interest. It is very likely that, for instance, genetic-based conformational changes brought forth in one molecule along a drug-related pathway will require complementary structural, quantitative, or functional changes in a downstream (or upstream) molecule to produce a detectable sum total effect on phenotype measurements. This genetic interaction is termed "epistasis" and it is yet unclear how best, computationally and statistically, to surmount the complexity arising from the combinatorial magnitude of all the possible interactions involved within a pathway. Moreover, the high dimensionality of the resulting analysis overwhelms traditional analysis methods, a problem exponentially prohibitive for large candidate gene studies and whole-genome investigations. The Multifactor Dimensionality Reduction (MDR) approach (Wilke et al., 2005) has been suggested as one potential solution for this problem, although sophisticated analytical approaches capable of modeling high order interactions and sizable datasets will have to be developed in order to handle genome-wide and large-scale candidate gene studies.

Gene-expression and proteomic profiling may in the future provide additional knowledge and complementary diagnostics associated with pathways relevant to drug response, although at this time it is difficult to differentiate incidental differences in expression levels from those that are causally relevant to drug response (Need et al., 2005). In conclusion, thanks to technological and computational advances, it is no longer justifiable to look at the effects of single genes in isolation, but rather incorporate the milieu of potential effects more comprehensively describing the sum total of a studied phenotype.

HapMap – A Public Resource for Marker Selection

The International HapMap Project was launched in October 2002 to create a public, genome-wide database of common human sequence variation, providing information needed as a guide to genetic studies of clinical phenotypes (The International HapMap Project, 2003). Four different ethnic populations were systematically genotyped for each SNP variant as follows: (i) 90 individuals (30 parent–offspring trios) from Yoruba, Ibadan, Nigeria; (ii) 90 individuals (30 trios) from Utah, USA (the Centre d'Etude du Polymorphisme Humain collection); (iii) 45 non-related Han Chinese from Beijing, China; and (iv) 44 non-related Japanese from Tokyo, Japan.

The HapMap project set out to describe patterns of association between typed polymorphisms (LD) in the above-described four population samples in order to identify a minimum set of SNPs ("tagging SNPs") sufficient to represent all common variants in the human genome. A publicly available software for tagging has been incorporated into the HapMap website (description and a more detailed version are available in de Bakker et al. [2005]), enabling any given user to select a desirable set of tag SNPs based on a variety of criteria (such as population ethnicity, force inclusion of SNPs with known functional effects or which have previously been described in the literature, and so on). The chief criterion for tagging capacity employed is the r^2 threshold. This is a study-independent measure of SNP utility that has become a leading standard for evaluating performance of marker sets. It represents the correlation coefficient between any observed marker and a putative causal allele, reflecting the expected drop in non-centrality of an association test statistic under specified conditions (Pe'er et al., 2006). It is customary to enforce a minimum pair-wise r^2 threshold of 0.7–0.8.

Analyses increasingly attest to the remarkable performance of tagging (Conrad et al., 2006; de Bakker et al., 2006), indicating that the HapMap samples provide an appropriate resource for selecting globally useful tags (although African populations remain partially unrepresented by tagging approaches due to their high diversity). Thanks to the fact that all phases of the HapMap database have been publicly available ever since the projects' inception, both commercial companies and academic laboratories routinely implement HapMap data in their drug research and development programs. In the realm of pharmacogenetics, for instance, elucidation of differential response to, and dosing of, warfarin anti-coagulation treatment as governed by *VKORC1* was performed using the HapMap data (Rieder et al., 2005). Another example, specifically designed to examine the capacity of HapMap tools to discover and validate PGx phenotypes, was recently published (Jones et al., 2007). In this study, HapMap SNPs in the thiopurine methyltransferase (*TPMT*) gene region (tags) were tested for association with cell line absolute levels of TPMT activity. It was expected that a variant of biochemically and clinically validated relevance to thiopurine plasma levels and induced toxicity will rank as most significantly associated in all analyses. Indeed, this SNP and others in high LD with it tested positively, out of a total of 66 HapMap

SNPs in the *TPMT* gene region. However, an agnostic genome-wide approach to assess genomic predictors of TPMT phenotype in this dataset ranked *TPMT* haplotypes at 97th place out of the 17,542 genes tested. The latter result demonstrates that whole-genome tagging approaches are useful screening tools for the highest few percent of associated genes; nonetheless, ultimately biology, biochemistry, and clinical expertise are required to decipher true associations from false-positives.

Validation of Association Results

Any results detected in "first stage" genetic analyses require further validation. This is usually accomplished by two lines of investigation: functional analysis and replication studies. Functional studies are aimed at revealing direct causality between the reported genetic variant and measurable functional modifications elicited in the encoded molecule by employing animal models (e.g., knockout mice) or *in vitro* investigations. Replication studies are performed in independent patient populations mimicking as closely as possible the study design settings and testing only the top priority fraction of SNP associations detected in the first stage. Replication analysis serves not only for confirmation of true association between a genetic marker and a phenotype of interest, but it is also a means for better assessing the true magnitude of the detected effect, as first publications tend to report inflated effects due to the phenomenon termed "the winner's curse" (Ioannidis et al., 2001).

Prospective pharmacogenetic analyses compromise an important step toward the validation of genetic markers as predictors of clinical management in "real-life" settings (Grossman, 2007). Although few such studies have been conducted thus far, it is becoming generally accepted that prospective analyses comprise necessary and integral evidence of the potential utility of genetic tests in routine health care management. Initiatives already prospectively monitoring patients for PGx outcomes include several studies aimed at analysis of cost-effectiveness of *HLA-B**5701* genotyping in abacavir-treated HIV-positive patients prone to suffer from hypersensitivity reaction (Hughes et al., 2004, 2007; Rauch et al., 2006; Zucman et al., 2007); a genotype-guided clinical cancer trial for management of rectal cancer by irinotecan therapy based on analysis of a polymorphic tandem repeat in the 5′-untranslated region of the *TYMS* enhancer region, resulting in 2–9 copies of a 28-bp repeated sequence (McLeod et al., 2005); and genotype-guided dosing analyses of warfarin therapy (Hillman et al., 2005).

FROM BENCH TO BEDSIDE: INTEGRATION OF PHARMACOGENETIC TESTING INTO CLINICAL PRACTICE

Analytic Assessment of Pharmacogenetic Tests and Their Utility in Clinical Practice

Demonstration of unambiguous association between genotype(s) and drug-response features in controlled retrospective datasets, albeit promising, does not guarantee the usefulness of routine genetic testing for the clinical decision-making process in the daily clinical environment. A whole host of factors need to be further assessed in order to predict and determine the cost-effectiveness and practical utility of a pharmacogenetic diagnostic test. This evaluation should follow recommendations such as those devised by the Centers for Disease Control (CDC, 2006), including four components: Analytic Validity; Clinical Validity; Clinical Utility; and Ethical, Legal, and Social implications. Each of these components focuses on a different aspect of test performance and applicability in real-life settings, starting at the laboratory performing the test, through clinical studies proving its benefits, to more subjective evaluation of managed care burden associated with introduction of the test to routine practice and reimbursement frameworks. Each of these components can be empirically measured to reflect high validity and clear utility standards:

1. *Analytic validity* of a genetic test defines its ability to accurately and reliably measure the genotype of interest. Empirically, analytic validity includes *analytic sensitivity* (or the analytic detection rate, =number of polymorphism carriers detected by the test divided by the total number of polymorphism carriers in the population); *analytic specificity* (=number of normal genotype carriers detected by the test divided by the total number of individuals who do not carry the polymorphism); *laboratory quality control* (including measurements such as inter- and intra-assay variability, repeatability, and so on); and *assay robustness* (measuring how resistant the assay is to changes in pre-analytic and analytic variables, such as inter-laboratory variability, DNA extraction methodology, and so on).
2. *Clinical validity* of a genetic test defines its ability to detect or predict the associated phenotype. Empirically, clinical validity includes *clinical sensitivity* (or the clinical detection rate, =the proportion of individuals who have a well-defined clinical phenotype and whose test values are positive); *clinical specificity* (=the proportion of individuals who do not have the well-defined clinical phenotype and whose test results are negative); *prevalence of the specific phenotype* (=the proportion of individuals in the selected setting who have, or who will develop, the phenotype); *positive predictive value* (=the proportion of individuals with a positive test result who have, or will develop, an unwanted response when the drug is administered, PPV); *negative predictive value* (=the proportion of individuals with a negative test result who will not have, or will not develop, an unwanted response when the drug is administered, NPV); *penetrance* (the frequency, under given environmental conditions, with which a specific phenotype is expressed by those individuals with a positive test result); and *modifiers* (genetic or environmental).
3. *Clinical utility* of a genetic test defines the elements that need to be considered when evaluating the risks and benefits

associated with its introduction into routine practice. Empirically, clinical utility includes *administration settings recommendations* (such as optimal time line for administration of the test, either prior to treatment initiation, during the first phase of dosing adjustments, or else); *availability and effectiveness of counter-interventions*; *quality assurance* (procedures in place for controlling pre-analytic, analytic, and post-analytic factors that could influence the risks and benefits of testing); *pilot trials* (assessing the performance of testing under real-world conditions, where inclusion criteria allow for individuals to experience co-morbidities, take concomitant medications, and so on); *health risks* (adverse consequences of testing or interventions in individuals with either positive or negative test results); *economic evaluation* (financial costs and benefits of testing); *facilities* (assess the capacity of existing resources to manage all aspects of the service); *education* (quality and availability of informational materials and expertise for all aspects of a screening service); and *monitoring* (assess a program's ability to maintain surveillance over its activities and make adjustments).

4. *Ethical, legal, and social implications* surrounding a genetic test represent the safeguards and impediments that should be considered in the context of all the other components.

FDA Regulation Policy and Its Impact on PGx Testing Application in Real-Life Health Care

The FDA has recognized the importance of PGx and encourages its use in drug development. Recognizing that the clinical component of the overall cost of successful new drug development is ~58% of total costs (DiMasi et al., 2003) and that ~50% of Phase III trials fail, the FDA is promoting identification of PGx biomarkers at early drug development stages that would predict which drugs are likely to either fail or succeed in Phase III trials. This approach is reflected in the FDA's 2004 white paper (FDA, 2004a), which identifies PGx as a key opportunity for the Critical Path. In addition, the FDA believes that there is value in applying long-established PGx testing to older, marketed drugs in the post-marketing period to improve their risk/benefit ratio by optimizing or individualizing dosing (Lesko and Woodcock, 2004). While multiple enthusiastic statements supporting the incorporation of PGx analysis to both new drug development and monitoring of marketed drugs have been made by FDA officials (Frueh et al., 2005; Lesko and Woodcock, 2002, 2004), there has not been a proactive regulatory action enforcing genomic data submission. In fact, ever since the publication of *Guidance for Industry: Pharmacogenomic Data Submissions* in 2004 (FDA, 2004b), relatively few drug labels have been updated to include recommendation for PGx testing (Table 15.2). The current policy refrains from enforcement of submissions, while promoting Voluntary Genomic Data Submission (VGDS). It is remarkable to note that despite the non-compulsory nature of this guiding principle, VGDS submissions are rapidly amassing and were filed for over 30 different compounds in the first year, exhibiting a growth trend going forward (Frueh, 2006).

EXAMPLES OF PGx TESTS: PROMISING NEW DEVELOPMENTS AND MARKETED PRODUCTS

Warfarin

Perhaps the best example of a successful pharmacogenetic association, for which the clinical relevance is clear, features management of treatment with the oral anti-coagulant warfarin, Warfarin, a derivative of coumarin, is prescribed for the long-term treatment and prevention of thromboembolic events, with more than 21 million prescriptions annually in the United States alone (Rieder et al., 2005). However, due to the drug's narrow therapeutic index, a variety of complications are associated with its treatment, even after dose adjustment according to age, sex, weight, disease state, diet, and concomitant medications. Investigation of pharmacokinetic and pharmacodynamic drug properties indicated the additive involvement of two genes in determination of warfarin maintenance dose. The first gene to be identified encodes CYP2C9, which is responsible for most of the metabolic clearance (~80%) of the more pharmacologically potent *S*-enantiomer of warfarin (Rettie et al., 1992). Both *CYP2C9*2* and **3* cause a reduction in *S*-warfarin clearance, with 10-fold variation seen from the genotype linked with the highest (*CYP2C9*1/*1*) to lowest (*CYP2C9*3/*3*) activity. Numerous studies have associated these genotypes with initial dose sensitivity, delayed stabilization of maintenance dose, delays in hospital discharge, and increased bleeding complications (Gardiner and Begg, 2006). However, it is estimated that *CYP2C9* variants account for only 10–20% of the total variation in warfarin dose, with additional genetic and environmental factors playing larger roles in dose determination. The second gene identified as a predictor of dosing encodes the vitamin K epoxide reductase complex protein 1 (VKORC1), targeted by warfarin. Consideration of the *VKORC1* genotype or haplotype, together with the *CYP2C9* genotype, and factors such as age and body size are estimated to account for 35–60% of the variability in warfarin dosing requirements.

Despite the fact that these data have been reproduced by multiple independent groups, it remains to be tested in large, prospective, clinical studies whether initial dose may be tailored to patients by *CYP2C9* and *VKORC1* genotyping, coupled with known clinical variables. While these studies are currently under way, the clinical pharmacology advisory panel to the FDA acknowledged (November 2005) the importance and potential for genotyping of *CYP2C9* and *VKORC1* during the early phase of warfarin therapy, and the drug label was amended accordingly in August 2007. A month later, the FDA cleared for marketing the Nanosphere Verigene Warfarin Metabolism Nucleic Acid Test to aid physicians manage warfarin therapy.

Trastuzumab

Trastuzumab therapy for the treatment of breast cancer (involving a monoclonal antibody specifically targeting HER2/*neu*

Table 15.2 FDA valid pharmacogenetic biomarkers – associated dosage guidelines in drug labels and availability of approved genetic tests (Summer, 2007)

Drug [# drugs with similar label references]	Gene (*variant*)	Gene function/ significance	Dosage guidelines	Label section	PGx test?	FDA-approved test available?
Voriconazole [6]	CYP2C19 (*poor metabolizers*)	Major metabolizer	1. Contraindicated concomitantly with CYP450 inducers; 2. Increased maintenance dose regimen outlined for Phenytoin; 3. No adjustments[a] for oral contraceptives inhibiting CYP2C19 or HIV protease inhibitors that inhibit CYP3A4; 4. Reduce Cyclosporine and Omeprazole by half; 5. Reduce Tacrolimus to one third	Clinical pharmacology; Drug Interactions;	No	AmpliChip/Roche
Celecoxib [1]	CYP2C9 (*poor metabolizers*)	Major metabolizer	No	Clinical pharmacology; Drug interactions;	No	No
Atomoxetine [17]	CYP2D6 (*poor metabolizers*)	Major metabolizer	Specific regimen suggested when strong CYP2D6 inhibitor co-administered	Clinical pharmacology; Drug interactions; CYP2D6 metabolism; General dosing information	No	AmpliChip®/Roche®
Capecitabine [2]	DPD (*deficiency*)	Rate-limiting metabolizer	Contraindicated	Contraindications; Clinical pharmacology; Precautions	No	No
Rusburicase [3]	G6PD (*deficiency*)	Severe hemolysis caused by hydrogen peroxide by-product	Contraindicated	Boxed warning; Contraindications; Warnings	Recommended	No
Rifampin, isoniazid, and pyrazinamide [1]	NAT (*slow acetylator*)	Isoniazid major metabolizer	No	Clinical pharmacology; Adverse reactions; Drug interactions	No	No
Azathioprine [2]	TPMT (**2, *3A and *3C*)	Metabolizer	Recommended altered regimen, but not specified	Warnings; Lab tests; Dosage and administrations; Drug interactions	Recommended	No
Irinotecan	UGT1A1 (**28*)	Conjugation of active metabolite	Consider reduction of dose in homozygotes	Clinical pharmacology; Warnings; Dosage and administration	No	Invader assay/Third Wave

This table is adopted from Grossman (2007). Details in this table are derived from package inserts of the listed drugs and the table of valid genomic biomarkers in the context of approved drug labels http://www.fda.gov/cder/genomics/genomic_biomarkers_table.htm.

Note – A drug label change was introduced in August 2007 *VKORC1* (in addition to *CYP2C9*) genotyping in patients requiring warfarin therapy. An accompanying genetic test (Nanosphere Verigene Warfarin Metabolism Nucleic Acid Test) was FDA-approved in late September 2007.

[a] Most adjustments relate to CYP3A4 drug–drug interactions, although it is a minor metabolizer of Voriconazole.

over-expressing tumors) is not only an example of a protein therapeutic for which an obligatory biomarker assay has been issued, but it is also an example of the utilization of PGx research for drug rescue: trastuzumab is marketed solely for the subset of patients (~10–25%) who over-express HER2/*neu*, providing care to eligible patients and returning the investment to the developing manufacturer. Interestingly enough, although in practice the obligatory biomarker assay has been set to measure protein over-expression by immunohistochemistry, studies have shown stronger association when patient subsets were determined by fluorescence *in situ* hybridization, reflecting gene copy number (Krejsa et al., 2006).

6-Mercaptopurine

In 1953, the drug 6-mercaptopurine (6-MP) was marketed in the United States for the treatment of leukemia. Despite great expectations in the medical world, about 20 years ago fatal toxicity was discovered in 0.3% of treated children. A similar scenario was repeated for azathioprine marketed in 1968. It was later discovered that polymorphisms within the *TPMT* gene underlie the large inter-individual differences in the enzyme's activity, leading to a high risk of thiopurine-induced toxicity in homozygotes for the defective alleles, and inadequate therapeutic efficacy in patients with high activity TPMT. Tests for TPMT activity (genotype, enzyme activity, and metabolite screening) are available in the United States and throughout Europe; however, clinical implementation of these tests is very low. This is contrary to expectations based on cost-effectiveness analysis of TPMT testing in children with acute lymphocytic leukemia (ALL) showing high savings per life-year (Zika et al., 2006). Current clinical practice for the management of leukemia via thiopurine medications dictates careful monitoring of white blood cell counts and clinical outcomes in a fashion that negates the necessity of incorporating the genetic test for prevention of serious adverse events. It is expected, however, that as genetic tests become generally accepted for a variety of conditions, it will become progressively acceptable both by physicians and health systems, as well as by the general public, to use *TPMT* genetic tests as prognostic tools.

AmpliChip

The first microarray-based gene-chip, approved both in the United States and EU, was released to the market by F. Hoffmann-La Roche Ltd (Switzerland) in 2003 as the AmpliChip CYP450®. The product was designed to identify key genetic polymorphisms in two CYP450 genes, *CYP2D6* and *CYP2C19*, the products of which are cumulatively responsible for much of the first pass metabolism of many pharmaceutical compounds. As highlighted by insurance companies who refuse to cover the costs ($600–$1300), the test has not been clearly demonstrated to convey clinical utility and sufficient cost-effectiveness (Grossman et al., 2008; Thakur et al., 2007) and is deemed "experimental, investigational or unproven." The regulatory agencies cleared this test based solely on analytical performance and validity information, but indicated its utility specifically for clinical application. Thus clinicians, as well as patients, were misled to expect firm impact on clinical decision-making guidelines. Until unambiguous evidence proves the clinical use of this and other genetic tests, caution is advised in their interpretation and application in health care management.

FUTURE DEVELOPMENTS REQUIRED FOR THE FIELD TO FULLY MEET ITS EXPECTATIONS

Table 15.3 summarizes steps still needed for PGx testing to materialize into practical tools used in clinical decision-making. First, in order to capture the entirety of processes involved in, and affected by, any given drug, both *in vivo* and in interaction with environmental factors, open communications between researchers, practitioners, regulatory agencies, and pharmaceutical industries must be established. Launching PGx educational programs within the academic curriculum will facilitate acceptance of genetic testing both by health care providers and by the general public.

Next, facilitated by the latter, large prospective studies must be conducted in order to truly evaluate the utility of genetic tests for specific indications in "real-life" clinical setting. Tailoring the research to specifically target PGx-based end-points, rather than adopting and artificially manipulating retrospective measurements from treatment efficacy clinical trials, will assist in elucidating "true" PGx effects. In this fashion, employing placebo, control, and multiple dosing treatment groups may act as means for detection of specific drug-induced genetic mechanisms.

As research progresses and technology develops the need for investigation of gene–gene and gene–environment effects in a computationally reasonable manner will become more and more pressing. Such lines of investigation will require large, often combined, datasets, necessitating the standardization of phenotype definitions by the research community.

Lastly, incorporation of genetic testing in clinical practice will only become possible if regulatory and funding agencies acknowledge its potential and promote its development by changing their policy. PGx is a field uniquely attractive to both academic medical centers and the pharmaceutical and biotechnological industries. As such, governmental agencies, such as the US FDA and the European Medicines Agency (EMEA), regulate the development, marketing, and clinical applications associated with maturation of research advances. In order for PGx to wholly fulfill its potential and expectations a structured framework of incentives, priorities, and policies must be devised that would promote allocation of resources by each of the concerned parties. A potential solution to improve surveillance might be sampling and privacy-protected DNA banking from the first 250,000 patients treated with a newly marketed drug, or a similar risk-management system coordinated with regulatory agencies (Roses, 2004).

The most pronounced deficiency identified in PGx research relates to the need to improve drug safety and efficacy profiles of generic, off-patent drugs. In this aspect it is important to mention

TABLE 15.3 Steps required for PGx to fully meet its potential as "the right drug for the right patient"

Future challenges

- Integrative approach: Cross-talk between geneticists, statisticians, pharmacologists, molecular biologists, physicians, regulatory agencies, and pharmaceutical companies.
- Education programs should be incorporated into the academic curriculum.
- Prospective studies have to be conducted to evaluate the potential predictive power and clinical utility of PGx testing in clinical settings. Possibly employ placebo and control treatment groups in analysis to elucidate specific drug-induced genetic effects.
- Focus on gene–gene interactions and the net genetic effect.
- Integrate environmental effects and gene – environment interactions into the statistical models.
- Standardize unequivocal and reproducible phenotype definitions.
- Genetics will get more and more acceptable as a tool for clinical practice as policy will catch up with scientific developments.
- Surveillance of ADRs in the post-marketing phase through risk-management systems coordinated by both manufacturers and regulatory agencies.
- Establishment of incentive structure for the industry to improve drug safety and efficacy beyond the terms of current patent protection.

that withdrawn medications lose their patent protection, and thus commercially driven pharmaceutical companies lose interest in rescuing these formulations by conducting safety PGx experiments. To date, it has yet to be demonstrated whether PGx would be cost-effective in resurrecting failed marketed drugs (Shah, 2006), but thorough investigations have yet to be conducted. Only controlled incentives, calling for prolongation of patent protection terms and similar motivations, will drive the pharmaceutical industry to invest the considerable costs and resources required.

2009 UPDATE

The last year has witnessed much progress in the field of PGx, with many publications and several regulatory changes that promote the overall usefulness and significance of PGx to clinical management and novel drug discovery and development.

Most of the published work has been focused on marketed drugs as conducted by various independent groups, collectively contributing both to the elucidation of PGx pathways and biological etiology, as well as the demonstration of clinical utility and economic cost-effectiveness. Examples that have already impacted the usage of drugs by drug label updates include carbamazepine, for which serious dermatological reactions have been highly associated with carriage of *HLA-B*1502* in subjects with ancestry from South, East, and South-East Asia; abacavir, for which hypersensitivity reaction has been highly associated with carriage of *HLA-B*5701*; and warfarin, for which dosing adjustment has been associated with variants in both *CYP2C9* and *VKORC1*. Cleared genetic diagnostics are available for all of the above, but in the case of warfarin, health outcomes and prospective genotype-guided and cost-effectiveness studies are only now being carried out to define the exact dosing adjustment algorithms that should guide healthcare providers in the management of patients.

Another important advance in the field was the adoption of PGx testing as clinical guidelines for the management of colorectal cancer with erbitux and vectibix. The National Comprehensive Cancer Network updated its colorectal cancer guidelines last year to include *KRAS* testing. More recently, the American Society of Clinical Oncology (ASCO) also recommended that patients test their tumors for *KRAS* gene status before treatment with Erbitux or Vectibix. It is expected that the US FDA will relabel these drugs in accordance soon.

Other published data have yet to reach regulatory discussion and decision-making, but have generated significant evidence on clinical impact that would clearly affect future treatment regulation. The first such example relates to a whole-genome association study (WGAS) conducted in statin-treated patients that identified risk variants in the *SLCO1B1* gene and strong association with an increased risk of statin-induced myopathy (Link et al., 2008). The authors studied two sets of patients and control groups from large trials, where the training set was derived from about 1200 subject study (80 mg simvastatin once daily), and tested in patients derived from a 20,000 subject trial (40 mg simvastatin daily). This genome-wide study illustrated the power of hypothesis-free analyses in the context of rare, yet severe ADRs with strong genetic etiology. *SLCO1B1* encodes the organic anion-transporting polypeptide OATP1B1, which mediates the hepatic uptake of most statins and their acids. Candidate gene studies reported in the last few years have shown the involvement of genetic markers in this gene with various drug response phenotypes associated with both the safety and efficacy of several statins. A similar paper that speaks to the utility of WGAS studies in the context

of severe ADR investigations was published last year (Nelson et al., 2008). It is therefore clear that lessons learned from disease susceptibility WGAS would be applicable to implementations of PGx (McCarthy et al., 2008).

Another example that illustrates the potential usage of PGx testing for future guidance of treatment prescriptions, particularly as second and third in-class medications – which do not bear a genetically-associated safety issues – launch into the market, is clopidogrel. This pro-drug, used as an antiplatelet agent as one of the most frequently prescribed drugs in the world, exhibits substantial inter-individual variability in pharmacodynamic response linked to increased risk of cardiovascular events. Data published in recent months indicate that *CYP2C19* genetic variants are involved in pharmacokinetic exposure (Brandt et al., 2007; Kim et al., 2008), pharmacodynamic response (Hulot et al., 2006; Frere et al., 2008), and clinical outcomes (Simon et al., 2008; Trenk et al., 2008). However, as each study adopted differential study designs, target populations, end-point definitions, and genotypic models, the practical utility of the unequivocal role that *CYP2C19* polymorphism plays in the clinical management of patients and the precise treatment guidelines that should be adopted by healthcare providers and insurers awaits further investigation.

The pharmacoeconomics of PGx studies has gradually become a mainstay of PGx diagnostics evaluation, and several groups across various therapeutic areas, drug classes, and geographic locations have employed simulation and trialed datasets to provide recommendations for or against implementation of particular PGx tests in routine healthcare (Huang and Ratain, 2009; Matchar et al., 2007; McClain et al., 2008; Smits et al., 2007). A review systematically surveying pharmacoeconomic analyses of genetic screening strategies, including recommendations for good practice, regardless of country and analysis origin was published by Vegter et al. (2008).

Overall, the above examples illustrate the successful implementation of WGAS as well as large pathway candidate gene studies in the context of PGx analysis. In addition, it is clear that large, well-powered, and appropriately designed PGx replication studies and prospective genotype-guided versus standard-of-care studies are becoming important milestones in the adoption of treatment guidelines and future regulation (as is the case for warfarin [Teagarden and Mayor, 2008]). These case studies also illustrate the growing need for refinement of the paradigm of the development of diagnostics that accompany the prescription of new drugs. Novel models promoted by the FDA advocate co-development of genetic diagnostics in tandem with the development of the drugs for which they will be specifically indicated (Food and Drug Administration, 2005; Hinman et al., 2009; Simon, 2008). The rapidly growing market for direct-to-consumer (DTC) genetic tests highlights the changing environment and the need for adjusting the regulatory frameworks to support enhanced oversight on indicated usage while incentivizing research institutions and industry to utilize PGx diagnostics for improved and safer treatment prescription (Hogarth et al., 2008). Thus an inherent requirement to demonstrate clinical validity and utility in the target population of interest is advocated to become an integral part of a diagnostics' submission package. As a direct result, clear guidance on safe and effective usage would be issued immediately upon marketing, based on objective measurements derived from appropriately powered clinical trials.

CHAPTER

Clinical Implementation of Translational Genomics

Wendy K. Chung

INTRODUCTION

In the 55 years since the structure of DNA was described by Watson and Crick, there have been remarkable advances in our understanding of the genetic basis for human variation and disease. We have now defined the genetic basis for over 2130 monogenic human disorders, and clinical genetic tests are available for over 1410 disorders (http://www.genetests.org/). Despite the remarkable advances in our scientific understanding of genetics and genomics, the impact of such information on medical care for common conditions has to this point been modest. With the complete sequence of the human genome and many other model organisms as well as detailed characterization of human haplotype structure, we have now begun elucidating the complex genetic basis for common diseases such as macular degeneration, diabetes, obesity, inflammatory bowel disease, and breast cancer using genome-wide association studies. In some cases the same allele will increase risk for one disease and protect against another. The *ApoE4* allele is associated with a protective effect for age-related macular degeneration yet susceptibility to Alzheimer disease and hyperlipidemia. As additional scientific discoveries unfold, we will be challenged to clinically integrate this new information into routine patient care to improve health and quality of life in a cost-effective, socially acceptable manner. Early adopters of this new genetic information will provide invaluable experience to guide future implementation strategies. In this chapter, we will review the current and projected future use of genetics and genomics in clinical medicine and define the steps to successful integration of genomic medicine to improve the quality of health care. A schematic of the elements necessary to develop clinical genomic medicine is provided in Figure 16.1.

GENETIC STRATIFICATION WILL ALLOW MEDICAL CARE TO BE INDIVIDUALIZED AFTER A DIAGNOSIS IS MADE

How will germline genomic variation be clinically utilized? There are emerging data that the genetic stratification of phenotypically similar diseases has important therapeutic implications. Genetic characterization following an initial diagnosis may clarify prognosis and response to therapy. Three examples to illustrate this point.

1. *Genetic testing may provide information about future risk.* Women with breast cancer due to mutations in *Breast Cancer 1/Breast Cancer 2* (*BRCA1/BRCA2*) have an increased risk for a second primary cancer, usually breast or ovarian cancer, for which increased surveillance, chemoprevention, or prophylactic surgery are recommended (Verhoog et al., 1998). However, women with breast cancer without *BRCA1/BRCA2* mutations are not at increased risk for ovarian cancer (Kauff et al.,

Essentials of Genomic and Personalized Medicine

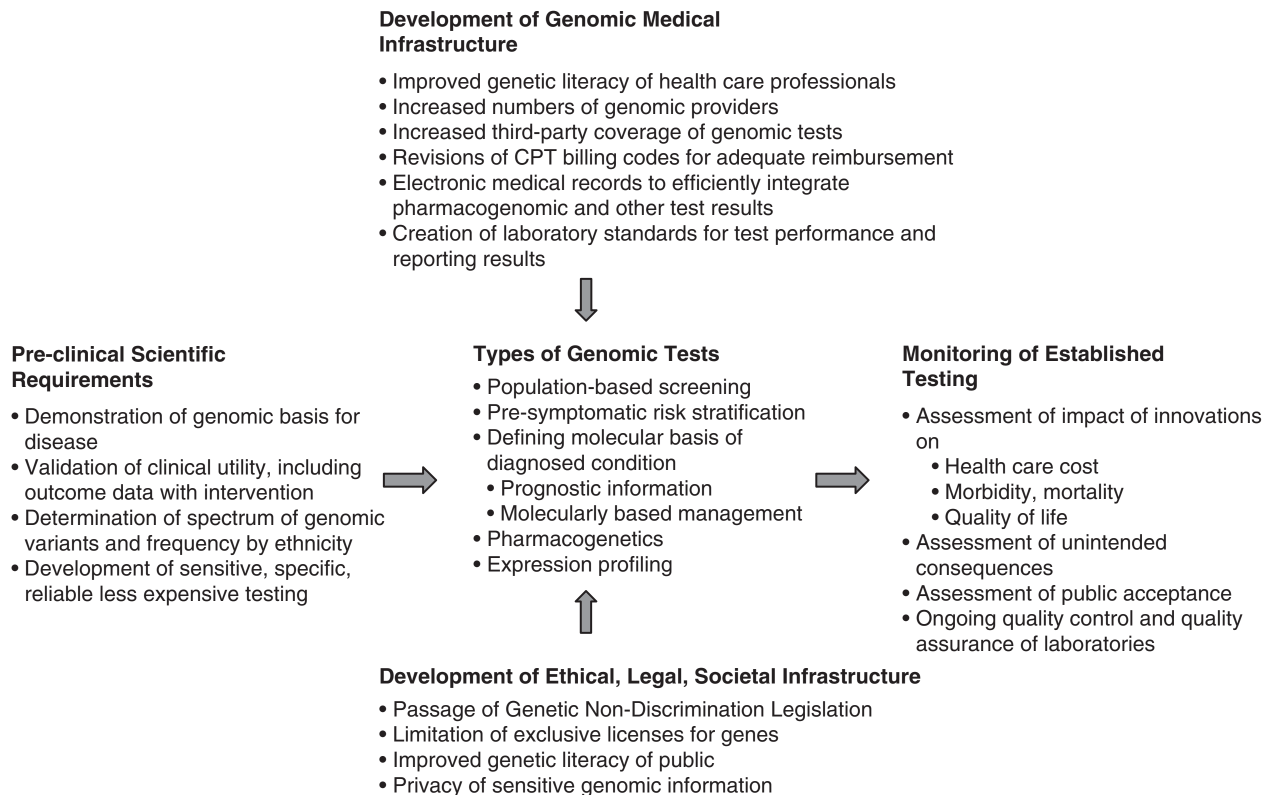

Figure 16.1 Development of clinical genomic medicine. The requirements to develop a health care system efficiently and effectively integrating genomic information are shown and include pre-clinical scientific data, improvements in medical infrastructure, changes in laws, policy, and public opinion, and monitoring of testing and its impact once established.

2005). Determining which women with breast cancer are at increased risk of ovarian cancer and should have prophylactic oophorectomies to reduce the risk of future ovarian cancer can be clarified with *BRCA1* and *BRCA2* testing.

2. *Genetic testing may provide information to optimize therapy*. Long QT syndrome (L\QTS) is an inherited predisposition to cardiac arrhythmias characterized by a prolonged QT interval on an electrocardiogram that can result in syncope and sudden cardiac death. There are currently nine different genetically identified causes of LQTS, all affecting cardiac ion channel conductance that are clinically difficult to distinguish. The three most common forms of LQTSs (LQT1, LQT2, and LQT3) have specific triggers for arrhythmias they can be avoided such as exercise-induced tachycardia in LQT1 and auditory stimuli during sleep in LQT2 (Schwartz et al., 2001). Specific molecularly based pharmacological intervention is also now available. For example, patients with LQT3, due to mutations in the cardiac sodium channel gene *SCN5A* that inappropriately activate and open the sodium channel, respond to sodium channel blockers such as flecainide (Moss et al., 2005). In contrast, beta-blockers are routinely prescribed for LQTS1 and LQTS2. Therefore, identifying the molecular subtype of LQTS allows for selection of the most appropriate medication and avoidance of specific triggers.

3. *Genetic testing may provide prognostic information to guide management*. An autosomal dominantly inherited form of diabetes called maturity onset diabetes of the young (MODY) is genetically heterogeneous and caused by mutations in six different genes. Prognosis, including diabetic complications, for patients with mutations in *Glucokinase* (MODY2) is much better than other forms of MODY. Molecular diagnosis can now provide reassurance that tight glycemic control is unnecessary to prevent diabetic complications in MODY2 patients who will remain only mildly hyperglycemic (Codner et al., 2006).

POPULATION-BASED GERMLINE GENOMIC SCREENING

Rather than waiting until a diagnosis is made, genetic and genomic variation can be used to prevent disease. Population-based genomic screening could provide the opportunity to improve health outcomes by disease prevention and increased surveillance to facilitate early diagnosis. It would allow population

stratification to identify individuals at increased risk who are most likely to benefit from preventive medications or interventions for which population-based therapy would not be appropriate based on cost or side effects of treatment. Data to support an individual's susceptibility to disease could also provide the necessary motivation to increase compliance with recommended health behaviors such as exercise and weight control for individuals at increased risk for diabetes and smoking cessation for lung cancer. Screening individuals at risk for adverse outcomes to specific environmental exposures would allow susceptible individuals to modify their work or home environment to minimize exposure. Screening individuals for adverse pharmacological reactions would provide a rational basis for drug selection and avoid harmful side effects. Such a strategy would ultimately increase the total number of drugs available for clinical use and decrease the cost of drug development by identifying and eliminating drug exposure to the small number of patients who would have adversely responded to the medication. Although there is great promise for population-based screening, it is important to ensure that the natural history and clinical utility (see section on clinical utility) have been adequately defined before introduction into clinical care. As an example, consider the case of hereditary hemachromatosis. Two common mutations with a single gene (*HFE*) account for the majority of autosomal recessively inherited hereditary hemachromatosis in Europeans (Jazwinska et al., 1996). Furthermore, because the complications of hereditary hemachromatosis are completely preventable by reducing iron stores through phlebotomy (which is inexpensive), presymptomatic screening for hereditary hemachromatosis could be clinically useful. With a frequency of 1 in 400 Caucasians carrying one or both of two common mutations in *HFE*, large-scale population-based screening is technically feasible. As many experts considered introducing hereditary hemachromatosis screening on a population-wide basis, it became increasingly apparent that the natural history of mutation carriers was incompletely understood and that the disease penetrance is less than 1% (Beutler et al., 2002). Although population-based screening for hereditary hemachromatosis still has clinical utility, the implications of a positive genetic test are less significant than had once been anticipated, dramatically altering the cost-benefit ratio. Criteria to use in considering further tests for population-based screening include the disease prevalence, disease penetrance, availability of sensitive, specific, and cost-effective screening tests which may depend upon the number of genes involved and the mutation spectrum, availability of acceptable means of prevention or early detection, and the infrastructure available to perform the screening and follow up the results with confirmatory testing.

NEWBORN SCREENING

Newborn screening is the largest population-based public health screening program currently in practice in the United States and throughout the world. Recent technological advances including tandem mass spectrometry and molecular genetic diagnostics have allowed many states in the United States to cost-effectively increase the number of disorders for which newborns are screened well beyond the classically screened diseases such as phenylketonuria, hypothyroidism, and galactosemia. Over 30 disorders are now screened in many US states. Most of recent expansion in newborn screening is for inborn errors of metabolism detected by metabolomic characterization of a dried spot of blood from a newborn heel stick. Additional molecular genetic diagnostic platforms have recently been added by many states as a second-tier screen to decrease the number of false-positives from metabolomic characterization. Two-tiered screening provides a complementary method to confirm inherited diseases with a small number of well-characterized mutations such as in medium-chain acyl dehydrogenase deficiency (MCAD), cystic fibrosis, and congenital adrenal hyperplasia. The use of tandem mass spectrometry and molecular genetic testing have now opened the possibility to screen for a vast number of inherited conditions. At the request of the General Accounting Office and Health Resources and Services Administration, the American College of Medical Genetics recently re-examined the criteria for determining which disorders to include in newborn screening (http://mchb.hrsa.gov/screening/). Unlike universally accepted screening for disorders such as phenylketonuria for which early detection provides the opportunity for complete prevention of permanent disabilities, some of the newly added disorders allow for early diagnosis and treatment initiation but do not provide a cure or effectively prevent all the long-term disabilities. There is now an ongoing, evolving dialogue about what disorders should be included in newborn screening and whether the criteria proposed by Wilson and Jungner (1968) must be satisfied. Cystic fibrosis is currently screened in newborns in 28 states. Krabbe disease, treatable only by bone marrow transplantation, is now performed in New York. Many other common genetic conditions such a spinal muscular atrophy, Fragile X, and muscular dystrophy have been considered even though only supportive care is currently available for these conditions. What treatment is efficacious enough to warrant population-based screening is debated. Clearly an important factor limiting screening for many conditions is availability of technology to allow for inexpensive, sensitive, and specific screening. Multiplexed DNA microarrays to screen for inherited disease susceptibility and infectious agents in newborns have been suggested (Green and Pass, 2005) and are being piloted. In general, pediatricians have endorsed the expansion of screening in high-risk infants (Acharya et al., 2005) since it leads to reduced time to diagnosis and initiation of treatment, decreased expense and invasiveness of diagnostic testing, and allows for informed reproductive planning for the family. However, as the number of disorders screened increases, it is equally necessary to improve test parameters to increase specificity and reduce the number of false-positive tests to spare the parents of unaffected children the anxiety of a potential diagnosis that will never be made (Waisbren et al., 2003). Not all genetic testing is appropriate for newborns. Genetic testing should be defined and limited to conditions for which there will be medical implications for minors, and no genetic testing should be performed for adult onset conditions for which there is no intervention during childhood.

SOMATIC GENOMIC VARIATION

In addition to testing for heritable germline genetic characteristic, we will need to characterize somatic variation over the lifetime of an individual, especially in characterizing oncological specimens. Cancer treatment is likely to be rapidly redefined with genomic characterization of tumors using a combination of comparative genomic hybridization, quantification of gene amplifications/deletions, identification of acquired genetic mutations, and gene-expression profiling. These methods are already clinically utilized and used on a small scale. Molecularly targeted medications with fewer side effects will be more frequently developed as we rationally develop drugs based upon specific molecular targets. Examples already include the tyrosine kinase inhibitor imatinib mesylate (Gleevec) for chronic myelogenous leukemia and gastrointestinal stromal tumors that over express the tyrosine kinases, trastuzumab (Herceptin) for *HER2* over expressing breast cancer, and gefitinib for activating mutations in *Epidermal Growth Factor Receptor* for non-small cell lung cancer (Lynch et al., 2004). These medications offer the possibility of increased efficacy and rely critically on accurate molecular tumor characterization to identify the subset of patients who will likely respond to these expensive therapies. Genomic Health Inc. offers another form of genomic tumor characterization, a limited expression profiling array (Oncotype Dx) of 21 genes for estrogen receptor positive, node negative, stage one or two breast cancer. The expression profile quantifies the likelihood of breast cancer recurrence in women with newly diagnosed, early stage breast cancer and assesses the benefit of chemotherapy with a numerical scoring system ranging from 1 to 100. The ability of this assay to analyze gene expression on paraffin embedded tissue offers an advantage over the requirement of freshly frozen tissue since new procedures for tissue handling and storage need not be developed to utilize this technology. The ability to simply, numerically quantify and integrate complex genomic information facilitates physician and patient communication and understanding to allow patients and physicians to make more rational decisions about therapy. Although not always covered by third-party payers, some patients are willing to personally bear the cost of testing to provide additional reassurance that chemotherapy will not benefit them and will allow them to avoid chemotherapy associated morbidity without increasing risk of recurrence. Third-party payer coverage will increase as clinical utility is demonstrated, patients and physicians requests for testing increases, and as diagnostic laboratories perform sufficient volumes of tests to negotiate carve out contracts with major health insurers and CMS to cover testing. There are currently multiple oncology clinical trials in progress to determine the precise algorithms by which expression profiles will be weighted and analyzed and to determine the clinical utility for prognosis and treatment efficacy (Buckhaults, 2006). Similar expression profiles from blood samples are currently being used to predict rejection for cardiac transplant recipients and obviate the need for an invasive cardiac biopsy if the expression profile indicates a low probability of rejection (Deng et al., 2006). It is likely that clinically relevant diagnostic tools will soon be available for multiple tumor types to assist with oncological management and multiple solid organ transplants to predict rejection.

NOVEL SOURCES OF GENOMIC VARIATION

In addition to the nuclear germline and somatic mutations resulting from alteration in one or a small number of nucleotides, there are additional sources of genomic variation, the clinical significance of which is not yet fully appreciated. Human genomic architecture and variation are now being characterized. It is likely that previously undetected variation in the copy number of genes will underlie a significant fraction of birth defects, mental retardation, and autism (de Vries et al., 2005; Schoumans et al., 2005; Sebat el al., 2007). It is also possible that copy number variation increases susceptibility to common psychiatric, neurological, and medical conditions (Sebat et al., 2004). Somatic copy number variation has long been associated with cancer and amplification or deletion of specific genes that may provide additional prognostic and therapeutic information (Pinkel and Albertson, 2005). Bacterial artificial chromosome and oligonucleotide arrays are currently being developed and are available on a research basis to provide a molecular karyotype with resolution of 10–100 kb and are recently clinically available with a resolution of 100–500 kb. It is likely that such oligonucleotide arrays will replace standard karyotypes as the first means of analyzing chromosomes for an overall assessment of genomic balance. However, to maximize its clinical utility, it will be necessary to characterize normal copy number variation and demonstrate clinically relevant associations of copy number variations/alterations with disease. As it has become less expensive to genomically characterize gene copy number on many of the same platforms used to genotype single nucleotide polymorphisms (SNPs), tests of association with common diseases will provide the data necessary to judge clinical validity and utility.

In addition to nuclear genetic variation, genetic variation also exists within the mitochondria which can vary from cell to cell and over the course of a lifetime due to mitochondrial heteroplasmy. Mitochips are currently available on a research and clinical basis to sequence the complete mitochondrial genome. As correlations between mitochondrial mutations are associated with diseases associated with degeneration and advancing age, it may become important to include methods to detect and quantify mitochondrial variation in blood as well as other tissues over the course of a patient's lifetime.

LABORATORY STANDARDS TO ENSURE ANALYTIC VALIDITY

As new methodologies and diagnostic tests such as those described above are developed, it will be necessary for diagnostic laboratories to maintain rigorous standards of quality control and quality assurance. New diagnostic assays will be developed in

Clinical Laboratory Improvement Amendment (CLIA) certified laboratories. Some assays will use reagents developed and utilized only by that laboratory ("laboratory developed tests") as has traditionally been done in molecular genetic diagnostic laboratories for rare and ultra-rare disorders. As molecular genetic testing is applied to more common disorders, it is more likely that analyte-specific reagents (ASRs) will be commercially prepared and packaged for wider distribution to a large number of laboratories. It will be necessary for novel diagnostic platforms to be FDA-approved before the platforms and ASRs can be widely distributed to commercial diagnostic laboratories. The rigorous review provided by the FDA for products such as the AmpliChip CYP450 provide assurance of the analytical performance (sensitivity, specificity, and reproducibility) of the diagnostic assay and interpretability of results by clinicians. Increasingly, review and oversight of novel diagnostic tests will be necessary to assure analytical quality; however, regulation by the FDA if not expeditious could impede the efficient transfer of diagnostic methods into clinical practice. Each laboratory will need to rigorously validate the analytical performance of new assays including splitting of samples within and between laboratories to compare results between analytical methods. Standards and guidelines for genetic testing have been developed and are regularly revised by the American College of Medical Genetics (http://www.acmg.net/resources/s-g/s-g-yes-no.asp). Regular proficiency testing including the use of common samples between laboratories will ensure ongoing test quality. It is anticipated that as new ASRs are developed, the level of technical expertise necessary to perform the assays and the cost of running the assays should decrease simultaneously as throughput increases with automation and multiplex assays. It is likely that in the future the majority of molecular genetic testing will move from the many small academic boutique laboratories currently performing most testing to large commercial laboratories and/or hospitals with larger capacity and potentially one day could be performed as point of care testing.

Communicating test results clearly and concisely is as important as the laboratory's analytical performance. Test reports should present sufficient detail about test methodologies to allow for comparison of methods between laboratories and allow the physician to determine the likelihood of a false-negative based upon the mutations included in the assay. As the scientific data and methods are likely to change over time, these reports will require periodic revision, especially with regard to clinical utility. Results should be succinctly reported in a final summary statement including sensitivity and specificity of the test, the possible implications of a positive and negative test result, and reference to or inclusion of necessary supporting data documenting clinical utility. Ideally, Gene Clinics (http://www.geneclinics.org/) or a similarly organized web-based format would provide periodically revised summaries of the genetic tests and their clinical utility. As data from these tests accumulate, de-identified centralized databases defined by gene or test should be maintained with phenotypic information and outcomes to allow for ongoing data collection and analysis to constantly improve test utility and interpretation, especially that of variants of unknown clinical significance.

CLINICAL VALIDATION AND CLINICAL UTILITY

Genomic testing is expected to simplify diagnostic work ups, provide prognostic information, improve and refine clinical management, identify individuals at increased risk, and decrease adverse outcomes. However, before this can be implemented, genomic testing will require clinical validation and demonstration of clinical utility before acceptance into health care. The data for such validation may initially come from studies of patients with the most severe disease manifestations. However, it will be important to analyze population-based samples as well to accurately determine association between genetic susceptibility and disease in an unbiased manner. Studies in multiple ethnic groups will allow characterization of allele frequencies in various populations. It is likely that large clinical trials will provide much of these data necessary for validation since many trials now routinely integrate genetic and genomic information to stratify response to therapy and adverse outcomes by genotype. Integration of genetic data into existing and developing clinical data collection systems such as birth registries, vital statistics, cancer registries, and biorepositories linked to electronic medical records will facilitate testing and validation of preliminary genetic associations and facilitate rapid, independent confirmation of results before clinical introduction.

Clinical utility is the ability in specific clinical circumstances of a genomic test to assist in clinical decision-making and improve health outcomes. Whenever possible, a genetic/genomic test should predict a defined clinical outcome with high positive and negative predictive value. Ideally, prospective, randomized, blinded controlled clinical trials genetically stratified prior to treatment would provide prospective data to validate clinical utility. To effectively evaluate the cost-effectiveness of a genetic test, the population frequency of the at-risk genotype, the age-related penetrance, morbidity and mortality of the disease, and the effects of interacting modifiable risk factors on genotypic expression must all be accurately known. Recommendations for clinical introduction of genetic testing should only be made when the diagnostic methodologies are reliable, patients have access to the clinical services necessary to make informed decisions and interpret the results of genetic testing, and when it becomes clinically apparent how to utilize the results of genetic testing. Once clinical testing is offered, it is also important to maintain ongoing data collection after testing is introduced to define any additional, unintended consequences.

As examples, we can compare the clinical utility of genetic testing for hereditary breast/ovarian cancer conferred by *BRCA1* and *BRCA2* and the risk for venous thromboembolism due to Factor V Leiden. The lifetime risks of breast cancer for carriers with *BRCA1* or *BRCA2* mutations are approximately 65% and 45%, respectively (Antoniou et al., 2003). Mutations carriers can pursue increased surveillance for breast cancer, risk reducing prophylactic mastectomy, or chemoprevention with tamoxifen. Arguments can even be made that with a mutation

frequency of 2.5% in the Ashkenazi population (Hartge et al., 1999), population-based screening for population-specific founder mutations in adult women should be considered. The clinical utility of *BRCA1/BRCA2* testing is derived in large part from the high penetrance of the mutations. On the other hand, thrombophilia susceptibility conferred by Factor V Leiden is the most commonly requested molecular genetic test, although the risk conferred is much more modest and ranges from two- to eightfold (Rosendaal, 1999). It has been proposed that women should be tested for the Factor V Leiden mutation prior to initiation of oral contraceptives due to the 30-fold increased risk of venous thrombosis for mutation carriers on oral contraceptives (Vandenbroucke et al., 1994). However, although the relative risk of thrombosis is significantly increased, the absolute risk is only 28/10,000 person years and the mortality is low in young women. Failure to use oral contraceptives by the numerous Factor V Leiden mutations carriers could have other unforeseen implications including unwanted pregnancies. Thus, no professional consensus has yet emerged about the utility of testing.

COST

A major impediment to integration of genetic/genomic information into health care has been the high cost of molecular genetic testing and the unwillingness of many third-party payers to cover this expense, many citing that it remains experimental. The cost of molecular genetic testing is determined largely by the costs of instrumentation, reagents, personnel, licensing fees, and professional liability insurance. As testing becomes increasingly automated and multiplexed using high-throughput assays on miniaturized scales, the cost of reagents and personnel will be reduced significantly. A goal of the National Human Genome Research Institute is to provide individual genome sequence for $1000 (Collins et al., 2003). Clearly if the technology can drive the cost of testing down to this extent, a major financial barrier to testing will be removed. Licensing fees have significantly increased the cost of testing for a limited number of conditions such as hereditary breast and ovarian cancer (*BRCA1* and *BRCA2*) to $3120 (http://www.myriadtests.com/) and LQTS to $5400 (http://www.pgxhealth.com/genetictests/familion/index.cfm). The genetic/genomic community is opposed to exclusive licenses on genes and is mixed in opinion on gene patenting, but it remains to be seen how much the gene patents and intellectual property regarding clinical utility of specific diagnostic testing will increase the average cost of testing.

In addition to the absolute cost of testing, the extent to which these costs are borne by third-party payers differs widely by laboratory, test, and payer. In the 12 years since *BRCA1/BRCA2* genetic testing became clinically available, the number of individuals tested has increased dramatically, in large part as insurance companies, Medicare, and recently Medicaid began to cover the cost of testing for patients meeting medical eligibility. While many patients might elect to pursue genetic testing for health maintenance and disease prevention, third-party payers are reluctant to expose themselves to this financial burden until the utility is proven. The majority of molecular genetic testing currently performed and paid for by third-party payers surrounds reproductive issues such as carrier screening for cystic fibrosis, recommended by the American College of Obstetrics and Gynecology for consideration in all women contemplating conception. Standard of clinical care guidelines endorsed by major professional medical organization are influential in getting coverage for new tests. Without third-party payer coverage for genomic testing, genomic testing will be utilized only by a small, motivated segment of society who can afford to self-pay.

A significant proportion of the financial benefit to genomic health care is attributable to preventive medicine and the opportunity to prevent chronic disease and cancer. Regional markets in which there are single, dominant insurers or organizations that are self-insured are more likely to initially support genomic health maintenance since they will see the financial benefits within a single organization. Markets with large numbers of competing insurers are reluctant to absorb large financial costs for which they will not personally see a return as consumers change between insurance carriers with regularity. However, as the cost incurred for genomic testing decreases and the utility becomes more apparent and as consumers demand this benefit, it is likely that additional major health insurance providers will add these services to both remain competitive and as a long-term cost-saving measure.

REIMBURSEMENT

Many diagnostic tests, especially those that are highly multiplexed, have been slow to be developed and made clinically available because the testing laboratories cannot charge third-party payers enough to cover their operating expenses. As new technologies for molecular genetic testing are developed, it will be necessary to revise and develop new Current Procedural Terminology (CPT) codes that accurately reflect the complexity of the testing. For many multiplex assays composed of hundreds to thousands of simultaneous assays, it will be necessary to raise the current ceiling for the maximum number of probes, hybridizations, and amplicons to reflect the complexity and cost of the new test methodologies. Once this ceiling is raised, laboratories may find it financially feasible to expand their testing platforms and test menus.

WHO WILL PROVIDE GENOMIC MEDICAL CARE?

Genetic medicine is currently provided in large part by board-certified medical geneticists and genetic counselors (see Box 1.1 in Chapter 1). Given the projected rate of growth and increasing specialization of genetic and genomic medicine and small number of 80 MD and/or PhD graduates per year in medical genetics (Korf et al., 2005), it will be necessary for all health care providers to integrate genomic information to some extent into their provision of health care. Genomics may follow other

diagnostic tests such as pathology, microbiology, and diagnostic imaging with specialized physicians performing and interpreting the tests, while practitioners become largely responsible for determining which patients require testing and how to utilize the test results in heath care. Medical geneticists will continue to play important roles in research, clinical development of the field, education, laboratory medicine, and possibly treatment, in addition to providing direct clinical care for patients with disorders with which they have clinical expertise.

Genetic counselors will continue to play vital roles in patient education and counseling. It will be important to recognize the role of genetic counselors by granting formal licensure and persuading insurers to reimburse for codes for genetic counseling to allow for reasonable reimbursement for genetic counselors' services. Genetic counselors may be increasingly employed by diagnostic laboratories to offer counseling to patients referred by their physicians for testing. The demand for genetic counselors will surpass supply and will necessitate expansion of training programs that currently graduate only 160 new genetic counselors annually. In the future, there may be a specialized track for *genomic* counselors who will provide patient education and laboratory support not for rare monogenic disorders, but for common, polygenic conditions. Other health care professionals and/or multimedia educational programs will also need to assist with patient education. Additional responsibility will be placed upon the patient to actively gather and share medical information with their family through the use of interactive, computer-based family history tools. However, the majority of medical professionals outside genetics are currently ill equipped to provide genomic medical care. When surveyed, 65% of obstetricians and gynecologists who routinely utilize genetics in their practice did not consider themselves sufficiently educated in genetics. They rarely referred patients for genetic counseling and 86% did not obtain informed consent for genetic testing (Wilkins-Haug et al., 2000). Genomic education on a massive, unprecedented scale will be necessary to implement genomic medicine (see Chapter 18).

GENOMIC LITERACY

Integration of genomic information into health care will require at least rudimentary understanding of genetics and genomics by health care providers and health care consumers. Increasingly, there will be medicolegal implications for physicians if they do not recognize specific heritable risks based upon the patient's personal or family history (Deftos, 1998). Additional time must be dedicated to genetics and genomics within medical training, beyond the average 29 hours currently allocated in 4 years of medical school (Friedman et al., 1998). Medical educators themselves will need to keep abreast of advances within genomics and rapidly revise curricula. Because genomic medicine is so rapidly changing, it will be necessary to also teach the standards by which genetic tests should be evaluated for scientific validity and clinical utility so practitioners will be equipped to judge new data as they emerge.

As genomics is integrated into medical, dental, nursing, and allied professional education, a new generation of health care providers will hopefully be capable of rapidly assimilating genomic information into the life cycle of their patients. The younger generation of health care providers is already anxious to adopt this new technology in their practices. Perhaps, they even place more confidence in this new scientific field than is yet warranted. A greater challenge remains for health care professionals educated prior to the expansion of genomics – perhaps graduating from medical school only 5 years ago. For previously trained health care professionals, it will be necessary to learn general underlying principles of genetics and genomics as well as specific tools relevant to their own area of clinical expertise. The National Coalition for Health Professional Education in Genetics (NCHPEG) has produced a set of core competencies in genetics essential for all health care professionals (http://www.nchpeg.org/eduresources/core/Corecomps2005.pdf). NCHPEG is currently developing a core curriculum for genetic education (http://www.nchpeg.org/eduresources/core/coreprinciples.pdf) and has produced a CD ROM "Genetics and Common Disorders: Implications for Primary Care and Public Health Providers" that should assist in educating health care professionals currently in practice. Geneticists will play critical roles as genomic medical educators and discern when information is clinically relevant for various subspecialty areas with clinical care recommendations supported by major medical professional organizations. Genomic educators will need to continuously update medical professionals with new discoveries and applications in simple terms that emphasize clinical utility. It will remain a scientific challenge to define clinical situations in which complex genomic information can be distilled into an appropriately simple interpretation that has unambiguous clinical implications that impact clinical outcomes.

Genomic literacy in the public must simultaneously improve and remove the mysticism and misconceptions some patients may have regarding hereditary information. We must enlighten those who believe genetics is deterministic who would otherwise fail to modify health behaviors, believing instead in an inevitable, unalterable fate. There is a wide and growing divide between patients utilizing genetic and genomic information in their health care, driven in part by education and socioeconomic status. Younger patients tend to utilize genetic information more aggressively and seek genetic information both out of curiosity and to make more informed life and reproductive decisions. Younger generations have also become accustomed to advances in assisted reproductive technology and increasingly push the ethical and social boundaries to use such genetic and reproductive technology for such trivial genetic factors as elective sex selection. Older patients tend to be less educated about emerging genomic technologies, and often the reason they cite for seeking genetic testing is to provide information for their children or grandchildren rather than for themselves.

As the public becomes more genetically literate, there will likely be a push from diagnostic laboratories to market genetic testing directly to consumers. This has already been done with

BRCA1/BRCA2 testing and is done with nutriceuticals. While such advertising campaigns may be effective in increasing-awareness and forcing health care professionals to learn new information about genetic testing, there will also be the danger that inappropriate tests will be ordered and potentially misused by patients and physicians who are not fully informed.

2009 UPDATE

There have been over 150 associations demonstrated between common SNPs and disease traits using Genome Wide Association Studies for diseases as diverse as age-related macular degeneration, type 1 and type 2 diabetes, obesity, inflammatory bowel disease, prostate cancer, breast cancer, colorectal cancer, rheumatoid arthritis, systemic lupus erythematosus, celiac disease, multiple sclerosis, atrial fibrillation, glaucoma, asthma, and restless leg syndrome. Because allele frequencies often vary between ethnic groups, it is likely that the relative importance of these common variants identified will depend upon ethnicity and/or geographic ancestry. To date most studies have been done in European Caucasians, and it will be extremely important to extend the studies to other ethnic groups.

Most of these associations have identified novel genes that were not previously known to be involved in the associated disease processes. The relative risk for most of these common variants has been modest. In only a few cases that have the common variants identified had effect sizes >2. These exceptions include Complement Factor H (CFH) in age-related macular degeneration (Edwards et al., 2005; Haines et al., 2005; Klein et al., 2005), *ApoE4* in Alzheimer's disease (Strittmatter and Roses, 1996), and *LOXL1* in exfoliative glaucoma (Thorleifsson et al., 2007). In general, these association signals have identified regions for further study but have not yet identified functional variants. Furthermore, it is possible that a single locus may contain multiple independent common risk variants, as has been suggested for CFH in age-related macular degeneration (Li et al., 2006; Maller et al., 2006) and at *IL23R* for Crohn's disease (Duerr et al., 2006). In rare cases, the same loci that have common variants conferring relatively small effect are also the same genes for which rare variants confer large effect in small numbers of patients. Such examples include the LDL receptor for familial hypercholesterolemia and *KIR 6.2*, *WFS1*, and *TCF2* for type 2 diabetes. It is yet to be determined whether this will be a more generalizable finding for other genes identified by association studies. There are now large efforts underway to try and identify mutations with large effects in the genes identified through the genome wide association studies. Clearly, there will be high clinical utility for these rare mutations conferring large phenotypic effects; however, it is unclear how frequently such rare mutations will be identified.

How the common variants with modest increased risk will be clinically utilized is unclear at this time. It will be important to validate the utility of individual as well as composite risks conferred by multiple SNPs for common disease susceptibility. It is most likely that this will initially be applied to diseases such as age related macular degeneration for which there is an extremely high relative risk based on a few common variants. Clinical testing for age related macular degeneration is already available through several clinical laboratories and genotypes are being incorporated into clinical trials. Clinical testing is available through several companies such as deCODEme, Navigenics, and 23andMe for many of the common polymorphisms identified through association studies. Initial studies in the area of type 2 diabetes suggest that the relative contribution of these additional common genetic variants will be minimal when the other clinical risk factors are fully utilized (Lyssenko et al., 2008; Meigs et al., 2008). Genetic testing for these common SNPs is not currently being covered by third-party payers and has fallen into the domain of direct-to-consumer marketing with out of pocket costs to consumers ranging in price from ~$1000 to $2500. How this information is being used by patients is not yet clear, but these early adopters will provide valuable insight into the future potential utility for using these common variants in disease risk stratification, how patients interpret their relative and absolute risks, and how such a risk interpretation influences health behaviors.

CHAPTER

The Role of Genomics in Enabling Prospective Health Care

Ralph Snyderman

INTRODUCTION

In the early 1900s, the emerging sciences of physiology, chemistry, immunology, microbiology, and radiology began to be introduced into the practice of medicine, which at that time, considered disease to be due to imbalances of bodily humors and transmitted through climacteric miasmas. For the first time in history, the application of science to medicine laid a solid foundation for understanding the pathophysiology of disease (Bynum, 2002; Snyderman, 2004; Snyderman and Williams, 2003). In particular, microbiology, through the identification of "causative" agents for numerous infectious diseases, had a profound impact on concepts concerning the cause and potential cure of illnesses. Given the increasing number of diseases determined to have specific "causes" along with the new found ability of chemistry to synthesize therapeutic "magic bullets," early 20th Century medicine logically pursued a scientific, reductionist approach to health care which continues today: that is, identify a disease's root cause and eliminate it. This approach has enabled medicine to reverse some diseases, prolong life, and at times, effect wondrous cures.

The reductionist approach to medicine, however, is limited in that the evolution of virtually all diseases is more complicated than a single root cause. The development of disease is based upon one's genetic susceptibilities, complex interactions between initiating factors, and health status. In the aggregate, these can lead to disease progression, or not (Figure 17.1). For example, while the tubercle bacillus is the causative agent of tuberculosis, the clinical manifestation of exposure, as a consequence of host susceptibility, can range from transient subclinical infection to rapidly fatal miliary disease. Even a well-defined genetic disease such as sickle cell anemia, known to be due to a single mutation, can have manifestation ranging from death in adolescence to far milder forms compatible with long-term survival. By focusing primarily on the reductionist model of disease development, our health care system has, unfortunately, not focused on the prevention or treatment of complex chronic diseases. At present, individuals with any of five chronic conditions account for roughly two-thirds of all health care expenses (Figure 17.2).

A more rational approach to health care is now possible. New emerging sciences, notably genomics, can transform medical practice now just as new applications of science and know-how transformed medicine 100 years ago (Figure 17.3). Genomic and related expanding fields of research can impact health care in numerous ways (Figure 17.4), but most profound may be their ability to predict risk, track disease progression and anticipate clinical events, thereby enabling truly personalized, predictive, preventative care. To do this, the strengths of today's disease-oriented reductionist approach must be integrated with an approach that focuses on prevention and minimization of disease with an emphasis on long-term strategies.

This personalized, predictive, and preventative approach to health care is known as "prospective health care" (Snyderman and

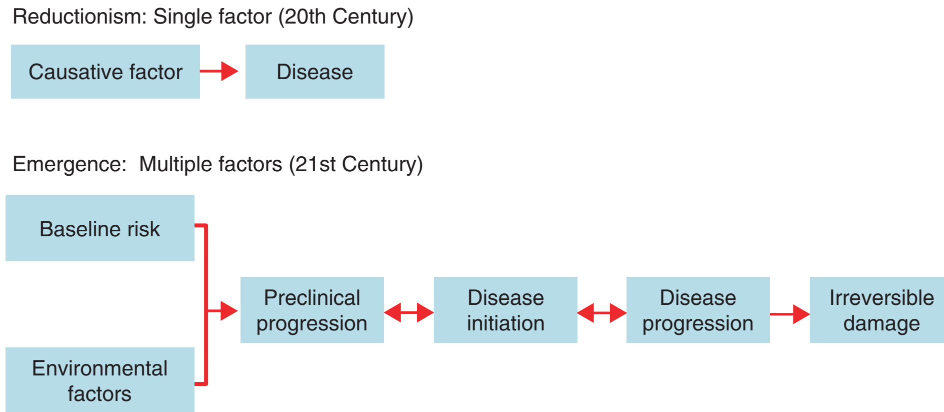

Figure 17.1 Concept of disease: reductionism versus emergence. The reductionist approach considers disease to be a consequence of a pathogenic factor; that is microbe. More accurately, disease development depends on the host's susceptibility to pathogenic factors and exposure to them (Snyderman and Yoediono, 2006).

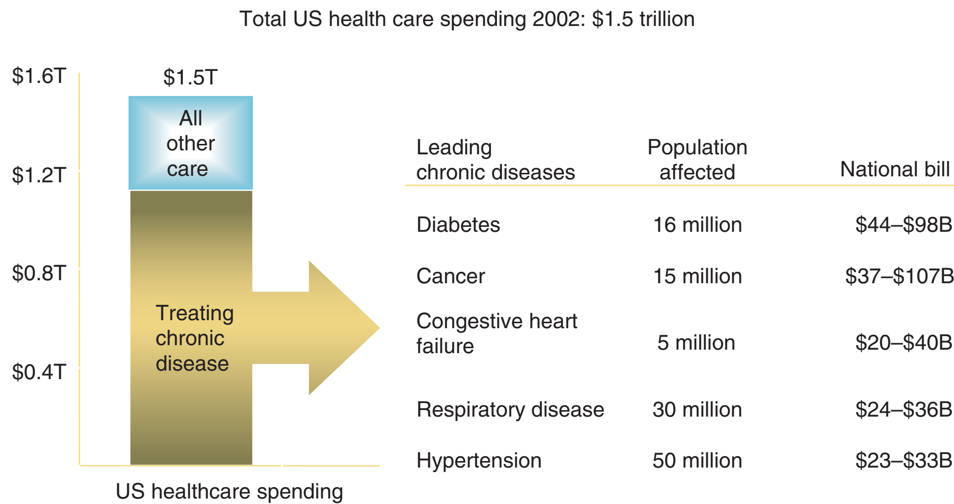

Leading chronic diseases	Population affected	National bill
Diabetes	16 million	$44–$98B
Cancer	15 million	$37–$107B
Congestive heart failure	5 million	$20–$40B
Respiratory disease	30 million	$24–$36B
Hypertension	50 million	$23–$33B

Figure 17.2 Consequences of current approaches to health care. While little is spent on prevention, nearly three-quarters of health care expenditures fund the treatment of late-stage chronic disease. (Source: American Heart Association, American Cancer Society, American Lung Association, National Institute of Diabetes and Digestive and Kidney Disease.)

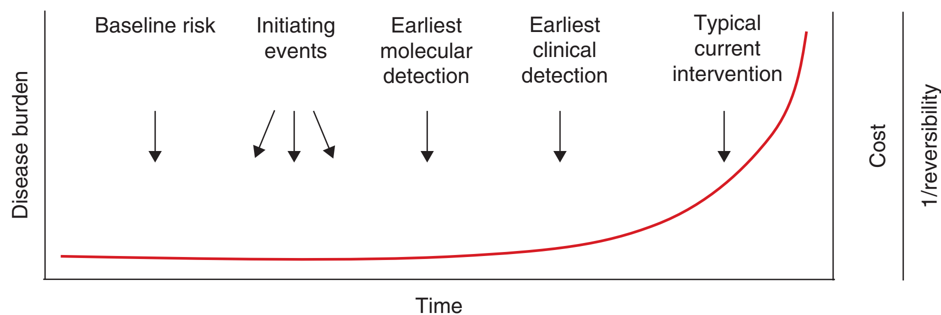

Figure 17.3 Disease progression. Diseases develop over time, with pathology increasing, reversibility decreasing and cost of care increasing (Snyderman and Yoediono, 2006).

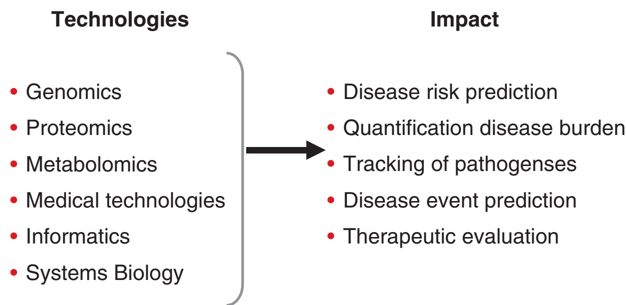

Figure 17.4 Impact of new technologies on prospective health care. Last century's science enabled reactive responses to disease while this century's science enables prospective approaches as well.

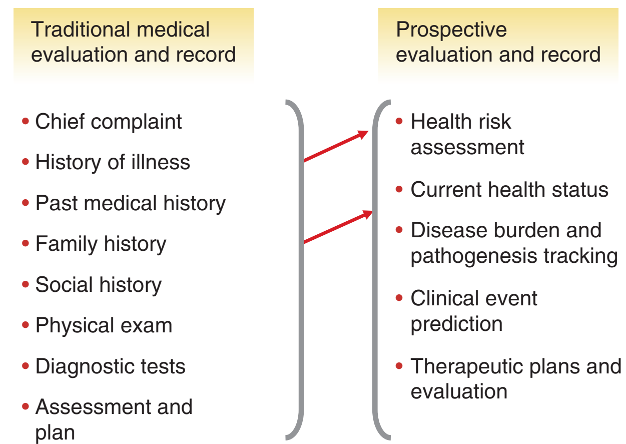

Figure 17.5 Current medical record versus prospective approach to health care. Physicians currently evaluate patients using a disease-focused approach. A more effective approach would include strategic health planning as indicated by the prospective approaches shown on the right (Snyderman and Yoediono, 2006).

Williams, 2003; Snyderman and Yoediono, 2006; West et al., 2006; Williams et al., 2003). Key features of prospective health care include personalized health risk assessment, tracking of pathogeneses, prediction of clinical events, and strategic planning to mitigate risks and evaluate therapeutic benefits. With a prospective health care model, individuals will be provided with personalized health plans which promote strategic health planning by incorporating individualized risk assessments for diseases, disease tracking, clinical event predictions and therapeutic planning (Figure 17.5). Genomic research will play an integral role in providing these capabilities given that the molecular processes underlying disease susceptibility, progression, and therapeutic response differ among individuals and can be measured, in part, through genomic analyses. Technological advances allowing the measurements at the DNA, mRNA, protein, and metabolic levels are already beginning to enable inferences regarding health risks or clinical outcomes (Snyderman and Langheier, 2006).

PREDICTIVE MODELS

At the core of prospective health care are personalized health risk assessment and predictive modeling. A predictive model uses statistical algorithms to identify factors that predict events (Anderson et al., 1991). The predictive model can be used to forecast events based on factors or biomarkers, which are most likely to correlate with or be causative of the future clinical event. The development of a predictive model uses various methods, such as logistical regression or neural network, to differentiate predictive factors from other variables which are not as useful for anticipating the clinical outcome of interest. The predictive model can then be applied to a current situation to determine the risk and timing of an event occurring. The better the model, the better the accuracy in predicting the occurrence and timing of the event. The details involved in developing a predictive model, as well as other related components such as individualized patient databases and risk model libraries, are beyond the scope of this chapter, but a simplified version is shown in Figure 17.6.

PREDICTIVE FACTORS

The predictive factors most commonly used for disease-related risk assessments encompass clinical, demographic, family history, and laboratory data. These types of data can provide insight into the likelihood of an individual developing a condition or event and are relatively cost-effective and collected routinely. However, generally they are limited in terms of being able to accurately predict *when* disease will occur. Furthermore, many false-positives and false-negatives are associated with these types of data, which are often epidemiologic in nature (i.e., Framingham Study) (Brindle et al., 2003; The International HapMap Consortium, 2003). Predictive factors, which serve as more accurate markers of disease susceptibility, likely will come in the form of biomarkers which are directly related to the cause of the clinical event. A biomarker is a characteristic (i.e., expressed gene, protein or metabolite) that is objectively measured and evaluated as an indicator of biological or pathogenic processes or pharmacological responses to therapeutic interventions. Genomic research will play an integral role in identifying predictive biomarkers which, in combination with other types of predictive factors, will enable more accurate risk analyses for baseline risk assessment, disease tracking, clinical event predictions and response to therapeutics. Biomarkers can be thought of as belonging to two general categories: (1) stable biomarkers that are inherited and/or change rarely over a lifetime, and (2) dynamic biomarkers which express ongoing biological activities. The latter include gene expression, protein expression and the measurement of metabolic factors. Measurement of genomic factors that lie in the causal pathway of a disease or a therapeutic response, or factors such as single-nucleotide polymorphisms (SNPs) that are highly associated with causal genes, will serve as better predictors of adverse outcomes than much of the demographic data now being collected. Stable DNA gene predictors will enhance baseline clinical risk assessment and primary prevention, while dynamic mRNA, protein and metabolic factors will reflect ongoing biological or pathological processes.

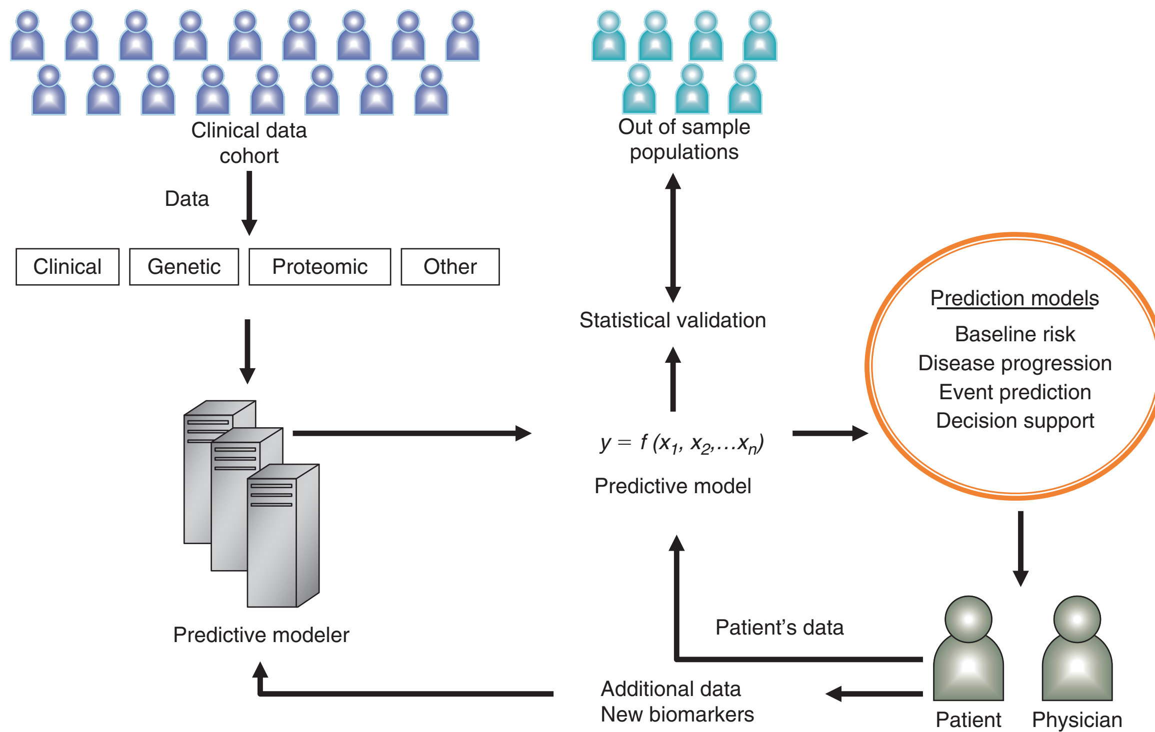

Figure 17.6 Methodology for creating clinical risk predictive models. Relevant clinical data and/or biomarkers are statistically analyzed to create validated risk models for particular clinical conditions or events (Snyderman and Yoediono, 2006).

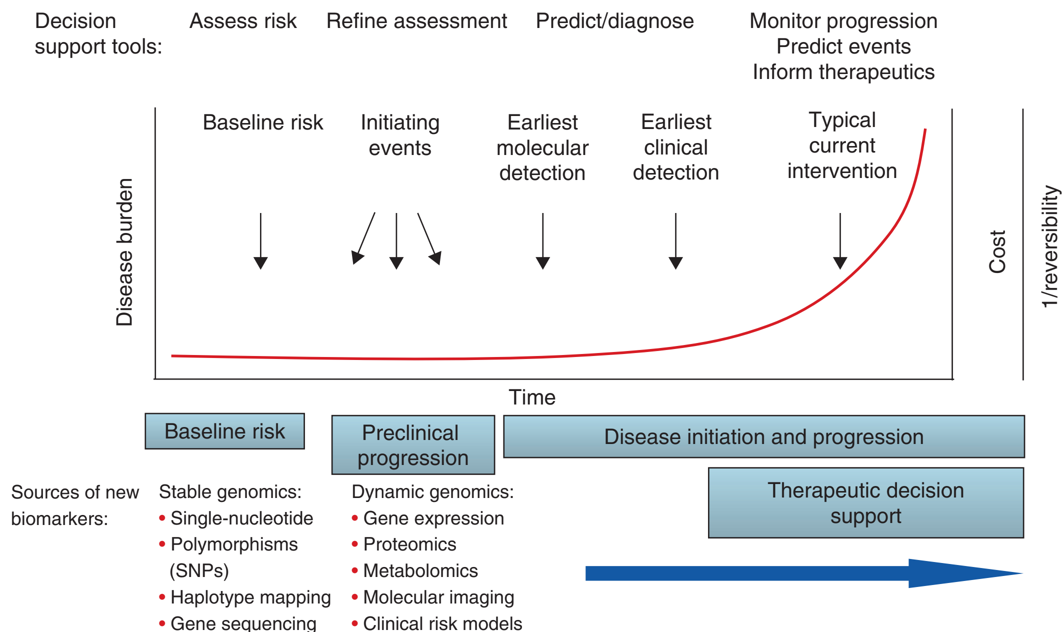

Figure 17.7 Contributions of new technologies to disease prediction and prediction of clinical events (Snyderman and Yoediono, 2006).

Analysis of these will enhance refined risk assessments to track disease progression, predict events, and guide therapeutic choices (Figure 17.7).

The advantage of genotypic data for baseline prediction is that they can be collected at birth or any time during one's life and, theoretically, needs to be collected only once. Baseline risk assessments using demographic data or static genomic information will likely have lower specificity (a higher number of false positives) than molecular measures that are dynamic and change as a function of time. Nonetheless, as more information regarding

inherited risks is gathered, baseline risk assessment will become increasingly useful. For secondary prevention (for example, predicting heart attack in an individual with diabetes), stable genomic data may be less valuable. In this case, relevant dynamic indicators will provide a more powerful predictor of the disease event. Over time, the cost of genotyping should plummet and the value of baseline risk analysis should increase markedly. Moreover, the identification of clinically valuable dynamic biomarkers is an area of fertile research and will enhance accurate ongoing risk assessment timing of disease events and prediction of therapeutic outcomes.

Identifying accurate predictors for baseline risk assessment will be facilitated greatly by clinical research and the HapMap project and the Genetic Association Information Network (GAIN) initiative, a public/private partnership between the NIH, foundation of NIH and industry. The GAIN study will fund $20 million of research to identify SNPs associated with common diseases. The International HapMap Consortium is characterizing common patterns of DNA sequence variation and the extent of linkage disequilibrium in the human genome. This will facilitate the characterization of genotypes and identification of key SNPs related to chronic disease; traditional and advanced association algorithms will allow the analysis of the HapMap (International HapMap Project, http://www.hapmap.org)(Niu, 2004; Liu et al., 2004; Evans et al., 2004). Online Mendelian Inheritance in Man (OMIM), a database of disease risk genes, is already revealing an increasing number of stable genomic factors that should be useful in risk assessment (Online Mendelian Inheritance in Man, http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=OMIM). The role of an individual's gene variants in altering their metabolism and response to drugs is becoming important in drug development and in certain areas of clinical practice, particularly oncology (Lee et al., 2005).

For individuals whose genes, SNPs, family history, or clinical information identify them as high risk for a particular disease, surveillance will be needed to track possible disease progression and, when relevant, to evaluate therapeutic support. Such tracking will likely include the measurement of dynamic factors, including gene-expression, proteomics, and metabolomic assessments. Analyses to track baseline risk and disease development will hopefully be incorporated into personalized health plans in the future (Langheier and Snyderman, 2004). For example, children with a family history of type 1 diabetes could have a baseline risk assessment that evaluates various predictive SNPs. Those determined to be at high risk could undergo a surveillance protocol, tracking their levels of biomarkers associated with actual disease development and progression. (Barker et al., 2004; Eisenbarth, 2004). As effective preventative therapies are identified, these analyses could guide appropriate intervention before β-cells are destroyed.

Initial applications of genomic technologies are being applied to predict outcomes in defined clinical conditions. For example, gene-expression microarrays and proteomic techniques show promise for identifying the aggressiveness of cancer, allowing the creation of predictive models for likely survival time with and without treatment (Anderson and LaBaer, 2005; Berchuck et al., 2005; Pittman et al., 2004; Rich et al., 2005). Moreover, gene expression in circulating mononuclear cells is being used to predict organ rejection in patients with heart transplants, obviating the need for myocardial biopsy in some conditions (Deng et al., 2006). Many gene-expression tests are being developed to gauge appropriate chemo-therapeutic regimens for a given patient's cancer (Bild et al., 2006).

2009 UPDATE

Emerging Initiatives

In 2007, the US Department of Health and Human Services announced a new initiative called "Personalized Health Care," the objective of which was to combine genomic research breakthroughs with advances in health information technology to enable gene-based medicine, where one's susceptibilities to diseases would be quantified as early as possible so that preventive countermeasures could be taken (Personalized Health Care, http://www.hhs.gov/myhealthcare). An example of one of the many programs encompassed by the "Personalized Health Care" initiative is entitled "The Cancer Genome Atlas," a collaboration between the National Cancer Institute and the National Human Genome Research Institute. Researchers have been utilizing evolving technologies such as large-scale genome sequencing to better understand the molecular basis of cancer. Initial efforts have focused on cancers affecting the brain, lungs, and ovaries. This goal of this project is to improve capabilities for preventing, diagnosing, and treating cancer at a personalized level (The Cancer Genome Atlas, http://cancergenome.nih.gov).

The NIH has also collaborated with the Food and Drug Administration (FDA), the Centers for Medicare and Medicaid Services (CMS), as well as the Pharmaceutical Research and Manufacturers of America (PhRMA) and the Biotechnology Industry Organization (BIO), on initiatives such as "The Biomarkers Consortium." The goal of this consortium is to identify and validate new biomarkers to help expedite the

development and utilization of therapeutics and technologies for personalized prevention, early detection, and treatment of diseases (The Biomarkers Consortium, http:/www.biomarker-sconsortium.org).

A project in The Biomarkers Consortium under consideration by the National Institute of Diabetes and Digestive and Kidney Diseases focuses on the identification of biomarkers associated with pre-diabetes and type II diabetes and the creation of more reliable, less expensive, and faster predictive tests (Zerhouni et al., 2007).

Academic health centers such as the Lewis-Sigler Institute for Integrative Genomics at Princeton University, the Broad Institute of MIT and Harvard, and the Center for Genomic Medicine at the Duke Institute for Genome Sciences & Policy (IGSP) have been dedicated to identifying and validating predictive biomarkers. One project at the Broad Institute, entitled "Clinical Proteomic Technology Assessment for Cancer (CPTAC)," is seeking to establish standards for protein biomarker assessment (Clinical Proteomic Technology Assessment for Cancer Program, http://www.broad.mit.edu/proteomics/CPTAC), and at Duke's IGSP researchers recently outlined a genomic-based strategy for the personalized treatment of patients who have advanced-stage ovarian cancer (Dressman et al., 2007).

Centers within academic institutions, such as the IGSP Center for Systems Biology at Duke University and the Center for Cancer Systems Biology (a collaboration between the Dana-Farber Cancer Institute and Harvard Medical School), have dedicated vast resources to personalized medicine. Researchers from the Center for Cancer Systems Biology detailed an approach to identify genes associated with increased breast cancer risk. By utilizing this strategy, they determined that hyaluronan-mediated motility receptor (HMMR) was a potential breast cancer susceptibility gene (Pujana et al., 2007).

Although many of the recent research initiatives have been genome-based, genomic advances alone will not likely be sufficient to enable personalized medicine. Rather, multiple rapidly evolving predictive technologies involving other "omics," such as proteomics and metabolomics, will complement and enhance clinical know-how and capabilities to allow better predictive approaches. For example, studies on risk-predictive modeling for breast cancer recurrence have shown that the predictive accuracy of a combined clinical and genomic model is higher than a model utilizing just one type of data (Pittman et al., 2004). Furthermore, a risk predictive model for severe adverse outcomes from cancer chemotherapy was developed using only clinical and laboratory data (Lyman et al., 2006).

Consumer-Directed Products

Although many risk assessment tools are directed toward providers, other companies have developed personalized risk assessment tools for sale to consumers (Navigenics, Inc., http://www.navigenics.com; 23andMe, https://www.23andme.com). An assessment is available that analyzes 250 serum proteins to provide early diagnosis of clinically unapparent diseases (Biophysical Corporation, http://www.biophysicalcorp.com). In addition, consumers receive a medical history interview and a follow-up doctor consultation. Likewise, consumers may pursue individualized health and nutrition recommendations, which are based in part upon a genomic analysis (Sciona, http://www.sciona.com). Still other options are available from companies that perform genomic analysis to identify known risk-associated variants. Consumers are offered predictive information and options for updated genomic analysis as new susceptibility factors are identified. The direct-to-consumer marketing of diagnostics and predictive tools is a relative new phenomenon and its value and means of regulation have yet to be determined (see also Updates for Chapters 13 and 18-21).

With the rapid evolution of fields such as genomics, patients have become increasingly concerned about medical privacy, genetic discrimination by insurers and employers, and related issues. Indeed, there has been evidence that even healthy persons with a genetic susceptibility for a condition have faced discrimination by insurance companies and that those with genetic diseases have had a difficult time getting health insurance (Plantinga et al., 2003; AHRQ Launches New "Effective Health Care Program" to Compare Medical Treatments, http://www.ahrq.gov/news/press/pr2005/effectivepr.htm). This is an evolving area, which will necessitate careful policy development. These issues as well as others, such as assessing the reliability of data entered by patients or the accuracy of risk assessment tools, are legitimate concerns, which must be continuously monitored and addressed by the appropriate constituents.

CHAPTER

Genome Policy Considerations for Genomic Medicine

Susanne B. Haga

INTRODUCTION

The success of the Human Genome Project will be measured largely with respect to advancements in biology and the realization of a new era of medicine based on the use of genomic data to predict, prevent, diagnose, and treat disease. However, the scientific challenge of sequencing the human genome will likely pale in comparison to the efforts required to translate genome sciences into personalized medicine. As we begin to apply the data and technologies arising from the Human Genome Project and subsequent projects including the HapMap Project (International HapMap Consortium, 2005) and the ENCODE Project (The ENCODE Project Consortium, 2007), the initial discovery, validation, and the development of a clinical test or therapy will be influenced by a range of science, health, and public policies. Although many of the policy issues are not unique to those faced by other new medical innovations, the genome revolution raises issues that span both the traditional science and health policy arenas (see Figure 18.1), some warranting resolutions specific to genomic medicine.

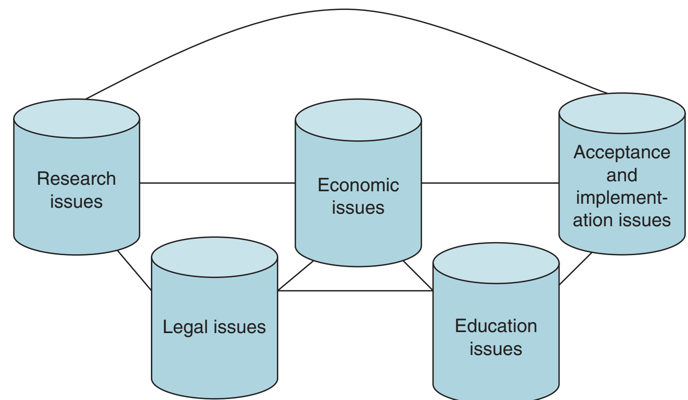

Figure 18.1 The spectrum and inter-connectedness of genome policy issues, based on (Haga and Willard, 2006).

This chapter will provide an overview of the major policy issues pertaining to the research, development, and translation of genomic medicine applications, including: research allocation and prioritization; the use and analyses of race in genome studies; the ethical issues linked to large-scale genome efforts such as biobanks, oversight, coverage, and reimbursement of new genomics applications; privacy and discrimination; and enhancing public and professional awareness. An in-depth analysis of several of the issues introduced here can be found in other chapters in this volume (see Chapters 13, 19 and 20).

GENOME RESEARCH AFTER THE HUMAN GENOME PROJECT

The completion of the Human Genome Project marked the beginning of a new era, rather than the end of an era (Collins, 2003). Although a substantial investment in basic research, it is unlikely that anyone could have foreseen the widespread impact of not only the ultimate product – a reference sequence of the human genome – but also the parallel technology development that enabled the early completion of the sequence of the human genome and the genomes of countless other species. Its impact on the biotechnology sector and other fields as diverse as evolutionary biology, agriculture, biodefense, and medicine is still in the early stages but its scope has been staggering already.

Research Allocation and Prioritization

In 2003, after the completion of the Human Genome Project, a new vision for genomics research was created (Collins et al., 2003). The next 5 years of genomic research would concentrate on three major areas – society, health, and biology. Across these three areas, six crosscutting research tracts were identified, including technology development and ethical, legal, and social issues. This differs markedly from past strategic plans that focused predominantly on mapping and sequencing of the human genome and model organisms (Collins and Galas, 1993; Collins et al., 1998, 2003).

Despite the huge investment in basic biomedical research and the excitement generated by the Human Genome Project, concerns have been raised that the investment has not resulted in the anticipated development of new products, as the number of submissions and approval of new drugs and diagnostics has been on the decline (FDA, 2004). Because of this and political pressures to demonstrate return on investment from the doubling of the US NIH budget, the emphasis over the past several years has shifted toward translational and clinical science (Zerhouni, 2005). Recognition of the importance of translational research has led to changes in science policy such as the development of the NIH Roadmap (Zerhouni, 2003) and emphasis on the development of new tools and applications (FDA, 2006a). Translational genomics research will be an important part in each of these new efforts (see Chapter 14).

Over the past decade, Europe has also increased its supports for both basic and translational genomics research. In 2001, the European Commission allocated €100 million for an initiative called *Genome Research for Human Health*. Starting in 2002, the European Community Framework Program for Research, Technological Development and Demonstration (otherwise known as FP6) identified genomics as one of its seven major thematic areas (European Commission, 2002). The research budget for life sciences, genomics, and biotechnology was more than €2 billion. The program aimed to promote European genomics research through three major strategies: establishing a robust infrastructure; fostering interdisciplinary research with other fields such as physics, chemistry, mathematics, and computer science; and integrating genomics into medicine and biotechnology. In 2007, FP7 was revised with the primary goal of supporting Europe's global competitiveness. Genomics and biotechnology continue to have a prominent role in the development of new applications in medicine and food and agriculture. For the first time, investigator-driven projects will be funded in addition to the continued support of network initiatives (European Commission, 2002).

The field of genome sciences has already taken the next step forward toward applying this new knowledge and capability to medically relevant initiatives. For example, the NIH Chemical Genomics project involves the development of a public repository of small organic molecules to study cellular pathways in health and disease and hasten the identification of new drug targets and drug development (NIH Chemical Genomics Center, 2005). The Medical Sequencing Project involves the sequencing of well-phenotyped patients with autosomal and X-linked Mendelian diseases as well as common diseases to identify the underlying genetic cause of disease (National Human Genome Research Institute, 2007).

With respect to diagnostic screening and testing, the emphasis on translational research has provided opportunities to gather data about the clinical utility of new tools. Demonstrating clinical validity and utility is critical to the development of clinical guidelines and reimbursement policies that will support the appropriate use of these tests. For example, the National Cancer Institute is supporting a long-term prospective study called The *T*rial *A*ssigning *I*ndividua*L*ized *O*ptions for Treatment (*Rx*), or TAILORx (National Cancer Institute, 2006). This study will explore whether an expression profile of 16 genes associated with risk of recurrence for women with early stage breast cancer is useful in identifying those women who will most likely benefit from chemotherapy in addition to radiation and hormonal therapy. The study will follow 10,000 women for a period of 10 years, with follow-up of up to 20 years after initial therapies. While clinical trials represent the gold standard of evidence, these types of studies will not be feasible for every new genome application given the cost and time required, and other study approaches will need to be utilized. The continued support across translational genome research will be critical to the development of safe and effective applications in genomic medicine.

Race and Genomics

Population genetics research has spurred debate regarding the validity and use of racial categories as a variable in biological research. In particular, genomics research has provided insight into the genetic diversity (or lack thereof) of the human population, giving rise to questions about the use of race as a variable in biomedical research and whether genomics could provide improved measurements of variation in place of the concept of race (Burchard et al., 2003; Cooper et al., 2003). While a major conclusion of the Human Genome Project was the high degree of sequence identity between individuals, subsequent research has focused on the small differences between individuals and populations, particularly with respect to disease (Foster, 2005).

For instance, the 3-year US-led HapMap project generated a map of one million common genetic variants through analyses of more than 200 genomes of individuals from four different populations (International HapMap Consortium, 2005).

Similar to the HapMap project, the Mexican Genome Project, started in 2005, sought to determine the genetic variation of the heterogeneous *mestizo* population in Mexico (Mothelet and Herrera, 2005). Mestizo refers to individuals with mixed ancestry of European (primarily Spaniards) and Indian. The goal of the project was to determine whether any genetic differences between populations may be correlated to known health differences. Preliminary analysis of data from the project concluded that mestizo ancestry is a mixture of 35 ethnic groups (Wall, 2007). In general, 65% of Mexican ancestry can be traced to indigenous populations and 35% is due to non-indigenous groups (African, Asian, and European). Not surprisingly, regional differences were also found as numerous indigenous populations existed for some time prior to the arrival of the Europeans. The medical implications of these data remain to be determined. However, it is anticipated that the data will benefit other Latin American countries as well and will aid in the development of safe and effective drugs for these populations which are not typically studied in clinical trials conducted by United States and European drug makers (Mothelet and Herrera, 2005).

For genomic medicine, the main question is whether race can be used as a surrogate for biological variance to aid prevention, diagnosis and treatment of disease. Studies have detected not only differences in the prevalence of genetic variants (Hall, 1999; Monaghan et al., 1996), but also in the risks associated with the same genetic variant (Helgadottir et al., 2006), implying a role for additional genetic or environmental factors. While studies have shown that individuals from populations around the world can be clustered genetically into six groups (Rosenberg et al., 2002), other studies have demonstrated a range of mixed ancestry in African-Americans, Hispanics, and Mexicans (Parra et al., 1998; Shriver et al., 2003; Sinha et al., 2006).

Our new understanding of human variation and ancestry has yet to impact federal policies regarding the use of race in biomedical research and clinical trials. Current policies such as the National Institutes of Health Revitalization Act (1993), the US Food and Drug Administration (FDA) (1998, 2005a), and the European Medicines Agency (1998, 2005) require that study participants be identified by race and/or ethnicity to ensure a diverse study population and to allow subset analysis. In light of recent findings, however, the application of race and ethnicity categories to biomedical research and the requirement to subset and analyze clinical trials data seem to be outdated and inadequate measures of differences in treatment outcome or response (Haga and Venter, 2003). Although self-identified race has been shown to correspond well with genetic clustering (Tang et al., 2005), it appears to be more problematic clinically since it has not always been shown to be a consistent and reliable measure (Hahn et al., 1996; Johnson, 1974; Rankin and Bhopal, 1999). Moreover, the context in which the self-identification is made may influence an individual's decision, resulting in variable responses depending on who is asking the question and how the information might be used (Senior and Bhopal, 1994).

In using race as an analytical variable, it is important to consider the two major constructs of race: the use of race as a *social* measure to detect differences of potentially important factors such as access to healthcare, environmental exposures, and lifestyle; or the use of race as a *biological* variable to identify genetic (and therefore, biological) differences between populations underlying differences in disease prevalence, severity, and outcome. While there is little disagreement that genetic epidemiology studies would benefit from more diverse sample populations (Ioannidis et al., 2004; Tang, 2006), which may be achieved through using race as a surrogate, it is still unclear what the significance (social and/or biological) of a positive association is between a given phenotype and race. Thus, difficulty in defining the impact of different factors makes race a poor surrogate in general, and direct measurement of relevant factors (e.g., diet, environment) may reduce some of the challenges arising from the use of such a broad undefined variable such as race. Genetics and genomics present an alternative measure of human variation for which race has been used as a surrogate that will lead to more definitive and quantifiable data points (Shields et al., 2005).

Another major issue is the relationship between genetic and genomic data and health disparities. Differences in disease prevalence and outcome between groups, typically characterized by race, have been well-documented (Institute of Medicine, 2003). If individual differences in disease predisposition, prognosis or response to drugs may be accounted for by genetic variation, could group health differences also be accounted for by genetic variation between populations? Despite the small role that genetics is believed to play regarding disease prevalence and outcomes of common diseases, there is an inherent danger of extrapolating differences detected in individuals from one group to an entire race, potentially resulting in unvalidated support of race as a biological category (Wiegmann 2006). Indeed, the temptation to attribute health disparities to genetic causes may distract from other types of social and biomedical research that may lead to greater reduction in these observed differences (Sankar et al., 2004). Furthermore, race-based medicines such as BiDil, a drug approved by the FDA for the treatment of heart failure in self-identified black patients, have the added potential of reifying the biological concept of race and hinder efforts to reduce disparities (Haga and Ginsburg, 2006; Kahn, 2005).

POLICY ISSUES IN LARGE-SCALE GENETICS AND GENOMICS RESEARCH

The shift to study the genetic etiology of common, complex diseases and the development of high-throughput technologies such as microarray analysis and new sequencing techniques at increasingly cheaper costs have enabled the expansion of study populations in genomic studies. Whereas genetic studies

traditionally focused on small groups, particularly families, genomics studies are characterized by the collection of genetic data on hundreds or thousands of individuals, healthy and affected. The demand for DNA samples from individuals of various phenotypes has led to the creation of local and national biobanks or biorepositories worldwide. Given the enormity of national biobanks, several policy issues arise, particularly with respect to research policy. Among the many issues that have been debated about biobanks are the scientific need and merit of a national biobank, the cost and feasibility of successfully establishing and operating a biobank, the required infrastructure, accessibility to samples and data, informed consent, intellectual property (IP), privacy and confidentiality of data, and disclosure of research results to participants. While current policies may be applicable to some of these issues as they are not unique to biobanks, new policies may be required to address some of these issues such as data-sharing and data disclosure and to help reassure the public.

Biobanking

Several years prior to the completion of the Human Genome Project, a number of countries contemplated setting up a national research resource or "biobank" that would contain both clinical specimens and data for the purposes of large-scale genetic epidemiology studies. Samples and data would be collected from 60,000 to one million individuals and stored for five to 30 years (Godard et al., 2004).

Given that a national biobank depends on the public's support and participation, engaging the public is critical to its success (Haga and Willard, 2006; Haga and Beskow, 2008). Two approaches have been used to communicate with the public about national biobanks – a communication or partnership approach (Godard et al., 2004). In Iceland, a brief public consultation took place in the form of radio and television programs, town hall meetings, and public surveys. In 1998, the Act on a Health Sector Database was passed, authorizing the Ministry of Health and Social Security in Iceland to license a private firm (deCODE Genetics, Inc.) to establish and maintain the Health Sector Database, which would store the health records of Iceland's 270,000 citizens. Strong criticism from researchers and ethicists worldwide quickly followed, particularly with respect to the issue of "presumed consent." In response, an option to decline was made available and about 10% of the Icelandic population chose to opt out.

In contrast, the United Kingdom embarked on a massive public 3-year consultation campaign about its proposed national databank. The national diallog included town hall meetings, focus groups, interactive workshops, and published reports. The exchange of information helped inform policy-making to ensure that public concerns were addressed while at the same time raised public awareness about the project. In addition, public comments were requested on procedural and governance documents.

Other countries such as Japan, Canada, Estonia, United States, Tonga, and Latvia are considering or have already established national biobanks. Their approach to public consultation has fallen in between Iceland's communication approach and the UK's partnership approach. The different approaches utilized are reflective of different cultures, attitudes towards scientific research, history, and government and healthcare systems.

Data Disclosure

Research results can be disclosed in a variety of formats including individual or aggregate reports. Aggregate reports would be the only way to inform participants about study outcomes if the samples are collected anonymously or pooled. However, aggregate reports may dilute the value of results to individuals because participants will be left with uncertainty regarding the significance of the findings for themselves specifically (e.g., whether they were found to be at high risk versus low risk) (Shalowitz and Miller, 2005).

A number of studies have examined the attitudes and responses of research participants with respect to access to clinical research results, though not specifically to results from genetic studies. In general, studies have found that disclosure of research results to participants, even those of a serious nature, do not result in negative psychological impacts in the majority of research participants (Bunin et al., 1996; Schulz et al., 2003; Snowdon et al., 1998; Shalowitz and Miller, 2008). Participants indicated they would want access to research results (Wendler and Pentz, 2007), even if upsetting (Schulz et al., 2003) or if not considered clinically valid or useful (Wendler and Emanuel, 2002).

Despite current evidence that research participants would like the option of requesting research results even if of little clinical utility, the practice does appear to be common. An analysis of consent forms in the Children's Oncology Group found that only two of 202 studies offered the option to participants to receive research results and only 10 of 202 studies offered to provide new information after the study was completed (Fernandez et al., 2003a). Although almost 80% of clinical investigators surveyed agreed that clinical trial results should be offered to research participants, about 60% of investigators only offered results less than 20% of the time (Partridge et al., 2004). Moreover, more than 60% did not believe that the disclosure of research results would have a negative impact on participants (Partridge et al., 2004). The major reasons given for not returning results include potential harm of research participants and time constraints and cost related to development of research summaries or individual reports and re-contacting of participants (Fernandez et al., 2003b; Rigby and Fernandez, 2005).

While several policies on data disclosure have been developed, few exist at the federal level. Of the guidelines specific to genetic studies, the importance of clinical relevance and utility is emphasized. For example, the NHLBI guidelines identified the availability of a clinical intervention (treatment or preventative) as a key criterion if results were to be returned to study participants (Bookman et al., 2006). It has been suggested that investigators have an ethical responsibility to offer participants access to research results (MacNeil and Fernandez, 2006). Providing an option to disclose research data shows respect to the research

participant (Shalowitz and Miller, 2005). Those investigators who choose not to provide access to research data should have to justify this decision (Shalowitz and Miller, 2005). Given concerns about the potential harms of unvalidated or inconclusive data, it has been suggested that the option for access to research results should be provided but not necessarily encouraged and that the uncertain nature of the results may be emphasized (Shalowitz and Miller, 2005). Because of these potential risks, it has also been suggested that a second consent should be obtained prior to disclosure of research results (Fernandez et al., 2003c, d).

Data-sharing

Publicly accessible genomic databases employ a range of data access policies. Initially, the leaders of the Human Genome Project determined that all data generated from the project should be placed in a public repository and accessible to all interested users (The Wellcome Trust, 1996, 2003). Rapid deposit of sequence data was required from each of the sequencing centers. This policy decision was influenced by concerns that access to basic data would be impeded if traditional methods of scientific data disclosure were followed. For new publicly funded, large-scale international collaborations, similar policies may need to be developed in advance to address issues of data-sharing, intellectual property and use of specimens (if applicable) (Chokshi et al., 1999). The 2006 NIH proposal specifying policies on data-sharing for NIH-supported or conducted genome-wide association studies is a step in this direction (National Institutes of Health, 2006a).

Several studies have examined data-sharing and data-withholding practices of US biomedical scientists and, in particular, geneticists. According to the most recent study, geneticists were more likely to engage in data-withholding practices than other life scientists (Blumenthal et al., 2006). Among academic geneticists, at least one-third of requests for additional information, data, or materials and 10% of post-publication requests were denied (Campbell et al., 2002). Twenty-eight percent stated that data-withholding impacted their ability to confirm research findings (Campbell et al., 2002). Reasons for withholding included concerns about additional time and effort, protection of junior investigators, and protection of data intended for future publications (Campbell et al., 2002). Delay in publication may be caused by factors such as IP or desire to maintain a competitive advantage (Blumenthal et al., 1997). These three surveys combined have assessed data-sharing practices from the 1980's until today and are among the few sources of information about these scientific practices in genetics or, by extension, genomics.

Little research has been conducted to assess public attitudes regarding sharing of biomedical research data and specifically genomic research data. The privacy of genomic information, even if de-identified or stored anonymously, is tenuous, since as few as 30 single nucleotide polymorphisms (SNP) may uniquely identify an individual (Lin et al., 2004). Therefore, participants may need to be informed about the potential risks due to data-sharing practices.

INTEGRATING GENOMIC MEDICINE APPLICATIONS IN HEALTHCARE

While human genetics has focused traditionally on testing for Mendelian and rare diseases through established techniques such as karyotyping, fluorescence *in situ* hybridization, and restriction fragment length polymorphism analysis, genomic medicine builds on new technologies such as genome-wide analysis of SNP and copy number variation, metabolomics and whole genome sequencing. These new technologies have led to testing for a broader range of diseases including common, complex conditions such as Type II diabetes. However, the expanded scope of clinical genomic applications necessitates consideration of the adequacy of current policies to ensure the safe, effective, and appropriate use of the genomic applications. In particular, changes may be need to be made to the regulatory system, education of health professionals involved in the provision of these new applications, and patient protections.

Oversight

In the United States, it is difficult to determine the actual number of traditional genetic tests performed annually given the privatized health care system; the only published survey data estimated that over 175,000 tests were performed in 1996 (McGovern et al., 1999). In contrast, the Clinical Molecular Genetics Society conducts annual audits of the UK National Health Service laboratories. In 2005–2006, 78,600 post-natal genetic tests were performed, almost 20% more than in 2004–2005 (Clinical Molecular Genetics Society, 2004–2005, 2005–2006). More than 1500 prenatal genetic tests were also performed, representing a 12% increase from the previous year (Clinical Molecular Genetics Society, 2004–2005, 2005–2006). Of particular interest, the number of predictive and confirmatory tests almost doubled over the prior year. About 85 conditions were tested for overall, although the majority of tests were for familial cancers such as breast cancer (*BRCA1/2*) and colorectal cancer (HNPCC and FAP). In the European Union, it is estimated that more than 700,000 tests are performed annually (Ibarreta et al., 2003).

In the United States, the Clinical Laboratory Improvement Amendments (CLIA) program administered by the Centers for Medicare and Medicaid oversees laboratory operations including quality control, quality assurance and analytical test validity. Laboratories are subject to inspection every two years by a state CLIA inspector or an accredited organization such as the College of American Pathologists. In 2006, 198,000 laboratories were registered by the CLIA program. Tests that are packaged and marketed as kits are considered medical devices and require clearance or approval by the FDA. However, as the majority of genetic tests are offered as a clinical laboratory service, otherwise known as a "home-brew" test, they are not currently subject to FDA regulations. In addition to analytical validity, FDA also reviews the clinical validity of tests.

Over the past decade, two federal committees have explored the adequacy of current regulatory oversight mechanisms of genetic tests. In 1997, a NIH-Department of Energy Task Force indicated that an assessment of current review processes of the validity and utility of genetic tests may be warranted, but stopped short of providing specific suggestions (Holtzman and Watson, 1997). In 2000, the Secretary's Advisory Committee on Genetic Testing recommended that the FDA regulate all genetic tests and that oversight of genetic testing laboratories under the CLIA be strengthened (Secretary's Advisory Committee on Genetic Testing, 2000).

To date, these recommendations have not been implemented, although the creation of a genetic testing specialty under CLIA has been proposed and debated (Centers for Disease Control and Prevention, 2000). Several guidance documents have been issued by FDA, resulting in a gradual increase in oversight of new genomics applications. In 2005, a guidance document was issued encouraging sponsors to voluntarily submit pharmacogenomics data to help prepare reviewers on the type and complexity of genomics-based data (FDA, 2005b). Two relevant draft guidances were also released in 2005 – a draft guidance on nucleic acid-based *in vitro* diagnostic devices for detection of microbial pathogens was released (FDA, 2005f) and another on the co-development process of drug-device combination products as evident from their concept paper (FDA, 2005e). In addition, other guidance documents have been developed focusing on drug metabolizing enzymes genotyping system (FDA, 2005c), multiplex technology (FDA, 2005d), analyte specific reagents (FDA, 2006b), algorithm-based genetic tests (FDA, 2006c), genetic toxicology studies (FDA, 2006d), and pharmacogenetic tests (FDA, 2007).

Direct-to-Consumer Marketing

Genetic services and applications are often promoted directly to consumers, similar to drugs and other healthcare services. However, for many of these services and products, the involvement of a health care professional is not required, and consumers can purchase goods directly from the laboratory or manufacturer (an "over-the-counter" test). Laboratory services include testing for paternity, lifestyle, health, and ancestry. Products include DNA-tailored cosmetics and nutritional supplements. Consumers who purchase these services may decline to share the results with their health practitioner due to fear of genetic discrimination.

Direct-to-consumer (DTC) provision of genetic services and products, particularly those that are not health-related, represent an emergent industry. However, at this early stage of research and development, the complex genetic etiology and role of environmental factors for many phenotypes and traits are not clearly understood. Therefore, many of the early tests promoted directly to consumers likely lack robust validity and utility. As these tests are not subject to FDA oversight, the evaluation of the validity of genetic tests and products may be challenging for some consumers. Consumers may be vulnerable to ambiguous and exaggerated claims. In addition, the complex nature of genetic information related to health may warrant consultation with professionals trained in genetics or other specialist to ensure appropriate test interpretation and intervention.

General advertising of genetic tests accessible only through a physician has also increased. For example, Myriad Genetics launched an advertising campaign in two cities in 2002 for the *BRCA1/2* breast cancer tests. A study conducted the following year to assess the impact of the campaign on women's awareness of the tests found that consumers were substantially more likely to have heard of the test and seen an advertisement (Jacobellis et al., 2004). However, despite the increased awareness, the perceived knowledge and interest in testing did not differ between the pilot and control cities. Physician knowledge of breast cancer testing did not differ between the pilot and control cities, although physicians reported ordering a significantly higher number of tests in the pilot cities (Myers et al., 2006).

DTC genetic services and products have raised concerns among a number of groups. In 2002, the UK Health and Science Ministers requested an investigation by the Human Genetics Commission into DTC genetic testing. The commission identified two potential harms from DTC genetic testing: the impact of inaccurate or misinterpreted test results on consumer health and the absence of an adequate informed consent process (UK Human Genetics Commission, 2003). As a result, the Commission recommended that stricter controls be put in place for DTC genetic tests and that predictive genetic tests should be restricted from DTC sale.

In the United States, the American College of Medical Genetics (2004 and 2008) recommends "a knowledgeable healthcare professional should be involved in the process of ordering and interpreting a genetic test" to prevent potential harms such as test misinterpretation and inappropriate follow-up. In 2006, an investigation conducted by the General Accounting Office concluded that DTC nutrigenetic tests were medically unproven and ambiguous (Government Accountability Office, 2006). To educate consumers about home genetic test kits, the Federal Trade Commission, the Centers for Disease Control and Prevention, and the Food and Drug Administration developed a fact sheet (Federal Trade Commission, 2006). And, in 2007, the American Medical Association's House of Delegates passed Resolution 522, which requested further study of the practice of DTC advertising of genetic tests and, in particular, at the existing oversight of this field (American Medical Association, 2007).

Access/Reimbursement

Coverage of genomic applications is intimately linked to uptake of a new test and integration into clinical practice. The demonstration of the validity and utility of a genomic application as well as cost-effectiveness is essential to securing reimbursement. More than 150 economic analyses of genetic services have been conducted, many for adult conditions such as cancer (Carlson et al., 2005; Phillips and Van Bebber, 2004). While many tests have been shown to be cost-effective, others still have questionable utility despite demonstrated clinical validity.

For example, a commercially available molecular profiling test known as Allomap has been shown to be cost-effective to identify heart transplant patients at risk for rejection compared to endomyocardial biopsy to detect rejection, mainly due to the cost-savings gained from not having to perform a biopsy (Evans et al., 2005). But several tests developed to guide therapy decisions are considered by some to be of questionable value (Matchar et al., 2006).

The increased involvement of FDA review of genomic tests and more focused translational research has encouraged the coverage of these applications. For example, in 2005, the Blue Cross Blue Shield Association's Technology Evaluation Center (TEC) assessed four gene expression profiles for use in the management of breast cancer. Based on the available evidence at the time, the report concluded that none of the profiles met the TEC criteria (Blue Cross Blue Shield Association Technology Evaluation Center, 2005). The TEC criteria include approval by federal regulatory bodies and evidence demonstrating an improved outcome and comparable benefits to existing alternative treatments or applications. However, in 2007, a second review of the Oncotype DX test (one of the four tests evaluated in 2005) concluded that the test now met the TEC criteria and was considered to be useful specifically regarding adjuvant chemotherapy for women with estrogen receptor-positive, node-negative, tamoxifen-treated breast cancer (Blue Cross Blue Shield Association Technology Evaluation Center, 2007).

In addition to evaluating both clinical validity and utility, pharmacogenetic testing policies must also consider coverage of the drugs identified as being most likely to perform well or least likely to cause adverse side effects. For tests that are co-developed with drugs, the cost of the testing and drug could be determined by a single policy decision. But in the event that a test indicates a different drug, payors may be forced to revise their coverage policies for drugs that are not listed on their formularies.

Health Professional Education

As the applications of genetic and genomic information have expanded beyond the traditional specialties of medical genetics, pediatrics, and obstetrics into other fields such as oncology, cardiology, neurology, and psychiatry, the education of health professionals needs to evolve as well. While a number of surveys have documented the variable level of physician knowledge of genetics (Metcalfe et al., 2002), none has assessed knowledge of the newer field of genomics. The uptake and use of new applications will be stalled until health professionals gain some understanding about the appropriate use of these tests and the interpretation and application of test results. As a result, the continuum of health education from graduate or professional school to continuing education should aim to increase awareness and understanding of these new tools and therapies across virtually all medical specialties (Challen et al., 2005; Gurwitz et al., 2003). In addition, it will be important for health professionals to understand other issues related to the use of these technologies such as implications for family members and privacy and confidentiality issues.

Re-defining Roles of Health Professionals

Due to the expected widespread use of genomic applications, some re-organization of health professional roles may be required, given the limited number of genetics specialists and new applications such as pharmacogenetic testing (see Table 18.1) (Guttmacher et al., 2001). For example, the pharmacist may play a much greater role in the integration of pharmacogenetic testing by helping to ensure that the drug and dosage are safe based on the patient's genotype (Clemerson et al., 2006). Monitoring pharmacogenetic information to assure appropriate drug dosing would appear to be a natural extension of the role of pharmacists. To fulfill this expanded role, pharmacists would need greater access to patient medical records (Clemerson et al., 2006), although physicians and patients have expressed concerns regarding patient confidentiality if full access were permitted (Porteous et al., 2003).

In contrast, a board-certified genetics professional (physician or genetic counselor) may have a revised, lesser or even non-existent role in the provision of genomic testing such as a pharmacogenetic profile as these tests become routine. The need for a genetics specialist may be determined by several factors including complexity in determining appropriate candidates for testing and interpretation of test results, the extent of the informed consent process, reimbursement policies, familial implications and the risks and benefits of the test. However, given the relatively small size of the genetics workforce, any new requirements for their services may not be feasible. Consultation by a board-certified genetics specialist may need to be reserved for only the most complicated cases.

To increase the number of physicians with training in genetics or genomics, one possibility may be to increase the number of dual board-certified specialties with medical genetics. For example, an individual dual-certified in medical genetics and pharmacology would have expertise in genetics and pharmacology and be able to advise the treating physician about the best choice of treatment based on the patient's pharmacogenetic profile and other clinical information. However, the training requirements to fulfill the medical genetics certification should be substantially revised to provide direct knowledge relevant to the individual's primary profession with greater focus on test appropriateness, interpretation and test utility. In addition, genetics certification should not lengthen the overall training program.

Pilot development studies have found that new roles associated with genetic testing were mostly fulfilled by non-genetics specialists, in particular nurses (Bennett et al., 2007). For example, the cancer family nurse specialist is trained to identify patients with a family history of cancer that would place them at increased risk and indicate testing (Bennett et al., 2007). Indeed, genetic competencies have been developed and training programs have been accordingly revised to meet these new needs and to enable nurses to adequately provide genetics services and guidance (Jenkins and

Table 18.1 Changing roles of health professionals in genomic medicine

Health professional	New or revised role
Primary care Physician	Increased focus on family-history assessment, identification of appropriate patients for testing, discussion of risks and benefits of testing, interpretation of test results, revision of medical management based on test results, focus on preventative strategies
Nurse	Enhanced family-history taking and counseling skills; enhanced education in corresponding areas of genetics (e.g., cancer genetics for oncology nurses); awareness of ethical, social, and legal issues associated with testing
Genetic or Genomic Specialist (Genetic Counselor or Physician)	Consultation reserved for complex genetic cases; interpretation of whole-genome data, including sequence; increased role in professional education development
Pharmacist	Increased understanding of genetic factors in drug safety and efficacy; enhanced education of genetic etiology of drug response; consideration of pharmacogenetic test results prior to drug treatment; increased collaboration with prescribing physician; increased patient education with respect to pharmacogenetic testing; added consideration of pharmacogenetic test result to determine appropriate dose adjustment or drug selection

Calzone, 2007; Lewis et al., 2006). Studies have demonstrated the equivalence of care provided by nurses trained in genetics compared to board-certified genetic counselors (Torrance et al., 2006). Several groups have developed professional genetic competencies including the National Coalition for Health Professional Education in Genetics (2005), and the National Health Service's National Genetics Education and Development Centre and the Skills for Health Service (2007) have developed general competences for non-genetics practitioners.

Privacy and Confidentiality

The issue of medical privacy is a major concern in the United States. In 2005, the National Consumer Health Privacy Survey reported that 66% of Americans were very or somewhat concerned about medical privacy (California Health Care Foundation, 2005). Due to concerns that employers or other groups may have access to a medical record, 11% of survey respondents indicated paying for a cancer test or procedure out-of-pocket. The predictive nature and often deterministic views associated with genetic information have likely contributed to the heightened concerns linked to testing. In addition, as the number of health professionals with access to a patient's genomic test results increases, the ability to safeguard the information increases becomes more challenging.

Genetic Discrimination

Genetic discrimination involves the inappropriate use of genetic information, primarily with respect to health insurance and employment, but including other areas such as life insurance, long-term care insurance, adoption services, egg and sperm banks or educational admissions programs. While the fear of genetic discrimination has existed prior to the start of the Human Genome Project, the solutions have been slow to come by and, at best, provide a patchwork of protections in the United States and around the world. For example, about two-thirds of states have enacted legislation to prohibit or limit the use of genetic information for risk selection and risk classification for health insurance purposes. Passage of national legislation would provide universal coverage against health insurance and employment discrimination on the basis of genetic information for all. But despite all of the interest and support shown by federal lawmakers including the past two US presidents, national legislation has only just been enacted. Unbelievably, it has taken longer to pass genetic anti-discrimination legislation than it actually took to sequence the human genome.

Since the first bill on genetic discrimination in health insurance was introduced in the United States in 1995, at least 20 other bills have been introduced, but only one has passed providing partial protection against genetic discrimination for the group insurance market. In 2007, the Genetic Information Nondiscrimination Act was re-introduced to "prohibit discrimination on the basis of genetic information with respect to health insurance and employment." In contrast to previous years, it swiftly moved through the three House committees who have jurisdiction and passed by a floor vote of 420 to 3, thus moving further along than in any previous Congress. The bill was also passed by the Senate and signed into law by President Bush in May 2008.

Despite universal condemnation against genetic discrimination (UNESCO, 1997, 2003), the development and implementation of national protections has also been slow outside the United States. For example, although "genetic features" is included in the European Union's Charter of Fundamental Rights' section on non-discrimination, countries have had variable success in providing national protections (European Parliament, 2000). Austria, Belgium, France, the Netherlands, Luxembourg, Greece, and Italy have enacted legislation prohibiting access of genetic information without consent.

Various initiatives have been undertaken in the United Kingdom, Australia, and Canada to protect against genetic

discrimination by life insurers and employers. Similar to the United States, a patchwork of provincial legislative protections in Canada exist. A recent review of the Canadian Human Right Act by the Department of Justice recommended that the definition of disability include genetic predispositions (Department of Justice, Canada, 2005). Australia has been particularly active in investigating the protections of genetic information. In 2000, the Attorney-General of Australia and the Minister for Health and Aged Care called for an inquiry into genetic discrimination. An extensive public consultation was undertaken including widespread dissemination of two consultation papers (Australian Law Reform Commission, 2001, 2002), 15 public forums around the country, and 185 meetings with key stakeholders and interested parties. In 2003, a final report was released containing 144 recommendations directed at local, regional, and national governments as well as statutory authorities (Australian Law Reform Commission, 2003). And in the United Kingdom, a moratorium is in effect banning the use of genetic testing information for insurance underwriting purposes until 2014 (Association of British Insurers, 2008).

Intellectual Property

Intellectual property (IP) of genes and genetic material has been a major point of controversy since the early years of the Human Genome Project. Nearly 20% of the human genome is under US patents, comprising about 4400 genes (Jensen and Murray, 2005). More than 60% of these patents are owned by private entities (Jensen and Murray, 2005). In addition, almost a dozen complete genomes have been patented or are pending patent approval (O'Malley et al., 2005). A constellation of issues pertaining to ownership has garnered significant attention and concern from various stakeholders. From the single laboratory to national advisory bodies to international organizations, gene patenting has become a controversial topic, particularly with respect to the limitation of access to gene-related inventions and benefit-sharing (World Health Organization, 2005; Canadian Biotechnology Advisory Committee, 2006). The patenting of genomes has significantly broadened the scope of IP, and its impact remains to be seen.

Although there has been a significant amount of debate about the patenting of genes, concern also exists about the licensing practices of patent holders, as exemplified by *BRCA1/BRCA2* and Canavan's disease. To address some of these concerns, the NIH has also taken steps to promote open access to its large-genomic datasets and encourage fair licensing practices through IP user agreements and guidance documents (National Institutes of Health, 2005). In addition, an amendment to a Request for Applications for genome sequencing centers requires applicants to develop an "IP Management Plan" to ensure wide availability of sequencing data generated by awardees (National Institutes of Health, 2006b).

2009 UPDATE

While advances stemming from the genome sciences are certain to impact the practice of medicine and our understanding of human development, biology, biochemistry, and physiology, the safe and appropriate use of this new information and its associated technologies will warrant new policies and an improved level of understanding by patients, consumers, and providers. Over the last year, direct-to-consumer testing has substantially expanded with at least three companies providing whole-genome risk profiling, ranging in cost from $399 to $2500 for risk information for several dozen (Navigenics) to nearly a hundred (23andMe, Inc.) diseases and traits (ironically, the lower priced test reports risk information for the greatest number of conditions). Although these companies claim not to be offering medical information, some health departments, notably in California, have demanded that the laboratories be CLIA-certified and retain professional staff or cease marketing their products within these states. While many of these companies have acquiesced to these requests, they and other genetic testing providers will likely face additional demands for oversight, particularly test standardization and validation, and have begun working with other groups to define these standards (DHHS, 2008a; Kaye, 2008). Thus, although the commercial success of these companies remains to be seen, they have pushed to the forefront many of the issues that have been facing genetic, and now genomic, testing providers for some time, namely oversight and regulation. In addition, these companies have spurred physicians and public health experts to highlight the need for additional research to validate genetic associations (Khoury et al., 2008) and to increase physician training and awareness in preparation of increased testing outside of the healthcare system (Haga and Willard, 2008).

With passage of the genetic non-discrimination protections, federal agencies in the United States have begun to work on policies to implement the new law, which will become effective in 2009. Although the signing of this legislation took more than a decade to achieve, there are gaps in the legislation as it does not prohibit life insurers and long-term care insurers from using genetic information in their policy decisions (Hudson et al., 2008). Although many states have laws prohibiting genetic discrimination, some more stringent than the federal legislation, it will be of interest to assess the impact of passage of federal protections on patient concerns and whether it substantially alleviates this fear and removes this barrier from the decision-making process. Education of health professionals, patients and consumers about the new federal protections will be essential part of realizing the benefits.

Personalized medicine will likely remain a top health initiative in the new administration in the United States. In 2007, then-Senator Barack Obama introduced a bill to facilitate oversight and development of personalized medicine tools

(S. 976). In 2008, a companion bill (H.R.6498) was introduced in the House of Representatives by Congressman Patrick Kennedy. Other government priorities, such as family-history taking tools (DHHS, 2009) and development of decision support tools (DHHS, 2008b), are key components in initiatives on health information technology and personalized medicine, as they will help facilitate uptake of new genomic-based applications and the appropriate use of these applications.

CHAPTER

Federal Regulation of Genomic Medicine

Janet Woodcock

INTRODUCTION

Regulation of the medical uses of genomic technologies is an evolving and controversial field. In the ideal case, medical product regulation strikes an appropriate balance between protecting patients and fostering innovation. Such balance can be difficult to achieve during the dynamic evolution of a new area of technology. Currently, the fields of genomic testing and pharmacogenomics are experiencing very active growth and corresponding regulatory and policy interest, and there is ongoing debate about the appropriate level of regulation of these technologies (Hudson, 2006; Javitt and Hudson, 2006). This chapter provides an introduction to both the regulatory framework and the ongoing policy challenges for genomic medicine.

Commercial introduction of genetic tests began in the late 1970s; however, the pace of introduction was slow at first and has rapidly accelerated over the last decade. It is estimated that over 1300 genetic tests are currently available in the United States (Gene Tests, www.genetests.org). Most of these are diagnostic tests for genetically based disorders. Recently, new types of *in vitro* diagnostics (IVDs) – for example, assays evaluating gene expression – are being introduced. Based on the current amount of activity in the field, an explosion of new assays can be anticipated over the next several years.

The landscape of genetic test regulation is somewhat confusing. The vast majority of available genetic tests are "laboratory-developed tests." Such assays are not FDA approved; rather, they are developed and conducted within a specific laboratory and are offered as a service by the laboratory. In contrast, all marketed test kits go through an FDA regulatory process of some type. Laboratories that develop an in-house test may submit an application for marketing clearance to the FDA; however, few have chosen to do so. This framework has resulted in a perception of an "uneven playing field" for the two assay categories. All laboratories reporting out human results require Clinical Laboratory Improvement Amendments (CLIA) certification. The CLIA program is administered by the Centers for Medicare and Medicaid Services (CMS). The respective roles of FDA and CMS have not been clear to all, especially newcomers, in the field and have resulted in considerable confusion. Recently FDA issued several "Guidance" documents intended to specifically clarify FDA regulation of newer diagnostic tests, including genomic tests. These will be discussed in more detail below.

Researchers interested in developing a specific assay for use in clinical medicine will need a basic understanding of the various regulatory regimes, as described further in this section. Exploratory assay development using human samples – for example, tissues or body fluids – can usually be conducted under the general human subject protection and privacy provisions implemented by academic institutions. Prior to undertaking analytical validation or clinical studies, however, it would be prudent for a developer to determine the potential regulatory

status of the test, and the types of studies and regulatory clearances needed to bring the test to market successfully. Further evolution of the current regulatory framework for genomic tests is likely if the new discipline of genomic medicine is as successful as is currently anticipated.

In contrast to genetic diagnostic testing, the field of pharmacogenomics is in fairly early development. Genomic technologies have been used extensively in drug discovery for over a decade, but application to drug development is a more recent phenomenon. Pharmacogenetics can be defined as the study of the genetic contributions to drug responses (see Chapter 15). Drug metabolizing enzyme polymorphisms are the best understood examples of pharmacogenetics because correlations between phenotypes and drug concentrations have been well worked out for a number of polymorphisms. Despite decades of study, however, metabolizing enzyme polymorphisms are rarely taken into account in drug development or clinical practice, in part because convenient assays have not been available. Recently, genetic tests for common drug metabolizing enzyme polymorphisms have been introduced and several have been approved by the FDA; however, as of this writing, no drug label contains *specific requirements* for dose adjustment based on metabolizing enzyme test results. Routine use of such tests awaits demonstration of added value. Pharmaceutical developers generally seek to eliminate, prior to clinical testing, candidate drugs that are subject to polymorphic metabolism or that may be prone to drug–drug interactions based on metabolic factors. Traditional clinical drug development processes have not included individualized dose adjustments, and there are strong commercial and logistical disincentives to incorporating such individualization. The first pharmacogenetically directed, dose-adjusted drug development program will likely involve:

- a promising molecule that developers are unable to engineer to avoid an undesirable metabolic pathway;
- an indication for a very serious or life-threatening illness; and
- an expected narrow therapeutic index (e.g., cancer therapeutics).

Much of the current scientific interest in drug metabolism involves marketed drugs, many of which are metabolized by polymorphic enzymes. Clinical practitioners have long been accustomed to performing empirical dose adjustments based on clinical parameters, for example, INR for warfarin, leukocyte counts for 6-mercaptopurine, or side effects for many drugs. There is considerable skepticism within the clinical and reimbursement communities about the value of up-front genetic testing and dose adjustment. Resolution of these issues will require randomized clinical outcome trials that demonstrate added safety or effectiveness, or improved patient convenience/adherence and/or cost-effectiveness as a result of testing and dose adjustment. From a scientific perspective, it is unquestionable that the many-fold variation in drug exposure often introduced by polymorphic metabolism has important clinical consequences in both drug development and in patient care, particularly for drugs with narrow therapeutic indices. However, ingrained practices change slowly, and, in any case, there is a need for evidence-based dosing algorithms for practitioners in instances where dose adjustment is found to be important (see for example www.warfarin-dosing.org).

Although drug metabolism is the best understood example, the promise of pharmacogenomics for drug and vaccine development and use is much more expansive. Pharmacogenomic tests are being explored for selecting patient subgroups for treatment (based on probability of response, prognostic category, or disease subtype), identifying patients with a high probability of an adverse response to therapy, and for monitoring response. Additionally, the field of toxicogenomics, that evaluates the genomic responses to toxicants, is expected to contribute much more sensitive toxicity assays and greatly enhanced understanding of the mechanisms of drug toxicity. All these applications are in the early stages of development. The most extensive clinical use occurs in the field of antiretroviral therapy, where HIV drug resistance testing is routinely performed by assaying the viral genome, and therapy is directed by the results. Both FDA-approved and laboratory-developed HIV drug resistance assays are commercially available. With respect to the human genome, the most developed examples occur in cancer, where various genomic assays are employed to provide information about tumor aggressiveness and prognosis, or about likelihood of response to a targeted therapy (e.g., imatinib, trastuzumab). NIH, FDA and the pharmaceutical industry are also pursuing efforts to understand the genetic basis of drug-related adverse events. An historical example of a genetically based drug adverse event is drug-induced hemolysis in people with G6PD deficiency (metabolism based); a non-metabolic, recent example is the abacavir hypersensitivity reaction (Rauch et al., 2006). It is expected that some, but not all, drug-related adverse events will have a genetic contribution.

Because of the potential for pharmacogenomics to improve drug safety and effectiveness, the FDA has been vigorously involved in efforts to foster this new field. In November 2003, the Agency established the "voluntary genomic data submission process," a kind of safe harbor where pharmaceutical developers can share genomic experiments and data with the FDA in a non-regulatory context (www.fda.gov/cder/genomics/GDS.htm). Multiple data submissions have been shared with FDA and this process is expected to help ease the transition of pharmacogenomic technologies into mainstream preclinical and clinical drug development.

Nevertheless, numerous policy questions related to the use and regulation of pharmacogenomics in drug development remain to be answered. For example, what regulatory standards should apply during co-development of a pharmacogenomic test and drug to be used in combination? What data and studies are needed to qualify genomic biomarkers for regulatory use? "Regulation of Genomic Tests" explores the regulatory framework for the use of pharmacogenomic technologies in drug development and therapy, and discusses various unresolved policy areas.

REGULATION OF GENOMIC TESTS

Researchers intending to translate basic genomic discoveries into new diagnostic or prognostic assays will need to have a basic understanding of the regulatory framework governing such tests.

FDA regulations define IVDs products as "those reagents, instruments and systems intended for use in the diagnosis of disease or other conditions, including a determination of the state of health, in order to cure, mitigate or prevent disease or its sequelae." The regulations go on to say: "These products are devices as defined in Section 201(h) of the Federal Food Drug and Cosmetic Act …" (21 CFR 809.3) Therefore reagents, systems, and assays for human use are considered medical devices under the law and are subject to FDA regulation. However, medical device regulation has considerable flexibility, and this has been exercised by FDA in its oversight of IVDs. Additionally, the FDA Modernization Act passed by Congress in 1997 called upon FDA to use an approach to device regulation that is "least burdensome" on manufacturers while still achieving public health objectives, and this charge is taken into account when implementing regulatory standards.

Regulation of *In Vitro* Diagnostics as Medical Devices

Prior to embarking on a development program for a genomic test, researchers and developers should strongly consider consulting with the FDA staff about the development plan. Most genomic assays regulated as medical devices will be overseen within the Office of *In Vitro* Diagnostic Device Evaluation and Safety (OIVD) in the Center for Devices and Radiological Health (CDRH) at FDA. CDRH offers assistance to researchers, developers, and device manufacturers, who can request a "pre-IDE" meeting with OIVD to discuss the proposed development plan. Such consultations can save time and prevent wasted efforts. Developers can submit their planned protocols for evaluating the performance of the IVD and reach agreement with FDA staff on the extent and nature of the studies. Contacts can be reached through the CDRH web page (www.fda.gov/cdrh/index.html). FDA has also recently published a relevant draft Guidance entitled "Pharmacogenetic Tests and Genetic Tests for Heritable Markers" that contains advice on product development (www.fda.gov/cdrh/oivd/guidance/1549.html).

Regulatory Classification of *In Vitro* Diagnostics

Medical devices are classified into categories, based on risk, that govern the intensity of their regulation. For IVDs, the risk determination is primarily a function of the intended use of the device, based generally on the claims sought by the manufacturer. Many types of IVDs have been formally classified by the FDA in regulations. Class I devices are considered low risk and are subject to the fewest regulatory controls. These so-called "general" controls include, for example, facility registration, requirements for label information and format, manufacturing procedures, and reporting of adverse events. Many (non-genetic) IVDs have been assigned to Class I and are exempted from submitting applications for marketing to the FDA. Class II devices are moderate risk and require additional controls. Many genomic tests will be considered Class II IVDs. As a relevant example, drug metabolizing enzyme genotyping systems are Class II. In making this determination, FDA published the document "Class II Special Controls Guidance Document: Drug Metabolizing Enzyme Genotyping System," in 2005 (www.fda.gov/cdrh/oivd/guidance/1551.html). This document explains what data to submit to FDA in a Premarket Notification Submission, also known as a 510(k) (see below) for a diagnostic of this type. By submitting this information, and also complying with the "general" controls, a manufacturer can meet the requirements for marketing a drug metabolizing enzyme genotyping system. Special controls vary with the category of IVD. In some cases, clinical studies may need to be submitted as part of a 510(k) submission for a Class II IVD.

Class III IVDs are considered high risk and often require submission of a Premarket Approval Application (PMA). PMAs usually include data from clinical studies. If a device category has not been classified, it is considered Class III.

Applications for Marketing *In Vitro* Diagnostic Tests

The Premarket Notification Submission or 510(k)

When submitting a traditional 510(k) application, a manufacturer intends to demonstrate that its IVD is "substantially equivalent" (the legal terminology) to a previously legally marketed IVD, called the "predicate device." If a predicate IVD exists, clinical data in the 510(k) for a genomic test would include information on the analytic validation of the test, plus comparisons with the predicate IVD performance, using appropriate clinical samples (Figure 19.1).

If no predicate exists, the FDA can, when appropriate, use a process know as a *de novo* 510(k) to establish the special controls needed for a Class II IVD, as discussed for the drug metabolizing enzyme genotyping test systems mentioned above. In these instances, the medical literature or submitted data can be used by FDA to help determine the needed extent of special controls. The *de novo* 510(k) may contain clinical data consisting of protocol-based testing of clinical samples, may sometimes also include data gathered in prospective clinical trials, and in some cases may include data derived from the clinical literature and/or information found in recognized clinical practice standards.

In February 2007 FDA approved Agendia's MammaPrint® as a *de novo* 510(k). This test is intended to evaluate the likelihood of breast cancer recurrence within 5–10 years in patients with Stage I or Stage II disease. It is the first FDA-cleared molecular test using genetic profiling to predict breast cancer prognosis and is indicated as a prognostic marker only. Total FDA review time for this application was 30 days; the entire process (which necessitated the firm submitting a petition for down-classification) took less than 180 days. The special controls guidance document for these types of assays, "Class II Special Controls Expression Profiling Test System for Breast Cancer Prognosis," has been published (www.fda.gov/cdrh/oivd/guidance/1627.pdf). The clinical data for this application was based on analyses of stored samples from various studies (www.fda.gov/cdrh/reviews/K062694.pdf).

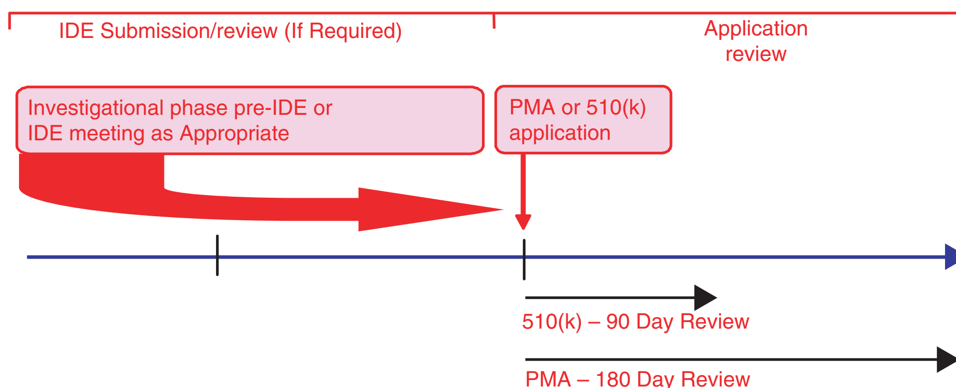

Figure 19.1 *In vitro* diagnostic development process. The requirement for an Investigational Device Exemption (IDE) filing is based on risk: most clinical studies of IVDs do not need to be conducted under an IDE. Sponsors may request a meeting with FDA at any time during the development process to obtain regulatory guidance on the development program or on how to submit an application: request a "pre-IDE" meeting if no IDE exists, or an "IDE" meeting if an IDE has been filed. The timeframe for FDA review depends on whether a 510(k) or PMA has been filed.

FDA has published extensive guidance on submission of 510(k)s for IVDs, including the documents "Format for Traditional and Abbreviated 510(k)s" (www.fda.gov/cdrh/ode/guidance/1567.pdf) and "Points to Consider for Collection of Data in Support of *in vitro* Device Submissions for 510(k) Clearance" (www.fda.gov/cdrh/ode/95.pdf) FDA has also recognized dozens of voluntary standards (most developed by the Clinical Laboratory Standards Institute or CLSI) for use in establishing test performance. Published guidances and FDA-recognized standards can be found on the CDRH web page (www.fda.gov/cdrh/index.html).

The Premarket Approval Application

The claims attached to certain genomic tests may cause them to be classified into Class III (high risk). An example of such claims could include prognostic information linked to therapeutic decision-making (e.g., more extensive radiation or chemotherapy for cancer). PMA submissions contain clinical data that substantiate these claims, usually derived from clinical trials. Developers often meet with the FDA staff to reach agreement on the design of these trials prior to their initiation.

Investigational *In Vitro* Diagnostics

Investigational device exemptions (IDEs) must be submitted to the FDA prior to beginning clinical studies of certain devices. IDEs are rarely needed for IVDs. In clinical studies where the results of the test will not be used in patient management, an IDE is not needed; however, the usual requirements for informed consent and IRB approval remain, where applicable. In those instances where the test results will determine management (e.g., patients are randomized to further interventions based on test results), an IDE should be submitted. OIVD staff may be consulted on the need for an IDE filing.

If investigational IVDs are shipped for research testing, for example, analytical validation, they should be labeled "For Research Use Only. Not for use in diagnostic procedures" (21 CFR 809.10 (c)(2)(i)). If they are shipped for use in comparative testing or as part of a clinical trial, they should be labeled "For Investigational Use Only. The performance characteristics of this product have not been established" (21 CFR 809.10 (c)(2)(ii)).

FDA recently issued a document entitled "Guidance on Informed consent for *In Vitro* Diagnostic Device Studies Using Leftover Human Specimens that are Not Individually Identifiable" that offers advice on the use of de-identified human specimens for testing (www.fda.gov/cdrh/oivd/1588.pdf).

Laboratory-Developed Tests

As stated above, the vast majority of currently marketed genetic tests are laboratory-developed tests that have not undergone the FDA review process. These tests are either fully developed by the laboratory or utilize a purchased "analyte-specific reagent" (ASR, see below) that is then configured into an assay by the laboratory, which carries out the test as a service. Such laboratory developed tests are not shipped for use outside the originating site. These tests are considered medical devices under the Food, Drug and Cosmetic Act (and the laboratories are considered device manufacturers), but FDA has not required marketing applications (using what is legally termed "enforcement discretion"), considering that the controls provided by the ASR regulations and the certifications for high complexity laboratories under CLIA (see below) to be sufficient. In September 2006 FDA issued a draft guidance document entitled "*In Vitro* Diagnostic Multivariate Index Assays" explaining that certain complex test systems, including certain genomic test systems, are Class II or Class III medical devices requiring 510(k) submissions or PMAs, respectively (www.fda.gov/cdrh/oivd/1610.pdf). The document defines the difference between *in vitro* diagnostic multivariate index assays (IVDMIAs) and the types of tests generally performed as laboratory-developed tests. This document and the related policy issues around laboratory-developed tests are generating considerable

discussion and debate, and the outcome of these debates will have consequences for developers of genomic tests.

Analyte-Specific Reagents

In 1997, FDA defined a group of reagents known as ASRs, and classified them (with some exceptions that are not germane to genomics) as Class I medical devices. This meant that ASRs were subject to "general controls" such as manufacturing and labeling requirements, but did not have to have applications cleared or approved by FDA to be put on the market. FDA accomplished this by publishing three regulations that defined and classified ASRs (21 CFR 864.4020), imposed restrictions on their sale, distribution and use (21 CFR 809.30) and established requirements for ASR labels (21 CFR 809.10(e)). In the regulations, ASRs were defined as "antibodies, both polyclonal and monoclonal, specific receptor proteins, ligands, nucleic acid sequences, and similar reagents which, through specific binding or chemical reactions with substances in a specimen, are intended for use in a diagnostic application for identification and quantification of an individual chemical substance or ligand in biological specimens" (21 CFR 864.4020). Thus, an ASR is a building block for an assay, but is not a test system. Subsequent to publication of these regulations, FDA observed a broadening of the implementation of ASRs beyond the stated parameters. Therefore, in September 2006, FDA issued a draft guidance entitled "Commercially Distributed Analyte Specific Reagents (ASRs): Frequently Asked Questions" (www.fda.gov/cdrh/oivd/guidance/1590.html). An important point in this document, for the purposes of this discussion, was that FDA did not consider "bundled" moieties (e.g., sets of primers), or extensively processed (e.g., arrayed on beads) reagents, or microarrays, to be ASRs. These distinctions are important to the genomic testing community and have elicited extensive comment. Undoubtedly the boundary between ASRs and test systems will continue to be clarified in the coming years.

Clinical Laboratory Improvement Amendments

Congress passed the CLIA in 1998. This law established quality standards for all laboratory testing to ensure the accuracy, reliability and timeliness of patient test results regardless of where the test is performed. The CLIA program is administered by the CMS (www.cms.hhs.gov/CLIA). The ASR regulations discussed above stipulated that the only clinical laboratories to which ASRs could be sold were those qualified under CLIA to perform high complexity testing (or alternatively, were regulated under the Veteran's Health Administration Directive 1106) (21CFR 809.30 (a)(2)). Currently, most genetic testing is performed by such laboratories. The oversight under CLIA relates to the quality of performance of laboratory testing. It does not extend to evaluation of the clinical utility of a given assay. There is ongoing controversy about the degree of oversight of genetic testing under CLIA (Hudson et al., 2006); specifically, whether there should be a specific genetic testing specialty area that would incorporate proficiency testing for genetic tests.

To summarize the current Federal regulation of genomic testing: most genetic tests are on the market as laboratory-developed tests. Such laboratories are subject to quality standards under CLIA. This is possible outside of FDA marketing clearance as a result of the ASR regulations and enforcement discretion on the part of FDA. FDA has approved a number of genetic tests, including tests for drug metabolizing enzyme polymorphisms, generally based on information available in the scientific literature. Recently, FDA issued draft guidances pointing out, among other things, that reagents such as micoarrays and sets of primers are not ASRs, and that IVDMIAs are not among the types of assays considered to be appropriate for laboratory-developed tests. These guidances have resulted in ongoing discussion and controversy, and the policy issues they raise have yet to be definitively resolved.

PHARMACOGENOMICS IN DRUG DEVELOPMENT AND CLINICAL MEDICINE: THE ROLE OF REGULATION

Researchers interested in translating genomic discoveries into new approaches to drug therapy will need to understand the challenges involved in incorporating these new scientific approaches into traditional drug development and use patterns. While genomic technologies are used extensively and routinely during drug discovery and in early drug development phases (e.g., lead optimization) routine utilization of genomics drops precipitously as candidates enter the animal safety and clinical testing phases. As a result, few investigational drugs now in the clinical pipeline are being studied in concert with pharmacogenomic assays (although most development programs include collection of human samples for potential genetic testing). Likewise, although extensive information exists about the contribution of drug metabolizing enzyme polymorphisms to variability in drug exposure, as of early 2007, no marketed drug label contains an explicit requirement (as opposed to recommendations) for dose modification based on genetic test results. (See "Genomics at FDA" (www.fda.gov/cder/genomics/genomic_biomarkers_table.htm) for an up-to-date list of pharmacogenomic tests utilized in drug labels.) These facts, when considered in light of the enormous potential for improvement in drug therapy that pharmacogenomics represents, demonstrate that the field is in its nascent stages.

Many barriers to rapid uptake of genomics in drug development and clinical medicine exist, beyond the purely scientific and technical challenges. Drug development is an enormously risky endeavor. Only about one in nine drug candidates entering clinical investigation reach the market, and every year promising candidates encounter catastrophic, highly public late-stage failures. Some compounds that reach the market fail to achieve commercial success. Additionally, drug development programs are extremely expensive. Furthermore, the clinical investigation and marketing application stages of development are subject to extensive regulatory scrutiny worldwide. These factors result in very conservative approaches on the part of pharmaceutical developers. Developing an investigational drug using a relatively untested pharmacogenomic-directed approach is perceived

as adding additional risk. The fact that drug development is a highly competitive activity also restricts the flow of information among developers, so that those who instigate new approaches may not share the successes or failures with others. Under these circumstances, the regulators may be the only group possessing a broad perspective on the state of the field.

Commercial considerations are also important in development. Developers normally pursue the broadest possible market for a new intervention. Many pharmacogenomic approaches (e.g., targeting therapy to a specific-identified population), would limit the indicated population. Complexity of use (e.g., dose adjustments, need for pre-testing) is also commercially undesirable and in fact can limit clinical uptake. For these reasons, along with the natural human optimism about the performance of a new discovery, pharmacogenomic tests have often been considered as a salvage approach when one-size-fits all development fails. Concerns about restrictions on markets are slowly being mitigated by the success of targeted therapies but still limit enthusiasm for pharmacogenomic approaches during drug development (Bernstein, 2006).

Once a drug is approved by the FDA, a manufacturer has a limited amount of time to recoup its investment before patent and exclusivity protections expire and generic competition occurs (generic copies are permitted for small molecule drugs but not for therapeutics approved as biological products). Therefore there is limited time to explore refinements of an approved therapy using pharmacogenomics. Once generic competition occurs there is no commercial incentive for further development.

The promise of pharmacogenomics and the barriers to its adoption led FDA to aggressively promote investigations of the new technology. Senior FDA staff published a 2002 paper calling for progress in the field and pointing out the Agency's interest (Lesko and Woodcock, 2002). In May 2002, a workshop between FDA and the pharmaceutical industry was held to explore barriers to information sharing (Lesko et al., 2003). At the workshop, industrial sponsors stated reservations about providing genomic information on compounds in development to the Agency because they feared uninformed questions and delays in product development; however, all agreed on the desirability of information sharing. FDA subsequently established a process for sharing data and results in a non-regulatory context, the "Voluntary Genomic Data Submission" (VGDS) (www.fda.gov/cder/genomics/GDS.htm). Subsequently, over thirty submissions of genomic data involving drugs in development, encompassing topics such as animal studies, preventive indications, identification of responsive subgroups, and genetic links to adverse events, have been discussed with FDA scientists. The goals of VGDS process include (1) encouraging the development and sharing of genomic data linked to therapeutic and preventive indications; (2) helping familiarize FDA scientific staff with the emerging uses of genomic information in drug development; (3) developing data standards and analytical methods suitable for regulatory use; and (4) enabling the transition of genomic studies from exploratory research to regulatory submissions. (See www.fda.gov/cder/genomics/presentations/Webinar.pdf for a detailed presentation of the VGDS process.) Subsequent workshops on drug-diagnostic co-development issues and on genomic data submission standards have been held (www.fda.gov/cder/genomics/biomarkers.htm, Hinman et al., 2006). The increased level of dialog between industry and the FDA has mitigated some of the concerns about regulatory barriers. The European Medicines Agency (EMEA) also instituted pharmacogenomics "Briefing Meetings" in 2003 (The European Agency for the Evaluation of Medicinal Products, 2003). In May 2005 FDA and EMEA held their first joint VGDS meeting, and additional joint meetings are occurring. Discussions of regulatory aspects of pharmacogenomics are now being held among regulators and industry worldwide under the auspices of the International Conference on Harmonization (ICH) of the Technical Requirements for Pharmaceuticals.

Translation from the laboratory into clinical development is only one of the translational barriers faced by new technologies. Achieving uptake in clinical practice and obtaining reimbursement are also major challenges: the utility and value of new technologies must be explicitly demonstrated. Ironically, the tight regulation of pharmaceuticals will tend to enhance acceptance of FDA-approved pharmacogenomic test-directed drugs. The regulatory standards for drug approval include the scientific demonstration of effectiveness and safety. When a new drug is approved in conjunction with a pharmacogenetic test, the likelihood of use as recommended in the drug label is very high – in part because of confidence in the approval standard, and in part because promotion (which is often extensive for a new therapy) is limited by law to the label uses. Conversely, "retrofitting" a pharmacogenetic test into established practice patterns can be very difficult. Both the clinical and reimbursement communities have made it very clear that, in the majority of cases, randomized outcome trials will be the standard that will govern acceptance – even for dose adjustment with drug metabolizing enzyme assays.

From a regulatory standpoint, the current issues in pharmacogenomics applied to drug development and clinical use include the following: development of an investigational drug incorporating a pharmacogenomic test; use of a pharmacogenomic test to enhance the performance of an approved drug; drug safety pharmacogenomics and toxicogenomics; and qualifying genomic biomarkers for regulatory use. These issues are discussed in more detail in the sections below.

Development of an Investigational Drug with a Pharmacogenetic Test to Select Patients for Therapy or for Monitoring

Use of diagnostics to discriminate among individuals who present with similar symptoms is routine clinical practice. Genomic tests are conceptually no different; however, these are new types of tests, and they will yield novel insights into the sources of human variability that are currently not utilized in decision-making. Pharmacogenomic tests may be used during drug development to identify patients with different disease subsets (that differ by prognosis, response to therapy, etc.), to identify individuals with disease responsive to an particular intervention (i.e., targeted therapies), to stratify individuals to different dose

regimens, to identify individuals with a high probability of an adverse reaction to treatment, or to monitor treatment response. In all these cases, the use of the diagnostic is intended to enhance drug safety or effectiveness. One major challenge in using pharmacogenomic tests during drug development is that often the assay itself must be developed in parallel. This raises the level of complexity significantly. A full discussion of the issues involved in a drug-diagnostic co-development program is beyond the scope of this chapter. The points below indicate the major areas that must be considered. FDA is planning to issue a guidance document covering this topic in detail (Woodcock, 2005).

Regulatory Considerations for Pharmacogenetic-Test-Directed Therapy Development

The types of data that need to be generated for an investigational drug paired with a pharmacogenomic test depend on the intended label claims for the drug and the test. If use of the drug requires results from the test, demonstration of the safety and effectiveness of the drug-test combination in the definitive trials will be required. If mention of the test in the drug label is strictly informational, a lesser standard of evidence applies. For example, data from retrospective analysis of samples might lead to a suggestion in the label that patients with result *x* on test *y* may have a lower probability of response. However, in this scenario, the drug would be indicated for the entire population, absent test *y*, and would need to be shown effective and safe in the entire population. Most pharmacogenomic information in current drug labels is of this latter type. Exceptions include trastuzumab and imatinib (Bernstein, 2006). Often, developers do not know, at the start of clinical trials, which label scenario they will end up with. In these cases, design of an adaptive program that could support either result may be desirable (see trial designs, below).

Drug and Diagnostic Development Considerations

Development of the Diagnostic Test

A reliable, reproducible test configuration should be achieved prior to use of the diagnostic in prospective drug trials. Stored samples are frequently used for this purpose, and methods for analytical validation of diagnostics are well worked out. A more significant challenge involves setting cut-off values for the test results. Genomic assays often contain multiple analytes, which are sometimes continuously variable, giving rise to a nearly infinite range of results. Use to direct drug therapy will require achieving unambiguous, often dichotomous (i.e., yes/no) results. These cut-offs often will be constructed via retrospective analysis of clinical samples from the investigational drug trials. This exercise will create an hypothesis: test *x* will segregate population *y* into distinct subgroups. This hypothesis can then be verified using additional stored samples or in prospective studies. Depending on the clinical implications of the subgroups, such data might suffice for a stand-alone claim for the diagnostic. However, a claim for use in combination with the drug will require trials demonstrating the clinical utility of the diagnostic as well as drug safety and effectiveness. If the results of such trials require retrospective analyses that readjust diagnostic cut-offs to achieve significant results, they will be regarded as hypothesis generating rather than confirmatory.

Trial Design Considerations for Investigational Drug Combinations

Major design issues arise in this context. These involve ways to integrate the developing information on drug and diagnostic performance when it is unclear whether the diagnostic adds value to the drug therapy (and it is still unclear if the drug has value). At the end of Phase 2 trials, developers may know that the diagnostic can discriminate subgroups but will not have information on how much this impacts performance of the drug. For example, suppose a genomic test appears to identify a patient subset more responsive to the therapy. One approach might be to perform an "enriched" trial, randomizing test-positive patients to investigational drug versus control. This trial answers the question: does the drug work in test-positive patients? It does not yield information on drug performance in test-negative patients (so it does not tell you if the test discriminates anything meaningful), or whether test-positive patients have generally better or worse prognoses. A more elaborate trial might enroll all patients with the condition and then stratify both treatment and control arms by genomic test result. This design can answer many questions but risks answering none definitively because of the multiple comparisons that arise. Simon (2005) and Temple (2005) have proposed various methodological approaches including adaptive designs to address these problems. A number of sequential designs could also be useful. The appropriate design in a given case will be influenced by both mechanistic (how plausible is the test-drug link?) and clinical considerations – for example, how much information on the test-negative subgroup is needed when a claim for effectiveness in the test-positive subgroup is sought? In cases where the mechanistic link is well understood – for example, HIV drug resistance – studying a test-defined subgroup alone is standard practice. In other cases, information on results from the test-negative group may be crucial. Developers should consult with FDA early in such development programs.

Dosing Adjustments

Incorporating pharmacogenetically driven dose adjustments into Phase 2 and 3 clinical trials is straightforward. Typically, dose finding is performed in the second phase of drug development. These trials evaluate the dose-response relationships for safety/tolerance and efficacy (which may be defined by a pharmacodynamic marker). "Dose-response" is more properly understood as "concentration response"; and there are excellent pharmacometric methods for analyzing the impacts of variables such as test results. When the effect of a polymorphism is large, the drug developer may then plan to adjust dosing in the efficacy trials for alleles with known effects on concentration. Questions will arise about default dosing for individuals with non-evaluable alleles, as well as how to extrapolate the results to populations with different allele frequencies. For life-threatening diseases, for example some cancer indications, where development programs may incorporate

a combined Phase 2–3 development program and may lack pharmacodynamic endpoints, opportunities to understand the impact of variation in drug metabolism are fewer, and evaluation should start as early as possible in the development program.

Pharmacogenomic Safety Tests

Drug toxicity is a major issue in development. Beyond toxicity attributable to relative overdosing from variable metabolism, genetically related adverse events can arise from drug target (or related pathway) polymorphisms, immunologic predisposition (e.g., abacavir hypersensitivity), genetically based disease variability, and genetically based organ vulnerabilities (White et al., 2006). Sorting out the mechanistic bases of drug adverse events will be straightforward in some cases and highly complicated in others. The size of most drug development programs will only allow elucidation of the most clear-cut genetic association. Regulatory issues do not complicate such investigations, except in the rare instance where the drug is not safe enough to be approved absent the test. In these cases, sponsors should discuss with FDA the amount of evidence needed to demonstrate that use of the test confers an adequate level of safety.

Pharmacogenomic Tests for Approved Drugs

It is likely that successful implementation of pharmacogenomic testing would significantly improve therapeutic outcomes of drug therapy. In particular, drug toxicity exacts a severe human and economic toll in the United States, being estimated as the 4th–6th leading cause of death, causing tens of thousands of hospitalizations, and costing billions of dollars (Budnitz et al., 2006; Lazerou et al., 1998). Surveys suggest that drugs with polymorphic metabolism contribute a disproportionate share of harm (Phillips et al., 2001). Nevertheless, as detailed above, there are significant barriers to even initiating the work that needs to be done. Once opportunities are identified out of the basic science, funding for controlled clinical outcome trials needs to be obtained. Pharmaceutical companies may sponsor trials for marketed drugs that are not off-patent. Trials of pharmacogenomic tests for off-patent drugs may require public funding or sponsorship by consortia of consisting of government, health care systems, the pharmaceutical industry, etc. For example, currently a number of groups are considering or initiating trials of pharmacogenetic-directed dosing of warfarin. Issues beyond funding include how to actively involve in consortia diagnostic companies and researchers who have developed tests.

FDA has been actively seeking, as an initial step, to incorporate established information on drug metabolizing enzymes into drug labels without stipulating testing and dose adjustment. Examples include 6MP (6-mercaptopurine) (the enzyme TPMT), atomoxitine (Strattera) (CYP2D6) and irinotecan (UGT1A1) (www.fda.gov/cder/genomics/genomic_biomarkers_table.htm) It is possible that in the future, pharmacogenetic-directed dosing could be explored during studies of these agents that are being conducted for other purposes. For a good discussion of the issues involved in developing pharmacogenetic information on a marketed drug (see Ratain, 2006).

Many rare, serious adverse drug reactions occur across multiple drug classes and may have a genetic association (e.g., Stevens Johnson syndrome). These reactions occur so infrequently, however, that it is likely that international consortia will be required to assemble adequate cases and controls to perform genetic analysis. Other serious drug side effects occur more commonly, within a drug class (e.g., tardive dyskinesia). Public private partnerships between government and industry are being explored as ways to gather cases and carry out the needed analyses.

Toxicogenomics

When the toxicant is a drug, the areas of toxicogenomics and pharmacogenomics overlap. Many drugs share mechanisms of toxicity with non-pharmaceutical chemicals. Mechanistic understanding of drug toxicity will greatly improve the science of drug safety. The current protocols for preclinical animal toxicology testing during drug development are highly empirical and offer few ways to evaluate the relevance of a given toxic finding to humans. Toxicogenomics may offer methods to discriminate by comparing cellular responses in various animal species and in human cells. In some cases, a toxic finding in an animal species may not be mechanistically relevant in humans. Toxicogenomics is also anticipated to be a source of more sensitive toxicity assays than currently those currently used in traditional animal and human testing. Under the auspices of the C-Path Institute, a nonprofit organization in Tucson, Arizona, a consortium of twelve pharmaceutical companies are pooling, evaluating and validating nontraditional toxicity assays (some of them genomic), on an organ system basis, with the intent of submitting the best performing assays to FDA for regulatory assessment (www.c-path.org/programs/SafePath/tabid/61/Default.aspx). It is expected that toxicogenomic tests will be generally relevant to drug development, rather than linked to a particular drug.

2009 UPDATE

The debate over the role and scope of federal regulation of genetic tests in the United States intensified in 2008. In April, the HHS Secretary's Advisory Committee on Genetics, Health, and Society (SACGHS) issued a report entitled "US System of Oversight of Genetic Testing: A Response to the Charge of the Secretary of Health and Human Services" (http://www4.od.nih.gov/oba/SACGHS/reports/SACGHS_oversight_report.pdf). This report contains an extensive set of recommendations for increased oversight by various federal agencies in the United States, including broader requirements for premarket clearance on the part of Food and Drug Administration (FDA). However, any new policy initiatives in this area will be the purview of the

new administration. It is widely recognized that any changes in regulatory policy should be accompanied by increases in funding for translational research as well as modifications of reimbursement policies (Hudson, 2008; Khoury et al., 2008; Woodcock, 2008). Such changes would help to provide adequate incentives for clinical development in the face of increased evidentiary requirements.

Pharmacogenomic testing could be described as having entered mainstream medicine in 2008. The FDA added genetic information to multiple drug labels, including abacavir, carbamazepine, and warfarin, with strong recommendations for pretesting in the case of abacavir and carbamazepine. The debate over the use of genetic algorithms for initial dosing of warfarin intensified. FDA is evaluating multiple additional pharmacogenetic tests for incorporation in drug labels. In December 2008, the FDAs Oncology Drugs Advisory Committee met to consider the proposal of the manufacturers of cetuximab (Erbitux) and panitumumab (Vectibix) that administration of these drugs be limited to patients whose tumors contain wild-type K-RAS. (http://www.fda.gov/ohrms/dockets/ac/08/briefing/2008-440961-00-FDA-index.htm.) This issue is currently under consideration at FDA. Additional diagnostic genetic tests were also approved by the FDA in 2008.

CHAPTER

Economic Issues and Genomic Medicine

David L. Veenstra, Louis P. Garrison and Scott D. Ramsey

INTRODUCTION

The era of genomic medicine offers significant promise for the development of novel health care technologies that ultimately improve patients' quality of life and life expectancy. As with any new health care technology, questions arise as to their potential budgetary impact and cost-effectiveness. But because genomic technologies inherently involve diagnostic or prognostic testing, and because of the complexities of incomplete gene penetrance and multiple gene and environmental interactions, their assessment can be more challenging. In addition, perhaps more than in any other area of medicine, questions have arisen in regard to the economic incentives to develop these technologies. Formal health economics frameworks can be used to gain insights into these issues, and provide guidance for resource investment, technology appraisal, and policy development.

In this chapter, we provide a brief introduction to the principles of health economics and discuss the unique aspects of the application of cost-effectiveness analysis to genomic medicine. We review drivers of the cost-effectiveness of genomic technologies and assess several recent state-of-the-art examples. We then examine the particular challenges in pharmacogenomics of economic incentives for developing genetic tests linked to therapeutics. Lastly, we propose an approach to help establish value-based reimbursement of genomic testing technologies. The content of this chapter will help readers understand the multidisciplinary nature of the factors that will influence the value of genomic medicine, and provides a framework for assessing these factors in a systematic, quantitative fashion.

ECONOMIC EVALUATION AND COST-EFFECTIVENESS ANALYSIS

Health Economics and Foundations of Economic Analysis

Drawing on methods and concepts from economics, clinical epidemiology, psychology, and the decision sciences, the field of "cost-effectiveness" research has synthesized a set of tools and a theoretical framework for evaluating the complex issues in health care (Garber and Phelps, 1997; Weinstein et al. 1996). At a broad level, effectiveness estimates are generally derived from randomized clinical trials, disease progression estimates from long-term follow-up epidemiological studies, quality of life values from health state preferences studies, and costs from a wide variety of sources including payment schedules (i.e., Medicare) and attributable- and micro-costing studies. These factors, which are often considered either explicitly or implicitly in decision-making, can be synthesized using decision analytic techniques to inform formal economic analyses as discussed below (Detsky et al., 1997).

Methodological Approaches to Economic Evaluation in Health Care

Several specific yet related methodological approaches are used in the economic evaluation of health care technologies: (1) cost-minimization, (2) cost-consequences analysis, (3) cost-benefit analysis, (4) cost-effectiveness analysis, and (5) cost-utility analysis (Flowers and Veenstra, 2004). These methods vary primarily in the way intervention effectiveness is valued. For example, for cost-minimization analysis, it is assumed there is no difference in effectiveness or side effects. In both cost-effectiveness and cost-consequences analysis, effectiveness is measured in natural, clinical units such as heart attacks or infections avoided. In cost-benefit analysis, a monetary value is assigned to effectiveness (e.g., a heart attack avoided might be "valued" at $100,000). And in cost-utility analysis, effectiveness is measured in quality-adjusted life years (QALYs), which account for improvements in both life expectancy and quality of life. Another characteristic that differentiates these methods is that cost-minimization and cost-consequences analyses do not involve the calculation of a ratio; for cost-minimization, only costs are presented, and in cost-consequences both costs and effectiveness are calculated, but not combined in a ratio. Of note, although "cost-effectiveness analysis" is a specific type of economic evaluation, the term is used generally to refer to all types of economic evaluation in health care.

In some cases, cost-effectiveness studies can be based on a single randomized clinical trial. However, because clinical trials are usually in a controlled setting, the costs incurred are not representative of utilization in a real-world setting. The "efficacy" observed in a controlled setting can also be distinguished from the "effectiveness" that could be expected in practice. Finally, the timeframe of clinical trials for chronic conditions are generally not sufficient to evaluate long-term outcomes. Because of these reasons, as mentioned above, modeling techniques such as decision analysis are often used to extrapolate the results from clinical studies using primarily epidemiologic and economic data from other sources.

In any economic evaluation, it is important that the technology being evaluated is compared to current medical practice. Weinstein and Stason, in 1977, defined the incremental cost-effectiveness ratio (ICER) as

$$\mathrm{ICER} = (C_2 - C_1)/(E_2 - E_1)$$

where C_2 and E_2 are the cost and effectiveness of the new intervention being evaluated, and C_1 and E_1 are the cost and effectiveness of the standard therapy (Weinstein and Stason, 1977). The costs and effects that are included in the equation depend on the perspective of the analysis. From a societal perspective, indirect costs and effects such as patient time away from work, downstream medical care costs years or decades after the intervention, and the quality of life of the patient and even their family need to be considered. Because of the all-encompassing nature of the societal perspective, it is generally better suited for national health care plans. More relevant to health care plans or providers in the United States is the payer perspective, which addresses primarily direct medical care costs incurred by the payer (e.g., drug cost, professional fees, hospital stay).

Resource Allocation Decision-Making

How can cost-effectiveness information guide health policy decisions? The favored approach, from an academic perspective, is to utilize cost-utility analysis because it allows for comparisons across interventions and diseases, accounts for impact on life expectancy and quality of life, and has theoretical foundations in welfare economics. Medical interventions are considered to be cost-effective when they produce health benefits at a cost comparable to other commonly accepted treatments. A general guide is that interventions that produce one QALY (equivalent to 1 year of perfect health) for under $50,000 are considered cost-effective, those between $50,000 and $100,000 per QALY are of intermediate cost-effectiveness, and above $100,000 per QALY generally is not considered cost-effective. The cutoff of $50,000 per QALY was derived loosely from the cost of providing dialysis for a patient for one year – a service paid for by Medicare for any US citizen. However, these criteria are somewhat arbitrary, and can vary across disease and indication-specific therapeutic areas, particularly in the United States (Neumann, 2007).

The application of cost-effectiveness analysis has increased dramatically in the past decade as a result of increasing health care costs and the desire to deliver the greatest health value for the money. The formal application of cost-effectiveness analysis to drug coverage decisions has its origins in countries with single-payer health care systems (e.g., government sponsored). Recently, multiple countries and health care systems have begun to adopt requirements for such pharmacoeconomic information. These requirements formalize an otherwise implicit demand for health care technologies that are cost-effective, and will influence, to a certain extent, "go/no-go" decisions in drug research and development.

The United Kingdom, Canada, and Australia all have formal requirements in place for cost-effectiveness information and programs in place for evaluating cost-effectiveness data – the National Institute for Health and Clinical Excellence (NICE, United Kingdom), the Canadian Agency for Drugs and Technologies in Health (CADTH, Canada), and the Pharmaceutical Benefits Advisory Committee (PBAC, Australia) (CADTH 2007; NICE 2007; PBAC, 2007), as well as several European countries such as the Netherlands (Drummond et al., 1999). In the United States, cost-effectiveness information is most often used in support of drug formulary listing in managed care settings. Many managed care organizations and pharmacy benefits managers utilize guidelines that require outcomes and economic information for formulary evaluation. In addition, the Academy of Managed Care Pharmacy (AMCP) has adopted guidelines for the submission of information, including outcomes and cost-effectiveness data, to support formulary consideration (Fry et al., 2003; Neumann, 2004; Spooner et al., 2007).

EVALUATING GENOMIC TECHNOLOGIES

Unique Aspects of Genomic Medicine

The tools of health economics and cost-effectiveness analysis can be used to assess any health care technology, from immunization strategies, to new drug therapies, to educational programs. Genomic medicine is not so unique (i.e., exceptional) that fundamentally new methods in economic evaluation are needed. However, genomics can add layers of complexity to health care interventions such that particular care should be taken in their evaluation.

Disease-Risk Testing

The validity of a prognostic genomic test will have a significant impact on its potential cost-effectiveness. The evaluation of validity will be similar to other non-genomic prognostic tests, yet potentially more complex, due to challenges in validating genetic markers with small contributions from multiple genes and environmental interactions. Thus, when undertaking an economic study, care should be taken that the performance of the test has been evaluated by peer review, and perhaps more importantly, reproduced by independent investigators in different patient populations. An issue that will be more unique, to a degree, to genetic testing for disease risk is whether to test family members. The potential costs and clinical and patient outcomes should be considered. If potentially substantial, this strategy should be included in the analysis (Ramsey et al., 2001).

Pharmacogenomics

Pharmacogenomics tests face a similar issue with validation of a test's ability to predict drug response and differentiating it from prognostic ability – that is, predicting disease prognosis rather than the effect of treatment on the disease. Furthermore, as discussed later in the chapter, the pairing of pharmacogenomic tests with drugs may lead to uncertainty about which – the test or the drug – provides the incremental value, and this can have implications for pricing or reimbursement decisions. Lastly, it is possible that genetic information obtained for one purpose may also provide information, for example, about disease risk. The potential impact of such ancillary information should be considered in a broad sense; for example, disease-risk information that is available after the test is conducted versus the use of CYP2D6 drug-metabolizing enzyme polymorphism data to help guide therapy for drugs other than the original one for which the test was obtained. Thus, there could be potential benefits but also harms (Henrikson et al., 2007).

Cost-effectiveness studies of both disease-risk and pharmacogenomic tests in some cases may benefit from more complex analytical frameworks and simulation methods. However, it generally is not possible, due to statistical power limitations, to identify specific risks for individual patients. Rather, in genetic association studies, patients tend to be categorized into larger subgroups to improve statistical power. For example, the breast cancer disease recurrence risk score (RS) derived from a 21-gene profile with the Oncotype Dx test could be utilized in a similar fashion to the Framingham models that predict the risk of a cardiovascular event based on non-genetic factors. In general, when more complex modeling approaches are employed, the added value should be explained in addition to justification of data sufficiency.

Cost-Effectiveness Framework and Drivers

We have previously developed a set of criteria, based on a formal cost-effectiveness framework, for evaluating the potential clinical and economic benefits of genomic tests (Table 20.1) (Flowers and Veenstra, 2004). The key aspects of these criteria are highlighted in the following paragraphs, and a more in-depth evaluation of the epidemiologic considerations in bringing pharmacogenomics to clinical practice is presented.

Assessing the incremental cost-effectiveness of a pharmacogenomic strategy involves evaluating factors that are common to the evaluation of all screening strategies, as well as factors that are specific to genetic testing. These include factors associated with the genetic variation of interest, the genetic test, the disease state, and the treatment options. Questions to consider in assessing the cost-effectiveness of a pharmacogenomic treatment strategy include:

- What is the frequency of the genetic variation?
- How closely is the variation linked to a consistent phenotypic drug response?
- Are there other significant influences on drug response such as diet, disease, or drug interactions?
- What are the sensitivity and specificity of the genomic test?
- How prevalent is the disease of interest?
- What are the characteristic outcomes associated with the disease with and without treatment?
- How does the pharmacogenomic strategy alter these outcomes?
- What alternative treatment options are available?
- How effective are current monitoring strategies for preventing severe adverse drug reactions and predicting drug response?

Pharmacogenomics is more likely to be cost-effective when: (1) the polymorphism under consideration is prevalent in the population and has a high degree of penetrance; (2) genetic testing is highly sensitive and specific, and less costly alternative tests that could be used to individualize therapy are not readily available; (3) the disease state involves outcomes with significant morbidity or mortality without treatment; and (4) the treatment involves significant outcomes and/or costs that can be impacted by genotype-individualized therapy.

Case Study: Gene-Expression Profiling and Breast Cancer Treatment

Breast cancer is the leading incident cancer among women of all major ethnicities in the United States and is the second highest

TABLE 20.1 Factors that influence the cost-effectiveness of genomic testing strategies

	Factors to assess	Features that favor cost-effectiveness
Gene	Prevalence Penetrance	• Variant allele is relatively common • Gene penetrance is high
Test	Sensitivity, specificity, cost	• High specificity and sensitivity • A rapid and relatively inexpensive assay is available
Disease	Prevalence	• High disease prevalence in the population
	Outcomes and economic impacts	• High untreated mortality • Significant impact on quality of life • High costs of disease management using conventional methods
Treatment	Outcomes and economic impacts	• Reduction in adverse effects that significantly impact quality of life or survival • Significant improvement in quality of life or survival due to differential treatment effects • Monitoring of drug response is currently not practiced or difficult • No or limited incremental cost of treatment with pharmacogenomic strategy

Adapted from Flowers and Veenstra (2004).

source of cancer mortality. Adjuvant chemotherapy has been shown to increase recurrence-free and overall survival, but also may produce significant toxicity such as alopecia, nausea/vomiting, and myelosuppresion, and may lead to longer-term complications such as permanent ovarian failure in pre-menopausal patients (Shapiro and Recht, 1994, 2001). Current NIH clinical guidelines (Eifel et al., 2001) recommend adjuvant chemotherapy for women with tumors larger than 1 cm or lymph node involvement. Additionally, tumor markers such as HER2 and histologic grade are used for risk assessment (Bast et al., 2001; NCCN, 1999). Despite widespread use, these criteria are imprecise predictors of distant recurrence (Sauter and Simon, 2002).

Gene-expression profiling (GEP) utilizing DNA microarrays (van de Vijver et al., 2002) or RT-PCR (Paik et al., 2004) has been proposed as an alternative approach to identify patients for adjuvant chemotherapy, (King and Sinha, 2001) potentially sparing low-risk patients from this treatment. There are two gene-expression profiles currently marketed for clinical use in breast cancer. One of these profiles, MammaPrint® (Agendia), was developed by van't Veer and colleagues at the Netherlands Cancer Institute (van de Vijver et al., 2002). The other test, Oncotype Dx™, was developed by Genomic Health, Inc. in the United States (Paik et al., 2004). The assay marketed by Agendia utilizes a 70-gene microarray-based profile performed on fresh frozen tissue and is intended for patients younger than 55 years with Stage I invasive breast cancer or Stage II node-negative invasive breast cancer. In contrast, the test marketed by Genomic Health employs a 21-gene profile utilizing RT-PCR for expression analysis on paraffin embedded tissue and is intended for patients with node-negative, estrogen receptor positive (ER+) disease. Although gene-expression profiling has been proposed as an alternative to clinical guidelines to identify appropriate patients for adjuvant chemotherapy, the potential long-term clinical and economic outcomes associated with gene-expression profiling are not clear. In other words, "Do the quality of life benefits and cost savings of avoiding chemotherapy outweigh the potential increased risk of recurrence in women not given chemotherapy and cost of the test?"

To address this question, we developed a decision analytic model to evaluate the incremental cost and QALYs of gene-expression profiling using MammaPrint versus NIH clinical guidelines in a hypothetical cohort of pre-menopausal early-stage breast cancer patients (Oestreicher et al., 2005). We assumed patients and doctors would follow test or guideline recommendations, and that chemotherapy response would be similar regardless of risk group, as no data to the contrary were available. Our findings suggested that use of MammaPrint gene-expression profiling could result in an absolute 5% decrease in the proportion of cases of distant recurrence prevented, 0.21 *fewer* QALYs, but a cost savings of $2800 (Table 20.2). Regardless of the test cutoff used to identify a poor prognosis tumor, the MammaPrint gene-expression assay did not produce equal or greater QALYs than NIH guidelines.

These findings are fairly striking, and importantly, what do they imply? First, test performance is very important when a pharmacogenomic test is being used to recommend against treatment that is standard of care. In this case, because of test sensitivity of 84% for MammaPrint versus 98% for NIH criteria, some women who will progress will be categorized as low risk and not recommended for chemotherapy. Secondly, the efficacy of treatment in women categorized as low risk versus high risk can have a significant impact. In other words, prognostic ability

Table 20.2 Performance, costs and outcomes of gene expression profiling versus NIH guidelines

Outcome	Gene Expression Profiling	NIH Guidelines	Difference
Sensitivity	84%	98%	−14%
Specificity	51%	5%	+46%
Proportion of women treated with chemotherapy	61%	96%	−35%
Proportion of distant recurrences prevented	29%	34%	−5%
Costs	$29,754	$32,636	−$2882
Quality-adjusted life years	9.86	10.08	−0.21

Adapted from Oestreicher et al. (2005).

to evaluate disease risk is important, but so is predictive ability for treatment response. In an evaluation of the clinical and economic utility of a test, these two aspects of test performance, disease-risk and treatment response, should be clearly delineated. In some cases, as illustrated here, prognostic (disease-risk) information alone may not be sufficient to justify utilization of a genomic test.

The Oncotype Dx assay has been evaluated for its ability to predict chemotherapy outcomes in addition to disease recurrence risk. Paik et al. reported in a retrospective study that women with a low RS are also unlikely to respond to chemotherapy (relative risk, 1.31; 95% CI, 0.46–3.78) (Paik et al., 2006). The impact of this effect was incorporated in a cost-effectiveness analysis conducted by Hornberger and colleagues (2005). Using a similar methodological approach to Oestreicher et al., the author developed a Markov model and forecast overall survival, costs, and cost-effectiveness of using the Oncotype Dx RS in patients classified as having low or high risk of distant recurrence based on National Comprehensive Cancer Network (NCCN) clinical guidelines. In the analysis, 8% of patients were classified as having low risk of distant recurrence by NCCN guidelines, and the RS reclassified 28% of these patients to an intermediate/high-risk group. The remaining 92% of patients were classified at high risk of distant recurrence by NCCN guidelines and the RS reclassified 49% of these to a low-risk group. Overall, use of the Oncotype Dx test was predicted to *increase* quality-adjusted survival by 0.09 years and reduce overall costs by $2000. The cost-effectiveness was most influenced by the propensity to administer chemotherapy based on test results, and by the proportion of patients at low risk as defined by NCCN guidelines. The author concluded that if applied appropriately, the test is predicted to increase quality-adjusted survival and save costs.

These cost-effectiveness studies served several valuable purposes. Most importantly, they clarified that without the ability to predict response to chemotherapy, these gene-expression profiles may not provide justifiable improvements (if any) in overall patient outcomes in a cost-effective manner. Thus, important areas for subsequent validation work have been highlighted. Furthermore, such analysis can help inform reimbursement decisions (Watkins et al., 2007). Thus, for example, with the Oncotype Dx test, assuming the prognostic and particularly the predictive validity of the test hold, the test may offer not only a cost-effective intervention, but potentially a cost-saving one. Another issue that remains to be addressed, preferably in "real-world" (non-controlled) settings, is the concordance of test results with actual treatments received. For example, a recent study indicated that a majority of sampled physicians and patients found the test results useful, but there was an absolute decrease in the proportion of patients choosing chemotherapy of only 2% (Lo et al., 2007). These treatment patterns may change as clinicians and patients gain experience in the use of genomic test results in decision-making.

Of note, in an effort to validate these retrospective findings, the first US-based phase III randomized controlled clinical trial – The Trial Assigning IndividuaLized Options for Treatment (Rx), or TAILORx, comparing the efficacy of Oncotype Dx for choosing women receiving adjuvant chemotherapy – was launched on May 23, 2006, to examine whether genes that are frequently associated with risk of recurrence for women with early-stage breast cancer can be used to assign patients to the most appropriate and effective treatment [http://www.cancer.gov/clinicaltrials/digestpage/TAILORx, accessed 11/9/06]. This study will provide valuable prospective validation of previous retrospective studies, as well as the modeled outcomes from cost-effectiveness studies.

ECONOMIC INCENTIVES AND THE FUTURE OF GENOMIC MEDICINE

Economic Incentives in Drug and Test Development

Eight years have elapsed since the initial sequencing of the human genome, and the number of new genetic tests commonly used in clinical practice is quite small. For example, a recent report from the Royal Society cautions: "Pharmacogenetics is unlikely to revolutionize or personalize medical practice in the immediate future" (The Royal Society, 2005). Robert Califf has argued that achieving this promise will require a major overhaul of the US clinical research enterprise as well as substantial educational efforts (Califf, 2004).

In two recently published papers, Garrison and Austin explored the lack of appropriate economic incentives that may in part be contributing to the current pace, in addition to the inherent challenges in genomics research (Garrison and Austin, 2006, 2007). The translation of the basic science of pharmacogenetics

and other "-omics" biomarkers as applied to drug development and clinical care is occurring in a complex legal, regulatory, and reimbursement environment. Understanding and appropriately shaping this environment is vital for encouraging biomarker research and personalized health care.

Suppliers of new medical technologies – both therapeutics and diagnostics – face a complex and heavily regulated commercial environment. Furthermore, the manner in which diagnostics are reimbursed in most developed countries may provide limited incentives for the development of new genomics-based tests. Both the proponents of genetic tests and the skeptics sometimes fail to appreciate this complexity. Proponents sometimes argue: "How could this not be a good thing?" We would be able to target drugs to the subgroups who respond most favorably and limit the delivery to those most likely to suffer side effects. Skeptics sometimes argue that no pharmaceutical company would have incentive to restrict its market to a smaller subgroup: "Why would they ever want to develop a test to do this?"

Both sides have a valid point to some extent, but neither represents the full complexity of the incentives involved. Garrison and Austin analyzed the incentives in terms of "value creation and capture." Innovative therapies can create aggregate economic value in at least five alternative ways that are not mutually exclusive. First, they may reduce mortality and morbidity compared to current treatments. Second, they may save on average on the costs of treating side effects or the underlying disease. Third, they may result in greater utilization by those afflicted. Fourth, they may encourage better compliance, providing individual patients with more net benefit. Fifth – and this is less recognized and is important for new diagnostic tests – they can make people better off by reducing uncertainty.

The authors developed and analyzed five different scenarios of combining a new genomics-based diagnostic with a therapeutic treatment. They argued that who captures the value created by the combination depends on a number of factors, and that it is the potential for value capture that generates the incentives for genomic test development and marketing. In thinking about incentives in this marketplace, it is important to keep a few key features in mind. First, intellectual property rights are essential to provide a basic incentive for the invention and development for new diagnostic tests and new therapeutics, particularly pharmaceuticals. It is widely known and appreciated that new innovative drugs receive temporary (20-year) patents that limit the ability of competitors to enter since they can't just copy the innovative compound and would have to develop and fully test a new molecule. It is less appreciated that effective patent life is 8–12 years, as it takes years to perform the trials that regulators review for licensing. A second key feature is that once a product is on the market and has a price, it can be difficult to change that price. Indeed, in some countries, "administered pricing" is used to set the price based on reference products or prices in other countries. The price granted in those situations may only relate in a limited way to the value created, and they may not be allowed to change over time. This is particularly true in Europe, whereas there is some ability to change pharmaceutical prices over time in the United States.

Diagnostics differ from drugs in that their prices are even more heavily controlled in most markets, as initial price is often pegged to perceived costs of provision rather than additional value created. This can be called "cost-based" pricing and reimbursement as opposed to "value-based" pricing and reimbursement. In effect, suppliers of new genomics-based diagnostics are likely to capture less of the incremental value they create.

Given these marketplace realities and constraints, Garrison and Austin argue that the incentives for value creation through a linked genomics-based diagnostic and therapeutic will depend on these factors as well as whether the therapy is already on the market. For their hypothetical exercise, they posited that a new diagnostic is developed in a market where only 20% of patients truly benefit from a treatment, but heretofore they could not be identified. Eliminating the 80% of users who don't benefit would be a great benefit to payers but would be damaging to the pharmaceutical company if they could not raise price for the 20% of responders. On the other hand, it should clear that if the test were available before the drug was launched, the company might have been able to charge a price nearly five times as high and still capture the same amount of value.

In principle, if the innovative diagnostic enters the market after that drug has a price, then the diagnostic manufacturer might be able to capture this value, creating a powerful incentive for developing the diagnostic. However, in a regulated, cost-based pricing and reimbursement environment for diagnostics, there will not be this strong incentive. Hence, if the drug manufacturer can't easily increase price for the 20% who respond, and if the potential diagnostic manufacturer can't capture the cost savings because of price controls, there will be a limited incentive to develop tests for already marketed products.

The authors point out that if the diagnostic and therapeutic could be developed in tandem, even more total economic value would be created due to the additional reduction in uncertainty. The drug manufacturer would be in a better position to capture this value, given that they operate in a relatively value-based pricing environment. However, drug development is a challenging and uncertain scientific enterprise in and of itself, and adding the complexity of companion diagnostic may not be that appealing unless the scientific rationale is already well developed.

In addition to the scientific and economic barriers highlighted above, two other factors deserve mention that might be inhibiting the development of pharmacogenetics-based test-drug combinations. One factor is the high cost of the basic research that is needed to validate genetic markers. Financing this remains a question: What should fall to the public sector, how much should the private sector contribute, and what is best done in partnership are under active debate. Second, approval and reimbursement for drugs in the United States and EU require greater levels of evidence than is customary for new diagnostic tests. Some would argue that the lower evidentiary requirements for regulatory approval of tests have discouraged the development of better clinical data and that payers practice "cost-based" reimbursement in part because of this lack of evidence on clinical and economic value. In contrast, both the AMCP Format for

Formulary Submissions guidelines in the United States and the requirements for submissions to the National Center for Clinical and Health Excellence (NICE) in the United Kingdom request economic models that synthesize the clinical and cost evidence to assess value added of new drugs. Similar standards and mechanisms do not exist for diagnostics, although the discussion is beginning. But asking for more evidence means raising the costs of developing – and particularly validating – new diagnostics. What are the incentives for diagnostic manufacturers if no additional rewards are forthcoming through the reimbursement system? Below we discuss a potential approach for incorporating evidence assessment into reimbursement decisions for genomic tests.

ESTABLISHING VALUE-BASED REIMBURSEMENT FOR GENOMIC TECHNOLOGIES

Rationale

Laboratory tests are an important yet often overlooked segment of health care and the health economy. For example, it has been estimated that as much as $56 billion was spent on laboratory diagnostic services in 2005 (Blue Cross Blue Shield Association, 2005). More importantly, laboratory tests initiate a cascade of decisions regarding further testing, prevention or treatment-decisions that ultimately determine health outcomes and costs of care. A recent report estimated that although diagnostics account for 1.6% of the Medicare total costs, they influence 60–70% of downstream treatment-decisions (The Lewin Group, 2005). Genomic testing for mutations, polymorphisms, and haplotypes expands the laboratory diagnostics market in many areas, including pregnancy and neonatal testing, predictive testing for disease susceptibility, and pharmacogenomic testing. As noted above, gene-expression profiling of tumors is a burgeoning field that includes both predictive and pharmacogenomic characteristics.

Historically, the evidence supporting the validity and clinical utility of laboratory tests has been limited (Feinstein 2002; Reid et al., 1995; Weinstein et al., 2005). The pathway to the marketing of tests does not require the same data as therapeutics, and technology assessments of laboratory tests have not undergone the revolutionary changes in evidence review that has occurred for drugs (Neumann, 2004). Instead, payment for tests is linked to an antiquated coding system, as noted above (Raab and Logue, 2001). Recently, we presented a rationale and outline for re-structuring the way laboratory tests are evaluated and reimbursed (Ramsey et al., 2006). We summarize those concepts below.

Process

We propose that coverage and reimbursement for laboratory tests, including genomic tests, should move toward an evidence- and value-based approach, using some of the tools that have been adopted for pharmaceutical assessment by many US health care payers.

Developing a Language for Describing Benefit

Test manufacturers, laboratory service providers, and health insurance plans will benefit from standardizing the way evidence supporting new laboratory tests is presented. Methodological standards for the evaluation of diagnostic tests have been published (Reid et al., 1995), and a useful framework has been proposed to evaluate diagnostic technologies (Table 20.3) (Fryback and Thornbury, 1991). While many agree about the value of using these domains to evaluate tests, including genomic tests, there is less agreement on how much evidence is necessary for an insurance coverage decision.

Considering the domains from Table 20.1 when applied to genomic tests, it is important to evaluate the incremental impact of a test; that is, the improvement that the new test provides over-current (non-genomic) strategies (Garrison and Austin, 2006). Since prospective trials directly comparing new laboratory tests with established diagnostic strategies are uncommon (particularly those evaluating their impact on patient outcomes), decision-analytic modeling techniques can aid evaluations (Buxton et al., 1997). Models help frame questions, provide transparent mechanisms for stating hypotheses about cause and effect, highlight deficiencies in clinical data, and force decision-makers to make explicit judgments about values for data that are used to inform the model. Published standards for models are readily accessible to decision-makers who wish to assess their quality (Weinstein et al., 2003).

TABLE 20.3 Hierarchy of diagnostic evaluation

Level	Characteristic	Description
1	Technical feasibility and optimization	Ability to produce consistent results
2	Diagnostic accuracy	Sensitivity, specificity, positive predictive value, negative predictive value
3	Diagnostic thinking impact	Percentage of times physicians' estimated probability of a diagnosis changes following the test result
4	Therapeutic choice impact	Proportion of times planned therapeutic strategy changes following test results
5	Patient outcome impact	Percentage of patients who improve with the test versus those who improve without the test
6	Societal impact	Cost-effectiveness

Adapted from Fryback and Thornbury (1991).

A Definition of Value for Genomic Tests

We define value for genomic tests as it is defined for other health technologies: the intervention provides an overall benefit to the patient at an acceptable cost; or in other words is cost-effective. There are four well-recognized criteria for identifying an intervention cost-effective: (1) Less costly and at least as effective; (2) More effective and more costly, with the added benefit worth the added cost; (3) Less effective and less costly, with the added benefit of the alternative not worth the added cost; and (4) Cost saving with an outcome equal to or better than that of the alternative. Assessing value for tests can be difficult because tests are intermediate steps in the treatment pathway. The advantage of a cost-effectiveness framework is that it allows flexibility, because value for genomic tests can be defined narrowly (e.g., least expensive way to make a diagnosis) or broadly (improves survival at an acceptable added cost).

A Format for Dialogue Among Genomic Test Manufacturers, Providers, and Payers

When health insurers and test representatives come together to discuss genomic tests, the process should be transparent, and adopting a standard format would help clarify expectations and improve the decision-making process. A useful template for tests has been developed by the AMCP for the evidence-based evaluation of drugs. More than 50 public and private health insurers covering over 100 million lives have adopted the AMCP format (Fry et al., 2003; Neumann, 2004). A template for manufacturer's reporting of clinical and economic information regarding laboratory tests is shown in Figure 20.1. Since the clinical utility of genomic tests is most often similar to other laboratory tests, the template accommodates differences in evidence that are typically available for new genomic tests.

Implementation

Some health plans might have a designated organizational unit that evaluates genomic tests, providing a structure for soliciting and reviewing manufacturer's products. In the case of pharmaceutical products, that unit is the Pharmacy and Therapeutics (P&T) committee. Health plan staff working with P&T committees usually are receptive to receiving information from manufacturers or service laboratories about new products. Indeed, the "unsolicited request" process pioneered by the AMCP was designed to create a structure for dialogue between manufacturers and payers. A similar scheme would improve transparency and the flow of information for new genomic tests.

P&T committee members are often not health plan employees. Having such a quasi-independent group evaluate novel laboratory tests may improve the credibility of the decision process in the eyes of manufacturers, clinical laboratories, physicians, and patients. Still, maintaining committees is costly, and may not be justified given the relatively low volume of genomic tests that are introduced annually. One option is to fold the test evaluation process into the existing P&T structure. Alternatively, payers could hire consultants to evaluate select genomic tests and make recommendations regarding coverage and reimbursement. Payers should be timely, in both coverage decisions and setting reimbursement levels, and when decisions are made, they should be supported with a rationale. In cases where requests for coverage are denied, such information allows manufacturers to design studies or collect other data that address concerns regarding the quality or content of the information supporting the product.

Genomic tests are developed under a different regulatory structure than pharmaceuticals and have a unique and complex function in medical care. Novel genomic tests often come to market with little information supporting their role in clinical decision-making or evidence regarding their impact on patient outcomes. We posit that patient care and outcomes will improve when there is a structured process for evidence generation and discussion between payers, manufacturers, and marketers. While it is unlikely and perhaps not necessary that the evaluation process for genomic tests will equal what is required for drugs, we can move much further toward a system that supports better gathering and sharing of high-quality evidence. Test manufacturers, clinical laboratories, payers, and clinicians all must play a role in this process.

1. Product Information
- 1.1. Product description.
- 1.1.1. Place of the product in therapy.
- 1.1.2. Disease description. The disease description should include the disease and characteristics of the patients in the target population.

2. Supporting Clinical and Economic Information
- 2.1. Evidence-table spreadsheets of all published and unpublished clinical studies.
- 2.2. Outcomes studies and economic evaluation supporting data
- 2.2.1. Evidence-table spreadsheets of all published and unpublished outcomes studies.

3. Cost-effectiveness Modeling Report
- 3.1. Model overview. We recommend that producers and users of modeling studies subscribe to the sound guidance provided by the ISPOR Good Practice Modeling Principles.

4. Supporting Information
- 4.1. References contained in dossiers.
- 4.2. References for economic models.

Figure 20.1 Evidence and transparency standard to support coverage and reimbursement for diagnostic, therapeutic, and genetic testing (from Ramsey et al., 2006).

ECONOMIC CHALLENGES

The primary economic challenges facing genomic medicine can be surmised as the following: (1) providing evidence of the value of genomics and (2) providing economic rewards/incentives commensurate with the value added. More specifically, as outlined in a recent report developed on the implications of pharmacogenomics for the pharmaceutical and biotechnology industries, there are several key challenges for genomic medicine (Garrison et al., 2007):

- Regulatory pathways have not yet been optimized to encourage the co-development of diagnostics and therapeutics.

- Current economic incentives – as reflected in our intellectual property and reimbursement systems for diagnostics and drugs – are generally not structured to reward appropriately and consistently innovative value creation for drugs, diagnostics, and pharmacogenomics-based targeted regimens.
- The integration of pharmacogenomic diagnostic development with pharmaceutical development is difficult because of differences in the underlying business and translational science models of the two sectors.
- Genomics technologies are perceived to raise ethical, legal, and social issues to such a degree that a special National Institutes of Health program was established to address them; although specific genomic applications may not always involve such issues, this suggests the broad range of stakeholders that will be involved in the public debates.
- Stakeholder literacy about genomics is limited, and positions on public policy issues are not yet clearly defined.

What can be done to help achieve these goals? We suggest several policy areas for focus (Garrison et al., 2007):

- Pharmaceutical and biotechnology companies will need to add a systematic evaluation of potential pharmacogenomic and other biomarkers as part of their due diligence research and development processes.
- Substantial federal government support for basic research generally will be critical before translational private research activities are viable.
- The pharmaceutical and biotechnology industries will be major beneficiaries of this basic research, and should participate actively in the public discussion of priorities.
- Companies will need to provide a rationale to regulators why they have or have not included genomics or other biomarkers in their clinical trial development programs.
- The pharmaceutical, biotechnology, and diagnostic industries have not taken a unified or proactive position on appropriate regulatory processes and initiatives, and it may not be possible to reach a consensus. Still, it may be a good time to begin a policy review and discussion.
- For pharmacogenomics-targeted pharmaceuticals to have greater commercial viability, the pharmaceutical, biotechnology, and diagnostic industries must engage in the public policy debate on national coverage and reimbursement issues for such drugs and tests.

Will cost-effectiveness analysis by itself speed the development of genomic medicine? This is not inherently likely. The fundamental challenges facing genomic medicine at this point are (1) the identification and validation of associations between genetic variation and clinically meaningful outcomes and (2) evaluation of interventions based on genomic information in prospective, comparative trials. However, cost-effectiveness analysis can help guide this process in several important ways:

- By identifying genomic technologies that have potential value in early stages of drug and test development, thus aiding research portfolio optimization.
- By providing a framework for value-based reimbursement of genomic technologies, thus conferring appropriate incentives to the market.
- By identifying areas where future research would provide significant value to the health care system even once a technology has been developed.

Thus, quantitative economic analyses in combination with scientific research and policy analysis can help optimize the benefits of genomic medicine to society. In summary, genomic medicine offers significant hope for fundamental improvements in health care outcomes. These gains can likely be achieved in a cost-effective manner, but the challenges of providing evidence of and reward for value will prove to be critical in the coming decade.

2009 UPDATE

There have been a number of recent publications addressing methodological issues pertaining to the economic evaluation of genetic testing, incentives for development and reimbursement, as well as studies of specific genetic testing strategies. Deverka and McLeod (2008) propose that two levels of evidence are needed before pharmacogenetic tests can have a major impact on clinical practice: genetic association data and outcomes data – the latter including improvements in patient outcomes and cost-effectiveness. The authors emphasize the importance of focusing on the latter evidence to facilitate the translation of pharmacogenomic technologies. Garrison and colleagues provide an overview of public policy issues related to the development and commercialization of personalized medicine, some of which is covered in this chapter (Garrison et al., 2008). Phillips et al. (2008) review existing evidence on utilization, preferences, and economic value of two case studies: HER2/neu antigen testing with trastuzumab treatment and genetic testing for Lynch syndrome.

Grosse, Wordsworth, and Payne address the challenges of valuing genetic testing – particularly in regard to non-clinical outcomes, such as impacts on patient quality of life, preferences, and 'information for information's sake' (Grosse et al., 2008). The authors discuss the relative merits of different economic measures and methods and conclude that because important outcomes of genetic testing do not fit easily within traditional measures of health, cost-effectiveness analysis do

not necessarily capture the full range of outcomes of genetic testing that are important to decision makers and consumers. Payne and colleagues conducted a systematic review of validated outcome measures of clinical genetics services (Payne et al., 2008). Thirty genetics-specific measures were identified; however, no single validated outcome measure encompassed all potential patient benefits, and the authors conclude that additional research in this area is needed. Vetger and colleagues performed a systematic review and critical evaluation of recent pharmacoeconomic analyses in pharmacogenomics (Vetger et al., 2008). Twenty studies were identified, the majority of which reported that genetic screening was cost-effective or cost-saving. However, several studies failed to provide sufficient evidence for an association between genotype and phenotype. The authors provide a list of recommendations for good pharmacoeconomic practice in pharmacogenomics.

Worth noting, recent research has provided greater clarification of thresholds for cost-effectiveness in the United States. Braithwaite and colleagues identified lower and upper bounds for the value society places on a quality-adjusted life-year (QALY) (Braithwaite et al., 2008). A lower bound was inferred by estimating the incremental cost-effectiveness of recent versus pre-"modern era" medical care in the United States. To infer an upper bound, they estimate the incremental cost-effectiveness of unsubsidized health insurance versus self-pay for nonelderly adults without health insurance. The authors estimate the value of a QALY between $109,000 and $297,000. The authors, and an accompanying editorial (Weinstein, 2008), conclude it is very unlikely that $50,000 per QALY is consistent with societal preferences in the United States.

Several evaluations of specific genetic testing applications are worth noting. First, a federally funded evidence review of gene expression profiling tests in breast cancer was reported (Marchionni et al., 2008). The review included an assessment of the evidence for the cost-effectiveness of these tests and concluded that "since the overall body of evidence is inconclusive about the economic outcomes associated with use of breast cancer gene expression tests, this is an area that will require further investigation." Schackman and colleagues conducted a cost-effectiveness study of HLA-B*5701 screening to guide antiretroviral selection for treatment of HIV (Schackman et al., 2008). The analysis was informed by data from the Prospective Randomized Evaluation of DNA Screening in a Clinical Trial study. The authors report that HLA-B*5701 testing added 0.04 quality-adjusted months (1.2 days) at an incremental cost of $110, and that testing remained the preferred strategy only if abacavir-based treatment had equal efficacy and cost less per month than tenofovir-based treatment.

Holland, Huston, and Noyes conducted a study to determine at what risk of mutation it is cost-effective to test women for BRCA1/2 mutations (Holland et al., 2008). The evaluation included estimates of health-care costs, life expectancy, likelihood of obtaining a mastectomy or oophorectomy, and patient preferences for treatment and certainty about their BRCA1/2 status. The costs and effectiveness of both the test and no-test strategies were very similar even when there was a small probability of mutation. Heitjan and colleagues explored the potential cost-effectiveness of a range of smoking cessation drug treatments, including varenicline, transdermal nicotine, bupropion, and the use of a genetic test to choose between transdermal nicotine and bupropion (Heitjan et al., 2009). The authors found that only under favorable assumptions was the genetically tailored approach competitive. Finally, Carlson and colleagues evaluated the potential cost-utility of EGFR testing to guide non-small cell lung cancer treatment. The authors found that that EGFR pharmacogenomic testing has the potential to provide clinically meaningful improvements in patient outcomes at a value similar to currently approved therapies, and additional research in this area is warranted (Carlson et al., 2009).

CHAPTER

Public Health Genomics

Alison Stewart, Marta Gwinn, Ron Zimmern and Muin Khoury

INTRODUCTION

In the mid-1990s, as the Human Genome Project gathered pace, some within the profession of public health began to realize that, in time, new knowledge and technologies stemming from this endeavor would have profound implications for the health of populations and the organization and delivery of health care services. These developments would mean that public health could no longer focus exclusively on social and environmental determinants of health, but would need to incorporate relevant knowledge from the molecular and cellular life sciences in the development of public health policies and programs.

Public health genomics is a new discipline that brings together genetic and genomic science, genetic epidemiology, and a recognition that scientific and technological advance must go hand in hand with an understanding of its ethical, legal, and social dimensions. It is distinct from "genomic medicine" in that its focus is primarily on populations, health services, and public health programs rather than on individual clinical care.

This chapter outlines the development of public health genomics over the last decade, sets out its key concepts, and describes examples of public health genomics programs and activities. New national, regional, and international networks are being established to further the goals of this new field.

THE DEFINITION OF PUBLIC HEALTH GENOMICS

The early practitioners of public health genetics suggested a variety of definitions for their discipline. At the University of Washington Institute of Public Health Genetics it was defined as "The application of advances in human genetics and molecular biotechnology to improve public health and prevent disease," while in the United Kingdom a modified form of the Acheson definition of public health was adopted, describing public health genetics as "The application of genetics on the art and science of promoting health and preventing disease through the organized efforts of society."

All of the early definitions emphasized that the subject matter of public health genetics was how the health of populations and the practice of public health and clinical medicine were affected by genetic science and technology. They also highlighted the importance of harnessing genetic knowledge for disease prevention; the word "prevention" in this context included not just measures to prevent or delay disease onset (primary prevention), but also, if disease was already present, interventions that enabled early detection and treatment, reduced disability, and delayed progression (secondary and tertiary prevention). The UK definition also made it clear that practitioners of public health genetics needed, as well as a working knowledge of genetic science, an understanding of the diverse views within society about genetics and its consequences, and an ability to work across a range of disciplines and cultures.

As the field broadened its outlook beyond the traditional connotations of "genetics" and began to think in terms of genomics, a new definition became necessary. As a result of the 2005 Bellagio workshop, public health genomics is now defined as: "The responsible and effective translation of genome-based knowledge and technologies for the benefit of population health" (Burke et al., 2006; Stewart, 2006).

The Bellagio definition makes a number of important points. By using the term "genome-based" it indicates that the

Copyright © 2010, Elsevier Inc.
All rights reserved.

scope of the knowledge base includes not only genes but also their protein products, the metabolites synthesized by those proteins, and the complex molecular and cellular interactions that make up a biological system. It also includes bioinformatics: the management and analysis of large amounts of biological information using advanced computing techniques. "Technologies" are mentioned explicitly in the definition because biotechnological developments such as drug delivery platforms, high-throughput sequencing technologies, and microarray applications are vital to the clinical exploitation of genomic science.

The adjectives "responsible" and "effective" convey two concepts: firstly, that any clinical tests or interventions resulting from genomic research must be fully validated before they are implemented and, second, that this evidence base must include due consideration of their ethical, legal, and social implications (often shortened to the acronym ELSI) (Clayton, 2003; Ojha and Thertullien, 2005).

Finally, the Bellagio definition emphasizes that public health genomics focuses on the health and health care of populations. This may at first sight seem to be at odds with the individual or familial nature of genomic information and the prospects for a future era of "personalized medicine." However, public health genomics recognizes that populations are not genetically homogeneous and that programs and policies incorporating differences in individual susceptibility to disease and response to treatment offer new opportunities that are complementary to the traditional "one size fits all" approach of public health.

KEY CONCEPTS IN PUBLIC HEALTH GENOMICS

Genes and Environmental Factors as Determinants of Health

Implicit in the various definitions of public health genomics is the recognition that all human characteristics – including susceptibility to disease – result from the combined effects of genes and environment. Figure 21.1 is a conceptual representation of determinants of health, showing the complex array of possible interactions between genomic determinants and the components of the physical and social environment.

The relative contributions of genes and environment to disease risk can vary widely. In the case of highly penetrant heritable conditions such as cystic fibrosis or Huntington's disease, a single genetic mutation may be sufficient to cause disease, but even for these diseases the range and severity of symptoms may vary widely among individuals, partly as a result of environmental factors. In the case of common chronic diseases, where a variety of low-penetrance genomic variants are implicated, the effect of environment is generally much more evident.

It is a mistake, however, to think of any disease as resulting from a fixed and quantifiable combination of genomic and environmental determinants. For example, phenylketonuria, a condition inherited in a Mendelian fashion, is classified as a genetic (heritable) disease because the environmental determinant (dietary phenylalanine) is ubiquitous and the mutation rare and highly penetrant. However, the disease could also be thought of as 100% environmental, because it is only manifest when phenylalanine is present. We might also characterize the situation by stating that the genomic defect is a necessary factor in the pathogenesis of phenylketonuria but not in itself sufficient.

From the representation in Figure 21.1 it is clear that the health status of an individual may be influenced by altering either genomic or environmental factors, or both. In the context of disease prevention, Juengst (1995) distinguished these two types of intervention as "genotypic" and "phenotypic." Genotypic intervention may be appropriate in some circumstances, such as the use of genetic testing to avoid the birth of a child affected by a highly penetrant genetic disease. However, in the context of common chronic disease, which does not usually develop until some time during adult life, only phenotypic intervention will generally be either feasible or ethically acceptable.

Public health genomics aims to prepare the ground for a future era when we have a much more complete understanding of the full range of genomic and environmental determinants of health and – crucially – how they work together. The hope is that this fuller understanding of disease etiology and of the mechanisms of disease at the molecular and cellular levels will enable development of new diagnostic tools, new therapies, and perhaps new preventive options (Guttmacher and Collins, 2005), and that this new era of genomic medicine will offer opportunities to achieve benefits for population health.

Enthusiasm about the potential benefits from genomic research must be balanced by realism about the likely time scale of these developments (Davey Smith et al., 2005; Haga et al., 2003). Unraveling the genomic contribution to disease susceptibility is an immensely complex task, and many applications in mainstream health care are unlikely to materialize for some decades to come. In the meantime, it is a key function of public health genomics to protect patients and health services from the damaging effects of interventions that are premature, not supported by robust evidence or do not fulfill the criterion of public acceptability.

Avoiding Genetic Exceptionalism

It is important to avoid "hype" about advances in genomics and it is equally important to dispel the notion that genetic or genomic factors have a significance and predictive power beyond that of other determinants of health, a view that has been dubbed "genetic exceptionalism" (Murray, 1997). A related pitfall is genetic reductionism, the tendency to over-simplify the relationship between a genetic factor and a disease or other phenotypic trait (Sankar, 2003). Genetic exceptionalism and reductionism demand special protection for genomic information on the grounds of its predictive power and implications for other family members but this thinking derives from a misguided attempt to extrapolate from the highly penetrant mutations associated with Mendelian disease to the much more weakly predictive variants associated with common disease.

Public health genomics recognizes that genes must be included among the determinants of health but their significance

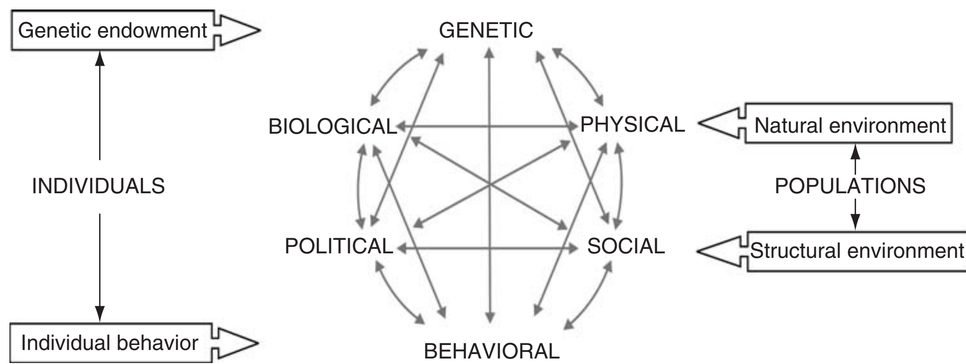

Figure 21.1 Determinants of health. The figure makes the point that external factors such as natural environmental and structural determinants are modifiable by interventions at the population level, whereas genetic factors and behavior are essentially individual (although they are, of course, influenced by external factors).

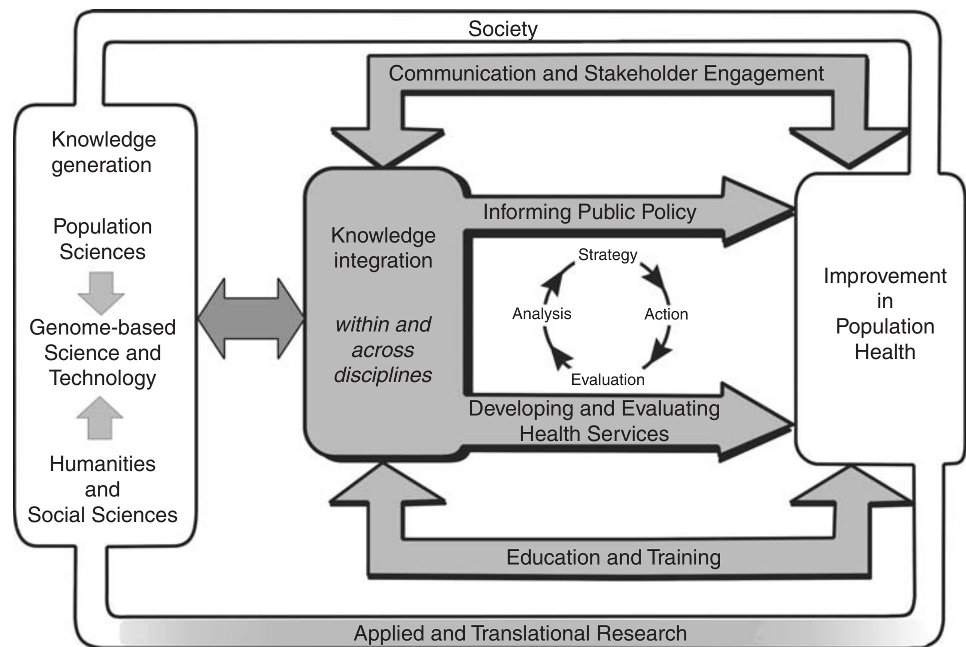

Figure 21.2 Strategy for the effective translation of genome-based knowledge and technologies for the benefit of population health. The shaded areas represent the "enterprise" of public health genomics.

should be kept in proportion: they should neither be overemphasized nor demonized. Genetic exceptionalism can lead to policy responses that are both disproportionate and irrational, in that they place restrictions on uses of DNA test information but leave other physiological or biomarker tests – which may be equally or even more highly predictive – unregulated.

THE "ENTERPRISE" OF PUBLIC HEALTH GENOMICS

The Bellagio workshop participants developed a visual representation of the "enterprise" of public health genomics, which is represented by the shaded regions of Figure 21.2; the aim of this representation is to convey a consensus understanding of what sorts of activities come under the banner of public health genomics, and how its work is conducted.

The starting point for the "enterprise" (but not part of the enterprise itself) is genomics research, shown at the left of Figure 21.2. Basic research is also needed in the population sciences (including, e.g., epidemiology and biostatistics) and in the humanities and social sciences (including law, philosophy, social anthropology, theology, and so on). Basic research can be thought of as the phase of knowledge generation.

Public health genomics comes into play with the phase of knowledge integration, both within and across disciplines. The

raw material for this process is the output from the research phase. Knowledge integration is defined as the process of selecting, storing, collating, analyzing, integrating, and disseminating information. This includes computer-based approaches to classifying, linking, and retrieving information (essentially, what an informatician would understand by the term "knowledge integration") but it is also a broader and more qualitative process encompassing selection, critical analysis, and synthesis of concepts and information from many different fields in the arts, humanities, biological, and social sciences. As the means by which information is transformed into knowledge, it is an essential step in making that information usable in the practical world of clinical medicine and public health practice.

The knowledge base generated by the knowledge integration function of public health genomics is used to underpin four core sets of activities: communication and stakeholder engagement; informing public policy; developing and evaluating health services; and education and training. Examples of some of these activities will be discussed later in this chapter.

Knowledge integration and the four core sets of activities set out *what* public health genomics does. *How* it carries out its work may be described by the cycle of public health action developed by the Institute of Medicine Committee for the Study of the Future of Public Health (1998) and others. This cycle consists of an initial phase of analysis followed by development of a strategy, implementation of that strategy, and evaluation of its outcomes. This is not a once-and-for-all process: successive rounds of the cycle lead to continued refinement of the strategy, both before and after implementation.

Research does have a place in the enterprise of public health genomics, as shown at the bottom of the diagram. Distinct from basic academic research, this is applied and translational research with direct applicability to health service implementation; such research can also identify gaps in the knowledge base that need to be filled by further basic research.

Finally, Figure 21.2 emphasizes that the whole enterprise of public health genomics – and the phase of basic research – is embedded within a societal context. The views and priorities of society play a part in determining what research is carried out and how it is used and, in turn, the perceived results of those activities shape societal attitudes.

CORE ACTIVITIES IN PUBLIC HEALTH GENOMICS

Knowledge Integration

Knowledge integration can be thought of as the driving force of public health genomics. A number of initiatives to support knowledge integration are underway at various centers. These activities aim to bring knowledge together from different sources across the sciences, arts, and humanities so that a multi-disciplinary resource is available for application to projects in public health genomics. For example, the HumGen database at the Centre de recherche en droit public (CRDP) at the University of Montreal, Canada, is a searchable international database of laws and policies relevant to the application of human genetics. The PolicyDB database curated by the Public Health Genetics Unit in Cambridge also deals with the policy field but differs from HumGen in that it concentrates mainly on the United Kingdom and the EU, and coverage includes policy for scientific research, public health, and health services as well as legal and bioethical documents.

A highly developed example of knowledge integration in public health genomics is the Human Genome Epidemiology Network (HuGE Net) initiative (Ioannidis, 2005). HuGE Net was set up by Muin Khoury in 1999 with the aim of assembling and critically analyzing population data on genotype prevalences and gene–disease associations emerging from research in genetic epidemiology. This task is an essential prerequisite to the development of any clinical or public health applications of this information. HuGE Net, discussed in more detail in another chapter of this book, has grown into an international multi-disciplinary initiative comprising around 800 collaborators in 43 countries. HuGE Net's core activities are information exchange through its website and newsletter, training and technical assistance in systematic review and meta-analysis, methodological development, knowledge base development, and information dissemination.

Another international initiative, spearheaded by the CRDP in Montreal, is the Public Population Project in Genomics (P3G) Consortium. The aim of P3G is "to provide the international population genomics community with the resources, tools, and know-how to facilitate data management for improved methods of knowledge transfer and sharing." P3G members include representatives from the major biobank projects underway across the world. A key feature is the P3G Observatory, a knowledge transfer platform that includes information on the design and status of the various projects and their governance arrangements, to enable comparisons and sharing of best practice.

Communication and Stakeholder Engagement

Productive dialogue with the public and other stakeholders, including patient groups, government, and industry, is important to ensure that scientific and clinical developments proceed in harmony with the attitudes and expectations of other sectors of society.

Among examples of work in this area, the Public Health Genetics Unit (PHGU) in Cambridge established a public panel to provide an independent perspective on its work and actively involved patients and carers in its service development projects. For example, a project on learning disability employed a mixture of online discussion, telephone interviews, and focus groups to develop a document, Parents as Partners, which provides detailed evidence of the value that parents place on a genetic diagnosis in learning disability, and sets out recommendations for the health service (Gogarty, 2006).

Service Development and Evaluation

This activity includes development of policies, programs, and services – both clinical and preventive – in the health sector;

strategic planning; service organization; manpower planning and capacity building; service review and evaluation; and guideline development.

The evaluation of population genetic screening programs, either proposed or current, is an example of work in this strand of public health genomics. In the United States, for example, public health leadership was instrumental in securing a rational approach to the proposed introduction of population screening for hereditary hemochromatosis. A multi-agency process produced a consensus statement that the current evidence base did not justify screening and made recommendations for further research (Burke et al., 1997). Further population-based research was funded to establish the penetrance of hemochromatosis-associated mutations and the prevalence of symptomatic hemochromatosis, and a web page is available on the website of the National Office of Public Health Genomics providing education about hereditary hemochromatosis for health care providers and the general public.

The public health genomics community has also taken the lead on the evaluation of DNA tests for clinical use, developing both the theoretical foundations for test evaluation and protocols for implementation in practice. For example, CDC's National Office of Public Health Genomics has convened a project known as EGAPP (Evaluation of Genomic Applications in Practice and Prevention) that aims "to develop a coordinated process for evaluating genetic tests and other genomic applications that are in transition from research to clinical practice." The EGAPP project draws on experience gained from application of an earlier evaluation protocol, the ACCE framework (standing for analytical validity, clinical validity, clinical utility, and ethical, legal, and social implications; Haddow and Palomaki, 2003). The UK's Public Health Genomics Foundation also has a strong involvement in genetic test evaluation, working with the UK Genetic Testing Network to develop and apply a protocol for the evaluation of tests funded by the National Health Service (Sanderson et al., 2005).

Informing Public Policy

The term "policy" refers to a broad range of public policies and programs that have a direct or indirect impact on the application of genomics in health care. Activities may encompass legal, philosophical, and social analysis at an applied level; development of regulatory frameworks; engagement in the policy making process; promoting relevant research; and seeking international comparisons.

Current policy issues include legal and regulatory frameworks for genetic testing; the funding of science and the prioritization of relevant research; consent, confidentiality, data protection, and the use of human tissue; attitudes to and relationships with the pharmaceutical and biotechnology industries; and the patenting of genes and genomic technologies. There is considerable academic research activity on these topics. For example, the US National Human Genome Research Institute "ELSI" program has an annual budget of around $18 million to support research on topics including privacy and fair use of genomic information, DNA banking, ethical conduct of genomic research, genetic discrimination, and the psychosocial impact of genomic testing and technologies. In the United Kingdom, the Economic and Social Research Council has also invested heavily in this field, supporting social science research in genomics through six Genomics Centers that together form the ESRC Genomics Network.

Despite the volume of theoretical work that has been done on these issues, however, there has been less attention to finding practical policy solutions; an aim of public health genomics is to fill this gap. The PHGU's policy team, for example, carried out detailed scrutiny of draft UK legislation governing the storage and use of human tissue samples for purposes including DNA analysis (Liddell and Hall, 2005). Flaws in the draft legislation were identified that could have impeded both research and clinical practice. Working with partner organizations in clinical genetics and biomedical research, PHGU was able to help influence the political process to achieve amendments that at least partly resolved these problems, and was involved in initiatives to produce practical guidance for health professionals needing to comply with the new legislation.

PHGU's mode of working on the Human Tissue Bill highlights another key aspect of public health genomics: the importance of forging working alliances with relevant stakeholder groups from research, clinical medicine, industry, patients, and the general public to achieve a consensus approach that is vital for securing "ownership" of a project and its conclusions.

Education and Training

As genomics and genomic technologies begin to have an impact on clinical practice, all health professionals will need to become "literate" in the general principles of genomics and its specific applications in their own specialist field. Public health professionals and health service managers will also need a working knowledge of genomics in order to make sound judgments about the planning and evaluation of health services (Burke, 2005).

Public health genomics contributes to these goals by promoting programs of genomic literacy for health professionals (as well as generally within society); specific training for public health genomics specialists; and development of educational materials, courses, workshops, and seminars. For example, a set of competencies in genomics for the public health workforce has been developed by the National Office of Public Health Genomics in Atlanta. Competencies are documented for the public health workforce as a whole and for specific groups including leaders/administrators, clinicians, epidemiologists, health educationalists, laboratory staff, and environmental health workers. For public health genomics specialists, the multi-disciplinary Masters and PhD programs developed at the Universities of Michigan and Washington offer a solid grounding in the field: the University of Washington Masters course, for example, includes core modules in genetic epidemiology; ethical and social issues; pharmacogenetics and toxicogenomics; genetics and the law; public perspectives on ethical issues; introduction to genetic services and bioinformatics; and economic and policy issues for genetic technologies and services.

In the United Kingdom, the PHGU led a project to develop a national strategy for genetics education for health professionals; the project's report (Burton, 2003) was one of the influences that led to the establishment of a government-funded NHS National Genetics Education and Development Centre in Birmingham. A multi-disciplinary post-graduate course in public health genomics is under development at Cranfield University, based on a textbook authored by members of the Public Health Genetics Unit (Stewart et al., 2007).

THE ROLE OF PUBLIC HEALTH IN THE TRANSLATION OF HUMAN GENOME DISCOVERIES INTO HEALTH APPLICATIONS

Public health has been traditionally identified with state, federal and local public health agencies; however, recent reports by the Institute of Medicine in the United States and others have adopted a more inclusive view, defining public health professionals as those working on improving health from a population perspective (IOM, 2003). "Public health professionals" are those employed not only in government but also in health care delivery, academia, community organizations, and the private sector; together, they are actors in the "public health system" (IOM, 2002), which is working to assure the conditions under which a population can be healthy. If we adopt the expanded view of public health as population health, it becomes much easier to consider genomics at the interface of the translational research agenda between medicine and public health.

Another reason to adopt an expanded view of population health is that future applications of genomics will occur primarily in the health care delivery system and not in the context of the national or state-mandated screening programs (traditional public health). Unfortunately, the sad history of eugenics will serve as constant reminder of horrifically failed applications for the perceived benefits of population health. Furthermore, the only current model of intersection of genetics and public health, namely newborn screening, should not necessarily serve as a model of future applications and joint partnership between medicine and public health. Undoubtedly, while newborn screening programs make important contributions to health, they continue to raise important ethical questions about informed consent, especially in the light of proposed expanded programs where health benefits are absent or less clear cut than medical emergencies provided by phenylketonuria (PKU) and congenital hypothyroidism. Thus, under the rubric of population health, collaboration between public health and medicine in genomics will emphasize the importance of an individual-oriented perspective but also the need for a population-based evaluation strategy and evidence-based health care with access of validated information to all segments of the population.

Advances in genomics have also been accompanied by an emerging emphasis on translational research, a movement fueled by the NIH road map initiative (Zerhouni, 2003, 2005) to accelerate the translation from basic science to clinical applications. The translation framework is based primarily on the discovery of new drugs and their accelerated use in human clinical trials, with little or no emphasis on prevention. However, the "bench to bedside" paradigm covers only part of the distance from discovering new knowledge to delivering health benefits at the population level (Green and Seifert, 2005; Horig and Pullman, 2004). In 2003, Claude Lenfant (2003), the retiring director of the National Heart, Lung and Blood Institute, presented the Shattuck lecture titled "Clinical research to clinical practice – lost in translation?" He described many discoveries of curative or preventive interventions that nevertheless do not reach the end of the translation highway and asked, "If we can't do it with aspirin, how will we do it with DNA?"

The "lost in translation" problem is complicated by the increasing costs of health care delivery and persistent inequities in access. Some have called the next stage in translation "translation type II" (Rohrbach et al., 2006), which requires more applied research on the best ways to deliver or disseminate interventions that work in real life settings (delivery research) and to evaluate health outcomes and population impact (outcomes research). In 2007, Westfall et al. (2007) proposed that the evaluation of evidence-based interventions in practice can be called "type 3 translation research." As shown in Table 21.1 we have also extended (Khoury et al., 2007b) the translation pathway to type 4 translation (T4) research, which seeks to evaluate the "real world" health outcomes of a genomic application in practice. We have reported that most human genomics research between 2001 and 2006, inclusive, was not translational and have estimated that no more than 3% of published research focuses on T2 and beyond. Indeed, evidence-based guidelines and T3 and T4 research currently are rare (Khoury et al., 2007b).

As discussed below, an enhanced focus on translation and translation research from T1 through T4 can foster a true partnership between medicine and public health in the genomics era in four major areas (see Figure 21.3).

THE FOCUS ON DISEASE PREVENTION AND HEALTH PROMOTION

Advances in genomics will provide new opportunities for disease prevention and health promotion – the main focus of public health, regardless of whether it is delivered at the individual level or through population-wide interventions. Understanding genetic effects and gene–environment interactions in disease processes could lead to the recommendation that certain subgroups avoid defined exposures or receive targeted interventions. Stratification by genotype or family history already provides a means for tailoring screening tests for early disease detection (e.g., colorectal cancer screening in genetically susceptible persons), a paradigm likely to be extended to early detection of other conditions.

Table 21.1 The continuum of translation research in human genomics: Types of research and *BRCA* example

Translation research phase	Notation	Types of research	Examples
TI	Discovery to candidate health application	Phases I and II clinical trials Observational studies	Is there an association between *BRCA* mutations and breast cancer?
T2	Health application to evidence-based practice guidelines	Phase III clinical trials Observational studies Evidence synthesis and guidelines development	What is the positive predictive value of *BRCA* mutations in at-risk women?
T3	Practice guidelines to health practice	Dissemination research Implementation research Diffusion research Phase IV clinical trials	What proportion of women who meet the family history criteria are tested for *BRCA* and what are the barriers to testing?
T4	Practice to population health impact	Outcomes research (includes many disciplines) Population monitoring of morbidity, mortality, benefits, and risks	Does *BRCA* testing in asymptomatic women reduce breast cancer incidence/improve outcomes?

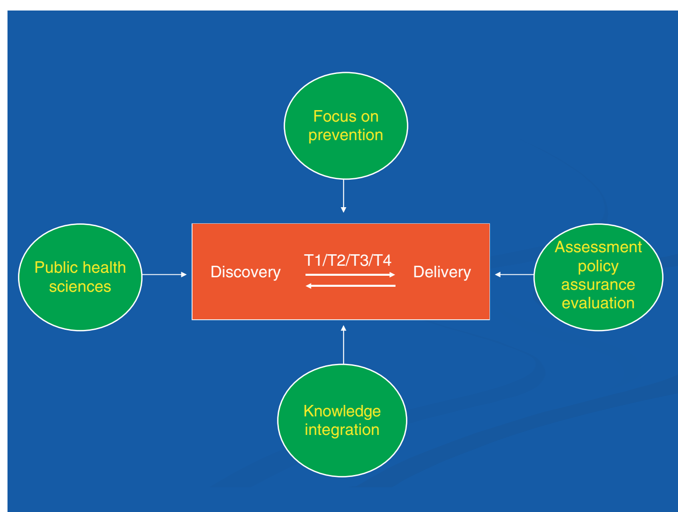

Figure 21.3 A framework for medicine-public health partnership in the genomics era (Adapted from Khoury et al., 2007a, b).

A review of the public health implications of genomic research related to asthma (UWCGPH, 2004) illustrates the potential opportunities and challenges for translating new knowledge into improved prevention and treatment of a common disease. Strong evidence supports a causal role for both genetic and environmental factors. Genomics research has identified numerous gene loci associated with asthma, and further studies of biological pathways associated with asthma, are likely to yield new approaches to prevention and therapy. The earliest clinical applications will be in pharmacogenomics, using genetic information to optimize therapy and prevent adverse events. The path for translating results of genomic research to population-level interventions will not always lead through genetic testing and knowledge of individual genotypes. For example, a study in Mexico of children with asthma found that supplementation with the antioxidant vitamins C and E improved lung function in children with a common polymorphism of *glutathione S-transferase M1* (*GSTM1*) who are exposed to ozone (Romieu et al., 2004). These findings might suggest a simple intervention – antioxidant vitamin supplementation – for children with asthma who are exposed to ozone. Without genotype-specific analysis, a potentially important population-level intervention could have been overlooked.

New gene discoveries are reported daily and have initiated dialog on the value of genetic information with respect to prevention. Consider, for example, the discovery in 2006 that a variant of the *TCFT7L2* gene is associated with increased risk of type 2 diabetes (Grant et al., 2006). This finding was noteworthy for several reasons. First, type 2 diabetes is a serious disease and a major public health problem. Family history is an important risk factor but until now, few genetic associations have been identified. The investigators replicated the association with *TCF7L2* in three independent populations and presented molecular evidence that the gene product is a high mobility group box-containing transcription factor related to blood glucose homeostasis. The gene product may act through regulation of proglucagon gene expression via the Wnt signaling pathway (Grant et al., 2006). The senior investigator commented to the *New York Times* that a practical consequence of the discovery could be a diagnostic test to identify people who are at increased risk of type 2 diabetes. He speculated that "these people, knowing their risk, would be motivated to exercise more and adopt a healthier diet" (Jannssens et al., 2006). However, a relatively simple analysis is sufficient to show that a test for *TCF7L2* variants by itself would have very poor predictive value, adding little to the risk

information already provided by family history, and would have limited utility for prevention (Jannssens et al., 2006). In particular, the hypothesis that genetic risk information of this kind will motivate behavioral change remains to be tested.

Once a genetic variant is discovered, producing a molecular test to detect it is theoretically straightforward. However, the clinical validity of such a test is highly dependent on population characteristics; these include not only prevalence of the genetic variant and the strength of its association with disease, but prevalence of the disease and interactions between this genetic variant and many other risk factors. Clinical utility is even more difficult to establish because it depends on the availability of a specific, effective intervention that adds value to existing practice. Although most gene discoveries for common diseases are not ready for prevention applications, they have, nevertheless, initiated a common interest in medical and public health to develop a common framework for how such discoveries can be evaluated for their potential applications for disease prevention.

2009 UPDATE

Two major developments set the stage for genome-wide association studies (GWAS): the International HapMap Project, which produced a database of genome-wide variation, and high-throughput genotyping technology, which has become increasingly efficient and accessible. Only a handful of GWAS appeared before 2007, when more than 100 such studies were published, followed by more than 120 in 2008 (Yu et al., 2009). Already, GWAS have identified more than 100 genetic associations with a wide range of common diseases and traits (Hindorff et al., 2009; Manolio et al., 2008). Very large study populations are required to detect the relatively small associations (i.e., per-allele odds ratios from 1.1 to 2.0) typically found in GWAS; thus, these studies have required unprecedented cooperation and collaboration among researchers in genetics, medicine, and epidemiology. Increasing interaction and interdependence among these disciplines is leading to a convergence in research approaches (McCarthy et al., 2008).

So far, most published human genomics research has focused on discovery: fewer than 3% of publications address the potential clinical validity or utility of genomic information for improving health or preventing disease (Khoury et al., 2007). Efforts to bridge the "translation gap" begin with knowledge synthesis and evaluation. For example, a consensus group has proposed grading the cumulative epidemiologic evidence for genetic associations as weak, moderate, or strong according to three criteria – amount of evidence, extent of replication, and protection from bias (Ioannidis et al., 2008). Applying this approach to evaluate all genetic associations with a specific disorder, such as schizophrenia, provides a "field synopsis" (Allen et al., 2008). Systematic review and synthesis (e.g., by meta-analysis) is indispensable for interpreting the burgeoning literature on genetic associations, which contains many false positive results, even in the GWAS era (Attia et al., 2009). For example, a field synopsis of DNA repair genes and susceptibility to cancer found that of 1123 studied associations, no more than three were supported by strong evidence (Vineis et al., 2009).

Increasing numbers of genetic tests are finding their way into clinical use, often before their validity and utility have been assessed. An initiative from the US Centers for Disease Control, the Evaluation of Genomic Applications for Practice and Prevention (EGAPP), has developed methods for evaluating the evidence for genetic tests proposed for use in a particular clinical setting (Teutsch et al., 2008). The first such evaluation addressed testing for cytochrome P450 polymorphisms to guide treatment with selective serotonin reuptake inhibitors in depressed adults (AHRQ, 2007); several additional recommendations have been published recently (EGAPP Working Group, 2008a, b, c). Information about pending EGAPP reviews and recommendations is available from the EGAPP website (http://www.egappreviews.org).

Recently, several companies have begun to offer personal genome scans directly to individuals via the Internet. These tests are based on the same arrays used for GWAS, and consumers are provided with summaries of research findings; individual results are most often presented as relative risks or odds ratios (usually less than 2.0). Although personal genome scans have received much popular attention, they so far provide little basis for medical decision-making or lifestyle advice (Hunter et al., 2008). It remains to be seen how consumers and/or healthcare providers will use such information.

Although it may seem paradoxical, the path to predictive personalized medicine passes through population-based research, because probabilistic risk estimates for complex disorders require inference from larger population samples. As observed before by critics of individualized preventive medicine, few risk factors for common chronic diseases have sufficient predictive ability to serve as screening tools; in this respect, common genetic variants associated with disease susceptibility are unlikely to be different.

Information about genetic variants, when integrated with other clinical and epidemiologic data, may be useful for defining groups of persons most likely to benefit from particular interventions. Tests for multiple genetic variants could also be expected to have greater predictive value than a test for a single variant. For example, a recent modeling study found that a test for seven common breast cancer susceptibility alleles would predict risks of incident disease that varied sixfold between women with the most and the fewest alleles; although the test provided insufficient discrimination to be useful at the individual level, the authors of this study suggested that it could be used to stratify

the population for risk-based targeting of mammographic screening (Pharoah et al., 2008).

Like other tests, genetic tests must be evaluated in the context of their application for a specific purpose. In general, clinical decisions hinge on the absolute risk of a particular outcome during a specified time interval and on the relative benefits and harms of different interventions at each level of risk – the measures that together define clinical utility (Zimmern, 2009). Even highly predictive tests may not be useful if their results have no bearing on intervention or treatment; even clinically useful tests, such as genotype-guided warfarin dosing, may not be cost-effective (Eckman et al., 2009). Some basic safeguards on translation of human genomic research include transparent reporting of study methods and results, systematic evaluation of cumulative evidence for association, careful assessment of clinical validity and utility, and clear communication to the public about what a genetic test result can or cannot tell us (Ioannidis et al., 2009).

CHAPTER

The Genomics of Hypertension

Chana Yagil and Yoram Yagil

INTRODUCTION

One of the promises of genomics has been that it would provide a better understanding and improve our ability to treat common diseases that afflict humanity. Hypertension is one of the most common and perhaps more important diseases that carry a high rate of morbidity and mortality. Hypertension, which is defined as systolic blood pressure above 140 mmHg and/or diastolic blood pressure above 90 mmHg, has a worldwide prevalence estimated at over 600 million people and in the United States alone at over 65 million. A wide variety of populations are affected worldwide, ranging over both sexes and all ethnic groups (Kearney et al., 2004).

Despite decades of intensive research in human populations and in experimental animal models, the pathophysiology underlying hypertension remains unresolved. In the majority of cases, hypertension is thought to result from an interaction of genes with environmental factors. In only a small minority of cases, genetic dissection of hypertension has uncovered single gene mutations that lead to the development of the so-called "monogenic" forms of the disease (Luft, 2001). The pathophysiology of these rare monogenic forms of hypertension has been elucidated during the past decade, but the pathophysiology underlying the common form of hypertension remains incomplete and elusive, hence the term "essential hypertension." Our current understanding of essential hypertension is limited to the knowledge that a yet undetermined number of "causative" genes encode for a probably larger number of proteins that are involved in a wide variety of pathophysiological pathways that somehow lead together to a rise in blood pressure and hypertension. These causative genes interact with a multitude of environmental factors, not all of which have yet been identified, and an unknown number of susceptibility genes. The susceptibility genes in turn modulate the response of the individual to the environment. Causative genes, environmental factors and susceptibility genes interact in a highly complex network (Figure 22.1), the outcome of which is a rise in blood pressure to abnormal levels that are clinically defined as hypertension. Hypertension thus belongs to the group of common multifactorial complex diseases.

The complexity of hypertension is perhaps best illustrated by Guyton's traditional model of cardiovascular dynamics (Figure 22.2a) in which multiple circuits of physiological mechanisms act in conjunction with one another to cause hypertension (Guyton and Coleman, 1969). The advent of genomics has allowed the translation of each component of Guyton's model into its underlying genetic make-up. Instead of simplifying the model, however, this allegedly "forward" step only renders the highly complex physiological scheme into an even more complicated micro-circuitry of genes and proteins that interact with

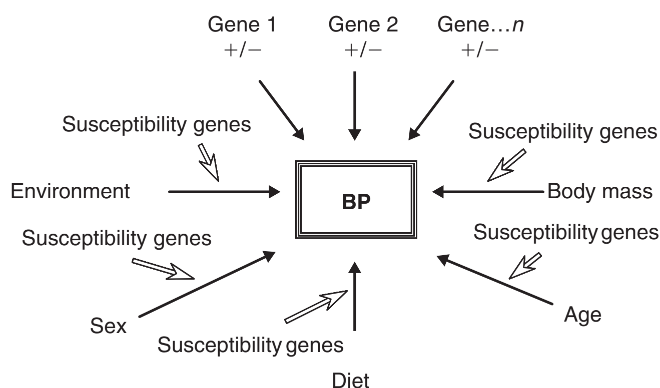

Figure 22.1 The complexity of hypertension. BP, blood pressure.

one another in multiple ways that eventually cause hypertension (Figure 22.2b).

Unraveling the huge complexity of the pathophysiology underlying the most common form of hypertension, the so called "essential hypertension," has been a daunting task which still remains far from being completed. The hope is that where traditional physiology has failed at large, genomics along with physiological genomics will provide more detailed insight into the mechanisms underlying essential hypertension, which will in turn facilitate a more rational therapeutic approach to the treatment of the disease, as well as development of new drugs for hypertension.

In this chapter, we will focus on how genomics has affected our understanding of the predisposition to hypertension, on our ability to screen, diagnose and determine the prognosis of patients with hypertension, on the applicability of genomics to the monitoring of hypertension and on the present and anticipated future impact of genomics on the treatment of hypertension.

PREDISPOSITION

In hypertension, two questions arise with regards to "predisposition." The first is what factors predispose the individual to develop hypertension. This issue will be discussed henceforth in depth. The second issue, which is of no lesser importance, is what predisposes a hypertensive individual to develop end-organ damage, the clinically significant and often devastating direct result of high blood pressure. End-organ damage, which determines the "clinical outcome" of hypertension, will be discussed in the section on "prognosis."

There is a major difficulty in dealing with the question what predisposes the individual to develop hypertension if one considers that if a subject lives to the age of 90, his/her likelihood to develop hypertension approaches 80–90% (Table 22.1). Most human beings are therefore "naturally" inclined and genetically predisposed to develop hypertension sometime in their lifetime, assuming that they live long enough. The incidence and prevalence of hypertension increase with age, and the immediate sequelae of hypertension, cardiovascular, cerebrovascular and renal disease indeed constitute important causes of morbidity and mortality in the elderly. The development of hypertension at an earlier age, however, perhaps "pre-maturely," is less frequent but more intriguing. The real issue of interest is therefore what confers the susceptibility of the individual to develop hypertension at an early age.

The issue of predisposition to develop hypertension, as with other multifactorial diseases, can also be viewed in a different way. One can ask the question what confers resistance, as opposed to susceptibility, of the individual to develop hypertension, resistance which prevents the development of hypertension at an early age as well as at a later age. It is possible, after all, that individuals are physiologically predisposed to hypertension and that blood pressure is maintained at "normal" levels through protective mechanisms, unless these fail.

Irrespective of whether sensitivity or resistance prevail, there is generalized agreement that the likelihood that an individual will develop hypertension sometimes along his/her lifetime is dependent on a multitude of factors, most likely a combination of genetic and environmental factors, notably "bad" genes in a "bad" environment (Geller, 2004).

Researchers have used genomics in an attempt to dissect the predisposition of the individual to environmental factors that leads to the development of hypertension and identify the culprit genes. A classical example has been the study of the susceptibility to dietary salt that causes hypertension. It has long been recognized that individuals are either salt-sensitive or salt-resistant. Those who are salt-sensitive develop hypertension when salt-intake is increased, and those who are salt-resistant remain normotensive, irrespective of dietary salt-intake. It has also been recognized that what renders individuals salt-sensitive and others salt-resistant is their genetic make-up. Studies in animal models such as the Dahl (Rapp, 1982) and Sabra (Yagil et al., 1996) rat models of salt-sensitivity provide unequivocal experimental proof that the trait of salt-susceptibility that leads to the development of hypertension is genetically inherited.

Have decades of research into the genetic basis of salt-susceptibility resulted in the detection of the genes or proteins that account for salt-susceptibility? Have genomics provided the solution to the question which mechanisms account for salt-sensitivity? There have been major problems in dissecting the genetic basis of salt-susceptibility directly in human populations where it is next to impossible to separate and isolate the various modulators of hypertension, including environmental factors, and focus on one at a time. It is certainly even more complicated in humans to combine interventional studies with genomic investigation of the underlying genes. Thus, there have been only few genomic investigations in humans that have aimed specifically at detecting susceptibility genes, and much of the investigation

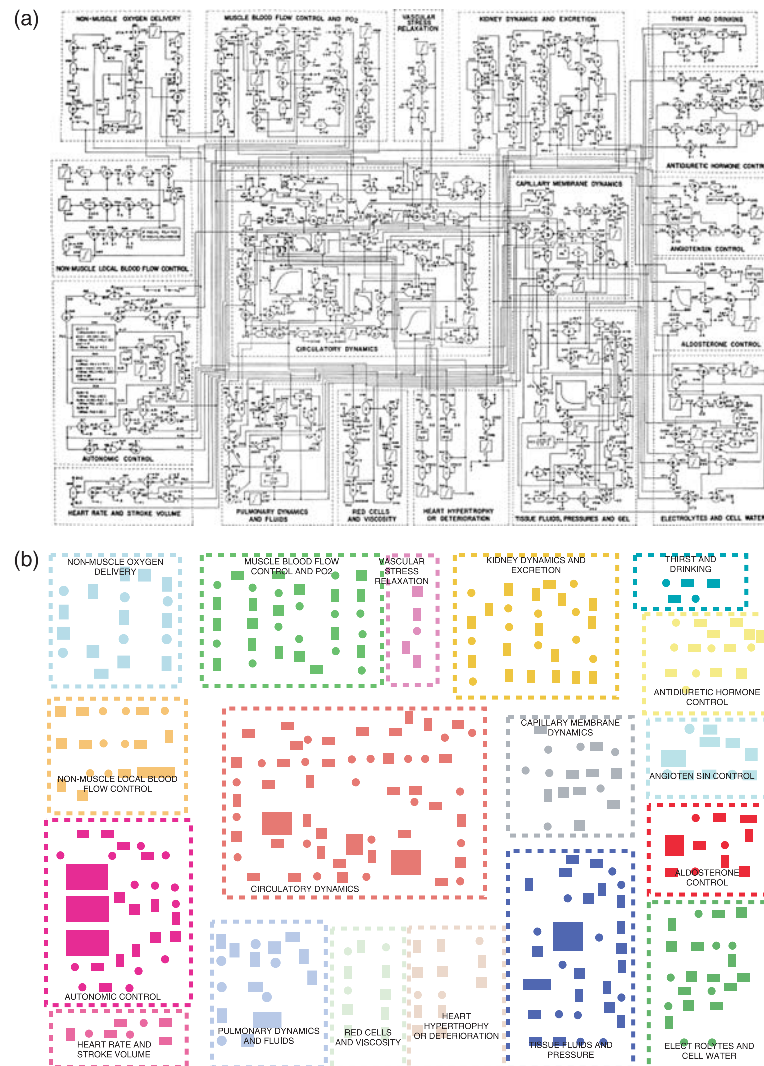

Figure 22.2 (a) Guyton's model of cardiovascular dynamics (adapted from Guyton, A.C., and Coleman, T.G. (1967). Long-term regulation of the circulation: interrelationships with body fluid volumes. In: *Physical Bases of Circulatory Transport Regulation and Exchange*. Saunders, Philadelphia, PA) and (b) after genomic annotation and translation of the model components into individual genes (colored boxes) .

had to be carried out in experimental models of the disease that allow not only isolation but also perturbations and alterations of single environmental factors, one at a time. Indeed, investigations of the genetic basis of salt-sensitivity using genomic approaches such as positional cloning in the experimental animal models of salt-sensitivity have yielded a large number of quantitative trait loci (QTLs), at least one on each autosome and on chromosome X (Garrett et al., 2002). A number of these QTLs, which allegedly incorporate within them the salt-sensitivity-related genes, have been confirmed through the use of genetically designed consomic and congenic strains (Cowley, Jr. et al., 2004a, b; Yagil and Yagil, 2003). A considerable number of genes have been identified within these QTLs as possible candidate genes for salt-susceptibility. Nonetheless, the investigation aiming to elucidate the genetic basis of salt-sensitivity or resistance is nowhere resolved and is actively ongoing. The search for the genetic basis of salt-susceptibility or the genetic basis for the predisposition to salt-sensitivity, however, is only one of the many directions that need to be investigated, as environmental factors other than dietary salt also predispose individuals to hypertension. What mechanisms predispose individuals to develop hypertension in face of stress? Climate? Obesity? Very little is known about these

TABLE 22.1 Prevalence of hypertension in the United States population during 1999–2000

Age (years)	Males (%)	Females (%)
20–34	11.8	3.1
35–44	19.2	18.6
45–54	36.9	33.4
55–64	50.7	57.9
65–74	68.3	73.4
>75	70.7	84.9

Health United States, 2003, NCHS.

other factors, and once again most of the data on susceptibility genes originate from studies in experimental models.

There have been attempts, nonetheless, to study genetic predisposition to hypertension directly in humans using a seemingly less sophisticated alternative approach aiming to link the hypertensive phenotype to variations in the composition of the genome by focusing directly on candidate genes and polymorphisms within those genes. It was thought that such association would allow identification of a predisposition of the individual who is not yet hypertensive but who carries the specific genetic variant to develop hypertension at a later age, the predisposition being expressed as "odds ratio." The list of candidate genes is long and has even merited a website listing 150 such candidate genes for hypertension (http://cmbi.bjmu.edu.cn/genome/candidates/candidates.html). Genetic polymorphisms within these candidate genes have been identified. Little insight has been gained, however, from attempts to associate these polymorphisms with hypertension, and no clinically useful information has been derived as to the ability to identify those individuals who are more prone to develop hypertension "prematurely." Possible explanations for this failure to identify clinically useful genetic polymorphisms may be related to the small population size that have been used in many of the studies, the possibility that the "wrong" candidate genes were chosen, or the inability to identify the polymorphisms that actually account for the development of hypertension. The link between genetic polymorphisms of candidate genes and hypertension remains thus elusive at this stage. Nevertheless, it is quite likely that the correct and relevant candidate gene variants will eventually be identified and these will help determine who within a population is predisposed to hypertension.

When dealing with predisposition to hypertension, one cannot overlook in this era of globalization the interesting, although emotionally laden, issue of ethnic/racial predisposition to hypertension. There is a disparity in the prevalence of hypertension amongst different racial/ethnic populations worldwide. Such variations in the prevalence of hypertension amongst different populations raises the question of whether there is ethnic/racial predisposition to hypertension and what has been the contribution of genomics to resolve the issue. The racial issue in relation to predisposition to disease in general has been difficult to deal with, as it may imply the existence of an inborn genetic flaw (Cooper and Kaufman, 1998). However, arguments regarding the existence or absence of racial or ethnic differences must also consider the large body of human genetic research in rarer Mendelian forms of diseases, some of which have been described as being largely restricted to single racial or ethnic populations. Racial differences may be within genetic subtypes that are particularly sensitive to environmental factors that can raise blood pressure. Race, however, cannot be regarded as an etiological factor *per se*, but rather as a "risk factor" for hypertension, without inferring causality. In this sense, race, as is age, should be considered a risk factor (O'Donnell and Kannel, 1998).

DIAGNOSIS

The diagnosis of hypertension at present is solely based on the measurement of blood pressure, using a blood pressure cuff, and on threshold levels above which subjects are defined as "hypertensive." Whether hypertension is best defined based on sporadic office measurements using standard blood pressure measuring devices or on 24-h intermittent measurements of blood pressure using an ambulatory blood pressure device (Pickering et al., 2006) is a matter that is still hotly debated and thus yet unresolved. The threshold values for hypertension, whether based on standard or ambulatory blood pressure measurements, are determined in many countries by national guidelines that base their decisions on observations that above a certain level, target organ damage occurs.

What is the place of genomics in the process of diagnosing hypertension? Because of the simplicity in the diagnosis of hypertension, genomics have no place in the process of determining whether a subject is hypertensive or not.

Genomics may have a place though, at least theoretically and conceptually, in diagnosing what type of hypertension the subject is suffering from. If one can grossly divide hypertension into "primary" or "essential" hypertension, two terms that are used interchangeably, and "secondary" hypertension, then it is theoretically possible that genomic tools might help eventually determine what kind of hypertension the subject has. Unfortunately, no genomic tools are yet available that differentiate between primary and secondary hypertension. This matter is further complicated by the fact that the term "essential hypertension" is used to describe hypertension of unknown or "idiopathic" origin. In fact, essential hypertension is likely to represent several separate clinical entities, the number and nature of which are presently unknown. Once the pathophysiological mechanisms of "essential hypertension" are elucidated, however, it is likely that virtually all cases of hypertension will be classified as "secondary," and the term "essential" for hypertension

will have become obsolete. But until that is achieved, all subjects with hypertension in whom a primary cause of hypertension has not been identified continue to be labeled "essential hypertension" by default, and the need to differentiate between primary and secondary hypertension prevails.

Genomics can be of help in identifying within the "secondary" hypertension group specific disease entities that are due to genetic alterations. This screening can be based on the search and identification of known mutations that are known to be associated with disease, or of patterns of gene expression that are typical for the disease. By identifying known specific genetic mutations, genomics can already be useful in the diagnosis of specific genetic variants that cause hypertension, the rarer forms of monogenic hypertension (Lifton et al., 2001). For example, Liddle's syndrome, a disorder that is associated with hypertension, low plasma renin and aldosterone levels, and hypokalemia, is due to a mutation in the sodium channel gene, specifically to a deletion or missense mutations of a PPPxY motif in the cytoplasmic COOH terminus of either the beta or gamma subunit of the epithelial Na channel (ENaC). Type 2 pseudohypoaldosteronism or Gordon's syndrome, is another hypertensive syndrome characterized by hypertension, hyperkalemia, normal renal function, and low or low-normal plasma renin activity and aldosterone concentrations; this clinical entity is due to mutations in WNK kinases 1 and 4 (Wilson et al., 2001). Glucocorticoid-remediable aldosteronism is a disorder in which a chimeric gene formed from the 11β-hydroxylase and aldosterone synthase genes (Lifton et al., 1992) results in ACTH stimulating aldosterone synthase, leading to persistent hyperaldosteronism. In congenital adrenal hyperplasia with 11β-hydroxylase deficiency, 10 different mutations of the *CYP11B1* gene have been identified (White et al., 1994), causing steroid 11β-hydroxylase deficiency with signs of androgen excess and hypertension. The syndrome of apparent mineralocorticoid excess arises from mutations in the gene encoding the kidney enzyme 11β-hydroxysteroid dehydrogenase, allowing normal circulating concentrations of cortisol to activate the mineralocorticoid receptors (Mune and White, 1996). Are there readily available clinically useful means to diagnose these genetic mutations that cause secondary hypertension? Theoretically, a specially designed DNA microarray could provide the answer. Unfortunately, such high-throughput genomic tools are not available yet to the clinician, not even for the known forms of monogenic hypertension.

PROGNOSIS

Hypertension constitutes a major risk factor for the development of heart disease and stroke, end-stage renal disease, and peripheral vascular disease and is a chief contributor to adult disability. The prognosis of hypertension is solely and entirely dependent on the development of such target organ damage. Even though the rule in general is that the higher the blood pressure, the greater the likelihood to develop organ damage, clinical observations indicate that not all individuals are similarly susceptible to develop organ damage. Certain individuals develop severe hypertension-related organ damage even when blood pressure levels are not high, and others are highly resistant to end-organ damage despite very high levels of blood pressure. The explanation for this interindividual variability in the susceptibility to develop end-organ damage lies in genetic determinants of target organ damage. In the following sections, we will discuss what is known about genetic determinants of end-organ susceptibility in hypertension.

Stroke, the most dramatic expression of cerebrovascular accident (CVA) and one of the most common complications of hypertension, is a complex trait and not as a mere consequence of hypertension. Like other complex diseases, stroke appears to result from an interaction between several genetic and environmental factors. The identification of the genetic determinants of stroke, much like hypertension, is a difficult task in humans, due to the genetic heterogeneity of human populations and the confounding presence of other risk factors. It is nonetheless clear that there is a genetic predisposition to the interaction between stroke and hypertension. Clinical observations have shown that subjects with well-controlled hypertension can develop strokes, whereas others with severe hypertension may not develop stroke. What renders some individuals sensitive to hypertension-related stroke whereas others resistant is unclear, although individual genetic susceptibility must come into play. The genes that render susceptibility to stroke have been subject of intensive research over the past decade (Rubattu et al., 2004b). Much of the research has been using an animal model of stroke, the stroke-prone spontaneously hypertensive rat (Nagaoka et al., 1976; Yamori et al., 1992). Among the genes that these studies have uncovered and that predispose to hypertension-related stroke is the gene encoding atrial natriuretic peptide (ANP) which has been identified in the stroke-prone spontaneously hypertensive rat but also in two different human populations (Rubattu et al., 1999a, b). The gene encoding fibrinogen is another stroke-related gene. Elevated fibrinogen levels have also been suggested as a factor that increases the risk of stroke and carriers of the A allele of the fibrinogen-455G/A polymorphism have increased plasma fibrinogen levels. Hypertensive patients carrying the A allele have been found to have a four-fold increased risk for lacunar infarcts (Martiskainen et al., 2003). The role of the renin-angiotensin-aldosterone system (RAAS) genes in predisposing to hypertension-related stroke has been under intensive scrutiny, but the only positive association that has been detected so far is between ischemic stroke and the AT1 receptor C1166/AT1 gene allelic variant (Rubattu et al., 2004a). No other RAAS gene has been identified as contributing to stroke.

Hypertensive heart disease is a term applied generally to heart diseases that are caused by direct or indirect effects of elevated blood pressure. Prolonged elevation of blood pressure can lead to a variety of changes in the myocardial structure, coronary vasculature, and conduction system of the heart leading to

the development of left ventricular hypertrophy, coronary artery disease, various conduction system diseases, and systolic and diastolic dysfunction of the myocardium (Diamond and Phillips, 2005; Gradman and Alfayoumi, 2006; Prisant, 2005). The clinical manifestations are angina pectoris, myocardial infarction, cardiac arrhythmias (especially atrial fibrillation) and congestive heart failure. Even though hypertension predisposes to hypertensive heart disease, there appears not always to be a direct correlation between the level of blood pressure and the type and severity of damage to the heart. Individual predisposition, based on the genetic make-up, is likely to determine whether an individual with hypertension will develop hypertensive heart disease, the specific subtype of cardiac damage and its severity. What are the genes underlying the individual susceptibility to hypertensive-induced cardiac disease? Even though there is a vast amount of basic and clinical research that has been carried out on the genes involved in left ventricular hypertrophy, coronary heart disease, diseases of the conduction system and dysfunction of the myocardium, very little if any data are available at this time on the individual genetic susceptibility to develop these complications as result of hypertension, and certainly none is of any clinical usefulness. Stated otherwise, a vast amount of information is available on the genes involved in the various forms of heart disease secondary to hypertension, well beyond the scope of this chapter, but no data are yet available that might allow prediction who will and who will not develop these cardiac complications.

Hypertensive nephrosclerosis, another important complication of hypertension, is characterized by long-term essential hypertension, minimal proteinuria and progressive renal insufficiency (Luke, 1999). This type of nephrosclerosis accounts for 26% of patients reaching end-stage renal disease (ESRD) each year in the United States. Hypertension is considered the second most common cause of ESRD in white people (24%) and the leading cause of ESRD in black people (33%) (http://www.emedicine.com/med/topic1611.htm). Much like cerebrovascular disease and hypertensive heart disease, nephrosclerosis develops in susceptible individuals with hypertension, at times irrespective of their level of blood pressure (Rostand et al., 1989). Part of the individual susceptibility to develop nephrosclerosis is due to genetic factors. The presence of such genetic factors has been demonstrated in an experimental animal model in which two genetically different yet histocompatible kidneys were chronically and simultaneously exposed to the same blood pressure profile and metabolic environment within the same host. The kidney of the one strain was inherently much more susceptible to hypertension-induced damage than the kidney of the other strain (Churchill et al., 1997). There have been several attempts to identify the genes that underlie the susceptibility to hypertensive nephrosclerosis in both experimental models (Griffin and Bidani, 2004) and in humans (Griffin and Bidani, 2004; Hayden et al., 2003). Linkage studies in the fawn-hooded hypertensive rat followed by construction of congenic strains have suggested that genes influencing susceptibility to hypertension-associated renal failure may exist on rat chromosome 1q (St Lezin et al., 1999). In humans, several genes have been proposed as predisposing to hypertensive nephrosclerosis, including the homozygous 677TT mutation of the *MTHFR* gene (Koupepidou et al., 2005). A genetic predisposition to hypertensive nephrosclerosis has also been attributed to ethnic\racial groups. For example, in the Multiple Risk Factor Intervention Trial (MRFIT), a significant loss in kidney function was observed in African-American but not in Caucasian subjects despite similar control of blood pressure (Flack et al., 1993). Similarly, the Modification of Diet in Renal Diseases (MDRD) study demonstrated that at equivalent blood pressure, African-Americans had a greater rate of reduction in glomerular filtration rate than Caucasians (Hebert et al., 1997). One of the possible explanations for the discrepant susceptibility of African-Americans and Caucasian subjects has the prevalence of the *DD* genotype, which is more common in former than in the latter population and which has been associated with a higher prevalence of progressive renal disease (Duru et al., 1994). African-Americans with hypertension also have increased angiotensinogen mutations compared with hypertensive Caucasians (Bloem et al., 1995), but whether these are related to the increased susceptibility to nephrosclerosis remains to be determined.

Although some genetic variants have been identified or at least suggested for stroke and nephrosclerosis, the data have been so far derived from studies in select populations and have not been validated at large. Their relevance to the general population remains unclear, and their usefulness will have to be validated in future studies in well-defined populations before they can be applied to clinical practice and determination of the prognosis of the hypertensive patient.

PHARMACOGENOMICS

The complexity of essential hypertension and the uncertainty as to the underlying pathophysiology render the management of hypertension problematic. Currently, such management is based mostly on our clinical perception of high blood pressure, on our limited knowledge of the pathophysiology of hypertension and on experiments in clinical pharmacology that have successfully achieved a reduction in blood pressure. How does pharmacogenomics apply to hypertension and how can it affect our therapeutic approach to the disease?

Based on the achievements of pharmacogenomics in clinical fields other than hypertension, it is clear that this field of genomics has the potential to significantly improve the clinical management of hypertension. Pharmacogenomics can be used to predict the targeted therapeutic response of anti-hypertensive drugs, the hypotensive effect, as well as the occurrence of untoward side effects which may limit patient compliance and use of the drug. Pharmacogenomics can also be useful in the development of new anti-hypertensive drugs. The first two applications of pharmacogenomics will be discussed in this section.

The blood pressure response of individuals to any single drug is highly variable and clinically very difficult to predict.

Ideally, pharmacogenomics could improve our ability to predict the effectiveness of an anti-hypertensive drug in any given patient by correlating a genetic profile with the type of response. Such prediction, however, has been very difficult to come by, as hypertension is in most cases multifactorial and involves a complex interaction between multiple genes and environmental factors. One should also not overlook the potential contribution of gender, ethnic and racial factors to the individuals' response to anti-hypertensive drugs, which complicates matters even further. Any piece of evidence for a genomic effect may therefore need to be validated in each of the numerous population subtypes before it can be applied to clinical use. This may turn out to be a huge cost-ineffective task, unless a major gene effect is discerned that heavily impacts the anti-hypertensive response of a wide variety of populations.

Investigators in the field of pharmacogenomics, nonetheless, have made sincere efforts to try to correlate genetic variability within known candidate genes with therapeutic effects of anti-hypertensive drugs, hoping to utilize this information to improve the clinical response of patients to those drugs (Trotta et al., 2004). Are these efforts truly relevant to the field of pharmacogenomics, or do they pertain to the much older field of pharmacogenetics? There is a fundamental conceptual difference between the two terms (Yagil and Yagil, 2002). Pharmacogenetics relates to the study of how *individual genes* affect the way individuals respond to medications, whereas pharmacogenomics refers to how *the individual's genomic composition as a whole* affects the way individuals respond to medicines. Pharmacogenetics focus on how a single gene modulates the effect of drugs. Pharmacogenomics deals, on the other hand, with how the genome as a whole modulates the action of drugs, involving multiple genes at a time. The tasks of pharmacogenomics and pharmacogenetics are nonetheless similar. They consist of tailoring drug therapy to the individual by developing specific tests that allow the clinician to optimize the drug regimen. These tests ultimately aim to identify the most suitable patient-specific therapy that can reduce adverse events and improve outcome. The promise of pharmacogenomics has been to use genomic data to achieve these goals. The published literature attests, however, to the achievements of pharmacogenetics, and only little if at all to those of pharmacogenomics (Turner and Schwartz, 2005). The matter is further complicated by the differentiation within the field of pharmacogenetics between pharmacokinetics and pharmacodynamics. Pharmacokinetics deal with mechanisms that affect the level of the drug in blood and ultimately at its target and that are influenced by drug absorption, distribution, excretion and metabolism. Pharmacodynamics deal with mechanisms which determine the interaction of the drug with its target and the subsequent events in the cells, organs and systems (Schwartz and Turner, 2004).

Reviewing the achievements of pharmacogenetics in hypertension on the basis of published reports, it appears that the results have so far been limited mostly to the blood pressure response to drugs, and even there only a limited number of genetic polymorphisms of a limited number of candidate genes have so far been successfully associated with the blood pressure response to drugs (Marteau et al., 2005; Turner and Schwartz, 2005). Most of the data relate to genetic polymorphisms within the RAAS. Polymorphisms of the genes that encode for renin, angiotensinogen, angiotensin converting enzyme, angiotensin II receptor type 1, angiotensin II receptor type 2 and aldosterone synthase genes have all been associated with a hypotensive or a lack of hypotensive response to anti-hypertensive drugs including diuretics, beta-blockers, ACE inhibitors, angiotensin II receptor blockers and calcium channel blockers (Turner and Schwartz, 2005). Additional data relate to polymorphisms of genes involved in signal transduction pathways including the G-protein alpha and beta-3 subunits, the alpha-2 adrenergic and beta-1 and 2 adrenoreceptors, endothelin and adducin (Turner and Schwartz, 2005). Of particular interest is the association of the G460W adducin polymorphism and the anti-hypertensive response to thiazides which appears to be valid for some but not all populations (Schelleman et al., 2006).

Are these pharmacogenetic data useful in clinical practice? Theoretically, yes, as it should be possible to obtain the genetic profile of each patient and find the best matching hypotensive therapy for the individual patient. The difficulty lies, however, in that most patients whose blood pressure is difficult to manage require more than one anti-hypertensive drug for blood pressure control, and very often up to three or four drugs. Much of the available data that associate gene polymorphisms with the magnitude of the blood pressure response stem from studies that did not take into account drug interaction. Therefore, a gene polymorphism that has been associated with a lack of hypotensive response during monotherapy may be associated with a much improved response during combination therapy. An additional problem in applying currently available data is that the studies that have reported positive associations have used different combinations and different drug doses in populations of varying ages, sizes and ethnicity, each and all having a potential impact on the resulting data (Marteau et al., 2005). As a result, the clinical usefulness of the currently available pharmacogenetics data with regard to tailoring anti-hypertensive therapy to the patient is at best questionable at this time. One possible exception is the adducin paradigm in which six linkage studies, 18 of 20 association studies, and four of five follow-up studies that measured organ damage in hypertensive patients suggest a potential clinical impact of adducin polymorphism on the management of hypertension (Manunta and Bianchi, 2006). Are patients currently being tested for the adducin polymorphism prior to being prescribed a diuretic? The answer lies in the fact that it is currently much simpler to prescribe the diuretic and wait 1 month to assess the response than to send DNA for adducin genotyping. Should patient genotyping become in the future a routine procedure, it is possible that clinicians might take into consideration the adducin genotype prior to prescribing a thiazide diuretic for hypertension.

In addition to predicting the therapeutic response to drugs, an important task of pharmacogenomics would be to predict untoward side effects to drugs. One example is the

development of cough when using angiotensin converting enzyme (ACE) inhibitors; another is orthostatic hypotension when using alpha blockers. It is likely that some individuals are more prone to develop such side effects than others, and that genetically mediated factors are involved. The task of pharmacogenomics is to identify the genes involved and specific polymorphisms that are associated with such side effects. Some data are already available, for example with respect to ACEI and cough, which has been associated with the I/D ACE gene polymorphism in some studies (Takahashi et al., 2001) but not in others (Zee et al., 1998). Attempts to associate this cough with polymorphisms of the genes encoding for chymase and the B2-bradykinin receptors have failed (Zee et al., 1998). The clinical implementation of such data, however scarce they may be, has not materialized as yet.

The conclusion at this time is that genetic variants of candidate genes are promising tools for individualizing anti-hypertensive therapy, but that they are currently of little value in the clinical practice of hypertension. It is nonetheless important to be aware of the available data, as they most likely represent early reports of a field that is bound to break out and expand from pharmacogenetics into pharmacogenomics. Further well-disciplined research is required at a global scale to produce data that will become useful for the clinical management of hypertension.

2009 UPDATE

Despite the increasing availability of novel technological and bioinformatic tools, the search for the genes that are responsible for the common forms of hypertension is continuing to evolve into an ever-increasing challenge. The reason may lie in the accruing awareness of the complexity of the genome that bears direct relevance to the pathophysiology of hypertension, including mounting evidence for pleiotropy (one gene accounting for multiple traits), epistasis (gene-to-gene interaction) and molecular heterosis (Shih and O'Connor, 2008); for genome-environment (ecogenetic) (Franks, 2008), genome–sex (Cowley, 2006) and genome–ethnic interactions (Minor et al., 2008); as well as for the existence of genomic variations within protein-coding genes and within regulatory regions, including micro-RNAs (McBride et al., 2006) and copy number variations (Hamet and Seda, 2007). The task of unraveling the genetic basis of hypertension is further complicated by our current understanding that there is need to incorporate into the investigation not only the nuclear genome but also the mitochondrial genome (Puddu et al., 2007), the transcriptome, the proteome and the phenome, each representing a highly challenging task in itself. Nonetheless, the search for the genetic and pathophysiological basis of hypertension is relentless.

Currently, the emphasis is shifting from studies in experimental models of hypertension, which are amenable to genetic manipulations and which continue to generate large amount of genomic data, to large-scale studies of human populations in which associations are sought with genetic loci. There have been multiple such studies, notable amongst which are attempts to perform high-resolution mapping using microsatellite markers by the Japanese (Yatsu et al., 2007) and by the US NHLBI Family Blood Pressure Program (Gu et al., 2007), which have successfully yielded multiple additional hypertension-related loci. Also notable are recent major efforts in the form of genome-wide association studies using SNPs, such as the attempt by the Wellcome Trust Case Control Consortium (2007) to identify genes involved in common human diseases, including hypertension, which unfortunately failed to identify genes from physiological systems previously implicated by clinical or experimental studies in hypertension. The Framingham Heart Study of the US NHLBI (Levy et al., 2007), which similarly attempted to find hypertension-related genes, also failed to detect significant associations relating to blood pressure. In both studies, however, when the level of stringency was reduced, associations could be detected between multiple genomic loci and blood pressure, some of which confirmed previously identified loci, but none of which were truly robust. Hypertension research now faces the challenge of how to proceed after such major genome-wide association experiments failed to provide robust candidate genes.

The question arises whether hypertension-related genes of major impact may ever be found, as the concept that a large number of genes with small effects is becoming increasingly entrenched in our understanding of the pathophysiology of hypertension (Charchar et al., 2008). A realistic view is that, despite the advances in genomics, biotechnology and bioinformatics, a full understanding of the genetic basis of hypertension will not be quickly achieved (Cowley, 2006). Much more effort and investment is required both in experimental models of hypertension and in studies directly in humans with cross validation between the two, before genetic and genomic variants are found that will lead to new insights into the genes and regulatory pathways underlying essential hypertension. Applying large-scale genomic analyses combined with pathway-centered physiological profiling and novel computational approaches in animal models and in humans should enable the multidimensional integration that is required to further our understanding of the pathophysiology of hypertension.

CHAPTER

Lipoprotein Disorders

Sekar Kathiresan and Daniel J. Rader

INTRODUCTION

Plasma lipoproteins are integral to energy and cholesterol metabolism, but disorders involving lipoprotein metabolism can predispose to atherosclerotic vascular disease (ASCVD). Genetic factors play an important role in influencing lipoprotein metabolism and therefore plasma levels of the major lipoproteins and risk for cardiovascular disease. Molecular characterization of classic Mendelian monogenic lipoprotein disorders has provided major insights into the physiology and regulation of lipoprotein metabolism and new targets for therapeutic drug development. Much attention is now focused on greater elucidation of the genetic factors that influence the complex lipoprotein phenotypes that are much more common and important in influencing cardiovascular risk in the general population. Lipoprotein metabolism is a ripe area for the application of genomic medicine because of frequency with which plasma lipids are measured in clinical practice, the quantitative importance of genetics in determining their levels, the large number of gene products involved in lipoprotein metabolism, and the broad clinical relevance of the field to the most important cause of morbidity and mortality in most of the world.

OVERVIEW OF LIPOPROTEIN METABOLISM

Lipoproteins are large macromolecular complexes that transport hydrophobic lipids (primarily triglycerides, cholesterol, and fat-soluble vitamins) through body fluids (plasma, interstitial fluid, and lymph) to and from tissues. Lipoproteins play an essential role in the absorption of dietary cholesterol, long-chain fatty acids, and fat-soluble vitamins; the transport of triglycerides, cholesterol, and fat-soluble vitamins from the liver to peripheral tissues; and the transport of cholesterol from peripheral tissues to the liver. Lipoproteins contain a core of hydrophobic lipids (triglycerides and cholesteryl esters) surrounded by hydrophilic lipids (phospholipids, unesterified cholesterol) and proteins that interact with body fluids. The plasma lipoproteins are divided into five major classes based on their relative density: chylomicrons, very-low-density lipoproteins (VLDL), intermediate-density lipoproteins (IDL), low-density lipoproteins (LDL), and high-density lipoproteins (HDL). Each lipoprotein class comprises a family of particles that vary slightly in density, size, migration during electrophoresis, and protein composition. The density of a lipoprotein is determined by the amount of lipid per particle. HDL is the smallest and most dense lipoprotein, whereas chylomicrons and VLDL are the largest and least dense lipoprotein particles. Most plasma triglyceride is transported in chylomicrons or VLDL and most plasma cholesterol is carried as cholesteryl esters in LDL and HDL.

The proteins associated with lipoproteins, called apolipoproteins, are required for the assembly, structure, and function of lipoproteins. Apolipoproteins activate enzymes important in lipoprotein metabolism and act as ligands for cell surface receptors. ApoA-I, which is synthesized in the liver and intestine, is found on virtually all HDL particles. ApoA-II is the second most abundant HDL apolipoprotein and is on approximately two-thirds of all HDL particles. ApoB is the major structural

protein of chylomicrons, VLDL, IDL, and LDL; one molecule of apoB, either apoB-48 (chylomicrons) or apoB-100 (VLDL, IDL, or LDL), is present on each lipoprotein particle. The human liver synthesizes apoB-100 and the intestine makes apoB-48, which is derived from the same gene by mRNA editing. ApoE is present in multiple copies on chylomicrons, VLDL and IDL and plays a critical role in the metabolism and clearance of triglyceride-rich particles. ApoC-I, apoC-II, and apoC-III also participate in the metabolism of triglyceride-rich lipoproteins.

The exogenous pathway of lipoprotein metabolism involves the absorption and transport of dietary lipids to appropriate sites within the body (Figure 23.1). Dietary triglycerides are hydrolyzed by lipases within the intestinal lumen and emulsified with bile acids to form micelles. Dietary cholesterol, fatty acids, and fat-soluble vitamins are absorbed in the proximal small intestine. Cholesterol and retinol are esterified (by the addition of a fatty acid) in the enterocyte to form cholesteryl esters and retinyl esters, respectively. Longer-chain fatty acids (>12 carbons) are incorporated into triglycerides and packaged with apoB-48, cholesteryl esters, retinyl esters, phospholipids, and cholesterol to form chylomicrons. Nascent chylomicrons are secreted into the intestinal lymph and delivered through the thoracic duct directly to the systemic circulation, where they are extensively processed by peripheral tissues before reaching the liver. The particles encounter lipoprotein lipase (LPL), which is anchored to proteoglycans that decorate the capillary endothelial surfaces of adipose tissue, heart and skeletal muscle. The triglycerides of chylomicrons are hydrolyzed by LPL and free fatty acids (FFAs) are released; apoC-II, which is transferred to circulating chylomicrons from HDL, acts as a cofactor for LPL in this reaction. The released FFAs are taken up by adjacent myocytes or adipocytes and either oxidized to generate energy or re-esterified and stored as triglyceride. Some of the released FFAs bind albumin before entering cells, and are transported to other tissues, especially the liver. The chylomicron particle progressively shrinks in size as the hydrophobic core is hydrolyzed and the hydrophilic lipids (cholesterol and phospholipids) and apolipoproteins on the particle surface are transferred to HDL, creating chylomicron remnants. Chylomicron remnants are rapidly removed from the circulation by the liver through a process that requires apoE as a ligand for receptors in the liver.

The endogenous pathway of lipoprotein metabolism refers to the hepatic secretion of apoB-containing lipoproteins and their metabolism (Figure 23.2). VLDL particles resemble chylomicrons in protein composition but contain apoB-100 rather than apoB-48 and have a higher ratio of cholesterol to triglyceride (~1 mg of cholesterol for every 5 mg of triglyceride). The triglycerides of VLDL are derived predominantly from the esterification of long-chain fatty acids in the liver. The packaging of hepatic triglycerides with the other major components of the nascent VLDL particle (apoB-100, cholesteryl esters, phospholipids, and vitamin E) requires the action of the enzyme microsomal triglyceride transfer protein (MTP). After secretion into the plasma, VLDL acquires multiple copies of apoE and apolipoproteins of the C series by transfer from HDL. As with chylomicrons, the triglycerides of VLDL are hydrolyzed by LPL, especially in muscle and adipose tissue. After the VLDL remnants dissociate from LPL, they are referred to as IDL, which contain roughly similar amounts of cholesterol and triglyceride. The liver removes approximately 40–60% of IDL by LDL receptor–mediated endocytosis via binding to apoE. The remainder of IDL is remodeled by hepatic lipase (HL) to form LDL; during this process most of the triglyceride in the particle is hydrolyzed and all apolipoproteins except apoB-100 are transferred to other lipoproteins. The cholesterol in LDL accounts for over half of the plasma cholesterol in most individuals. Approximately 70% of circulating LDL is cleared by LDL receptor–mediated endocytosis in the liver. Lipoprotein(a) [Lp(a)] is a lipoprotein similar to LDL in lipid and protein composition, but contains an additional protein called apolipoprotein(a) [apo(a)]. Apo(a) is synthesized

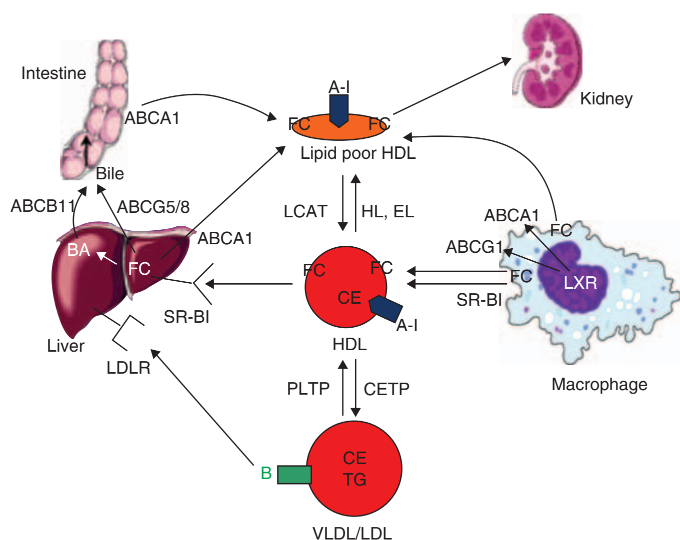

Figure 23.3 HDL metabolism and reverse cholesterol transport. This pathway transports excess cholesterol from the periphery back to the liver for excretion in the bile and feces.

in the liver and is attached to apoB-100 by a disulfide linkage. The major site of clearance of Lp(a) is the liver but the uptake pathway is not known.

HDL metabolism is complex (Figure 23.3) (Rader, 2006). Nascent HDL particles are synthesized by the intestine and the liver. Newly secreted apoA-I rapidly acquires phospholipids and unesterified cholesterol from its site of synthesis (intestine or liver) via efflux promoted by the membrane protein ATP-binding cassette protein A1 (ABCA1). This process results in the formation of discoidal HDL particles, which then recruit additional unesterified cholesterol from the periphery. Within the HDL particle, the cholesterol is esterified by lecithin-cholesterol acyltransferase (LCAT), a plasma enzyme associated with HDL, and the more hydrophobic cholesteryl ester moves to the core of the HDL particle. As HDL acquires more cholesteryl ester it becomes spherical, and additional apolipoproteins and lipids are transferred to the particles from the surfaces of chylomicrons and VLDL during lipolysis. HDL cholesterol (HDL-C) is transported to hepatoctyes by both an indirect and a direct pathway. HDL cholesteryl esters can be transferred to apoB-containing lipoproteins in exchange for triglyceride by the cholesteryl ester transfer protein (CETP). The cholesteryl esters are then removed from the circulation by LDL receptor–mediated endocytosis. HDL-C can also be taken up directly by hepatocytes via the scavenger receptor class BI (SR-BI), a cell surface receptor that mediates the selective transfer of lipids to cells. HDL particles undergo extensive remodeling within the plasma compartment by a variety of lipid transfer proteins and lipases. The phospholipid transfer protein (PLTP) has the net effect of transferring phospholipids from other lipoproteins to HDL. After CETP-mediated lipid exchange, the triglyceride-enriched HDL becomes a much better substrate for HL, which hydrolyzes the triglycerides and phospholipids to generate smaller HDL particles. A related enzyme called endothelial lipase (EL) hydrolyzes HDL phospholipids, generating smaller HDL particles that are catabolized faster. Remodeling of HDL influences the metabolism, function, and plasma concentrations of HDL.

PLASMA LIPID AND LIPOPROTEIN LEVELS AND ATHEROSCLEROTIC CARDIOVASCULAR DISEASE

Plasma total cholesterol was firmly established as an independent risk factor for cardiovascular disease in 1961 after researchers at the Framingham Heart Study demonstrated that participants with total cholesterol >245 mg/dl had a threefold increased risk of future coronary heart disease (CHD) compared with participants with a total cholesterol <210 mg/dl (Kannel et al., 1961). Subsequently, it was clarified that the two major lipoproteins carrying cholesterol, LDL and HDL, are associated with opposite influences on risk for cardiovascular disease, with LDL cholesterol (LDL-C) associated with increased risk and HDL-C with decreased risk. In observational studies, every 1 mg/dl increase in LDL-C has been shown to be associated with a 2% increased risk for cardiovascular disease, whereas every 1 mg/dl increase in HDL-C is associated with a 2–3% decreased risk (Gordon and Rifkind, 1989). For both LDL-C and HDL-C, there is a continuous, graded relationship between blood levels and subsequent risk for cardiovascular disease. Thus genetic factors that influence plasma levels of LDL-C and HDL-C are critically important to the risk of developing cardiovascular disease. The independent relationship of triglyceride levels and cardiovascular disease has been a topic of debate over the years, but recently a general consensus has developed that triglycerides are an independent predictor of risk for cardiovascular disease. Thus genetic factors that influence triglycerides are also important determinants of risk for cardiovascular disease.

INHERITED BASIS FOR BLOOD LIPID TRAITS

Though lipid levels are affected by many nongenetic factors, interindividual variability in lipids has been shown to have a strong inherited component. In simplest terms, an important role for shared genes is suggested by the fact that the correlation between family members for LDL-C, HDL-C, or triglycerides is considerably greater than that between unrelated individuals. Heritability, or the proportion of total phenotypic variance that is due to genetic variance, has been consistently estimated to be ~50% for the major blood lipid traits. For example, in the Framingham Heart Study, heritability for single time-point measurements of LDL-C, HDL-C, and triglycerides are 0.59, 0.52, and 0.48 (Kathiresan et al., 2007).

Broadly, traits that have an inherited basis may display a simple (or Mendelian) pattern of inheritance where variation at a single genetic locus is both necessary and sufficient to cause a phenotype. Alternatively, traits may depend on multiple genetic loci (or multifactorial inheritance). For blood lipid disorders, both patterns of inheritance are operational. Mendelian syndromes where LDL-C, HDL-C, or triglyceride levels are extremely high or low have been successfully studied and a number of specific genes have been isolated (see below). Knowledge derived from these genes has transformed our understanding of lipoprotein biology and treatment of cardiovascular disease (Goldstein and Brown, 2001). However, each of these syndromes is individually rare in the population and cannot explain the overall heritability of blood lipids.

Instead, blood lipid variation in the population depends on the additive effects of multiple loci. As initially demonstrated by the British geneticist R.A. Fisher in 1918 and now widely accepted, the additive effects of alleles at multiple loci can lead to a continuous trait that is normally distributed in the population. This is likely to be the case for blood lipid levels. However, several aspects of the underlying genetic architecture for lipid levels are unknown. Important unanswered questions are (1) how many loci affect blood lipid variation? and (2) at each locus, what is the number and frequency of alleles that affect risk? Emerging data from large population-based sequencing and genotyping studies suggests that the number of loci will be large, at least greater than 20. In addition, each locus is likely to harbor a spectrum of alleles rare and common in the population.

SCREENING FOR LIPID DISORDERS

Guidelines for the screening and management of lipid disorders have been established by an expert Adult Treatment Panel (ATP) convened by the National Cholesterol Education Program (NCEP) of the National Heart Lung and Blood Institute. The NCEP ATPIII guidelines published in 2001 recommend that all adults over age 20 to have plasma levels of cholesterol, triglyceride, LDL-C, and HDL-C measured after a 12-h overnight fast. In most clinical laboratories, the total cholesterol and triglycerides in the plasma are measured enzymatically and then the cholesterol in the supernatant is measured after precipitation of apoB-containing lipoproteins to determine the HDL-C. The LDL-C is estimated using the following equation: LDL-C = Total cholesterol − (Triglycerides/5) – HDL-C. (The VLDL-C is estimated by dividing the plasma triglyceride by 5, reflecting the ratio of cholesterol to triglyceride in VLDL particles.) This formula is reasonably accurate if test results are obtained on fasting plasma and if the triglyceride level does not exceed ~300 mg/dl, and by convention cannot be used if the TG are greater than 400 mg/dl. The accurate determination of LDL-C levels in patients with triglyceride levels greater than 300 mg/dl requires application of ultracentrifugal techniques or other direct assays for LDL-C. Further evaluation and treatment is based primarily on the plasma LDL-C level and the assessment of overall cardiovascular risk. The fact that screening for lipids is so widely performed has resulted in frequent identification of extreme lipid phenotypes due to Mendelian syndromes as well as widely available data for genetic studies in populations. Thus the genetics and genomics of lipids is among the most widely studied of complex genetic traits that are broadly clinically important.

GENETICS OF LDL-C

Studies of the genetic basis of substantially elevated or reduced LDL-C levels have provided major insights into the regulation of LDL metabolism and novel targets for therapeutic development. We first review the Mendelian disorders of high and low LDL-C (Table 23.1) and then review the current state of knowledge regarding common polymorphisms and their association with LDL-C levels.

Mendelian Disorders Primarily Causing Elevated LDL-C Levels

Familial Hypercholesterolemia (FH)

Familial hypercholesterolemia (FH) (Rader et al., 2003) is caused by loss-of-function mutations in the LDL receptor. Homozygous FH, caused by mutations in both LDL-receptor alleles, is a rare (approximately 1 in 1 million persons) condition characterized by markedly elevated cholesterol (greater than 500 mg/dl), cutaneous and tendon xanthomas, and accelerated atherosclerosis developing in childhood. Because they work through upregulation of the LDL receptor, statins, cholesterol absorption inhibitors, and bile acid sequestrants have only modest effects in reducing cholesterol. Liver transplantation is effective in decreasing LDL-C levels and gene therapy has been attempted. LDL apheresis is the therapy of choice at this time. Heterozygous FH is one of the most common (approximately 1 in 500 persons) single gene disorders. It is characterized by substantial elevations in LDL-C (usually 200–400 mg/dl), tendon xanthomas, and premature atherosclerotic cardiovascular disease. Treatment usually requires more than one drug, usually a statin plus a cholesterol absorption inhibitor and often a bile acid sequestrant and/or niacin. In some cases, LDL apheresis should be considered.

Familial Defective Apolipoprotein B-100 (FDB)

Familial defective apoB-100 (FDB) (Tybjaerg-Hansen and Humphries, 1992) is caused by mutations in the receptor binding region of apoB-100, which impairs its binding to the LDL receptor and delays the clearance of LDL. FDB is generally recognized as an autosomal dominant condition and occurs in approximately 1 in 700 persons of European descent. Like heterozygous FH, FDB is associated with elevated LDL-C and normal triglycerides. The most common mutation causing FDB is a substitution of glutamine for arginine at position 3500 in apoB-100; other mutations have also been reported that have a similar effect on apoB

TABLE 23.1 Mendelian disorders of lipoprotein metabolism

Genetic disorder	Gene	Lipoproteins affected	Clinical findings	Genetic transmission
LDL cholesterol				
Familial hypercholesterolemia	(*LDLR*)	↑ LDL	Tendon xanthomas, CHD	ACD
Familial defective apoB-100	(*APOB*)	↑ LDL	Tendon xanthomas, CHD	AD
Autosomal recessive hypercholesterolemia	(*ARH*)	↑ LDL	Tendon xanthomas, CHD	AR
Sitosterolemia	*ABCG5* or *ABCG8*	↑ LDL	Tendon xanthomas, CHD	AR
Autosomal dominant hypercholesterolemia	*PCSK9* (gain of function)	↑ LDL	Tendon xanthomas, CHD	AD
Abetalipoproteinemia	*MTP*	↓ LDL	Fat malabsorption, spinocerebellar degeneration, retinopathy, possible hepatic steatosis	AR
Hypobetalipoproteinemia	(*APOB*)	↓ LDL	Fat malabsorption, spinocerebellar degeneration, retinopathy, possible hepatic steatosis	ACD
PCSK9 deficiency	*PCSK9* (loss of function)	↓ LDL		ACD
HDL cholesterol				
APOA-I mutations	*APOA1*	↓ HDL		AD
Tangier disease	*ABCA1*	↓ HDL	Hepatosplenomegaly, enlarged orange tonsils, CHD	ACD
LCAT deficiency	*LCAT*	↓ HDL	Corneal opacification, hemolytic anemia, progressive renal insufficiency	AR
CETP deficiency	*CETP*	↑ HDL		AR
Triglycerides				
Lipoprotein lipase deficiency	(*LPL*)	↑ Chylomicrons	Eruptive xanthomas, hepatosplenomegaly, pancreatitis	AR
Familial apolipoprotein C-II deficiency	(*APOC2*)	↑ Chylomicrons	Eruptive xanthomas, hepatosplenomegaly	AR
Familial hepatic lipase deficiency	(*LIPC*)	↑ VLDL remnants	Premature atherosclerosis, pancreatitis	AR
Familial dysbetalipoproteinemia	(*APOE*)	↑ Chylomicron, and VLDL remnants	Palmar and tuberoeruptive xanthomas, CHD, PVD	AD

AD, autosomal dominant; ACD, autosomal co-dominant; AR, autosomal recessive.

binding to the LDL receptor. FDB is treated with statins and often additional drugs, similar to the treatment of heterozygous FH.

Autosomal Recessive Hypercholesterolemia (ARH)

Autosomal recessive hypercholesterolemia (ARH) (Garcia et al., 2001) is caused by mutations in the *ARH* gene, which produces a protein that regulates LDL receptor–mediated endocytosis in hepatocytes. ARH is very rare and in some ways the clinical presentation resembles homozygous FH. However, in contrast to FH, the condition is formally recessive and obligate heterozygotes have normal cholesterol levels. Statins and other LDL upregulating therapy sometimes result in partial LDL lowering response.

Autosomal Dominant Hypercholesterolemia (ADH)

Autosomal dominant hypercholesterolemia (ADH) is caused by apparent gain-of-function mutations in the proprotein convertase subtilisin/kexin type 9 (*PCSK9*) gene (Abifadel et al., 2003). PCSK9 is secreted by hepatocytes and appears to downregulate the density of functional LDL receptors in hepatocytes by promoting endosomal degradation rather than recycling of the receptor (Horton et al., 2007). Interestingly, loss-of-function mutations in this gene appear to cause low LDL-C levels (see below). The discovery of the molecular basis of ADH ultimately led to the identification of PCSK9 as a novel therapeutic target.

Sitosterolemia

Sitosterolemia is caused by mutations in one of two members of the adenosine triphosphate (ATP)-binding cassette (ABC) transporter family, ABCG5 and ABCG8 (Berge et al., 2000). These genes are expressed in the intestine and liver where they form a functional complex to limit intestinal absorption and promote biliary excretion of plant- and animal-derived neutral sterols. In sitosterolemia, normally the low level of intestinal absorption of plant sterols is markedly increased and biliary excretion of plant sterols is reduced, resulting in increased plasma levels of sitosterol and other plant sterols. Because the hepatic LDL receptor is downregulated, LDL-C levels tend to be high in this condition. Patients with sitosterolemia often have tendon xanthomas and are at risk for premature cardiovascular disease. Treatment of sitosterolemia is focused on dietary counseling, cholesterol-absorption inhibitors, and bile acid sequestrants, rather than statins.

Mendelian Disorders Primarily Causing Reduced LDL-C Levels

Abetalipoproteinemia

Abetalipoproteinemia is caused by mutations in the gene encoding microsomal transfer protein (MTP) (Sharp et al., 1993), a protein that transfers lipids to apoB in the ER, forming nascent chylomicrons and VLDL in the intestine and liver, respectively. It is a very rare autosomal recessive disease characterized by extremely low plasma levels of cholesterol and no detectable apoB-containing lipoproteins in plasma (Rader and Brewer, 1993). Abetalipoproteinemia is characterized clinically by fat malabsorption, spinocerebellar degeneration, pigmented retinopathy, and acanthocytosis. Most clinical manifestations of abetalipoproteinemia result from defects in the absorption and transport of fat-soluble vitamins, especially alpha tocopherol (vitamin E) which is dependent on VLDL for efficient transport out of the liver. The discovery of MTP as the basis of abetalipoproteinemia led to the concept of MTP inhibition as a novel therapeutic target for lowering LDL-C levels.

Familial Hypobetalipoproteinemia

Familial hypobetalipoproteinemia generically refers to low LDL-C levels that have a genetic basis. Historically it has been used to refer to low LDL-C due to mutations in apoB (Schonfeld et al., 2005). There is a range of missense and nonsense mutations in apoB that have been shown to reduce secretion and/or accelerate catabolism of apoB. Individuals heterozygous for these mutations generally have LDL-C levels less than 100 mg/dl. They appear to be protected from the development of ASCVD. There are rare patients with homozygous hypobetalipoproteinemia who have mutations in both apoB alleles and have plasma lipids similar to those in abetalipoproteinemia.

PCSK9 Deficiency

More recently, loss-of-function mutations in PCSK9 have also been shown to cause low LDL-C levels (Cohen et al., 2005; Kotowski et al., 2006), and therefore PCSK9 is another molecular cause of the generic phenotype of familial hypobetalipoproteinemia. The mechanism is uncertain, but presumably involves reduced PCSK9-mediated targeting of the LDL receptor to degradation pathways, resulting in upregulation of the hepatic LDL receptor and increased catabolism of LDL. This condition, which is more common in people of African descent, provided the opportunity to demonstrate that the effects of lifelong low LDL-C levels are a substantial reduction in CHD with no other adverse consequences (Cohen et al., 2006). This strongly supports the concept that aggressive LDL-C reduction is associated with long-term substantial reduction in cardiovascular risk.

Common Gene Variants Segregating in Populations with LDL-C Levels

Common gene variants within at least seven loci, *APOB*, *APOE*, *CILP2/PBX4*, *HMGCR*, *LDLR*, *PCSK9*, and *SORT1*, have been reproducibly related to LDL-C (Benn et al., 2005; Boright et al., 1998; Kathiresan et al., 2008a; Kotowski et al., 2006; Saxena et al., 2007; Sing and Davignon, 1985; Willer et al., 2008). In Table 23.2, we present representative associations of single nucleotide polymorphisms (SNPs) in these genes with LDL-C from a single community-based cohort study in southern Sweden, the Malmo Diet and Cancer Study-Cardiovascular Cohort (Berglund et al., 1993). These variants vary in frequency from 1% at *PCSK9* to 48% at *APOE*. These SNPs explain 0.5–1.7% of the interindividual variability in LDL-C in the population (Kathiresan et al., 2008b). In comparisons between the major and minor allele homozygote classes, the difference in LDL-C ranges from 4 mg/dl at *HMGCR* to 51 mg/dl at *PCSK9*. Variants in other genes have been reported to be associated with LDL-C but have been reproduced less frequently.

GENETICS OF HDL-C

Studies of the genetic basis of substantially reduced or elevated HDL-C levels have also provided important insights into the regulation of HDL metabolism and novel targets for therapeutic development. We first review the Mendelian disorders of low and high HDL-C (Table 23.1) and then review the current state of knowledge regarding common polymorphisms and their association with HDL-C levels.

Table 23.2 Association of common single nucleotide polymorphisms and low-density lipoprotein, high-density lipoprotein cholesterol or triglycerides in the Malmo Diet and Cancer Study – Cardiovascular Cohort[a]

SNP, single nucleotide polymorphism; MAF, minor allele frequency; M/M, major allele homozygote; M/m, heterozygote; m/m, minor allele homozygote.
[a] Plus–minus values are means ± sd. To convert values for cholesterol to millimoles per liter, multiply by 0.02586. To convert values for triglycerides to millimoles per liter, multiply by 0.01129;
[b] Association analyses were conducted using multivariable-adjusted lipid concentration (adjusted for age, age^2, sex, and diabetes status) as the phenotype;
[c] Within each cell are the alleles for the SNP on the forward strand of the human genome reference sequence (from National Center for Biotechnology Information Build 35), the mean unadjusted cholesterol value in mg/dl plus minus standard deviation in mg/dl, and the number of individuals of that genotype class.

Mendelian Disorders Primarily Causing Reduced HDL-C Levels

ApoA-I Deficiency and Structural Mutations

A rare cause of extremely low HDL-C is complete deficiency of apoA-I either from apoA-I gene deletion or nonsense mutations which result in virtually absent plasma HDL (Ng et al., 1994; Norum et al., 1982; Schaefer et al., 1982). Most of these cases are associated with premature CHD, consistent with the concept that apoA-I is atheroprotective and supportive of the concept that apoA-I elevation could be a therapeutic strategy. Another relatively rare cause of low HDL-C are missense or nonsense mutations that result in structurally abnormal or truncated apoA-I proteins. The best known of these mutations is apoA-I_{Milano}, where a substitution of cysteine for arginine at position 173 (Chiesa and Sirtori, 2003) results in increased turnover of the mutant apoA-I_{Milano} protein, as well of the wild-type apoA-I and a substantial reduction in HDL-C. The low HDL-C levels, however, are not associated with an increased risk of atherosclerosis. Animal studies with intravenous infusion of recombinant apoA-I_{Milano} show less atherosclerosis (Chiesa and Sirtori, 2003), and a small trial of the intravenous infusion of apoA-I_{Milano}–phospholipid complexes in humans demonstrated a reduction from baseline in coronary atheroma volume as measured by intravascular ultrasound (Nissen et al., 2003). There have been several other apoA-I structural mutations described that cause low HDL-C (von Eckardstein, 2005) but structural apoA-I mutations are rare, and in the general population apoA-I mutations are not a common source of variation in HDL-C levels.

Tangier Disease (ABCA1 Deficiency)

Tangier disease is caused by loss-of-function mutations in both alleles encoding the gene *ABCA1* (Bodzioch et al., 1999; Brooks-Wilson et al., 1999; Rust et al., 1999). It is characterized by cholesterol accumulation in the reticuloendothelial system causing enlarged orange tonsils, hepatosplenomegaly, intestinal mucosal abnormalities, and peripheral neuropathy, as well as markedly low HDL-C (<5 mg/dl) and apoA-I levels (Hobbs and Rader, 1999). The lack of ABCA1 results in markedly impaired efflux of cholesterol and phospholipids from cells to lipid-free apoA-I. The lack of intestinal and hepatic ABCA1 is probably largely responsible for the low HDL due to impaired lipidation of newly secreted apoA-I by these organs. Poorly lipidated apoA-I is then extremely rapidly catabolized. Impaired cholesterol efflux from other tissues, particularly macrophages, results in cholesterol accumulation leading to many of the typical clinical characteristics of this disorder. However, Tangier disease patients do not develop rapidly accelerated atherosclerosis to the extent one might expect based on the cholesterol efflux defect and the extremely low HDL-C levels. Heterozygotes for ABCA1 mutations have reduced HDL-C levels that are intermediate between Tangier disease and normal but have no evidence of cholesterol accumulation in tissues. However, they are at some increased risk for premature CHD. Mutations in ABCA1 have been found to cause low HDL-C levels in some families in which Tangier disease homozygotes are not found (Brooks-Wilson et al., 1999; Marcil et al., 1999). Rare private mutations in the *ABCA1* gene may even be a cause of low HDL-C levels in the general population (Cohen et al., 2004). As a result of the discovery of the molecular basis of Tangier disease, ABCA1 is now a major target for the development of new therapies intended to upregulate ABCA1 expression (Linsel-Nitschke and Tall, 2005).

Lecithin:Cholesterol Acyltransferase (LCAT) Deficiency

LCAT deficiency is caused by loss-of-function mutations in both alleles of the *LCAT* gene (Kuivenhoven et al., 1997). LCAT is the enzyme that esterifies the free cholesterol present on HDL to cholesteryl ester, creating a cholesteryl ester core and resulting in maturation of HDL. In the absence of functional LCAT and cholesterol esterification, mature HDL particles are not formed and nascent HDL particles containing apoA-I and apoA-II are rapidly catabolized (Rader et al., 1994). Two genetic forms of LCAT deficiency have been described, complete deficiency known as classic LCAT deficiency and partial deficiency known as fish-eye disease (Kuivenhoven et al., 1997). In addition to extremely low HDL-C, both types of LCAT deficiency are characterized by corneal opacification, but only individuals with complete LCAT deficiency have low-grade hemolytic anemia and progressive chronic kidney disease leading to end-stage renal disease. Interestingly, neither form of LCAT deficiency is clearly associated with premature coronary disease despite the markedly reduced HDL-C levels (Kuivenhoven et al., 1997), raising questions about the importance of LCAT in protecting against CHD. LCAT heterozygotes have relatively normal HDL-C levels. Nevertheless, promotion of LCAT activity is of therapeutic interest as an HDL-raising approach.

Mendelian Disorders Primarily Causing Elevated HDL-C Levels

Cholesteryl Ester Transfer Protein (CETP) Deficiency

CETP deficiency is caused by loss-of-function mutations in both alleles of the *CETP* gene (Brown et al., 1989). CETP transfers cholesteryl esters from HDL to apoB-containing lipoproteins in exchange for triglycerides (Rader, 2006). Lack of functional CETP results in markedly elevated HDL-C levels due to lack of HDL remodeling, accumulation of cholesteryl esters in HDL, and slower turnover of apoA-I and apoA-II (Ikewaki et al., 1993). LDL-C levels are also low because of increased catabolism of LDL and apoB with endogenous upregulation of the LDL receptor (Ikewaki et al., 1995). CETP deficiency is extremely rare outside Japan; among the Japanese the most common mutations are a 5′ donor splice site intron 14 G to A substitution and a missense mutation in exon 15 (D442G) (Inazu et al., 1990). Heterozygous individuals for CETP deficiency have 60–70% of normal CETP activity and only a modest increase in HDL-C levels, and otherwise normal LDL-C levels. Whether homozygous or heterozygous CETP deficiency is associated with increased, decreased, or unchanged cardiovascular risk remains to be resolved (Rader, 2004). Nevertheless,

the identification of CETP deficiency led to the concept that CETP is a therapeutic target for inhibition as an HDL-raising strategy (Rader, 2006). The current status of CETP inhibition is unclear due to failure of the CETP inhibitor torcetrapib, which caused increased mortality in a phase III outcomes trial (Tall et al., 2007).

Common Gene Variants Segregating in Populations with HDL-C Levels

Common gene variants within at least nine loci (*ABCA1*, *ANGPTL4*, *APOA5*, *cluster*, *CETP*, *GALNT2*, *LIPC*, *LIPG*, *MVK/MMAB* and *LPL*) have been reproducibly found to be associated with HDL-C (Boekholdt et al., 2005; Frikke-Schmidt et al., 2004; Guerra et al., 1997; Kathiresan et al., 2008a; Lai et al., 2004; Rip et al., 2006; Willer et al., 2008). Common genetic variation in the *ABCA1* gene is clearly associated with variation in HDL-C levels in the general population and may even be associated with CHD risk (Brousseau et al., 2001; Clee et al., 2001). Common *CETP* polymorphisms are also associated with HDL-C levels, though the association with CHD risk is less clear (Boekholdt and Thompson, 2003). The most commonly studied SNPs in *CETP* are the Taq1B polymorphism (associated with increased HDL-C) and the I405V SNP (also associated with modestly increased HDL-C) (Boekholdt and Thompson, 2003). In Table 23.2, we present representative associations of SNPs in these genes with HDL-C from a single community-based cohort study in southern Sweden, the Malmo Diet and Cancer Study-Cardiovascular Cohort (Berglund et al., 1993). The variants associated with HDL-C vary in frequency from 7% at *APOA5* to 49% at *CETP* (Kathiresan et al., 2008b). These SNPs explain 0.2–2.5% of the interindividual variability in HDL-C in the population. In comparisons between the major and minor allele homozygote classes, the difference in HDL-C ranges from 3 mg/dl at *ABCA1* for to 7 mg/dl at *APOA5*. In addition to the five genes in Table 23.2, the nonsynonymous variant in *ANGPTL4* (E40K) has been strongly related to HDL-C (Romeo et al., 2007).

GENETICS OF TRIGLYCERIDES

Studies of the genetic basis of substantially elevated triglyceride levels have been useful in understanding the regulation of triglyceride metabolism. We first review the Mendelian disorders of high triglycerides (Table 23.1) and then review the current state of knowledge regarding common polymorphisms and their association with triglyceride levels.

Mendelian Disorders Influencing Triglyceride Levels

Familial Chylomicronemia Syndrome (LPL Deficiency and ApoC-II Deficiency)

The familial hyperchylomicronemia syndrome (FCS) is caused by homozygosity for loss-of-function mutations in one of two genes, LPL and apoC-II (Santamarina-Fojo, 1992). These conditions are virtual phenocopies and are therefore discussed together. FCS is characterized by extreme hypertriglyceridemia (greater than 1000 mg/dl) usually presenting in childhood with acute pancreatitis, eruptive xanthomas, lipemia retinalis, and/or hepatosplenomegaly.

Chylomicron triglycerides are hydrolyzed in muscle and adipose capillary beds by LPL with apoC-II acting as a required cofactor, thus loss of function of either protein produces the phenotype of hyperchylomicronemia. Interestingly, despite the markedly elevated triglyceride (and cholesterol) levels, premature atherosclerotic cardiovascular disease is not generally a feature of this disease. This observation contributed to our understanding of the importance of the nature of lipoprotein, not just the lipid, in determining cardiovascular risk. Primary therapy is restriction of total dietary fat.

ApoAV Deficiency

Genetic deficiency of apoAV due to loss-of-function mutations on both alleles causes late-onset hyperchylomicronemia (Priore Oliva et al., 2005). In addition, heterozygosity for mutations such as Q139X can lead to the same phenotype due to a dominant negative effect (Marcais et al., 2005). ApoAV is a minor apolipoprotein that promotes LPL-mediated hydrolysis of lipoprotein triglycerides. Subjects with apoAV deficiency have a severe lipolysis defect and markedly reduced VLDL catabolism.

Familial Dysbetalipoproteinemia (Type III Hyperlipoproteinemia)

Familial dysbetalipoproteinemia (FD), or type III hyperlipoproteinemia, is caused by mutations in the gene for apolipoprotein E (apoE) (Mahley et al., 1999). ApoE on chylomicron and VLDL remnants normally mediates their catabolism by binding to receptors in the liver. FD is usually caused by homozygosity for a common variant called apoE2, which differs from the wild-type apoE3 form by a substitution of a cysteine for an arginine at position 158. ApoE2 has impaired binding to lipoprotein receptors such as the LDL receptor, resulting in defective removal of chylomicron and VLDL remnants. About 0.5% of individuals are homozygous for apoE2 but the prevalence of FD is only about 1 in 10,000, indicating that other genetic or environmental factors are required for expression of the phenotype. Because remnant lipoproteins are elevated and contain both triglycerides and cholesterol, plasma levels of both triglycerides and cholesterol are elevated. Palmar xanthomata and tuberoeruptive xanthomata on the elbows, knees, or buttocks are distinctive skin findings in this condition. Importantly, premature atherosclerotic CVD is common in this disorder, an observation that helped to clarify that remnant lipoproteins are highly atherogenic. This disorder is important from a clinical genomics sense, because it is one of the few genetic lipid disorders in which genotyping is clinically indicated for diagnosis; the finding of the *apoE2/E2* genotype is diagnostic in the appropriate clinical setting.

Hepatic Lipase Deficiency

Hepatic lipase (HL) deficiency is caused by loss-of-function mutations in both alleles of the *LIPC* gene (Hegele et al., 1993). HL deficiency is characterized by elevated plasma levels of cholesterol and triglycerides due to the accumulation of circulating lipoprotein remnants as a result of lack of HL activity. HL deficiency is very rare and therefore it is difficult to determine its true relationship to atherosclerotic CVD.

Common Gene Variants Segregating in Populations with Triglyceride Levels

Common gene variants within at least ten loci, *ANGPTL3*, *ANGPTL4*, *APOB*, *APOA5*, *CILP2/PBX4*, *GALNT2*, *GCKR*, *LPL*, *MLXIPL*, and *TRIB1*, have been reproducibly related to triglyceride levels (Benn et al., 2005; Kathiresan et al., 2008a; Kooner et al., 2008; Pennacchio et al., 2001; Rip et al., 2006; Saxena et al., 2007; Willer et al., 2008). In Table 23.2, we present representative associations of SNPs in these genes with triglycerides from a single community-based cohort study in southern Sweden, the Malmo Diet and Cancer Study-Cardiovascular Cohort (Berglund et al., 1993). These variants vary in frequency from 7% at *APOA5* to 48% at *APOB*. These SNPs explain 0.3–0.7% of the interindividual variability in triglyceride in the population (Kathiresan et al., 2008b). In comparisons between the major and minor allele homozygote classes, the difference in triglycerides ranges from 9 mg/dl at *APOB* to 39 mg/dl at *APOA5*. In addition to these variants, the same 3% nonsynonymous variant in *ANGPTL4* noted above with regard to HDL-C has been related to triglyceride level (Romeo et al., 2007).

GENETIC LIPID DISORDERS WITHOUT CURRENT PROVEN MOLECULAR ETIOLOGY

Familial Combined Hyperlipidemia (FCHL)

Familial combined hyperlipidemia (FCHL) is a dominantly inherited condition characterized by elevated triglycerides, elevated cholesterol, and reduced HDL-C (Grundy et al., 1987). Premature ASCVD is common in patients with FCHL. The metabolic basis of FCHL is thought to be hepatic overproduction of VLDL. It is the most common inherited lipid disorder, with a prevalence of approximately 1 in 200 persons. The genetic basis of FCHL is not well understood, and probably several different genes can cause a similar phenotype (Shoulders et al., 2004; Suviolahti et al., 2006). Genome-wide linkage studies have demonstrated a repeated linkage of FCHL to a locus on chromosome 1q21-q23 (Coon et al., 2000; Pajukanta et al., 1998), and association with SNPs in the gene encoding the upstream transcription factor 1 (USF1) has been repeatedly shown to be associated with the FCHL phenotype (Coon et al., 2005; Pajukanta et al., 2004). Because USF1 is a transcription factor known to regulate the expression of genes involved in lipid metabolism (Lee et al., 2006), it is plausible, though unproven, that genetic variation in USF1 expression or function could cause the phenotype of FCHL. However, the mechanisms of this association are unknown, and other genes likely contribute to the phenotype of FCHL. The molecular basis of FCHL is one of the most important questions in the field of the genomics of lipid disorders, and additional discoveries in this area are likely to provide important insights into the pathophysiology of hepatic VLDL overproduction as well as new targets for the development of new therapies for lipid disorders.

Familial Hypertriglyceridemia (FHTG)

Familial hypertriglyceridemia (FHTG) is an autosomal dominant trait characterized by elevated triglycerides with normal or only modestly increased total cholesterol levels, and LDL-C levels are usually normal. In contrast to FCHL, FHTG is often not associated with increased risk of ASCVD. Both VLDL overproduction and reduced VLDL catabolism have been implicated in causing this phenotype, but the pathophysiology is not well understood. The molecular basis of FHTG has not yet been elucidated.

Familial Hypoalphalipoproteinemia

Familial hypoalphalipoproteinemia is a dominantly inherited trait characterized by low HDL-C levels, usually in the setting of relatively normal TG levels. Premature CVD is often, but not always, associated with this condition. Accelerated catabolism of apoA-I is thought to be the metabolic basis of this trait (Lewis and Rader, 2005). ABCA1 mutations can cause this phenotype, but this phenotype occurs in families without ABCA1 mutations and is likely caused by mutations in more than one other gene.

Familial Hyperalphalipoproteinemia

Familial hyperalphalipoproteinemia is a dominantly inherited trait characterized by high HDL-C levels. This trait is usually, but not always, associated with lower risk for CHD and increased longevity. Interestingly, while homozygous CETP deficiency is a cause of hyperalphalipoproteinemia as discussed above, obligate heterozygotes for CETP generally do not have exceptionally elevated HDL-C levels. The molecular basis of this condition is not known, but the discovery of genes that cause this phenotype would increase our understanding of the regulation of HDL metabolism and potentially provide new targets for the development of therapeutics for raising HDL.

INFLUENCE OF LIPID-MODULATING MUTATIONS ON RISK OF ATHEROSCLEROTIC CARDIOVASCULAR DISEASE

Mendelian Syndromes and ASCVD

With regard to LDL, the recognition of FH was instrumental in proving that elevated LDL-C levels cause accelerated ASCVD

without a requirement for additional traditional risk factors. This observation strongly supported the concept that reduction in LDL-C would reduce risk of ASCVD, a hypothesis subsequently proven with large CV outcome trials. Other Mendelian syndromes of elevated LDL-C, such as FDB, ARH, and ADH, though less common, have also been associated with early onset ASCVD, consistent with this concept. Mendelian syndromes of low LDL are generally not common enough to allow definitive demonstration of protection against ASCVD (much more difficult to prove than accelerated disease), but studies of patients with hypobetalipoproteinemia due to apoB mutations are consistent with the concept that the risk of CVD is reduced (Schonfeld et al., 2005). Overall, the study of Mendelian disorders of high and low LDL has had a major impact on the understanding of the role of LDL as a risk factor for atherogenesis.

Mendelian syndromes of HDL are generally not prevalent enough to allow definitive proof of a relationship to CVD. However, inability to synthesize apoA-I, while rare, has been consistently associated with accelerated ASCVD (Norum et al., 1982; Schaefer et al., 1982). In contrast, Tangier disease, while associated with similarly extremely low HDL-C levels, has not been associated with markedly increased ASCVD (Schaefer et al., 1980). In a similar fashion, LCAT deficiency is also associated with extremely low HDL but is also not associated with increased CVD (Kuivenhoven et al., 1997). Conversely, while CETP deficiency is associated with extremely elevated HDL-C levels, its relationship to CVD still remains uncertain.

Finally, the sole Mendelian disorders associated with hyperchylomicronemia, LPL deficiency and apoC-II deficiency, have not been convincingly associated with increased cardiovascular risk, confirming the relative lack of atherogenicity of chylomicrons. Conversely, FD (type III hyperlipoproteinemia) is also associated with elevated triglycerides but in this case due to elevated remnant lipoproteins, and causes substantially increased risk of ASCVD. These Mendelian disorders of elevated triglycerides demonstrate that it is the nature of the lipoprotein that is elevated, not the plasma level of triglycerides *per se*, that determines the risk of atherosclerosis.

Common Mutations in Aggregate Affecting CVD Risk

As common SNPs influence blood lipid levels and blood lipids affect risk for cardiovascular disease, a natural question is whether lipid-modulating SNPs influence risk for cardiovascular disease. One of the best examples illustrating this issue is that of PCSK9, with relatively common variants Y142X or C679X causing reduced LDL-C levels and substantially reduced risk of CHD (Cohen et al., 2006). However, for many other common variants that influence LDL-C (e.g., at the *APOB* and *APOE* loci), the connection to cardiovascular disease has less compelling evidence. Likewise, common SNPs in CETP and HL that reproducibly influence HDL-C levels have not been definitively associated with cardiovascular outcomes; the same is true for common SNPs that influence plasma triglyceride levels. A key limiting factor may be that each common SNP only modestly affects the lipid level. This raises the hypothesis that a combination of lipid-modulating SNPs might contribute to risk for cardiovascular disease. With the recent establishment of several reproducible associations for each of the three lipid traits, it is now feasible to test this hypothesis in prospective studies. The identification of a panel of lipid polymorphisms that influence CVD risk could help target preventive therapies or aid in risk prediction at the population level.

FUTURE DIRECTIONS IN GENETICS AND GENOMICS OF LIPOPROTEINS

Over the next few years, the widespread application of the genome-wide association study (GWAS) method is expected to lead to substantial progress in defining the inherited basis for blood lipids. The GWAS is defined as an experiment in which a substantial set of common SNPs across the genome (~300,000–500,000 SNPs) are simultaneously tested for association with disease or quantitative risk factors for disease (Hirschhorn and Daly, 2005). Blood lipid levels and ASCVD are among the phenotypes being widely studied by this approach and the early results are promising. Table 23.3 summarizes the design features of several GWASs recently completed or in progress for lipid or ASCVD phenotypes.

For blood lipids, an early example is the Diabetes Genetics Initiative of Broad, Lund And Novartis. This study was designed to examine type 2 diabetes but 18 other phenotypes including blood lipids were analyzed as secondary traits (Saxena et al., 2007). Patients with type 2 diabetes and controls were genotyped for ~500,000 SNPs across the genome and these SNPs were tested for association with blood LDL-C, HDL-C, triglycerides, apoB, apoA-I, and apoA-II. Several findings from this study highlight key issues in defining the genetic basis for lipid levels. First, the largest effect size for a common SNP approached ~2% of trait variance explained (e.g., an *APOE* cluster SNP at 2.1% of LDL-C variance and a *CETP* SNP at 2.1% for HDL-C variance). As most other common variants will each individually confer a more modest effect size (<1% of trait variance explained), large sample sizes will be needed to convincingly demonstrate that a gene variant influences lipid levels. Second, several loci with common alleles affecting lipid levels (*APOE*, *ABCA1*, *APOA5*, *CETP*, *LIPC*, and *LPL*) have also been shown to cause Mendelian syndromes or contain multiple rare alleles. Thus, sequencing all loci with validated common alleles will be required to define the spectrum of common and rare alleles at each locus and the full impact of each locus on trait variation. Third, loci previously unsuspected to play a role in lipid phenotypes may be identified using an unbiased discovery approach such as GWAS. For example, a highly significant association with triglycerides was observed for rs780094 ($P = 3.7 \times 10^{-8}$), explaining 1% of residual variance in triglyceride levels. This single SNP was then tested in 5217 individuals from the Malmö

TABLE 23.3 Selected genome-wide association studies for atherosclerotic cardiovascular disease and/or lipid phenotypes

Study	Ascertainment scheme	Ancestry	N	Phenotypes
Diabetes Genetics Initiative (Saxena et al., 2007)	Cases with type 2 diabetes, controls free of diabetes from Sweden and Finland	European	2931	LDL-C, HDL-C, triglycerides, apolipoproteins
FUSION (Scott et al., 2007)	Cases with type 2 diabetes, controls free of diabetes from Finland	European	2457	LDL-C, HDL-C, triglycerides
SardiNIA (Scuteri et al., 2007)	Family-based sample from 4 towns in Sardinia, Italy	European	4305	LDL-C, HDL-C, triglycerides
Framingham Heart Study (Splansky et al., 2007)	Community-based prospective cohort study from single town in Framingham, USA	European	~9000	LDL-C, HDL-C, triglycerides, apolipoproteins, lipoprotein subfractions, others
Atherosclerosis Risk in Communities (ARIC, 1989)	Community-based prospective cohort study, four communities in United States	European, African-American	~16,000	LDL-C, HDL-C, triglycerides, apolipoproteins, others
Kosrae (Bonnen et al., 2006)	Founder population on island in South Pacific	Asian	~3000	LDL-C, HDL-C, triglycerides
Jackson Heart Study (Wilson et al., 2005)	Community-based prospective cohort study from single town in United States	African-American	~4000	LDL-C, HDL-C, triglycerides
McPherson et al. (2007)	Hospital-based case collection; incident cases from two community-based cohort studies, and prevalent coronary artery calcium in a community-based cohort study	European	4277 cases, 20,054 controls	Coronary artery bypass grafting, angioplasty, myocardial infarction, coronary artery calcium
DeCode (Helgadottir et al., 2007)	Population-based registry from Iceland	European	4589 cases, 12,768 controls	Myocardial infarction
WTCCC (WTCCC, 2007; Samani et al., 2007)	UK-wide ascertainment of cases aged <66 with at least one affected sibling	European	1988 cases, 3004 controls	Myocardial infarction, coronary artery bypass surgery or angioplasty
German MI Family Study (Samani et al., 2007)	Premature MI and at least one first-degree relative with premature CAD; cases from cardiac rehabilitation programs	European	875 cases, 1644 controls	Myocardial infarction
Myocardial Infarction Genetics Consortium (MIGen)	Premature MI; 3 hospital-based case collections, a community-based ascertainment of cases, and cases from two prospective cohort studies	European	~3300 cases, ~3300 controls	Early-onset myocardial infarction
PennCath/Medstar	Cardiac cath-lab based collection of premature angiographic CAD with or without history of MI; controls older and free of CAD by angiography	European	~1000 cases with MI, ~1000 cases without MI, ~1000 controls	Obstructive coronary atherosclerosis on angiography, MI, LDL-C, HDL-C, triglycerides, apolipoproteins, others

Diet and Cancer Study–Cardiovascular Cohort and the association was replicated ($P = 8.7 \times 10^{-8}$). This SNP resides within the gene glucokinase regulatory protein (*GCKR*), which regulates glucokinase (GCK), the first enzyme in the glycolytic pathway, and has the potential to influence hepatic TG synthesis.

For ASCVD, three separate studies have identified a locus on chromosome 9p21 as reproducibly and highly significantly associated with myocardial infarction (MI) or coronary artery disease (Helgadottir et al., 2007; McPherson et al., 2007; Samani et al., 2007). The risk allele at 9p21 is common at ~47% frequency in

controls, and each copy of the risk allele increases risk by ~25%. The associated SNPs exist in a 190-kilobase region of strong linkage disequilibrium which contains two cyclin-dependent kinase inhibitors – CDKN2A and CDKN2B. Though the association is robust, the mechanism behind which the associated SNPs confer risk for MI or coronary artery disease remains to be defined. In addition to the 9p21 variant, the study by Samani et al. (2007) highlighted six other loci with either convincing or suggestive evidence for association. From the three initial GWASs for ASCVD, it is clear that the effect sizes of common variants will be less than an odds ratio of 1.4 per copy of the risk allele. Several of the newly discovered loci, including 9p21, do not seem to be acting through established risk factors such as lipids. As additional studies are performed, the number of loci and alleles affecting ASCVD should become clear.

PHARMACOGENETICS OF LIPID-MODULATING THERAPIES

Drug therapy to modulate lipids with the goal of preventing or treating atherosclerotic cardiovascular disease is well established clinically and commonly used in practice. The three major classes of drugs used to reduce LDL-C are HMG CoA reductase inhibitors (statins), cholesterol absorption inhibitors (currently ezetimibe is the only member of this class), and bile acid sequestrants. The three major classes of drugs used to treat the HDL-TG axis are nicotinic acid (niacin), PPARα agonists (fibrates), and omega 3 fatty acids ("fish oils"). Interindividual variability in response to all of these classes is substantial and undoubtedly influenced by genetic factors. A limited number of studies have investigated the genetic variation underlying response to lipid-modifying drugs.

Statins inhibit 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase, the rate-limiting step in cholesterol biosynthesis, and in doing so alter cholesterol metabolism in the hepatocyte, resulting in compensatory upregulation of the LDL receptor, leading to increased LDL catabolism. A few studies have investigated candidate genes with regard to variability in LDL-lowering response to statins. In a study involving the treatment of 1536 healthy persons with moderate hypercholesterolemia with pravastatin 40 mg for 24 weeks, 148 SNPs in 10 candidate genes were assessed with regard to LDL-C reduction. Two common SNPs in strong linkage disequilibrium, rs17244841 and rs17238540, in the gene encoding HMG-CoA reductase were significantly associated with reduced LDL-C reduction on pravastatin (Chasman et al., 2004). In another study in 1360 individuals on atorvastatin therapy, 43 SNPs in 16 candidate genes were assessed with regard to LDL-C reduction. A significant association with HMG-CoA reductase was not found, but a modest significant association with the *apoE2* polymorphism was noted, whereby heterozygotes had 3.5% greater LDL-C reduction (Thompson et al., 2005). Thus the majority of the variability in statin response remains unexplained by the existing candidate gene studies.

Ezetimibe inhibits cholesterol absorption in the small intestine by binding to the enterocyte brush border cholesterol transporter NPC1L1. This reduces cholesterol transport from intestine to liver and results in secondary compensatory upregulation of the LDL receptor, leading to increased LDL catabolism. Hegele and colleagues identified a patient who exhibited extremely poor clinical response to ezetimibe with regard to LDL lowering and sequenced the *NPC1L1* gene, finding two rare nonsynonymous polymorphisms in NPC1L1, V55I and I1233N, that were absent in control subjects and suggesting that compound heterozygosity for these mutations may have caused the lack of response to ezetimibe (Wang et al., 2005). In a follow-up study, 101 dyslipidemic subjects were treated with ezetimibe for 12 weeks and common *NPC1L1* SNPs and haplotype were assessed for association with LDL-C reduction. Subjects treated with ezetimibe lacking the common NPC1L1 haplotype 1735C-25342A-27677T had significantly greater reduction in LDL-C (36%) than subjects with at least one copy of this haplotype (24%) (Hegele et al., 2005). Thus genetic variation in NPC1L1 appears to influence the response to ezetimibe treatment.

Nicotinic acid activates the G protein-coupled receptor GPR109A on adipocytes, resulting in reduced adipocyte triglyceride lipolysis and FFA release and reduced flux of FFA to the liver (Offermanns, 2006). This is believed to be the primary mechanism of TG-lowering of nicotinic acid; the mechanism of HDL-raising remains uncertain. While polymorphisms in GPR109A have been described (Zellner et al., 2005), no studies of the pharmacogenetics of niacin response have been reported to date. Fibrates are PPARα agonists that activate the transcription of a variety of lipid metabolism genes in multiple tissues, including muscle, adipose, and liver. The triglyceride lowering and modest HDL-raising mechanisms of fibrates are due to regulation of several genes, including LPL, apoA-I, and apoC-III. Only a few pharmacogenetic studies of fibrate lipid responses have been reported to date. In 292 hypertriglyceridemic subjects treated with fenofibrate for 3 months, the TG-lowering response to fenofibrate was reduced in carriers of the P207L mutation in LPL and greater in carriers of the apoE2 polymorphism and the L162V polymorphism in PPARα (Brisson et al., 2002). In 791 hypertriglyceridemic subjects treated with fenofibrate for 3 weeks, carriers of the C56G tagSNP in *APOA5* had a greater decrease in TG and increase in HDL-C (Lai et al., 2007). Interestingly, carriers of C56G also had a greater response to fenofibrate after a defined fat load. Thus, genetic variation clearly plays a role in determining fibrate response, though additional work is required.

IMPLICATIONS OF GENOMICS OF LIPOPROTEIN METABOLISM FOR THE DEVELOPMENT OF NOVEL THERAPIES

The study of the genetics and genomics of lipoprotein metabolism has led to several novel therapeutic targets. The discovery of the molecular basis of FH being mutations in the LDL receptor

led to the concept that upregulation of the LDL receptor could be a strategy for reducing plasma levels of LDL-C. While statins were developed based on their ability to inhibit HMG-CoA reductase, the rate-limiting step in cholesterol biosynthesis, their physiological effect in the liver is upregulation of the LDL receptor with consequent reduction in LDL-C levels. Despite the success of statins and other LDL-lowering therapies such as cholesterol absorption inhibitors, there remains a need for additional LDL-lowering therapies. The fact that mutations that impair the biosynthesis of apoB cause reduced LDL-C levels supports the concept of targeting apoB therapeutically. While small molecule approaches to apoB inhibition are impractical, an approach using an antisense oligonucleotides (ASO) has been shown to be effective in animal models as well as in humans. The efficacy of an ASO targeted to apoB (apoB-ASO) was demonstrated in hypercholesterolemic mice (Crooke et al., 2005). In a phase I multiple-dose study in subjects with mild dyslipidemia, subcutaneous injection of an apoB-ASO reduced plasma apoB by up to 50% and LDL-C by up to 44% (Kastelein et al., 2006). Alternatively, small-interfering RNA (siRNA) molecules complementary to apoB mRNA also significantly reduced the plasma concentration of apoB-containing lipoproteins in nonhuman primates (Zimmermann et al., 2006). Thus inhibition of apoB expression using systemic administration of either an ASO or siRNA to apoB reduces LDL-C levels comparable to that seen in subjects heterozygous for familial hypobetalipoproteinemia.

As discussed above, another Mendelian disorder associated with low LDL-C levels is abetalipoproteinemia. The discovery that genetic deficiency of MTP causes abetalipoproteinemia led to the concept that MTP inhibitors would disrupt VLDL assembly and secretion, with consequent reductions in circulating LDL (Burnett and Watts, 2007). Indeed, studies in mouse models have demonstrated that small molecule inhibitors of MTP effectively reduce plasma levels of total and LDL-C (Liao et al., 2003; Spann et al., 2006). Furthermore, an MTP inhibitor was shown to be effective in substantially reducing cholesterol in the Watanabe heritable hyperlipidemic (WHHL) rabbit, a model of homozygous FH (Wetterau et al., 1998). Finally, a small clinical trial in six subjects with homozygous FH definitively demonstrated that MTP inhibition reduces LDL-C levels in humans by reducing hepatic apoB production (Cuchel et al., 2007). After titrating the dose over 4 months, LDL-C was reduced by 51% and apoB by 55% at the highest dose of the MTP inhibitor. ApoB kinetic studies demonstrated a marked reduction in LDL apoB production as the basis for the reduction in LDL-C and apoB. This trial also demonstrated the mechanism-based increase in hepatic steatosis associated with MTP inhibition, which occurred in four of the six subjects. While this clearly requires more study, including longer-term trials, it is possible that high-dose MTP inhibition could be developed as an orphan drug approach for homozygous FH patients and that lower doses of MTP inhibition could potentially have a role in treating patients who are unable to reach LDL-C goal on present therapies.

The story of PCSK9 provides the best example in the lipoprotein field of how human genetics can identify novel therapeutic targets. As discussed above, it was first discovered that rare nonsynonymous variants of PCSK9 can cause a form of ADH (Abifadel et al., 2003). After studies of overexpression of PCSK9 in mice unexpectedly caused elevated LDL-C levels (Benjannet et al., 2004; Maxwell and Breslow, 2004), loss-of-function mutations in PCSK9 were shown to result in substantially reduced LDL-C levels (Cohen et al., 2005). Importantly, individuals heterozygous for loss-of-function mutations in PCSK9 were subsequently shown to have markedly reduced lifetime risk of CHD (Cohen et al., 2006; Kathiresan et al., 2008c). A compound heterozygote with loss-of-function mutations in both *PCSK9* alleles has been reported to have a very low LDL-C but is in good health (Zhao et al., 2006). Thus, inhibition of PCSK9 is an extremely attractive target based on the human genetics. Because PCSK9 is upregulated by statin therapy, the addition of a PCSK9 inhibitor to a statin could result in additive or even synergistic reduction of LDL-C.

Investigation of the human genetics of HDL has provided important information regarding potential therapeutic targets. The fact that LCAT deficiency is a cause of severely low HDL supported the concept that LCAT upregulation or stimulation would be a strategy for raising HDL. More importantly, the discovery of *ABCA1* as the mutated gene in Tangier disease created immediate interest in ABCA1 as a therapeutic target for upregulation as a strategy to raise HDL-C levels and inhibit or regress atherosclerosis. Perhaps the best example of human genetics identifying a potential therapeutic target for HDL is that of CETP deficiency. As noted above, CETP-deficient subjects have markedly elevated HDL levels, directly identifying CETP as a target for inhibition as an approach to raising HDL. While the first CETP inhibitor to enter phase III, torcetrapib, failed to reduce cardiovascular events, it has the off-target property of raising blood pressure. Thus the status of CETP inhibition as a therapeutic approach remains uncertain. Other molecular causes of high HDL could provide additional new targets for therapeutic development.

CLINICAL RECOMMENDATIONS FOR GENETIC TESTING FOR LIPID DISORDERS

The majority of lipid disorders are diagnosed based on the clinical presentation, and genetic testing is not usually clinically indicated. For example, while heterozygous FH has a prevalence of 1 in 500 individuals, the majority of LDL-receptor mutations are (with the exception of a few regions in which a founder effect is present) private and could not be screened for short of sequencing. Furthermore, knowledge of the specific mutation, or even that the gene defect is in the LDL receptor and not, for example, in apoB, has no direct impact on the clinical care of the patient. Therefore, in FH genetic screening is not recommended. One exception to this might be in prenatal diagnosis of homozygous

FH. If both parents have heterozygous FH, the chance of a homozygous child is one in four. Knowledge of the specific mutations in each parent (which would require sequencing) could permit prenatal testing for these mutations. This same rationale and approach could be applied to other serious lipoprotein disorders, for example, abetalipoproteinemia in which knowledge of the specific mutation(s) through sequencing could be used for prenatal diagnosis.

The one major exception in which genetic testing is clinically recommended for diagnosis of lipid disorders is in the definitive diagnosis of FD (also called type III hyperlipoproteinemia). If this diagnosis is suspected on clinical grounds, it can be confirmed by performing apoE genotyping (with a focus on the apoE2 polymorphism). The finding of homozygosity for apoE2/E2 in the appropriate clinical setting is diagnostic for FD, and may help with clinical management decisions and family counseling. Interestingly, clinical apoE genotyping generally includes typing for not only the apoE2 but also the apoE4 polymorphism. This is not associated with FD, but is associated with Alzheimer's disease, raising the issue of providing unwanted genetic prognostic information that has no immediate clinical utility and could impact on issues such as insurability if recorded in the medical record. Thus, while clinically appropriate, apoE genotyping should be performed only after careful consideration, and ideally should be limited to typing for the apoE2 polymorphism when being done for diagnosis of FD.

2009 UPDATE

Progress continues to be made in applying the GWAS approach to the discovery of novel loci associated with variation in plasma lipid levels. Kathiresan et al. (2009) utilized approximately 40,000 persons assembled from cohorts, case-control studies, and clinical trials to identify 30 distinct loci associated with lipoprotein concentrations (at a genome-wide significant p value of $<5 \times 10^{-8}$), including 11 loci that had not previously been identified as genome-wide significant. The 11 newly defined loci included *ABCG8*, *MAFB*, *HNF1A*, and *TIMD4* associated with LDL cholesterol; *ANGPTL4*, *FADS1-FADS2-FADS3*, *HNF4A*, *LCAT*, *PLTP*, and *TTC39B* associated with HDL cholesterol; and *AMAC1L2*, *FADS1-FADS2-FADS3*, and *PLTP* associated with triglycerides. *ABCG8* and *LCAT* have been shown to cause Mendelian forms of dyslipidemia (sitosterolemia and LCAT deficiency, respectively), further strengthening the connection between loci for mendelian dyslipidemic syndromes and those with common variants of modest effect. Indeed, at least 11 of the 30 loci (*ABCG8*, *LCAT*, *APOB*, *APOE*, *LDLR*, *PCSK9*, *CETP*, *LPL*, *LIPC*, *APOA5*, and *ABCA1*) not only harbor common variants associated with variation in plasma lipids but also low-frequency variants and/or rare mutations that cause mendelian syndromes. Finally, the use of an allelic dosage score suggested that the cumulative effect of multiple common variants contributes to polygenic dyslipidemia.

Aulchenko et al. (2009) studied over 20,000 persons from 16 different population-based cohorts and identified 22 distinct loci associated with plasma lipids including six new loci: *ABCG5*, *TMEM57*, *DNAH11*, and *FADS3-FADS2* associated with total and/or LDL cholesterol and the *CTCF-PRMT8* region and *MADD-FOLH1* region associated with HDL. Sex-specific differences in effect size were demonstrated for *HMGCR*, *NCAN*, and *LPL*. Allelic dosage scores were associated with carotid intima media thickness and CHD incidence. The genetic risk score improves the screening of high-risk groups of dyslipidemia over classical risk factors.

Sabatti et al. (2009) used the Northern Finland Birth Cohort 1966 for GWAS of lipid and other metabolic traits and identified three new lipid loci: *AR* and *FADS1-FADS2* with LDL cholesterol and *NR1H3* (*LXRA*) with HDL cholesterol. A low-frequency (MAF = 0.017) variant in the AR was found to be associated with markedly increased LDL in males, associated with a mean LDL elevation of 28 mg/dl.

Low-frequency variants (0.5–5% allele frequency) are likely an important source of variation in plasma lipid levels but are rarely captured by genome-wide genotyping platforms. Pollin et al. (2008) found through a GWAS that about 5% of the Amish in Lancaster County are heterozygous for a null mutation (R19X) in the gene encoding apoC-III (*APOC3*), resulting in reduced plasma apoC-III and lower triglyceride and LDL-C levels and higher HDL-C levels. Furthermore, individuals with R19X had reduced coronary artery calcification compared with noncarriers, consistent with a cardioprotective effect of this rare variant.

Medical resequencing studies will be required to identify the majority of the low frequency variants and all of the rare variants (<0.5% allele frequency) that have a quantitatively large effect size on plasma lipids. As one example of this approach, Romeo et al. (2007) resequenced the coding region and proximal intronic regions of *ANGPTL4* in a multiethnic sample of 3551 individuals and found an excess of nonsynonymous variants in individuals with TG levels in the lowest quartile. One variant, E40K, was present in 3% of Caucasians and was associated with significantly lower plasma levels of TG and LDL cholesterol (LDL-C) and higher levels of HDL cholesterol (HDL-C) in two other large cohorts. More recently, Romeo et al. (2009) reported the resequencing of coding regions in the genes encoding the angiopoietin-like proteins (ANGPTL3, -5, and -6) and identified multiple rare nonsynonymous variants in *ANGPTL3* and *ANGPTL5* associated with low plasma TG levels. These studies have established that *ANGPTL3*, *ANGPTL4*, and *ANGPTL5*, but not *ANGPTL6*, play nonredundant roles in TG metabolism.

Resequencing of individuals ascertained on the basis of extreme lipid traits, rather than those from the tails of a normal distribution, may provide a more efficient method of identifying rare mutations and low-frequency variants with

large effect sizes on lipid phenotypes. Edmondson et al. (2009) resequenced the *LIPG* gene encoding the enzyme endothelial lipase in individuals with extremely high HDL-C levels and controls with relatively low HDL and found a significant excess of rare variants in the high HDL group; analysis of variants created by site-directed mutagenesis proved them to be loss-of-function mutations. In addition, a low-frequency variant N396S was found to be highly associated with elevated HDL-C in multiple cohorts and within families and was also proven to have reduced lipolytic activity.

One of the critical questions regarding loci that influence plasma lipids is whether they also influence risk of CHD. This question can be addressed using mendelian randomization. The key concept is that if a locus altering plasma lipid level is causal for CHD, then gene variants at that locus would also be associated with CHD in a manner consistent with the effect on lipids. Willer et al. (2008) tested whether SNPs associated with LDL cholesterol, HDL cholesterol, or triglycerides also related to risk for CHD. Interestingly, they observed that nearly all variants related to LDL cholesterol were associated with CHD but that this was not the case for variants related to HDL cholesterol or triglycerides. This observation raises the provocative hypothesis that only certain genetic mechanisms that alter plasma HDL cholesterol or triglycerides affect risk for CHD.

Testing this hypothesis for the *CETP* locus is of particular interest as drug development programs targeting this protein are ongoing. Thompson et al. (2008) conducted a meta-analysis of studies reporting on the relationship between *CETP* gene variants, HDL cholesterol, and risk for CHD. They observed that *CETP* variants that increase HDL cholesterol modestly reduced the risk for CHD. Ridker et al. (2009) reported similar findings in a prospective cohort study. These studies are important, as they suggest that the HDL-raising effect of reduced CETP expression may reduce cardiovascular risk, albeit modestly. Even larger studies are needed to definitively evaluate whether genetic loci which affect HDL cholesterol or triglycerides in turn alter risk for CHD.

The explosion of GWAS for lipid traits and related phenotypes (such as response to lipid-lowering therapy) has the potential to impact on the evolution of "personalized medicine." For example, genetic risk score based on the counting of the number of "adverse" alleles influencing lipids may enhance risk prediction compared with measurement of lipids alone (Kathiresan et al., 2008). Furthermore, genetic information could influence treatment decisions. For example, a GWAS study of statin myopathy performed in the SEARCH study of two different doses of simvastatin revealed a highly significant association with a locus encoding the organic ion transporter SLCO1B1 responsible for transporting simvastatin into the liver (Link et al., 2008). Carriers of the rare allele were at significantly increased risk of statin myopathy and also had a reduced response with regard to LDL lowering. In concept, genotyping for this allele could influence the choice of type or dose of statin to reduce the risk of myopathy. The coming year will see a large number of studies addressing the genetic determinants of the response to lipid-altering therapy.

Finally, several GWASs focused directly on atherosclerotic cardiovascular disease phenotypes have been reported and in sum, they have identified ~14 loci for MI or CHD (at genome-wide levels of significance) (Erdmann et al., 2009; Gudbjartsson et al., 2009; Kathiresan et al., 2009; Ozaki et al., 2009; Tregouet et al., 2009). For example, in the largest of these studies, the Myocardial Infarction Genetics Consortium found nine loci associated with early-onset MI with genome-wide significance:21q22 near *MRPS6-SLC5A3-KCNE2*, 6p24 in *PHACTR1*, 2q33 in *WDR12*, 9p21, 1p13 near *CELSR2-PSRC1-SORT1*, 10q11 near *CXCL12*, 1q41 in *MIA3*, 19p13 near *LDLR*, and 1p32 near *PCSK9*. Of note, five of the 14 loci defined in recent studies have been previously related to LDL cholesterol; these include *LDLR*, *PCSK9*, 1p13 near *CELSR2-PSRC1-SORT1*, *TCF1*, and *LPA*. These results further strengthen the now unequivocal causal relationship between LDL cholesterol and CHD.

CHAPTER

Genomics of Myocardial Infarction

Carlos A. Hubbard and Eric J. Topol

INTRODUCTION

Despite advances in screening and treatment, coronary artery disease (CAD) and myocardial infarction (MI) remain the leading causes of death in the world (Bonow et al., 2002). The global economic implications of MI are staggering, with the 2006 estimated cost of CAD at over $142 billion in the United States alone (Thom et al., 2006). The economic consequences are particularly felt in developing countries which account for 80% of the burden of cardiovascular disease and where resources for prevention and access to treatment are limited (Yusuf et al., 2004). Therefore, a better understanding of the molecular mechanisms that impart risk would have a dramatic economic effect by allowing earlier detection of individuals at highest risk and targeting preventive therapies to individuals most likely to benefit.

Advanced atherosclerotic disease can lead to the formation of large lesions that can encroach upon the lumen of the coronary vasculature and result in ischemic injury and even infarction when myocardial oxygen demand is high. However, the catastrophic consequences of CAD are generally related to acute MI due to the rupture of vulnerable plaques and subsequent occlusive thrombosis. Although there is a high prevalence of atherosclerotic coronary disease worldwide, only a fraction of patients with this disease progress to having an acute MI. Although a number of risk factors have been shown to contribute to the development of cardiovascular disease, a family history of CAD remains one of the most powerful independent predictors of risk, which suggests a significant genetic component to the disease. Several linkage studies suggest that the genes responsible for plaque rupture and thrombosis may differ from the genes responsible for atherosclerotic disease progression, which may account for this discrepancy.

PREDISPOSITION

Genetic Influence on Risk of MI

Data from the Swedish Twin Registry (Lichtenstein et al., 2002) have been used in several studies to establish the moderate but significant effect of genetic factors on the relative risk of death due to CAD. Monozygotic twins have a significantly higher relative risk of death from CAD than dizygotic twins even when outcomes are adjusted for the effects of conventional risk factors associated with CAD (Marenberg et al., 1994; Zdravkovic et al., 2004). Even among siblings who are affected by MI the angiographic location of disease is remarkably concordant (Fischer et al., 2005). The molecular events that lead to plaque rupture and acute MI are likely influenced by a host of intricately related genetic factors involved in a variety of cellular processes such as the inflammatory cascade, extracellular matrix regulation, apoptosis and lipid metabolism. Advances in molecular biology have provided us with an array of tools to begin elucidating the genetic factors underlying these diverse mechanisms.

A significant number of genes involved in the inflammatory cascade are clustered on the short arm of chromosome 6p21 in the major histocompatibility complex region. A review of the available literature regarding polymorphisms of genes (TNF-alpha, lymphotoxin-alpha, HLA-DR, heat shock protein 70-1, hemochromatosis gene and C4) in this region points out the

Essentials of Genomic and Personalized Medicine

All rights reserved.

variability in the results to date (Porto et al., 2005). In most cases the strong linkage disequilibrium among these genes appears to point to a complex haplotypic pattern of cardiovascular risk rather than a single genetic variant.

Atherosclerotic plaque instability is a central concept in the current theories of the process of plaque rupture. The matrix metalloproteinase (MMP) gene family has been implicated in the development of unstable plaques. The proteins MMP-1, 2, 3, 7, 8, 9, 12, 13 and 14 are all expressed in atherosclerotic plaques (Faber et al., 2002). Upregulation of MMP-9 by a functional polymorphisms in the promoter region of the gene was shown to correlate with an increase in angiographically significant CAD (Zhang et al., 1999). Also expressed in plaques are the tissue inhibitors of metalloproteinases (TIMPs), which bind and inhibit the activity of MMPs. Upregulation of TIMP-1 and TIMP-2 expression in human saphenous vein cultures resulted in a reduction of neointimal thickening (George et al., 1998a, b). The balance between MMPs and TIMPs affects overall plaque stability such that derangements in the regulation of this process may lead to plaque rupture and MI.

Genome-wide Scans for Linkage

Several genome-wide scans have been performed on diverse ethnic populations in order to identify genes responsible for the development of CAD (Table 24.1). In a Finnish population, loci that correlated with CAD were identified on chromosomes 2q21.1–22 (LOD = 3.2) and Xq23-26 (LOD = 3.5) (Pajukanta et al., 2000). In a northeastern Indian population, a site on chromosome 16p13-pter (LOD = 3.06) was suggestive for CAD (Francke et al., 2001). In an Australian population, a locus on chromosome 2q36-37.3 (LOD = 2.63) was found to significantly correlate with the presence of CAD (Harrap et al., 2002). A whole genome scan of 1406 individuals from 513 German families with a history of early CAD or MI identified a locus for MI on chromosome 14q12.3-13.0 (LOD = 3.9) (Broeckel et al., 2002). The diversity in loci identified by these studies may be due in part to the phenotypic inconsistencies, diversity of the ancestry of the populations, and inadequate statistical power.

The GENECARD study was a genome-wide scan for genetic regions linked to early-onset CAD in over 400 families with a history of early-onset CAD (Hauser et al., 2004). This analysis identified a region on chromosome 3q13 (LOD = 3.5) that was associated with early-onset CAD. Other regions of chromosome 3q have been associated with CAD in three earlier studies (Broeckel et al., 2002; Francke et al., 2001; Harrap et al., 2002). The Diabetes Heart Study also identified linkage of this region of chromosome 3q13 with CAD in type 2 diabetics (Bowden et al., 2006).

A genome-wide scan for susceptibility genes for MI in a population of European-American ancestry from 428 multiplex families with familial premature CAD and MI identified a significant locus for MI on chromosome 1p34-36 (LOD = 11.68) but did not detect a significant locus for CAD (Wang et al., 2004). The chromosome 1p34-36 locus contains the gene for connexin-37 (CX37), which is a gap junction protein expressed in the arterial endothelium and is involved in vascular growth, aging and regeneration after injury. The C allele of the CX37 SNP P319S has previously been shown to be associated with CAD in a Taiwanese population, as well as carotid intima thickening in Swedish men (Boerma et al., 1999; Yeh et al., 2001). The T allele of this same CX37 SNP has also been associated with risk for MI in a case-control study of Japanese men (Yamada et al., 2002). Whether connexin-37 or another gene(s) accounts for the linkage peak remains unresolved.

Accordingly, studies are targeting the smaller population of individuals with CAD who ultimately suffer MI. Evidence is mounting that some of the genes responsible for progression to MI may differ from the genes responsible for CAD. Although multigenetic interactions are likely responsible for the majority of cardiovascular risk, some exceptions have more recently been described with findings of significant risk being directly attributable to variants in a single gene. The development of the International Haplotype Map is allowing researchers to utilize single nucleotide polymorphisms (SNP) to hone in on the areas of interest identified by linkage studies and identify specific genes that are associated with CAD and MI (Table 24.2).

Association Studies

The GENEQUEST study was the first high-throughput SNP study of individuals with premature MI (Topol et al., 2001). This study examined 72 SNPs of 62 vascular genes in 398 families identified three members of the thrombospondin (TSP) gene family of matricellular proteins, TSP-1, -2 and -4, which were associated with familial premature MI. The findings of significant association of TSP-2 and TSP-4 with premature MI have subsequently been replicated in other studies and by different investigators (Boekholdt et al., 2002; McCarthy et al., 2004; Wessel et al., 2004).

The TSP-1 SNP results in a substitution of serine for asparagine at residue 700 of the protein and although rare (1% frequency),

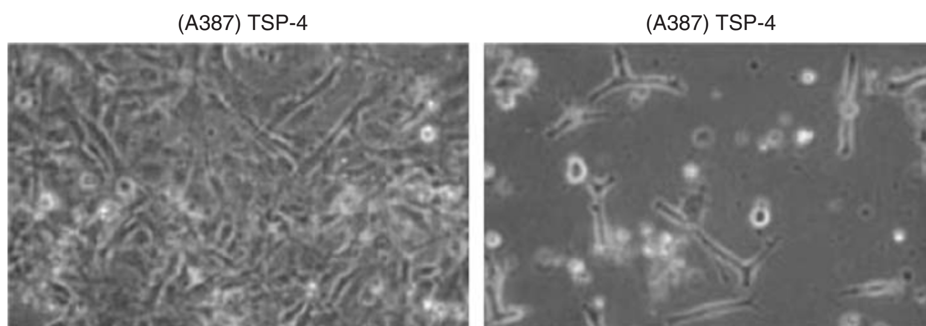

Figure 24.2 Effect of TSP-4 variants on adhesion of HUVECs. Cells were plated on plastic preincubated with purified TSP-4 variants (50,000 cells/well of 24-well plate) and photographed after 24 h of culture. The presence of the P387 variant interferes with HUVEC cell binding and proliferation. (Reproduced with permission from Stenina et al., 2003.)

homozygous individuals had the highest association with MI (OR = 8.66). The TSP-1 SNP has been shown functionally to increase surface expression and platelet aggregation, which may account for its high association with MI (Narizhneva et al., 2004) (Figure 24.1). The TSP-4 SNP is more common with the minor allele present in over 30% of individuals and confers a near twofold risk of MI (OR = 1.89). The TSP-4 SNP results in a substitution of proline for alanine, which has been correlated with gain-of-function, proatherogenic effects by interfering with endothelial cell adhesion and proliferation (Stenina et al., 2003) (Figure 24.2), along with activation of neutrophils (Pluskota et al., 2005).

Another gene that has been identified as a heritable risk for MI is the gene for the transcription factor myocyte-enhancing factor 2A (MEF2A) (Wang et al., 2003). In a large pedigree study of a family with a history of premature CAD and MI, a genome-wide scan identified a locus on chromosome 15q26 that was highly associated with risk (Figure 24.3). An analysis of the candidate genes in this area revealed a 21-bp deletion mutation in exon 11 of the MEF2A gene that imparts an autosomal dominant inheritable risk of MI. This deletion was shown to prevent localization of MEF2A in the nucleus and disrupts transcription. A subsequent study of over 400 nonrelated MI cases and controls found MEF2A nonsynonymous point mutations in exon 7 in MI cases but not controls (Bhagavatula et al., 2004). These point mutations also appear to limit the transcription activity of MEF2A and provide further evidence of the importance of this gene in the development of CAD and risk for MI.

Recently, further analysis of the GENECARD data has identified two SNPs in the 3′ untranslated region of the transcription factor GATA2 gene as being significantly associated with early-onset CAD (Connelly et al., 2006). GATA2 is expressed in hematopoietic stem cells but also in locations susceptible to the development of atherosclerosis such as aortic endothelial cells and smooth muscle cells. The association of the GATA2 SNPs with early-onset CAD was identified first in the familial early-onset CAD cohort of GENECARD

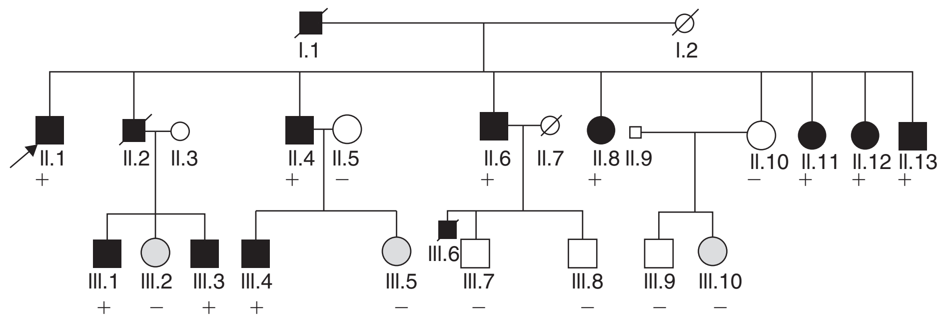

Figure 24.3 MEF2A intragenic deletion cosegregates with CAD in kindred QW1576. The pedigree shows genetic status: +indicates presence of the 21-bp deletion of MEF2A (heterozygous); −indicates the absence of the deletion. Individuals with CAD are indicated by solid squares (males) or circles (females). Individuals under 50 years of age without known CAD are shown in light gray. The proband is indicated by an arrow and deceased individuals are indicated by a slash (/). (Reproduced with permission from Wang et al., 2003.)

and was subsequently validated in a separate nonfamilial young affected CAD case-control cohort. The functional significance of the GATA2 SNPs is unknown, but these findings suggest that GATA2 regulated genes may be significantly involved in early-onset CAD and its progression.

A number of inflammation-mediating molecules, such as the cytokine lymphotoxin-alpha (LTA), have been implicated in the process of plaque rupture. A massive genome-wide SNP study of Japanese patients analyzed over 65,000 SNPs in 13,738 genes and found 2 functional SNPs in the LTA gene that were highly associated with risk of MI (Ozaki et al., 2002) (Figure 24.4). These SNPs were shown to increase expression of vascular cell adhesion molecule and E-selectin which creates a proinflammatory environment. The PROCARDIS Consortium later confirmed the association of a functional allele of LTA (N26 [804A]) with CAD in white Europeans (2004).

LTA protein binds to galectin-2, a member of the galactose-binding lectin family, and this binding is critical for the extracellular expression of LTA. Recently a SNP in *LGALS2* encoding galectin-2 has been shown to be significantly associated with susceptibility to MI by affecting the transcriptional level of galectin-2 leading to altered secretion of LTA (Ozaki et al., 2004). LTA and galectin-2 were shown to be expressed in smooth muscle cells and macrophages in the intima of atherosclerotic plaques but not in normal medial smooth muscle cells. The TT allele of galectin-2 was shown to confer protection while the CC allele confers susceptibility to MI (Ozaki et al., 2004).

A key regulator of the inflammatory cascade, the 26S ubiquitin-proteasome system, has also recently been implicated in susceptibility to MI, further emphasizing the role of inflammation in the pathogenesis of MI. A SNP (exon 1-8C/G) located in the 5′ untranslated region of exon 1 of the proteasome subunit α type 6 (PSMA6) gene was identified in a whole-genome case-control association study of Japanese patients as being significantly associated with MI (OR = 1.36) (Ozaki et al., 2006). The exon 1 -8C/G SNP was shown to alter the transcription levels of the PSMA6 gene both *in vitro* and *in vivo*. The PSMA6

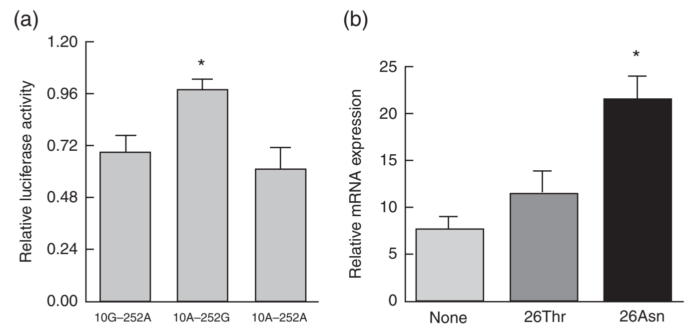

Figure 24.4 Functional SNPs of LTA gene. (a) Transcriptional regulatory activity is affected by the SNP in Intron 1 of LTA (252A → G) as measured by relative luciferase activity (*$p < 0.01$); (b) Induction of adhesion molecules such as VCAM1 is differentially affected by 26Asn-LTA and 26Thr-LTA in HCASMC cultures following treatment with medium only (white) or with 20 ng/ml of 26Thr-LTA (gray) or 26Asn-LTA (black) for 4 h (*$p < 0.01$). (Reproduced with permission from Ozaki et al., 2002.)

gene codes for an α subunit of the 20S proteasome, which is the core particle for the 26S ubiquitin-proteasome system that degrades IκB protein. IκB inhibits the activation of the nuclear factor κB (NF-κB) which regulates the expression of many genes in the inflammatory pathway.

A recent genome-wide association study not limited to candidate genes examined 11,053 SNPs in 6891 genes and found four gene variants that were associated with MI. These gene variants encode a tyrosine kinase (ROS1 [OR 1.75]), the cytoskeletal protein paladin (KIAA0992 [OR 1.40]), and two G protein–coupled receptors (TAS2R50 [OR 1.58] and OR13G1 [OR 1.40]). At this point, the underlying biological mechanism for these associations is unknown and warrants further investigation, which could yield new therapeutic strategies (Shiffman et al., 2005). The same group published a genome-wide

association study for early-onset MI and identified a platelet degranulation gene – VAMP8 – as having an odds ratio of 1.75 in 3 separate cohorts (Shiffman et al., 2006).

Adding to the complexity of the molecular landscape of CAD and MI is the finding of an untranslatable but presumably functional RNA transcript that has been associated with MI in a large case-control GWAS using 52,608 SNPs in a cohort of Japanese patients (Ishii et al., 2006). This functional RNA has been designated the myocardial infarction associated transcript (MIAT), and one SNP in exon 5 was shown to affect transcriptional levels of the gene. The mechanism by which this RNA transcript contributes to susceptibility to MI remains to be identified but examples of other noncoding functional RNA molecules have been demonstrated to influence important transcriptional processes in other models of disease.

The Leukotriene Pathway

More recently, variants of the arachidonate 5-lipoxygenase-activating protein (ALOX5AP) gene have been shown to confer a significant risk for MI. ALOX5AP plays a key role in the inflammatory leukotriene biosynthetic pathway. A genome-wide scan of 296 Icelandic families identified a four-SNP haplotype, called HapA, in the *ALOX5AP* gene that confers a nearly twofold risk of MI and stroke (Helgadottir et al., 2004). This association was further verified in a cohort of British patients with another haplotype, called HapB, of the *ALOX5AP* gene which also conferred a nearly twofold risk of MI. Individuals with these at-risk haplotypes were shown to have a significantly increased neutrophil production of leukotriene B4 (LTB4) supporting the role of this gene in the inflammatory process implicated in atherosclerosis and plaque rupture.

Another gene in the same leukotriene biosynthetic pathway as ALOX5AP has recently been implicated in risk of MI. A study of 1553 Icelandic individuals with history of MI demonstrated that a haplotype, called HapK, of the leukotriene A4 hydrolase (LTA4H) gene was associated with a relative risk of 1.45 ($p = 0.035$) for MI and additional cardiovascular disease (Helgadottir et al., 2006). This association was also confirmed in three separate cohorts from the United States population. The HapK haplotype was also shown to correlate with increased neutrophil production of LTB4. Of further interest, in the United States cohorts tested the relative risk of MI for African-American carriers of the HapK haplotype was much higher (RR = 3.57) although the haplotype was less frequent in this population. This suggests that the LTA4H variant may interact with other gene variants more common in African-Americans, although to date these other gene variants have yet to be determined.

PCSK9 – A Key Player in LDL Cholesterol Receptor Modulation

Genetic variations in the proprotein convertase subtilisin/kexin type 9 serine protease (PCSK9) gene have been shown to reduce LDL cholesterol levels. The results of a massive 15 year longitudinal study of nonsense and missense genetic variants of PCSK9 were recently published (Cohen et al., 2006). The presence of a nonsense mutation (2.6% of the African-American cohort) was associated with a 28% reduction in mean LDL cholesterol and an 88% reduction in risk of cardiovascular events ($p = 0.008$; HR = 0.11) (Figure 24.5). The presence of a missensevariation of PCSK9 was associated with a relatively lower 15% reduction in LDL cholesterol and a 47% reduction in cardiovascular risk ($p = 0.003$; HR = 0.50). Nonsense mutations of PCSK9 were rare (6 of 9537 subjects) in the Caucasian cohort. This study elegantly demonstrates two important concepts. First, ethnic background can be used as a crude marker to identify patients with underlying genetic susceptibilities. Secondly, the benefits conveyed by modification of known conventional risk factors such as LDL cholesterol levels are likely determined by underlying genetic mechanisms and inheritable susceptibilities.

Chromosome 9p21 Identified as a Hotspot for Risk of MI

One of the most exciting developments in the field of cardiovascular genomics is the recent discovery of a strong association of a region of chromosome 9p21 with MI. What makes this discovery so important is that it has been replicated in four separate GWAS spanning multinational cohorts including thousands of cases and controls (Helgadottir et al., 2007; McPherson et al., 2007; Samani et al., 2007; WTCCC, 2007). These studies have shown that over 20% of Caucasians are homozygous for this genetic variation and that it carries a greater than 20–30% risk of MI.

The chromosome 9p21 region of interest contains the genes for two cyclin-dependent kinase inhibitors, *CDKN2A* ($p16^{INK4a}$) and *CDKN2B* ($p15^{INK4b}$). These genes are involved in cell cycle regulation, and *CDKN2B* expression is induced by TGF-β, which may play a role in the pathogenesis of atherosclerosis. Another gene in this region is methylthioadenosine phosphorylase, which is involved in adenine and methionine salvage. Further adding to the excitement surrounding this area is the additional finding of an association of this 9p21 region with type 2 diabetes mellitus, which is a strong conventional risk factor for CAD and MI and suggests a common mechanism of risk for these diseases (Saxena et al., 2007; Scott et al., 2007; Zeggini et al., 2007). However the SNPs which have been associated with CAD and MI are not within these genes, and to date it is not clear what the mechanism is by which these genetic variations might influence susceptibility to CAD and MI.

It is important to note that in each GWAS there were findings of loci of interest that were not replicated in the other studies. This demonstrates the need for cautious interpretation of the findings from a single GWAS and the critical need for replication of findings by independent validation studies. The elucidation of the association between chromosome 9p21 and MI is an elegant example of the degree of scrutiny required for the investigation of other GWAS findings.

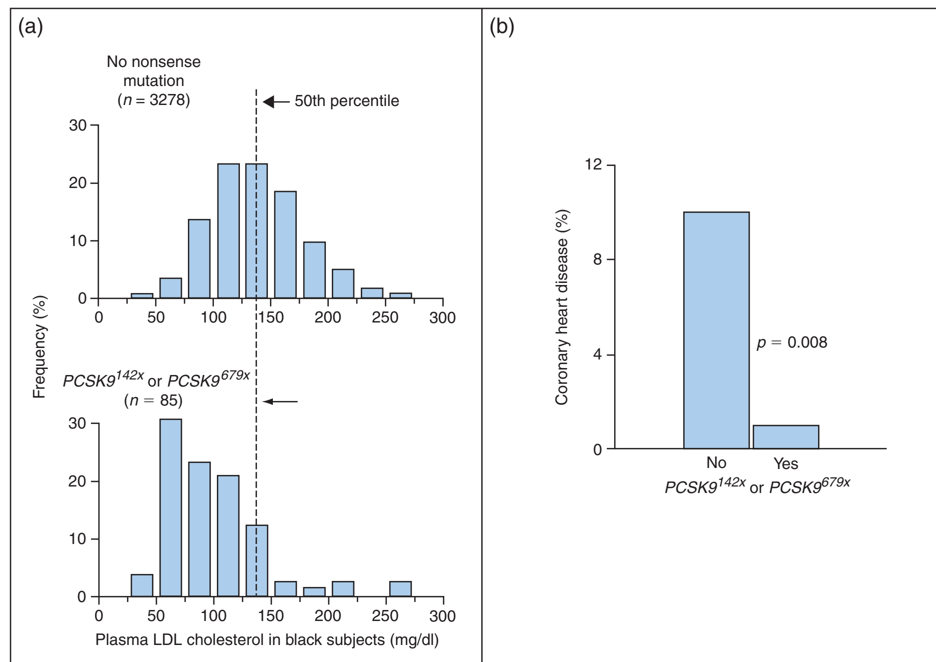

Figure 24.5 Distribution of plasma LDL cholesterol levels (a) and the incidence of coronary heart disease (CHD) (b) among African-American subjects, according to the presence or absence of a $PCSK9^{I42X}$ or $PCSK9^{679X}$ allele. (Reproduced with permission from Cohen et al., 2006.)

Conventional Risk Factors and Environmental Influences

Although genetic factors may play a significant role in the development of CAD and MI, the fact is that 80–90% of patients with CAD have conventional risk factors such as hypertension, hyperlipidemia, diabetes mellitus or cigarette smoking (Khot et al., 2003). Environmental influences such as diet have also been shown to play an important role in the development of CAD as well. Results of the Nurse's Health Study demonstrated *trans*-fat intake was associated with increased risk of CAD, whereas there was an inverse association with polyunsaturated fat intake (Oh et al., 2005).

What remains to be determined is to what extent the effect of these conventional risk factors and environmental influences is dependent upon underlying genetic interactions. It has been shown that increased dietary arachidonic acid significantly enhanced atherogenesis in carriers of variant 5-lipoxygenase genotypes, whereas increased dietary intake of n-3 fatty acids appeared to reduce atherogenesis in this population (Dwyer et al., 2004). As mentioned previously, carriers of nonsense and missense mutation of the PCSK9 gene show significantly reduced levels of LDL cholesterol and enjoy a protective benefit against cardiovascular risk (Cohen et al., 2006). This suggests that susceptibility to conventional risk factors may ultimately depend upon complex genetic and environmental interactions.

SCREENING STRATEGIES

Currently, screening for cardiovascular risk is based on various models that incorporate gender, age, ethnicity and behavioral and disease risk factors. Obviously, risk associated with gender and ethnicity imply a genetic component, but it is likely that the susceptibility to behavioral and disease risk factors is also based on genetic heritability.

Ongoing whole-genome SNP association studies will lay the groundwork for more extensive and definitive identification of SNPs and haplotypes associated with MI. These haplotypes will likely allow us to identify patients at increased risk for CAD and MI before the onset of disease and regardless of exposure to conventional risk factors.

The identification of genetic susceptibility traits will allow for more accurate risk stratification of patients than is achievable with current clinical models. The presence of a particular trait may carry such significant risk as to directly identify patients at risk, as is the case for *BRCA1* gene variant carriers who are at high risk for breast and ovarian cancer. More commonly a genetic trait may be integrated into the risk assessment calculation of more conventional models to improve the accuracy of the risk prediction.

Early identification of patients at risk can prompt risk factor modification and early genetically tailored pharmacological interventions, which could greatly decrease the morbidity and

mortality associated with these diseases. Future models of cardiovascular risk will likely be based on these complex multigenetic and environmental interactions. However, the technical difficulties and financial burden associated with genetic analysis must be overcome before these traits can be economically and efficiently incorporated into every day clinical practice.

Although genetic variation can result in the presence or absence of a particular protein and thereby result in a disease state, it is more common that these variants result in differential expression of a particular protein. For example, a SNP in *LGALS2* has been associated with increased risk of MI (Ozaki et al., 2004). The *LGALS2* SNP encodes for the protein galectin-2 and results in alterations in the transcriptional levels of galectin-2 which binds to LTA. This could result in altered levels of LTA secretion and intravascular inflammation which is thought to be associated with CAD and MI. The expression levels of a number of other proteins, such as C-reactive protein, have also been shown to correlate with risk of MI and it is certain that these expression levels are similarly genetically determined. Findings such as these may lead to the development of protein-based assays, which are faster and more economical than DNA analysis and are more amenable to every day clinical use.

PROGNOSTIC IMPLICATIONS OF MI

Heart Failure and Ventricular Remodeling

Greater than 20% of patients treated for initial MI will develop acute heart failure and the incidence increases with recurrent MI. Post-MI heart failure conveys a three- to sixfold increase in risk of death and is the result of the complex processes of myocardial necrosis and ventricular remodeling. Studies have shown that female gender as well as complex phenotypic traits, such as hypertension and diabetes, is associated with increased risk of post-MI heart failure, which suggests a genetic component to the process. The incidence of post-MI heart failure has been shown to decrease dramatically 8 days after MI (Thomas et al., 2005). Identification of the early molecular mechanisms responsible for the development of post-MI heart failure may yield targets for future therapies.

Risk for Repeat Myocardial Infarction

A recent analysis of atherosclerosis-related gene SNPs in 1586 Japanese patients from the Osaka Acute Coronary Insufficiency Study revealed that G allele carriers at the position 252 of the LTA gene were independently associated with an increased risk of death after acute MI compared to noncarriers who also suffered acute MI as well as recurrent MI when (hazard ratio = 2.46; 95% CI = 1.24–4.86) (Mizuno et al., 2005). This study would suggest that although risk for MI may be a function of multiple genetic polymorphisms, the presence of a select group of polymorphisms may confer an even higher risk for carriers. A better understanding of the functional influences of these polymorphisms as they are discovered will allow for more accurate risk stratification.

Response to Post-MI Medical Therapy

Administration of β-blocker therapy post-MI has been shown to reduce infarct size and mortality, however all patients may not derive equivalent benefit. A recent prospective study of response to β-blocker therapy in patients with two common polymorphisms of the β 2-adrenergic receptor demonstrated a significant difference in 3-year survival which was genotype specific (Lanfear et al., 2005). Similar results have previously been shown for risk of incident coronary events (Heckbert et al., 2003). Genetic markers such as these may allow us to discriminate between treatment responders and nonresponders and should allow for individualized therapies as well as better risk stratification.

PHARMACOGENOMICS OF MI

HMG-CoA Reductase Inhibitors

HMG-CoA reductase inhibitors, commonly referred to as "statins", reliably lower atherogenic lipoproteins and have been shown to decrease the incidence of MI in numerous studies (Davidson, 2005; Schwartz et al., 2005). These drugs have also been shown to have significant anti-inflammatory effect and lower serum levels of inflammatory markers such as C-reactive protein (Ridker et al., 1999). These effects appear to correlate with a reduction in the rate of atherosclerotic plaque progression and possibly even plaque regression (Ridker et al., 2005; Nissen et al., 2005; Nissen et al., 2006).

Studies have also suggested an effect of statin therapy on ventricular remodeling post-MI. Simvastatin was shown to reduce the incidence of heart failure in patients with CAD in a retrospective analysis of the Scandinavian Simvastatin Survival Study (4S) trial (Kjekshus et al., 1997). However, this finding was not replicated with the use of pravastatin in the CARE study (Lewis et al., 2003).

Although overall significant benefit has been demonstrated with the use of statin therapy, considerable interindividual variation exists in the response to statin therapy. It is likely that genetic factors are responsible for this variation in individual response. Multiple genes have been implicated as potential modulators of statin response but few of the findings have been replicated (Kajinami et al., 2004). Identification of genetic haplotypes that correlate with increased response to statin therapy will allow responsive individuals to be targeted for therapy while nonresponders may avoid the side effects of a nonbeneficial and costly therapy.

Antiplatelet Therapies

Aspirin Resistance

Aspirin irreversibly binds cyclooxygenase, which plays a key role in the process of platelet aggregation. The benefit of aspirin antiplatelet therapy for the reduction of all-cause mortality, nonfatal MI and recurrent MI has been well established (Antiplatelet Trialists Collaboration, 2002). However, not all patients appear to receive equal benefit from aspirin therapy and have been

classified as aspirin resistant. Several mechanisms of aspirin resistance have been proposed but one of the most studied mechanisms involves polymorphisms of the IIIa subunit of the platelet glycoprotein IIb–IIIa receptor, which is the final common pathway in platelet aggregation. The PLA2 polymorphism of the glycoprotein IIb–IIIa receptor is present in over 30% of patients with CAD. Heterozygous carriers of the PLA2 allele have also been shown to be aspirin resistant (Cooke et al., 2006; Hanjis et al., 2006). This polymorphism may represent a genetic component for aspirin resistance, and there are likely others that may affect other steps in the platelet activation cascade. Recently a significant association with a synonymous SNP in the platelet gene for the adenosine 5-diphosphate (ADP) receptor P2Y1 was found in an aspirin-resistant population (Jefferson et al., 2005). Identification of patients with gene-mediated aspirin resistance could further reduce the incidence of MI by the use of different antiplatelet therapies in this population.

Clopidogrel Resistance

One of the major advances in the treatment of acute MI has been the use of the ADP receptor antagonist clopidogrel. ADP is released by activated platelets and by binding to the platelet $P2X_1$, $P2Y_1$ and $P2Y_{12}$ receptors greatly accelerates platelet aggregation. Clopidogrel irreversibly binds the $P2Y_{12}$ receptor and blunts ADP-mediated platelet aggregation. However, just as is the case with aspirin therapy, there is significant interpatient variability in the response to clopidogrel. One suggested mechanism for this difference in response is polymorphisms of the $P2Y_{12}$ receptor gene. Although the known mutations of this gene have been shown to result in congenital bleeding disorders, one study has identified a polymorphism in healthy subjects that was associated with increased platelet response to ADP stimulation as well as peripheral artery disease (Fontana et al., 2003). Also, clopidogrel is a prodrug that requires activation by the hepatic cytochrome P3A4 and cytochrome P3A5 enzymes. Numerous SNPs have been identified in these genes, which could affect clopidogrel metabolism and lead to decreased activation. Polymorphisms of the $P2Y_{12}$ receptor and cytochrome P3A genes could account for some of the observed resistance to clopidogrel (Nguyen et al., 2005).

NOVEL AND EMERGING THERAPIES

Drug-Eluting Intracoronary Stents

Currently there is some debate regarding the use of drug-eluting stents for the treatment of acute MI (Saia et al., 2003; Valgimigli et al., 2005); however numerous studies have shown a significant reduction in the rate of in-stent restenosis with the introduction of this technology (Bavry et al., 2005; Hill et al., 2004). These stents are coated with immunosuppressant or cytotoxic agents that reduce the incidence of restenosis. Currently, the two most commonly used agents in the United States are sirolimus and paclitaxel, but a variety of other agents are currently in development.

Sirolimus is a cytostatic macrolide antibiotic which inhibits smooth muscle proliferation by halting cell cycle progression. Smooth muscle proliferation is a key component of the neointimal proliferation process which leads to restenosis. Paclitaxel is a cytotoxic agent which disrupts microtubule assembly and kills proliferating or dividing cells. In addition, these drugs may also inhibit apoptosis of the existing smooth muscle cells and contribute to the stabilization of vulnerable plaque (Faber et al., 2002; Smith et al., 2003). As more is discovered about the molecular mechanisms that promote restenosis, novel therapeutic agents may be developed to more specifically inhibit neointimal proliferation while preserving the cellular mechanisms of healing and plaque stabilization.

Leukotriene Inhibitors

Variants in the *ALOX5AP* gene and the *LTA4H* gene have been shown to be associated with risk of MI (Helgadottir et al., 2004, 2006). Recently, in a randomized trial of 191 patients at risk for MI with *ALOX5AP* or *LTA4H* gene "gain-of-function" haplotypes, an ALOX5AP inhibitor was studied for its effects on common biomarkers associated with MI risk. A 4-week trial of the ALOX5AP inhibitor resulted in a significant and dose-dependent reduction in serum C-reactive protein and amyloid A. Also, the use of the ALOX5AP inhibitor attenuated the generation of leukotriene B4 and myeloperoxidase by activated neutrophils and the urinary metabolite of LTB4. However, there was a significant 9% increase in serum plasma Lp-PLA2 levels with a corresponding 8% increase in LDL cholesterol noted at the highest dose of the ALOX5AP inhibitor. Currently, a clinical trial is underway to determine if the use of this ALOX5AP inhibitor will affect the overall risk of MI in this at-risk patient population (Hakonarson et al., 2005). A study of dietary modification in over 400 patients with ALOX5AP gene promoter polymorphisms demonstrated that increased intake of n-3 fatty acids appeared to reduce atherogenesis in this population (Dwyer et al., 2004). This suggests that in addition to gene targeted pharmacological treatment, gene targeted behavioral modification strategies may yield further reduction in risk of MI.

2009 UPDATE

The number of SNPs associated with CHD and MI continues to grow at a steady pace. Also, SNPs associated with traditional risk factors for CHD such as dyslipidemia are increasingly being identified and replicated by large GWAS (Aulchenko et al., 2009; Kathiresan et al., 2008, 2009; Kooner et al., 2008; Sabatti et al., 2009). Variants associated with increased LDL cholesterol have been shown to convey increased risk of CHD, whereas variants associated with favorable lipid profiles, such as the null mutation variant (R19X) of the apoC-III gene (APOC3), have been shown to be cardioprotective (Pollin et al., 2008; Willer et al., 2008).

The association of SNPs within chromosome 9p21 with CHD and MI were described in 2007 (Helgadottir et al., 2007; McPherson et al., 2007; Samani et al., 2007; Wellcome Trust Case Control Consortium, 2007). Further studies have confirmed these associations across diverse ethnic populations, and a high-risk haplotype has been identified (Abdullah et al., 2008; Anderson et al, 2008; Hiura et al., 2008; Shen et al., 2008; Zhou et al., 2008). These findings have led to enthusiasm that a new susceptibility gene or genetic mechanism for CHD and MI may ultimately be elucidated. The 9p21 risk variants have also been associated with abdominal aortic aneurysm and intracranial aneurysm, suggesting a vascular phenotype that does not necessarily invoke atherosclerosis (Helgadottir et al., 2008); however, the specific role of genes near the 9p21 region in disease susceptibility has not yet been established. Of interest, the high-risk haplotype identified in this region does localize with a large antisense non-coding RNA gene known as ANRIL (Broadbent et al., 2008). It has been postulated that ANRIL may exert its effect via transcriptional regulation of neighboring genes or yet to be identified gene(s) (Hamsten and Eriksson, 2008).

Another allele of interest has been the Trp719Arg polymorphism of the kinesin-like protein 6 (KIF6 gene). Kinesins are motor proteins involved in intracellular transport and their role in MI and CHD are unknown. A genetic analysis of patients enrolled in the CARE and WOSCOPS studies revealed that carriers of the 719Arg allele had a 50% increased risk of CHD or recurrent MI compared to non-carriers (Iakoubova et al., 2008b). This allele was also shown to be associated with increased risk of CHD in patients from the ARIC study and the Women's Health Study (Morrison et al., 2007; Shiffman et al., 2008).

It has been recently shown that the benefit derived from standard statin therapy in reduction of cardiac events in the CARE study and of CHD in the WOSCOPS study was primarily confined to carriers of the KIF6 719Arg allele (Iakoubova et al., 2008b). In addition, the 719Arg carriers were shown to account for the benefits seen from intensive lipid lowering therapy in the PROVE IT – TIMI 22 study (Iakoubova et al., 2008a). Importantly, non-carriers of the 719Arg allele were shown not only to be at lower risk for MI but also do not appear to receive significant benefit from statin therapy. These findings suggest that genetically tailored therapies for heart disease may be approaching, thereby allowing for better allocation of limited resources to responders and limiting potentially harmful side effects in non-responders.

CHAPTER

Acute Coronary Syndromes

L. Kristin Newby

INTRODUCTION

At least 2 million individuals are hospitalized each year with acute coronary syndromes (ACS), and 1 in 5 deaths in the United States is a result of ischemic heart disease (Rosamond et al., 2007). Despite its common occurrence and severe consequences, the exact molecular mechanisms that trigger an ACS are not fully elucidated, and the prognostic tools to identify which individuals are at risk for a first or subsequent ACS event are limited. Although it is clear the there is a genetic component to the occurrence of coronary artery disease (CAD) and acute coronary syndromes, most clinically applicable work thus far has fallen into the use of protein biomarkers measured from peripheral blood for use as diagnostic or prognostic tools. However, few examples exist of the use of these biomarkers to actually guide treatment. With rapid advances in technology, ACS and its treatment are ripe for exploration using genomics and related techniques such as proteomics and metabolomics. This chapter will briefly review what is known of the genetics and genomics of ACS, examine protein-based biomarkers and their combinations as an example of the forerunner of clinical proteomics, and conclude with an examination of the potential applications of "omic" techniques for refinement of diagnosis, risk stratification and management of ACS in the future.

PREDISPOSITION

Clinical Risk Factors and Risk Prediction

The development of CAD and the occurrence of myocardial infarction (MI) are complex processes. Although several clinical characteristics that predispose to these processes are now commonly known, including male sex, cigarette smoking, diabetes, hypertension, hyperlipidemia, and obesity, it is increasingly recognized that these characteristics provide only a superficial understanding of what predisposes to acute coronary syndromes. In addition, the ability to use these characteristics to discriminate individuals at risk from those who are not is at best modest. For example, the most widely used instrument for prediction of the risk for death or MI over a 10-year time horizon among individuals without known coronary disease, the Framingham Risk Score, which considers many of these clinical factors, has a c-index of only 0.69 in men and 0.72 in women (Ohman et al., 2000; Wilson et al., 1998). That is, for pairs of individuals, one who has a death or MI event and one who does not, the Framingham Risk Score will correctly select the one with an event only 69% of the time among men and only 72% of the time among women. Clinical models that assess the risk of a second event after the occurrence of an ACS, such as Global

Registry of Acute Coronary Events (GRACE) model, which estimates the risk for in-hospital and 6-month death or MI (Eagle et al., 2004; Granger et al., 2003), have somewhat better predictive ability. The discriminative capability of the GRACE model (c-index 0.84) was enhanced by the addition of biomarker information (serum creatinine and creatine kinase [CK]-MB) to clinical characteristics. Still, the ability to discriminate which individuals will have an ACS event could be improved further, opening the door for the use of omic technologies, including RNA expression, proteomics, and metabolomics, to better characterize disease state and risk for future events.

Genetic Predisposition

Consensus on the existence of genetic predisposition for CAD is well-established. Family history has been shown repeatedly to be a robust, independent risk factor for CAD (Ciruzzi et al., 1997; Schildkraut et al., 1989; Shea et al., 1984), even after adjustment for shared environmental factors (Schildkraut et al., 1989; Zureik et al., 1999), and the heritability of CAD is particularly strong in early-onset forms, where the relative risk of developing early-onset CAD in a first-degree sibling is between 3.8 and 12.1, depending on the age-of-onset in the proband (Hauser et al., 2004).

Despite this, no single genetic variant has been identified that accounts for a major fraction of the large burden of CAD and cardiovascular events. Further, despite the wealth of published literature implicating genes in CAD, most association studies have been plagued by low strength of association and lack of replication. For summaries of the body of work in the genetics of coronary disease and MI, the reader is referred to excellent reviews in references by Ginsburg et al. (2005) and Chen et al. (2007). Most recently, variants of 2 genes in the 59-lipoxygenase (5-LO) pathway were associated with cardiovascular events in an Icelandic population: 5-LO activator protein (*FLAP*) associated with a twofold increase in MI and stroke (Helgadottir et al., 2004) and a haplotype (*HapK*) spanning the leukotriene A4 hydrolase (*LTA4H*) gene with a relative risk of 1.45 for MI among patients with other vascular disease (Helgadottir et al., 2005). When HapK was validated in cohorts from the United States, there was an even stronger, threefold increase in risk among African Americans.

Two recent, independent case-control genome-wide association studies, which were replicated in multiple independent populations, provided the first evidence of a common genetic variant (risk allele frequency ~45%) located on chromosome 9p21 that is associated with substantial risk of coronary heart disease or MI (Helgadottir 2007; McPherson et al., 2007). Homozygotes for the risk allele comprise 20–25% of the Caucasian population. Of note, this variant, in the region of tumor suppressor genes *CDKN2A* and *CDKN2B*, was associated with MI with an odds ratio of 1.26 for heterozygotes for the risk allele, and 1.64 for homozygotes. Still, these associations are modest and at this point provide little useful information to guide contemporary clinical care.

SCREENING

There are currently no purely genomic tools that have been identified to screen the general population for risk of future ACS, identification of current ACS events or for risk of death or recurrent ischemic events after an ACS. However, early results with expression profiling suggest potential applications for screening. RNA expression profiling using micorarray technology has been shown to accurately classify both the presence and severity of atherosclerotic lesions in aortic tissue (Seo et al., 2004) and to identify genes potentially involved in plaque rupture (Faber et al., 2001), a pathophysiological precursor to the clinical syndrome of ACS. Importantly, since access to tissue is challenging for screening, diagnosis or prognostic testing in ACS, studies have shown that gene expression profiling from circulating monocytes and peripheral blood leukocytes correlates with the extent of carotid vascular disease (Patino et al., 2005) and CAD (Ma and Liew, 2003), suggesting that blood can be used as a reporter tissue for events occurring in the vessel wall.

Unbiased metabolomic profiling of human serum by proton nuclear magnetic resonance (NMR) analysis also has predicted the presence and severity of CAD (Brindle et al., 2002). In fact, in this study, NMR-based analysis of human serum was better at differentiating individuals with one-, two-, and three-vessel CAD than a model of traditional clinical and laboratory risk factors. In addition, in a study of 53 cases with angiographic CAD and 53 controls without angiographic CAD, large-scale pooled plasma proteomics using LC/MS/MS technology identified differential expression of proteins and peptides between groups (Donahue et al., 2006). Of 731 proteins and peptides identified, 95 were differentially expressed in cases and controls. Among these were proteins involved in natural host defense mechanisms, growth, inflammation, and coagulation. These results suggest the potential for development as biomarkers, in addition to their use to further explore the mechanistic underpinnings of CAD and ischemic events. More recently, a study using urine proteomics identified biomarker patterns that correlated with the presence of angiographically severe CAD (Zimmerli et al., 2007). From more than 1000 polypeptides characterized per sample, 15 characterized a unique biosignature for CAD, which when used to predict CAD in a second cohort did so with a sensitivity of 98% and a specificity of 83%. Interestingly, after coronary intervention and increasing physical activity, the pattern reverted towards that of healthy controls, an observation that suggests potential not only for screening and diagnosis, but also for monitoring disease progression.

In summary, although genomic approaches to screening for CAD or quantifying future risk for ACS are not yet ready for clinical application, this is an active area of research with early results that suggest promise for applications to clinical care, development of biomarkers of disease state and risk and use as research tools to enhance understanding of the molecular underpinnings of ACS.

DIAGNOSIS

Conventional Diagnostic Tools

The acute coronary syndromes encompass a spectrum of pathophysiological processes manifest as plaque instability and plaque rupture or erosion, coronary thrombosis with varying degrees of coronary artery and microvascular occlusion and reductions in blood flow leading to myocardial ischemia and in some cases, myocardial necrosis (Fuster et al., 1992a, b). The diagnosis of ACS is largely a clinical one, relying on a patient's description, or history, of the event that led him to seek medical attention and a small number of readily available objective diagnostic tools. The first and most readily available objective assessment of a patient with suspected ACS is the 12-lead electrocardiogram (ECG). Based on the ECG, patients can be stratified into 2 primary groups, those with ST-segment elevation MI (STEMI) and those with non-ST-segment elevation (NSTE) ACS. About two-thirds of patients will have NSTE ACS and 1/3 will have STEMI (Figure 25.1; Morrow et al., 2007). This electrocardiographic distinction is clinically important as it immediately defines a divergence in treatment strategy. Patients with STEMI generally have a totally occluded major coronary artery and benefit from rapid reperfusion therapy with percutaneous revascularization or administration of intravenous fibrinolytic therapy. For an excellent review and current recommendations for the management of STEMI, the reader is referred to the American College of Cardiology/American Heart Association (ACC/AHA) guidelines for management of patients with STEMI (Antman et al., 2004).

In a small case-control study, platelet RNA expression analysis implicated 2 candidate proteins (CD69 and myeloid related protein-14) that differentiated STEMI patients from those with stable CAD (Healy et al., 2006). However, in the context of STEMI, these findings are mostly of interest as a research tool given the central role of the ECG in diagnosis and management of STEMI patients. This work does offer proof of principle and, as discussed subsequently, could have more relevance for application to identification of NSTE ACS patients.

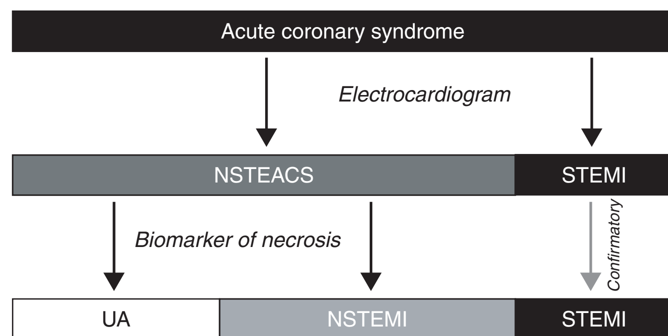

Figure 25.1 Diagnostic flow and distribution of types of acute coronary syndromes.

Patients whose initial ECG does not reveal ST-segment elevation are further subdivided into 2 groups, largely on the basis of measurement of levels of biomarkers released into the blood stream as a result of ischemic myocardial injury and necrosis. Although a number of markers have been used historically (SGOT, LDH, total CK), over the past 2 decades mass assays for the cardiac-specific isoenzyme of creatine kinase (CK-MB) and more recently, cardiac-specific isoforms of troponin T and I have been the recognized diagnostic gold standards for MI. With the publication of the joint ESC/ACC Task Force recommendations for MI redefinition in 2001, troponin, because of its enhanced sensitivity and specificity for myocardial necrosis, became the preferred diagnostic marker of MI in most clinical situations (Alpert et al., 2000). The 2007 revision of this document refined the definition of MI further in an attempt to achieve consensus, particularly on appropriate clinical situations for the use of troponins and/or CK-MB for MI diagnosis and diagnostic parameters of the assays, that would be applicable and practical across medical practice and clinical trials around the world (Thygesen et al., 2007). Along with the National Academy of Clinical Biochemistry (NACB) Practice Guidelines for Laboratory Medicine (Morrow et al., 2007), these documents summarize the base of evidence and recommendations for the use of biochemical markers in the diagnosis of ACS. Key recommendations for the use of biochemical markers to diagnose MI are shown in Table 25.1.

Need for Novel Biomarkers for Diagnosis of ACS

While CK-MB and troponins are useful diagnostic tools for MI, they only become elevated after irreversible myocardial injury has occurred. Ideally, one would identify patients with an acute coronary syndrome early, at a point when therapeutic intervention might mitigate myocardial damage. Further, the group of patients without ECG changes or biomarker elevations on presentation is a particularly challenging group to manage, especially when the clinical presentation is atypical. Over 6 million Americans present to emergency departments each year for evaluation of chest pain syndromes; clearly the vast majority are not ultimately diagnosed with an ACS. Admitting all of these individuals to the hospital is not practical from the perspective of resource use and costs, but the medico-legal risk associated with missing a patient with MI and discharging him from the emergency department is high. Missed MI, which carries a two-fold increased risk of death (Pope et al., 2000), is the leading cause of malpractice claims against emergency department and primary care physicians (Karcz et al., 1996; Rusnak et al., 1989). Therefore, there is a tremendous need for refined diagnostic testing to identify who among this large number of patients with normal ECG and troponin levels at presentation is having an ACS and to identify as early as possible those who need treatment or who can be safely sent home. While this is an area of great diagnostic need, few such tests are commercially available, making this clinical situation poised for the application of omic technologies to identify unique molecular signatures that

distinguish patients with unstable angina or pre-infarction from those with non-cardiac diagnoses.

In current practice, serial testing of multiple necrosis markers with different release kinetics after myocardial injury (CK-MB, troponin, and myoglobin) has been shown to identify MI in more patients in a general emergency department cohort and to do it as much as an hour earlier than conventional single marker testing with troponin or CK-MB (Newby et al., 2001). However, even earlier detection, before necrosis occurs, could be clinically beneficial for triage and treatment. Ischemia modified albumin (IMA) and myeloperoxidase are FDA-approved assays for use as adjuncts to ECG and troponin testing in this situation, but each has limitations to its widespread adoption.

The albumin cobalt binding (ACB) test takes advantage of modification of the *N*-terminus of albumin in the setting of ischemia (Bar-Or et al., 2001), reducing its ability to bind cobalt. The increased free cobalt can then be detected with special assays (Bar-Or et al., 2000). Importantly, in human angioplasty models of myocardial ischemia, IMA becomes positive within a few minutes after the onset of ischemia (Sinha et al., 2003), suggesting that it could be an ideal tool for early differentiation of chest pain patients in the emergency department. Unfortunately, the sensitivity, specificity, and positive predictive value of this test are far too low for use as a diagnostic tool for ischemia or pre-infarction or to guide treatment decisions in those with a positive test. However, it does have excellent negative predictive value, and when combined with negative troponin testing and non-diagnostic ECG can exclude the diagnosis of ischemia with a negative predictive value of over 97% (Peacock et al., 2006).

Myleoperoxidase is an enzyme activated in and released by activated neutrophils and monocytes; it is believed to have a pathophysiological role in ACS and may be a marker of plaque instability (Apple et al., 2005; Malech and Naussef, 1997). A study published in 2003 suggested a potential role for myeloperoxidase in early emergency department diagnosis and risk stratification (Brennan et al., 2003). In this study, among 604 patients presenting with chest pain to the emergency room, myeloperoxidase levels were elevated at baseline among patients who were initially troponin-negative, but subsequently troponin-positive, even when fewer than 3 hours had elapsed since the onset the symptoms. Further, there was a correlation of myeloperoxidase with both short and long-term outcomes. However, leukocyte and monocyte activation and myeloperoxidase release can occur in the setting of a number of disease states (Apple et al., 2005); therefore, like the ACB test, the low specificity of elevated myeloperoxidase levels for ACS precludes its use as a stand alone marker for diagnosis of ischemia. It must be interpreted in the context of clinical findings and other laboratory data.

Omic Technologies in Diagnosis of ACS

One of the most intriguing investigations that foreshadows the potential application of omic technologies to diagnostic test development for use in management of patients with suspected ACS involved metabolomics. In a small case-control study of 36 patients who underwent stress testing with nuclear myocardial perfusion imaging, unbiased metabolomic profiling of blood obtained pre- and post-test using LC/MS technology identified small molecules that changed in abundance differentially between patients with ischemia and those without (Figure 25.2) (Sabatine et al., 2005). After statistical analysis of the output, a score reflecting the presence or absence of change in the 6 most discordantly regulated metabolites predicted ischemia with a

Table 25.1 Class I recommendations for use of biochemical markers for diagnosis of myocardial infarction

Recommendation	Level of evidence
Biomarkers of myocardial necrosis should be measured in all patients who present with symptoms consistent with ACS.	Level of evidence: C
The patient's clinical presentation (history, physical exam) and ECG should be used in conjunction with biomarkers in the diagnostic evaluation of suspected MI.	Level of evidence: C
Cardiac troponin is the preferred marker for the diagnosis of MI. Creatine kinase MB (CK-MB) by mass assay is an acceptable alternative when cardiac troponin is not available.	Level of evidence: A
Blood should be obtained for testing at hospital presentation followed by serial sampling with timing of sampling based on the clinical circumstances. For most patients, blood should be obtained for testing at hospital presentation and at 6–9 h.	Level of evidence: C
In the presence of a clinical history suggestive of ACS, the following are considered indicative of myocardial necrosis consistent with MI a. Maximal concentration of cardiac troponin exceeding the 99th percentile of values (with optimal precision defined by total CV $< 10\%$) for a reference control group on at least 1 occasion during the first 24 h after the clinical event (observation of a rise and/or fall in values is useful in discriminating the timing of injury). b. Maximal concentration of CK-MB exceeding the 99th percentile of values for a sex-specific reference control group on 2 successive samples (values for CK-MB should rise and/or fall).	Level of evidence: C

Figure 25.2 Scatterplot of the statistical significance changes in metabolite levels according to case (ischemia) or control (no ischemia) status. Significant changes ($p < 0.05$) are represented as colored circles; no significant change as black dots. Red indicates and increase in concentration and green a decrease in concentration. The rim of the circle reflects change in the controls and the center reflects changes in the cases.

Figure 25.3 Conceptual framework for clinical proteomics efforts as proposed by the National Heart, Lung and Blood Institute clinical proteomics working group.

c-index of 0.83. Much work remains to translate this finding to practical clinical utility (e.g., validation in unselected emergency department populations with suspected ischemia, development of assays that are practical for use in hospital clinical laboratories and in real time), but the concept highlights the possibilities for application of omic technologies to the early detection of ACS.

The use of proteomics, both candidate-based approaches and unbiased approaches, as a platform for discovery and development of novel biomarkers of cardiovascular disease has been widely espoused (Anderson, 2005a, b; Arab et al., 2006; Granger et al., 2004). Figure 25.3 shows a conceptual framework for such efforts proposed by the NHLBI clinical proteomics working group. Despite this enthusiasm, the use of proteomics to distinguish ACS patients from those without ACS is in its infancy. Recently, however, in a small study of 11 patients with acute MI, 8 with unstable angina and 9 age-matched controls without known coronary

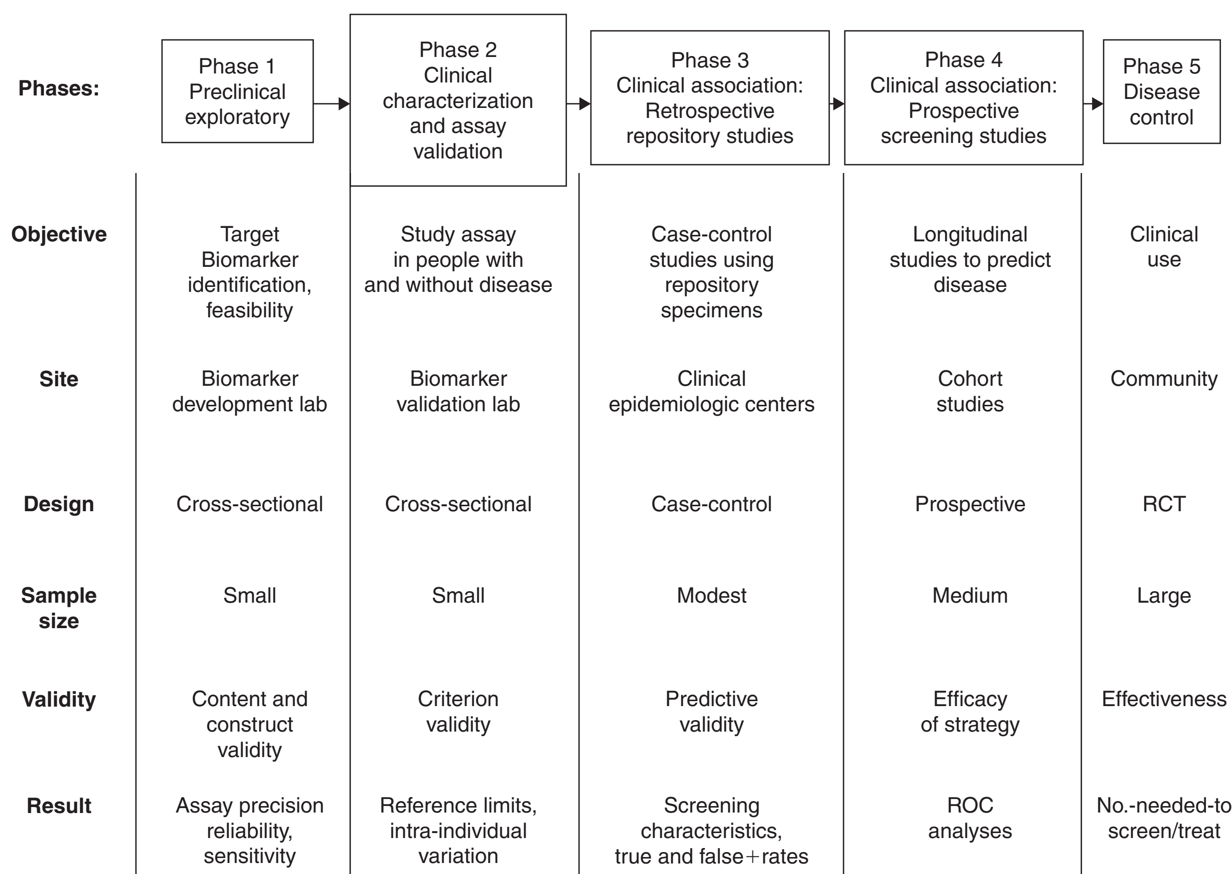

Figure 25.4 A 5-step process that is essential to move from biomarker discovery to clinical utility.

disease, Mateos-Cáceres and colleagues published a seminal report on the used of 2d gel-based proteomics to identify changes in the protein map that discriminated patients with acute MI from those with unstable angina based on changes relative to controls (Mateos-Cáceres et al., 2004). These observations provide support that proteomics may lead to usable clinical tools to distinguish disease state in the clinical setting of suspected ACS. In an excellent review of the development of biomarkers in cardiovascular disease, Vasan has outlined a 5-step process that is essential to move from discovery findings such as this to clinical utility (Figure 25.4; Vasan, 2006).

Finally, as mentioned above, the use of platelet RNA expression profiling (or possibly peripheral blood RNA expression analysis), either directly or to identify candidate protein biomarkers of ACS, may prove to be a useful tool for differentiating difficult to diagnose NSTE ACS presentations from non-ACS presentations or to identify NSTE ACS earlier after presentation.

PROGNOSIS

The goals of "biomarker" testing are multifold. As described in previous sections screening for disease and diagnosis are important applications. However, equally important is the ability to use the information from biomarker testing to discern not only the presence or absence of disease, but more importantly to relate biomarker information to prognosis or downstream meaningful clinical outcomes. Although the concept of using genetic and genomic, proteomic, and metabolomic approaches for risk stratification and to refine prognosis in ACS is appealing, substantial work remains to bring this conceptual construct to clinical utility.

That there is a need for such advances to refine clinical models of risk is undenied, and numerous examples of the development and use of biomarker assessment for prognosis or risk stratification abound in the ACS literature. Although hundreds of individual proteins, in addition to routine laboratory tests, have been identified as predicting clinical outcome, only a few have sufficient evidence to support their use in routine clinical practice. Guidelines for the use of biomarker testing for risk stratification in ACS were recently published by the NACB, and class I recommendations are summarized in Table 25.2 (Morrow et al., 2007). In this regard, there is substantial evidence for use of troponin (I or T), b-type natriuretic peptide (BNP) or *N*-terminal proBNP, and high-sensitivity c-reactive protein (hsCRP) for risk stratification of ACS patients. Each of these biomarkers contributes incremental information to that from easily assessable clinical and laboratory parameters and there are commercially available, high-quality assays for clinical use. Although many

Table 25.2 Class I recommendations for use of biochemical markers for risk stratification in ACS

Recommendation	Level of evidence
Patients with suspected ACS should undergo early risk stratification based on an integrated assessment of symptoms, physical exam findings, ECG findings, and biomarkers.	Level of evidence: C
A cardiac troponin is the preferred marker for risk stratification and, if available, should be measured in all patients with suspected ACS. In patients with a clinical syndrome consistent with ACS, a maximal (peak) concentration exceeding the 99th percentile of values for a reference control group should be considered indicative of increased risk of death and recurrent ischemic events.	Level of evidence: A
Blood should be obtained for testing on hospital presentation followed by serial sampling with timing of sampling based on the clinical circumstances. For most patients, blood should be obtained for testing at hospital presentation and at 6–9 h.	Level of evidence: B

other novel protein markers have been identified (Ginsburg et al., 2005; Morrow et al., 2007), their independent contribution to risk stratification remains to be proved and development of assays for routine use in hospital laboratories remains.

As a forerunner to the application of proteomics (or other multidimensional omic technologies) to risk stratification of ACS patients, many studies have now demonstrated the utility of combining information carried by multiple markers of risk into a common risk prediction model. For example, in one study, a simple score based on measurement of troponin, BNP and hsCRP provided additive, complementary information to that from any marker alone in the context of clinical markers of risk (Sabatine et al., 2002). Additionally, investigators from the CAPTURE trial used a candidate protein approach, to identify six proteins (hsCRP, troponin T, CD40 ligand, myeloperoxidase, vascular endothelial growth factor (VEGF), placental growth factor, and pregnancy-associated plasma protein [PAPP]-A) that together refined prediction of 6-month death or MI compared with use of any single marker in both ACS and general emergency department patients with suspected ACS (Heeschen et al., 2005). In another report (Baldus et al., 2003), five markers each had independent additive value, and in a multivariable model, each protein marker had more predictive information than any clinical variable.

Finally, one of the most important insights into the use of protein biomarkers in ACS risk stratification came from investigators in a substudy of the GUSTO-IV trial. They examined use of markers of multiple processes (necrosis, troponin; inflammation, hsCRP, and neurohormonal activation, NT-proBNP) in the context of clinical characteristics and routine laboratory testing (Westerhout et al., 2006), and made the important observation that the prognostic utility of a given marker depended on the outcome of interest. NT-proBNP, troponin T, and hsCRP were all independently associated with mortality at 1 year, in addition to heart rate, creatinine clearance, and ST-segment depression. However, only troponin T, creatinine clearance and ST-segment depression predicted risk for future MI. In addition, the relative strengths of the association of a biomarker with risk for subsequent events varied according to the time frame in which it was assessed. Thus, protein biomarkers may vary in their utility for short- and long-term risk stratification after ACS, but protein biomarkers consistently comprise several of the most important independent predictors of risk.

2009 UPDATE

The development of genomic biomarkers for use to evaluate clinical risk, speed development, and assess safety and efficacy of therapeutics and guide treatment decisions remains a major focus of activity of the FDA Critical Pathway initiative, including a specific focus in heart disease, and the NIH through multiple avenues including partnership with the FDA and others in the Biomarker Consortium (Biomarkers Consortium, 2009; US Department of Health and Human Services, 2008). However, work to establish a uniform framework for critical evaluation and translation of this work to practical utility in the clinical setting, clinical trials, or drug discovery and development remains an ongoing process.

Although academic activity in biomarker research has remained high over the past year (a simple PubMed search for "biomarkers" in "acute coronary syndromes" yielded nearly 400 citations for the year 2008), there persist the challenges of sample size, determination of independent and incremental contribution to routinely available clinical characteristics or laboratory tests and validation in separate cohorts. Perhaps the most interesting example of new research in ACS that may have near-term practical utility was the finding in 2208 French patients of an association between carrying more than one CYP2C19 loss-of-function alleles and a 2-fold higher 1-year rate of major adverse cardiovascular outcomes after MI (Simon et al., 2009). This association was particularly strong among patients undergoing percutaneous coronary intervention (nearly 4-fold increase in death, MI, or stroke). These findings, if validated in other populations and confirmed prospectively,

could have important implications for clopidogrel dosing or alternate selection of new, more potent antiplatelet agents such as prasugrel based on genetic screening. While limited to smaller populations and less immediately clinically applicable, new examples of the application of metabolomic (Vallejo et al., 2009) and gene expression (Nakayama et al., 2008; Wingrove et al., 2008) profiling in characterization of coronary disease and ACS populations continue to emerge.

Finally, major efforts to establish the large, longitudinal clinical databases and specimen biorepositories that will be necessary to fuel future genomic research and confirm preliminary findings such as these have been initiated and are well underway. For example, the UK Biobank, which has as a goal collecting blood and urine samples and baseline and longitudinal clinical information from 500,000 Britons between the ages of 40 and 69 by the end 2008, had already enrolled half of its target population (UK Biobank, 2009). Thus, there is a continually emerging confluence of scientific interest in and recognition of the need for genomic research in ACS, along with the support and growing resources that should be expected to lead to major advances over the coming years.

CHAPTER

Heart Failure in the Era of Genomic Medicine

Ivor J. Benjamin and Jeetendra Patel

INTRODUCTION

Heart failure has been conveniently subdivided according to abnormalities in the cardiac cycle: namely, systolic heart failure (SHF) and diastolic heart failure (DHF). SHF is associated with decreased cardiac output and ventricular contractility, termed systolic dysfunction, and is attributed to a loss of ventricular muscle cells. Dilated cardiomyopathy (DCM) is characterized by impaired systolic function and myocardial remodeling and enlargement of one or both ventricles. Idiopathic dilated cardiomyopathy (IDCM) refers to primary myocardial disease in the absence of coronary, valvular or systemic disease. The ventricular remodeling of DHF, however, is characterized by normal chamber size with impaired ventricular filling from abnormal myocardial stiffness during the relaxation phase. More recently, the clinical syndrome of heart failure with preserved ejection fraction (HFPEF) – left ventricular ejection fraction $> 50\%$ – has been recognized in several cross-sectional studies (Bhatia et al., 2006; Owan et al., 2006).

PREDISPOSITION (GENETIC AND NON-GENETIC)

In western societies, ischemic heart disease (~60%) and hypertension are the most common causes of ventricular systolic dysfunction but there is now irrefutable evidence for genetic defects whose onset and progression occur in adulthood (e.g., familial cardiomyopathy) (Benjamin and Schneider, 2005; Morita et al., 2005). Beginning in the late 1950s, distinct alterations in the size and geometry of the left ventricle, termed "ventricular remodeling," were being recognized, but the ensuing debate for over three decades was primarily focused on morphological classifications. Hypertrophic cardiomyopathy (HCM) is characterized by predominant and marked thickening of the left circumferential ventricular wall (i.e., hypertrophy), small LV cavity size and hypercontractility. Such patients including young athletes were prone to sudden cardiac death attributed pathophysiologically to subaortic stenosis and cavity obliteration triggering inadequate cardiac output and lethal arrhythmias. In contrast, dilatation of left ventricular cavity and reduced systolic function are the hallmarks of dilated cardiomyopathy (DCM). In 1991, the Seidmans' laboratory at Harvard Medical School reported for the first time that mutations in the gene encoding the β-myosin heavy chain, a major structural and contractile protein, was the genetic basis for familial HCM associated with sudden death, ushering in the present era of cardiovascular genomic medicine. This seminal discovery permanently shifted the paradigm from the morphological to the molecular, enabling basic insights into disease pathogenesis to be viewed from how single gene defects orchestrate profound alterations at the biochemical, metabolic, hemodynamic, and physiological levels. In parallel, genetically engineered animals models became the state-of-the art for establishing causality

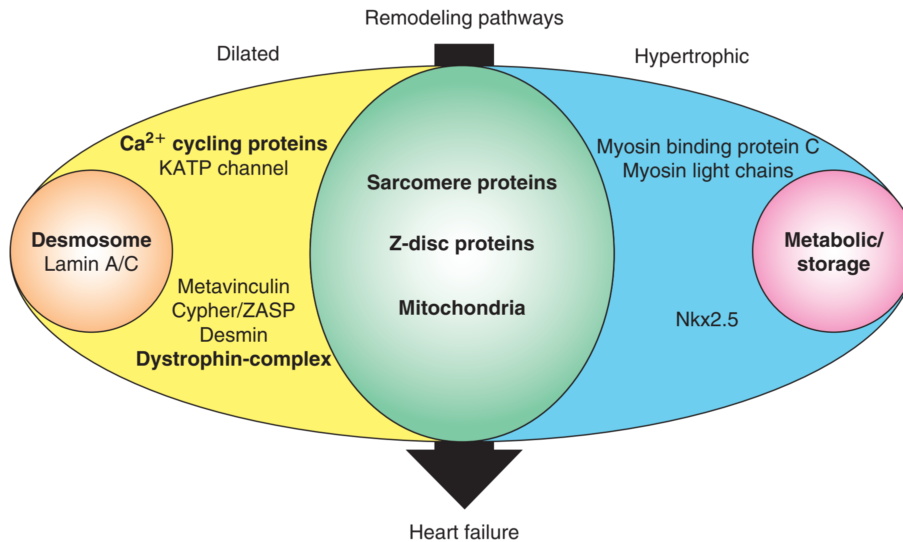

Figure 26.1 Human gene mutations can cause cardiac hypertrophy (blue), dilation (yellow), or both (green). In addition to these two patterns of remodeling, particular gene defects produce hypertrophic remodeling with glycogen accumulation (pink) or dilated remodeling with fibrofatty degeneration of the myocardium (orange). Sarcomere proteins denote β-myosin heavy chain, cardiac troponin T, cardiac troponin I, α-tropomyosin, cardiac actin, and titin. Metabolic/storage proteins denote AMPactivated protein kinase γ subunit, LAMP2, lysosomal acid α 1,4-glucosidase, and lysosomal hydrolase α-galactosidase A. Z-disc proteins denote MLP and telethonin. Dystrophin-complex proteins denote δ-sarcoglycan, β-sarcoglycan, and dystrophin. Ca^{2+} cycling proteins denote PLN and RyR2. Desmosome proteins denote plakoglobin, desmoplakin, and plakophilin-2. (Reprinted with permission from Morita et al., 2005.)

and, ultimately, a basis to test proof-of-concept leading to disease prevention.

Many more single genetic defects are routinely being linked to familial heart failure (Figure 26.1) but an important future challenge is to establish how inherited and acquired factors conspire to drive the growing epidemic of heart failure.

Severe occlusive coronary disease is the substrate for acute coronary syndromes, myocardial infarctions and subsequent pump failure as shown in Figure 26.2. The high prevalence of heart failure in African-Americans with hypertension underscores potential gene–environment interactions in selected populations. Infectious etiologies (e.g., rheumatic heart disease) are declining but valvular heart disease from iatrogenic causes (e.g., diet pills, toxins) remains an important risk factor (Figure 26.2). Viruses (e.g., Coxsackie's B3, parvovirus) are the major suspected culprits for idiopathic dilated cardiomyopathy (IDCM) in which the postviral sequalae of inflammation and apoptosis trigger ventricular remodeling and dilation (Liu and Mason, 2001). IDCM accounts for 30% of cases of DCM. Heart failure on presentation in the peri-partum or post-partum period has a variable clinical course from severe pump failure to complete recovery. The most common cause of right ventricular heart failure (RVHF) is left ventricular systolic dysfunction. In addition, RVHF is associated with congenital heart disease (e.g., tetralogy of fallot), primary pulmonary hypertension, and arrhythmogenic right ventricular dysphasia and right ventricular infarction. Stress cardiomyopathy is a rare reversible form of left ventricular dysfunction associated clinically with emotional stress, angiographically with "apical ballooning," and pathophysiologically with excess sympathetic activation (Wittstein et al., 2005). This entity remains a diagnosis of exclusion, which mimics ST segment elevation MI (STEMI) on presentation, has a much more favorable clinical outcome than STEMI. Lastly, thyrotoxicosis, Paget's disease and severe chronic anemia are rare causes of high output heart failure. Individuals afflicted with HFPEF are more commonly older age, female gender and have a history of hypertension and atrial fibrillation.

SCREENING

The New York Heart Association (NYHA) functional classification scheme, an older but widely used screening tool, assesses the severity of functional limitations of individuals afflicted with heart failure. The four classes of the NYHA classification are linked to increasing severity of signs and symptoms and correlate well with prognosis. This classification scheme, however, has important limitations since diverse pathophysiological processes leading to symptomatic heart failure are overlooked (Dunselman et al., 1988). Accordingly, the American College of Cardiology and American Heart Association (ACC/AHA) Classification of Chronic Heart Failure was developed to account for the multiple stages and predisposition conditions associated with the clinical syndrome. Designed to encompass emerging scientific evidence, an expert panel periodically assembles these updates, which are the most widely used and authoritative sources on the evaluation, management, performance measures, and outcomes on heart failure (Bonow et al., 2005; Hunt et al., 2005; Radford et al., 2005). In turn, these guidelines incorporating preclinical

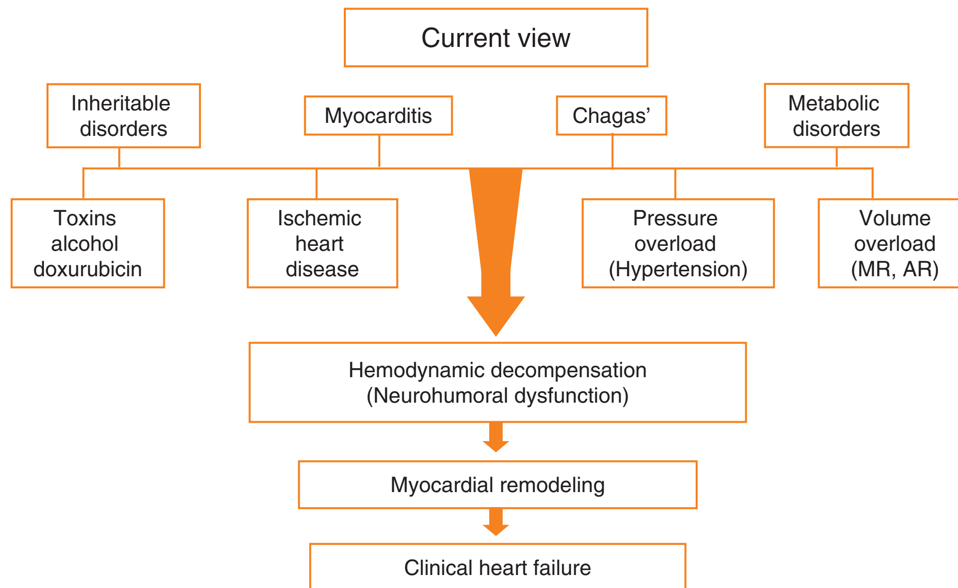

Figure 26.2 The schematic diagram illustrates the different etiologies and multiple compensatory and adaptive pathways implicated in the clinical syndrome of heart failure.

stages, risk factors, pathophysiologic stages, and clinical recognition of heart failure are further subdivided into four stages.

Stage A patients are at high risk for developing heart failure, but have had neither symptoms nor evidence of structural cardiac abnormalities. Major risk factors include hypertension, diabetes mellitus, coronary artery disease and family history of cardiomyopathy. In selected patients, the administration of angio-tensin converting enzyme (ACE) inhibitor is recommended to prevent adverse ventricular remodeling.

Stage B patients have structural abnormalities from previous myocardial infarction, LV dysfunction or valvular heart disease but have remained asymptomatic. Both ACE inhibitors and beta-blockers are recommended.

Stage C patients have evidence for structural abnormalities along with current or previous symptoms of dyspnea, fatigue and impaired exercise tolerance. In addition to ACE inhibitors and beta-blockers, optimal medical regimen may include diuretics, digoxin, and aldosterone antagonists.

Stage D patients have end-stage symptoms of heart failure that are refractory to standard maximal medical therapy. Such patients are candidates for left ventricular assist devices (LVADs) and other sophisticated maneuvers for myocardial salvage or end-of-life care.

PATHOPHYSIOLOGY

Neurohumoral Mechanisms

Low-cardiac output and systemic hypoperfusion elicit a cascade of compensatory mechanisms but predominantly activation of the neurohumoral pathway for augmenting fluid retention (Figure 26.2). Sympathetic nervous system activation increases heart rate and peripheral vasoconstriction from the release of catecholamines, triggering increased afterload and myocardial oxygen consumption. Catecholamines also increase renin secretion, cell death, fibrosis, and myocardial irritability, underlying substrates for lethal arrhythmias and sudden death. In contrast, natriuretic peptides released from specialized cells in the atria exert hormonal actions in distant vascular beds, stimulating vasodilation, and diuresis. Afterload reducing agents and beta-adrenergic blockers have significantly reduced the morbidity and mortality while improving the survival of patients with heart failure. Likewise, antagonists of aldosterone, which promotes salt and water retention, have proven clinical benefits.

Myocardial Remodeling

Left ventricular dysfunction and systolic heart failure secondary to myocardial infarction or ischemia are the prerequisites of low-ejection fraction and elevated pulmonary pressures with congestion. Acquired or inherited conditions that either decrease cardiomyocyte viability and/or increase cell death will ultimately trigger pump failure and symptomatic heart failure. Given the heart's limited capacity for regeneration, terminally differentiated ventricular cardiomyocytes may undergo hypertrophy in response to increase metabolic and homodynamic demands. Activation of the "fetal gene program" orchestrates transcriptional upregulation of genes encoding contractile and cytoskeletal proteins – the prerequisite for compensatory hypertrophy. Recruitment of such adaptive mechanisms provides a variable but stable and asymptomatic interval – perhaps lasting years – before cardiac decompensation. The ensuing ventricular dilatation is a pathologic form of adaptation, termed "ventricular remodeling," affecting intrinsic cardiac mass, the extracellular matrix, collagen deposition and fibrosis as shown in Figures 26.2 and 26.3. Whereas low levels of reactive oxygen species (ROS) serve as stress signals in

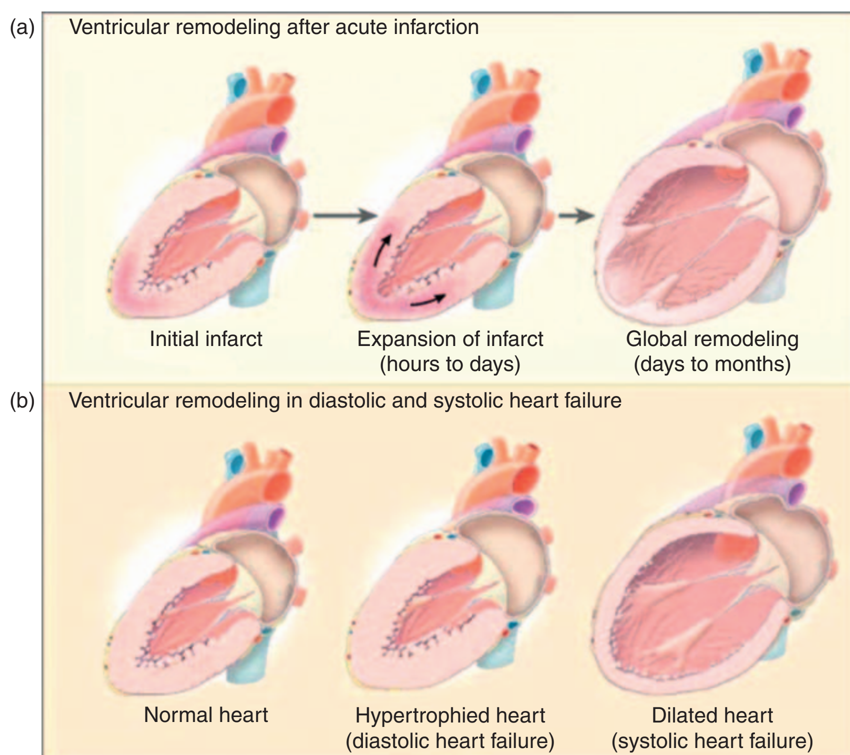

Figure 26.3 Ventricular remodeling after infarction (a) and in diastolic heart failure (b). (Adapted from Jessup et al. *N Engl J Med* 348, 2007–2018.)

redox-dependent regulation, elevated levels of ROS caused by mitochondrial dysfunction may alter myocardial energetics, cardiac metabolism, and trigger the release of cytochrome *c*, thereby activating cell survival/death pathways. Endothelial dysfunction gives rise to the aberrant release of nitric oxide, a potent vasodilator, and/or reactivity with ROS to form peroxynitrite, which causes oxidative damage and cellular injury. Progressive remodeling, in attempts to maintain systolic function and homeostasis (Stage B), leads to valvular regurgitation from inadequate apposition of the mitral leaflets, increasing myocardial stress and, ultimately, decompensated heart failure (Stage C and Stage D).

Mechanisms of Cell Death in Heart Failure

Progressive loss of cardiomyocytes from either necrosis or apoptosis with diverse pathogenic states contributes to the pathogenesis of heart failure as shown in Table 26.1 and Figure 26.4 (Liew and Dzau, 2004; Wencker et al., 2003). Apoptosis or programmed cell death is activated by signaling cascades, via either the extrinsic or intrinsic cell survival/death pathways (Danial and Korsmeyer, 2004). Ligands such as TNF-α, which bind to cognate receptors at the plasma membrane, mediate cell death through the extrinsic pathway, whereas the Bcl-2 family – consisting of both pro- and anti-apoptotic proteins – regulates the intrinsic pathway. Mitochondria play a central role in cell survival/death principally from the initiation of stress signals (e.g., ROS) and release of mitochondrial cytochrome c, which initiates complex formation and the activation of apoptotic proteases (e.g., caspase-9) (Danial and Korsmeyer, 2004). The role of apoptosis in chronic heart failure, which ranges between 80 and 250 myocytes per 100,000 nuclei in failing human hearts was elegantly validated by Wencker and coworkers using transgenic mice harboring a fusion protein FKBP fused with a conditionally active caspase (Wencker et al., 2003). In contrast, low-level inhibition of apoptosis prevented DCM and death, suggesting possible therapeutic strategies for combating heart failure.

DIAGNOSIS

Newly diagnosed patients with heart failure most commonly seek medical attention for either gradual or abrupt onset of the classical signs and symptoms with pulmonary congestion. The clinical spectrum varies widely but dyspnea on exertion, peripheral edema, orthopnea, and paroxysmal nocturnal dyspnea are not uncommon. Exertional chest pain or angina at rest requires an immediate evaluation to determine if biochemical evidence of myocardial damage demands more aggressive management for acute coronary syndromes. Elevated jugular venous distension from right ventricular failure, ascites, and cachexia are more ominous signs for low-cardiac output and decompensation, requiring urgent attention, preferably, from a provider who specializes in heart failure management.

Routine diagnostic studies include an electrocardiogram, chest radiograph, and B-type natriuretic peptide, the latter having the best predictive value for distinguishing between CHF and

TABLE 26.1 The genetic basis of cardiomyopathies

Symbol	Chromosome	Gene product	Cardiomyopathy type
ACTC	15q11–14	Cardiac muscle α-actin	Hypertrophic and dilated
ABCC9	12p12.1	Member 9 of the superfamify C of ATP-binding cassette (ABC) transporters	Dilated
CSRP3, MLP	11p15.1	Cysteine- and glycine-rich protein 3	Dilated
DES	2q35	Desmin	Dilated
DSP	6p24	Desmopfakin	Dilated
LMNA	1q21.2–21,3	Lamin A/C	Dilated
VCL	10q22.1–q23	Metavlnculin	Dilated
MYBPC3	11p11.2	Cardiac myosin-binding protein C	Hypertrophic and dilated
MYH6	14q12	Cardiac muscle a-isoform of myosin heavy chain (heavy polypeptide 6)	Hypertrophic
MYH7	14q12	Cardiac muscle a-isoform of myosin heavy chain (heavy polypeptide 7)	Hypertrophic and dilated
MYL2	12q23–24.3	Myosin regulatory light chain associated with cardiac myosin-β(or slow) heavy chain	Hypertrophic
MYL3	3p21.2–21.3	Myosin light chain 3	Hypertrophic
PLN	6q22.1	Phospholamban	Dilated
PRKAG2	7q35–36	γ2 non-catalytic subunit of AMP-activated protein kinase	Hypertrophic
SGCB	4q12	β-Sarcoglycan (43kDa dystrophin-associated glycoprotein)	Dilated
SGCD	5q33–34	δ-Sarcoglycan (35kDa dystroph in-associated glycoprotein)	Dilated
TAZ, G4.5	Xq28	Tafazzin	Dilated
TTN	2q31	Titin	Hypertrophic and dilated
TCAP	17q12	Titin-cap	Dilated
TPM1	15q22.1	Tropomyosin 1 (α)	Hypertrophic
TNNI3	19q13.4	Troponin I, a subunit of the troponin complex of the thin filaments of striated muscle	Hypertrophic
TNNT2	1q32	Cardiac isoform of troponin T2, tropomyosin-binding subunit of the troponin complex	Hypertrophic and dilated

non-CHF patients (Maisel and McCullough, 2003). Noninvasive echocardiography is the most commonly used diagnostic tool for the assessment and follow-up of patients with heart failure with or without preserved ejection fraction. Coronary angiography should be performed to exclude reversible causes for left ventricular dysfunction or to guide prompt revascularization. If the coronary vessels are widely patent in the setting of global dysfunction, then endomyocardial biopsy should be considered to assess for reversible causes including viral myocarditis (Liu and Mason, 2001). Equilibrium radionucleotide angiography (ERNA) is another noninvasive diagnostic study that assesses both left and right ventricular systolic function. Screening tools such as contrast computer tomographic angiography and magnetic resonance imaging (MRI) are gaining attention as emerging technologies with equivalent sensitivity and specificity as the invasive angiogram for coronary arteriography. MRI may also uncover unsuspected infiltrative cardiomyopathy, arrhythmogenic right ventricular dysplasia, and is superior for the assessment of myocardial viability before revascularization.

PROGNOSIS

Over 5 million Americans or 1.5% of the US population have chronic heart failure, and there is a similar prevalence at risk of undiagnosed left ventricular dysfunction (Braunwald and

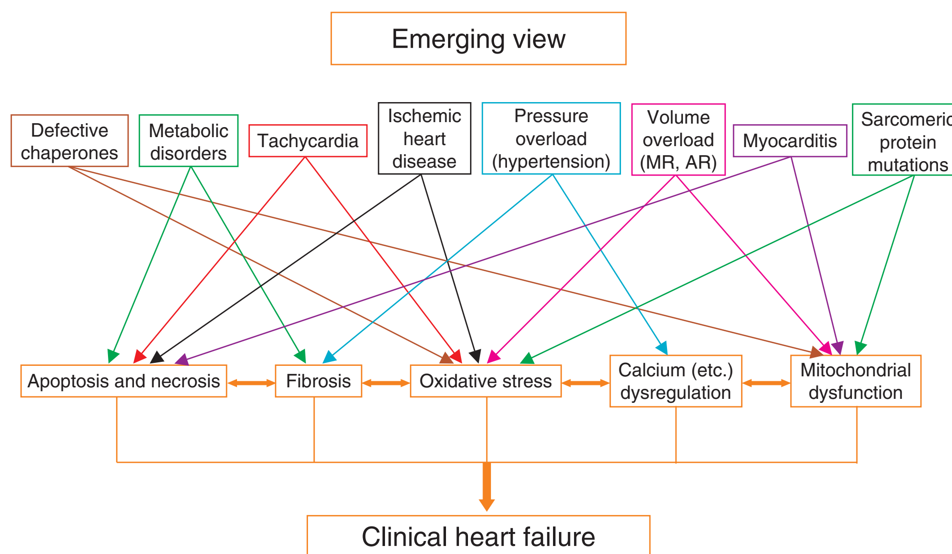

Figure 26.4 At the cellular and molecular levels, crosstalk among pathways related to oxidative stress and calcium dysregulation, for example, may contribute to secondary apoptosis and necrosis. In spite of considerable insights about mechanisms, current therapies focus on reversing neurohumoral imbalances but rarely on underlying mechanisms.

Bristow, 2000). With over 550,000 new cases of heart failure, the disproportionate health and economic burden exceeds 24 billion dollars annually (DiBianco, 2003). Soon, heart failure will become the number one cause of death worldwide, eclipsing infectious disease (Bleumink et al., 2004). Whereas new pharmacologic management and revascularization techniques continue to improve the survival after acute myocardial infarction, the prevalence of chronic heart failure appears to be increasing as the population ages (Braunwald and Bristow, 2000). Notwithstanding, heart failure accounts for 20% of all hospital admissions in patients older than 65, and the hospitalization rate has increased by 159% in the past decade (Jessup and Brozena, 2003). Available treatments for heart failure have only modestly improved the morbidity and mortality (Jessup and Brozena, 2003), and, for patients with advanced heart failure, the prognosis still remains grim with 1-year mortality rates between 20% and 45%, overshadowing the worse forms of some cancers (Jessup and Brozena, 2003).

PHARMACOGENOMICS

Substantial phenotypic heterogeneity in heart failure and the variability of responses among individuals taking pharmacologic agents have been attributed to common polymorphisms in the genome (Liggett, 2001). A surmountable hurdle, however, is the robustness of the association between putative genetic markers and therapeutic response. Recent lessons from studies of human heart failure illustrate handsomely both the enormous potential and challenges for pharmacogenomics – a maturing discipline in which an individual's genetic determinants are used to predict drug response and outcomes (Evans and Relling, 1999; Liggett, 2001). Liggett and coworkers have demonstrated that non-synonymous single-nucleotide polymorphisms of the β_1-adrenergic receptor (β_1-AR), a member of the seven membrane-spanning receptor superfamily, alters the therapeutic response to β-blockers during heart failure (Liggett et al., 2006). Stimulatory effects between β_1-AR and heterotrimeric G proteins G_s mediate both beneficial and deleterious signal transduction pathways during the onset and progression of heart failure. Because β_1-AR is the major subtype in cardiac myocytes, increased catecholamines exert potent cardiomyopathic effects, cardiac remodeling and abrogation of gene expression, which are antagonized by β_1-AR blockers resulting in improved outcomes. A single nucleotide variation at nucleotide 1165 in the gene encoding β_1-AR results in either Arg or Gly at position 389 residue (Liggett et al., 2006). In response to inotropic stimulation, human trabeculae muscle with the β_1-Arg-389 residue from either nonfailing or failing hearts exhibited significantly greater contractility than β_1-Gly-389 polymorphism.

As shown in the β-Blocker Evaluation of Survival Trial (BEST), which evaluated the β-blocker bucindolol for the treatment of Class III/IV, insights into the mechanisms for pharmacogenomic phenotypes involving the Arg/Gly polymorphism of the β_1-AR owe much credit to the DNA Study Group (Feldman et al., 2005; Liggett et al., 2006). The foresight of BEST investigators to recognize the power of genetic haplotyping underscores the importance for all future well-designed human trials to include contingencies for pharmacogenomics in an era of genomic medicine. Notwithstanding the success gleaned from a highly penetrant single-gene trait such as Arg/Gly polymorphism of the β-AR, future advances will require undertaking the more formidable challenges related to multigene traits that influence drug metabolism and response for therapeutic individualization (Evans and McLeod, 2003).

The recent African-American Heart Failure (A-HeFT) enrolled 1050 black patients with NYHA class III or IV to receive a fixed dose of two well-established medications, isosorbide

dinitrate and hydralazine, in a placebo controlled ran-domized multicenter trial. Combination nitrates and hydralazine, termed BiDil, when added to standard therapy was efficacious improving survival in blacks. But the implications of this high-profile study have drawn considerable scientific and ethical scrutiny owing to the marketing strategy of this therapy, which under the proprietary label, was advanced as a novel approach for race-based management. Because physical and genetic traits are not interchangeable, A-HeFT *per se* might prove to be poor surrogate for studies of pharmacogenetics since neither BiDil's efficacy in other racial and ethnic groups nor genetic markers for predicting the response of blacks to BiDil were ever tested.

In contrast, polymorphisms in the ACE pathway have been extensively studied, especially the ACE DD polymorphism, which had significantly higher death and need for transplant compared to II and ID genotypes (McNamara et al., 2001). With concurrent β-blocker treatment, patients with ACE DD polymorphism showed improved survival but benefited with a higher ACE dosage (McNamara et al., 2004), supporting the clinical utility of genetic information in clinical management. For at-risk populations, the pace for moving bidirectional bench ⇔ bedside and bedside ⇔ community-based practices should accelerate using evidence-based strategies emerging from disciplines such as health outcomes.

MONITORING

Genomic Profiling

Heart failure encompasses dynamic processes in which the activation or deactivation of distinct pathways at different stages in the pathogenesis suggest opportunities for intervention and even prevention before irreversible decompensation. A fundamental question, therefore, is how to develop improved diagnostic and prognostic indices that may guide improvements in treatment and outcomes for heart failure. A major goal of microarray-based analyses is to identify genes whose similar patterns of expression accurately represent the disease state or biological process. Such information, however, is often insufficient to identify the causal mechanisms but provides a comprehensive picture of the underlying process, which can predict responses to therapy or disease stage.

Both unsupervised and supervised approaches are applied to determine if previously unrecognized or unexpected patterns of expression exist in the datasets. Hierarchical clustering, for example, is an unsupervised approach that may be used after gene expression profiling to identify interdependent pathways before the onset of overt heart failure. Identification and validation of genes or novel pathways that are activated earliest may improve early detection and, ultimately, will be essential for designing therapies that prevent the natural history and progression of disease. If individual genes have different predictive power, then a "weighted voting scheme," based on the levels of gene expression, can be designed and tested before widespread application. Considerable caution in data interpretation is warranted, however, as comparisons from different laboratories may be skewed considerably by patient selection, different treatments, and clinical stages.

While many technical details and microarrays are beyond the scope of this chapter, considerable attention is being paid to standardization of data collection, normalization, and data reporting. Most peer-reviewed journals have instituted policies for primary sequence databases to be deposited before publication using the "minimal information about a microarray experiment" or MIAME standards (Ball et al., 2002; Ball et al., 2004; Brazma et al., 2001). We predict that meta analyses of large datasets hold particular promise for finding universal themes for classification, clinical staging, and predicting outcomes from gene expression profiles.

Transcriptional Profiling of Heart Failure

Neurohumoral, hemodynamic and environmental factors participate in remodeling the failing heart, but genetic, molecular, and cellular events are inscribed at the transcriptional level. Signaling pathways and biological processes implicated in the hypertrophic response of the heart are shown in Figure 26.4. Early genetic markers of cardiac hypertrophy include transcriptional reprogramming of genes encoding contractile proteins, oncogenes, neurohumoral factors, and transcription factors have been identified. Genes encoding proto-oncogenes c-jun, c-fos, c-myc, skeletal α-actin and ANF are also activated in response to hypertrophic stimuli. (Izumo et al., 1988; Komuro et al., 1988; Mulvagh et al., 1987; Schwartz et al., 1986). In angiotensin II receptor type 1alpha knockout mice, cardiomyocytes were capable of evoking increased protein synthesis and mitogen-activated protein kinase (MAPK) activation when stretched, strengthening the primary role of mechanical stretch in maintaining the hypertrophic phenotype. The mechanisms by which mechanical stress is converted into biological response are yet to be fully elucidated. High-density oligonucleotide arrays have also identified multiple genes, representing diverse biological process (e.g., myocardial structure, myocardial assembly and degradation, metabolism, protein synthesis, and stress response), which were differentially expressed in nonfailing and failing human hearts (Yang et al., 2000). Other larger studies of human heart failure have confirmed the role for MAPKs, mechanical stress and neurohumoral pathways in heart failure (Kudoh et al., 1998). Likewise, genetic pathways identified during acute and chronic pressure overload reflect differential gene expression during distinct phases may represent potential target for therapy. A substantial limitation, however, remains that lack of reproducibility and reliability in the sample sets owing to selection bias and differences in etiology, age, sex, mode of onset, treatment regimens and clinical course.

End-stage heart failure is associated with an increased activity and alterations of multiple gene products including the extracellular matrix/cytoskeletal (e.g., collagen types I and III, fibromodulin, fibronectin, and connexin 43) (Tan et al., 2002). When gene expression profiling was applied in a transgenic model of tumor necrosis factor-α overexpression, a large number of immune response-related genes were over-expressed, along with a IgG deposition in myocardium, supporting activation of immune system and inflammatory mechanisms in the development and

progression of heart failure (Feldman and McTiernan, 2004; Kubota et al., 1997).

Gene expression profiles of heart failure caused by alcoholic cardiomyopathy and familial cardiomyopathy suggest that the onset and disease progression may involve different genetic determinants. A provocative study by Blaxall and coworkers has reported that genomic profiling in a murine model of heart failure reverted to the normal phenotype after rescue by expression β-adrenergic receptor kinase and suggested mild and advanced heart failure maybe similar in mice and humans (Blaxall et al., 2003). As previously mentioned, the conclusions must be interpreted cautiously owing to the complexities of heart failure related to the imprecision associated with genetic, physiologic, and clinical phenotypes.

A Case for Biologic Reclassification of Heart Failure

Gene expression profiling has significantly improved the diagnostic classification of specific conditions (e.g., breast cancer, chronic myelogenous leukemia) but remains a formidable challenge for deciphering meaningful insights about the biological mechanisms underlying disease pathogenesis (Quackenbush, 2006). Among inheritable forms of cardiovascular diseases, recent advances of single-gene disorders have fundamentally altered our understanding about the cellular processes, metabolic alterations and transcriptional reprogramming of the diseased heart (Seidman and Seidman, 2001). Much like the success seen for tumor classification and other improvements in cancer therapeutics (Bell, 2004; Quackenbush, 2006), and beyond the availability of genetic tests for disease-causing mutations of cardiomyopathy (Morita et al., 2005), the development of genomic tools that are causally linked to disease pathogenesis, termed a "molecular signature," will likely accelerate progress for early detection, targeted therapy and disease monitoring of inheritable heart failure (Bell, 2004). We suggest that the opportunities exist for microarray-based profiling, proteomics, metabolomics, and genome-wide technologies to propel the transition from clinicopathologic to clinico-genomic classifications for heart failure.

Different gene profiles for failing and nonfailing hearts have already permitted differentiation among heart failure with different etiologies, as shown recently by Donahue and colleagues in Table 26.2 (Donahue et al., 2006). Considerable discordance, however, exists as our ability to diagnose heart failure using genomic profile lags substantially behind clinical management. Important obstacles remain, such as limitations in procuring tissue samples needed for genomic profiles and their transition from use as research tools into the realm of clinical diagnostics.

Biomarkers Versus Biosignatures for Heart Failure

Considerable biological heterogeneity of heart failure demands more robust tools to guide clinical outcomes. Much recent attention has focused on biological markers, or biomarkers, which objectively measure and evaluate normal biological processes, pathologic process, or pharmacological response to therapeutic intervention (Vasan, 2006). Current enthusiasm for biomarker strategies, however, has also brought confusion and ambiguity for applications in clinical practice. Too often, highly fragmented information obtained from patients at different clinical stages precludes meaningful analysis and extrapolation to broader subclasses.

Accordingly, we propose that an integrative approach – that encompasses our ability to predict the onset, rate of progression, and response to therapy and/or clinical outcome with reproducibility and reliability may circumvent such limitation of biomarkers – requires the development of a molecular signature or "biosignature." In order to circumvent existing limitations of biomarkers, proof-of-concept for such biosignatures, however, may require tissue sampling and serial analysis for identification and validation (Figure 26.5). Among eight individuals with IDCM but with similar clinical characteristics for chronic heart failure at baseline, Lowes and colleagues reported that serial sampling was superior to cross-sectional gene expression profiling since there was less variance in the differences on gene chip analysis of endomyocardial biopsies (EMB) from the same patient than among the different subjects with similar phenotypes (Lowes et al., 2006). Because these biological processes may precede the transition into heart failure and premature death, future work should address the intriguing possibility that distinct metabolic pathways might be linked to novel molecular signatures in disease pathogenesis (Figure 26.5).

Protein aggregation cardiomyopathy (PAC) (also termed desmin-related myopathy – DRM) is a multi-system disease, caused by the missense R120G mutation in the gene encoding the human small HSP αB-crystallin (hR120GCryAB). To understand the pathogenic mechanisms by which hR120GCryAB expression causes cardiotoxicity and heart failure, our group has shown in recent genetic studies in mice that selective hR120GCryAB expression in the heart induces a novel toxic gain-of-function mechanism involving reductive stress, apparently emanating from increased activity of glucose 6-phosphate dehydrogenase (G6PD) (Rajasekaran et al., 2007). Reductive stress refers to an abnormal increase in the amounts of reducing equivalents (e.g., glutathione, NADPH), which has been demonstrated in lower eukaryotes (Simons et al., 1995; Trotter and Grant, 2002) but has not been commonly shown in the mammals and/or in disease states (Chance et al., 1979; Gores et al., 1989).

Such genetic evidence, that dysregulation of G6PD activity is a causal mechanism for R120GCryAB cardiomyopathy, forms the rationale for ideas related to metabolic and genetic pathways that might codify biosignatures. What metabolic changes occur before the onset of detectable myopathic or pathologic alterations, and how does such imbalance contribute to cardiomyopathy and heart failure? Does reductive stress exert direct or indirect consequences on mitochondrial (dys)function? Applications in redox proteomics and multiplex protein markers are presently being pursued to determine if glutathionylation, for example, of key components in mitochondrial and other metabolic pathways are causally linked to disease pathogenesis.

Molecular Diagnosis of Allograft Rejection

Although peripheral blood mononuclear cells (PBMCs) are abundant and highly accessible sources of genomic material, a potential for diagnostic inaccuracy and therapeutic failure exists

Table 26.2 Discovery projects in heart failure

Comparison	Subjects	Platform	Finding
Failing versus non-failing	2 cases (1 ICM and 1 DCM) 2 control cases	Affymetrix Hu 6800	Alterations of expression of cytoskeletal and myofibrillar genes, genes encoding stress proteins, and genes involved in metabolism, protein synthesis, and protein degradation
Failing versus non-failing	7 cases (DCM) 5 control cases	Cardiochip (custom array)	Upregulation of genes for atrial natriuretic peptide, sarcomeric and cytoskeletal proteins, stress proteins, and transcription/translation regulators Down-regulation of genes regulating calcium signaling pathways
Failing versus non-failing	8 cases (DCM) 7 control cases	Affymetrix Hu 6800	103 differentially expressed genes with most prominent being atrial natriuretic factor and brain natriuretic peptide
Failing versus non-failing	10 cases (DCM) 4 control cases	Custom arrays	364 differentially expressed genes Up-regulation being most prominent in genes for energy pathways, muscle contraction, electron transport, and intracellular signaling Down-regulation was most prominent in genes for cell cycle control
Failing versus non-failing	9 cases (5 ICM and 4 DCM) 1 control case	Affymetrix HG-U95A	95 differentially expressed genes with notable up-regulation of atrial natriuretic peptide and brain natriuretic peptide Prominent pathways up-regulated include cell signaling and muscle contraction
Failing versus non-failing	6 cases (DCM) 5 control cases	Affymetrix HG-U133A	165 differentially expressed genes, the most prominent being structural and metabolic genes
Failing versus non-failing	5 cases (DCM) 5 control cases	Custom array for apoptotic pathways	Differentially expressed genes in apoptotic pathways
Pre- and post-left ventricular assist device	6 cases (3 DCM and 3 ICM)	Affymetrix Hu 6800	530 differentially expressed genes (295 up and 235 down) with prominent changes in genes for metabolism
Pre- and post-left ventricular assist device	7 cases (DCM)	Affymetrix HG-U133A	179 differentially expressed genes (130 up and 49 down There was prominent up-regulation in nitric oxide pathways and down-regulation of inflammatory genes
Pre- and post-left ventricular assist device	19 cases (8 DCM and 11 ICM)	Affymetrix HG-U133A	107 differentially regulated genes (85 up and 22 down) Prominent was the up-regulation of genes regulating vascular networks and down-regulation of genes regulating myocyte hypertrophy
HCM and DCM versus non-failing	3 DCM 2 HCM 3 control cases	Cardiochip (custom array)	Multiple genes and pathways up- and down-regulated some common to DCM and HCM some distinct to each

DCM = dilated cardiomyopathy; HCM = hypertrophic cardiomyopathy; ICM = ischemic cardiomyopathy.

if there is discordance between the information in PBMCs and underlying condition in the diseased tissues. Significant progress has been made for patients after cardiac transplantation, which could change existing paradigms for clinical decision-making and management of allograft rejection. Standard protocols after heart transplantation requires patients to undergo serial EMB as a means to monitor for rejection and to guide immunosuppressive therapy. Such surveillance maneuvers are invasive, expensive and carry considerable risks such as perforation of the ventricular wall and hemopericardium. Analysis of the histological data by expert pathologists is subject to inter-observer variability and the diagnosis of acute rejection has been controversial (Nielsen et al., 1993; Winters and McManus, 1996). Horwitz and colleagues were among the first to demonstrate that gene expression

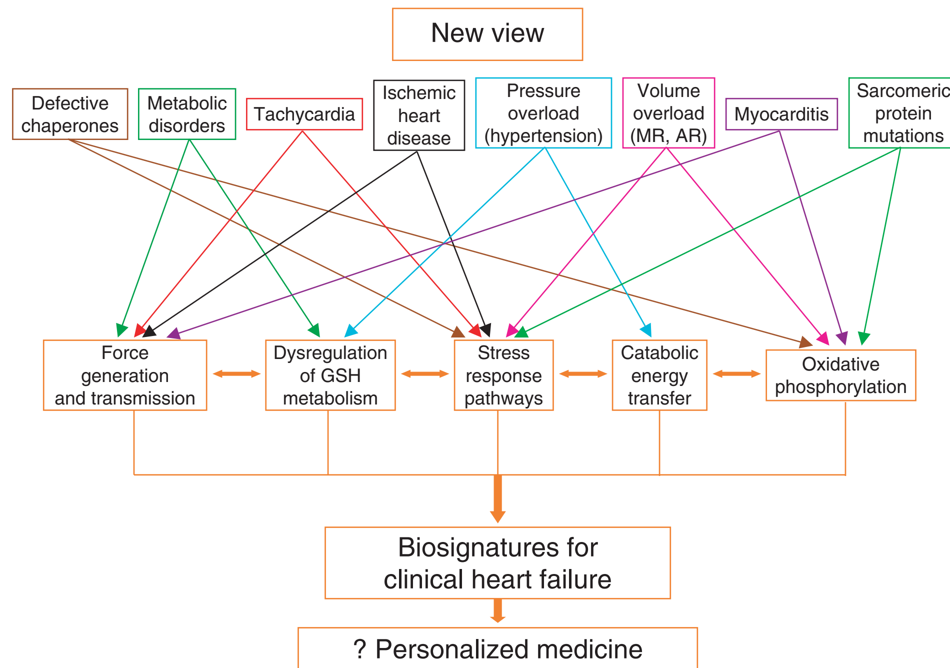

Figure 26.5 New diagnostic approaches, based on information that integrates genes and molecular pathways at the onset, progression and end stages are needed to improve heart failure classification. "Biosignatures" for heart failure – developed from microarray analysis technologies, proteomics and genomic technologies – are proposed here to integrate the biological processes and molecular mechanisms for rationale drug design and treatment in the post genomic era of personalized medicine.

profiles of PBMCs might provide an alternative approach of the diagnosis of allograft rejection (Horwitz et al., 2004). Patients who subsequently developed acute rejection had a distinct genomic profile compared with patients without any rejection and, after treatment for rejection, the majority (98%) of differentially expressed genes returned to baseline.

The CARGO (Cardiac Allograft Rejection Gene Expression Observational) study prospectively investigated gene expression analysis from PMBCs as a diagnostic tool to predict transplant rejection (Mehra, 2005). From the core group of 11 genes associated with immune response pathways, which were identified by quantitative real-time polymerase chain reaction (QT-PCR) and assigned weighted scores, CARGO investigators were able to predict rejection with a sensitivity and specificity of 80% and 60%, respectively (Deng et al., 2006). Owing to reduced sensitivity and specificity immediately after transplantation, the test may also be unreliable for the diagnosis of low/intermediate grade rejection. Now commercially available (AlloMap®), this landmark study provides proof-of-concept that gene expression profiling in PBMCs are predictive for acute rejection pathways in cardiac transplant patients. One important implication is that genomic profiling of specific targets expressed in peripheral blood will increasingly be used as a sensitive marker for transplant rejection but direct evidence that such monitoring should guide therapeutic management awaits further independent validation.

2009 UPDATE

Identification and characterization of the pathways and mechanisms by which common genetic variants (polymorphisms) contribute to the initiation and propagation of life-threatening conditions remain the foundations for personalized medicine in cardiology. Among established targets of neurohormonal antagonists associated with mortality benefits for heart failure, a pharmacogenomic interaction is suggested where common sequence variations of genes encoding neurohormonal signaling alter an individual's therapeutic response (Dorn, 2007). Epigenetic alterations are now being considered in light of such effects on the development of cardiac hypertrophy and heart failure. For example, recent analysis of ventricular tissue from both experimental and human heart failure has revealed epigenetic changes such as trimethylation of histone H3 at lysine-4

or lysine-9, which were present between the regions of genes encoding signal transduction pathways (Kaneda et al., 2009).

Autocrine and paracrine factors elaborated by the heart serve as key sensors that self-regulate cardiomyocyte contraction, growth, and programmed death (Dorn, 2007). For the irreversibly damaged myocardium, the clinical trials of adult stem cell therapy have suggested potential benefit but there is less confidence in the current approaches being used for regeneration of cardiac tissue (Mayorga et al., 2009). A recent catalog of proteotypic peptides in heart human has been developed to serve as a public reference to guide future targeted mass spectrometry experiments monitoring protein biomarkers (Edwards et al., 2008; Kline et al., 2008). The discovery of human gene polymorphisms and/or gene variant expression holds particular promise as therapeutic targets for ameliorating adaptive and maladaptive mechanisms related to stress-response pathways.

CHAPTER

Genomic Assessment of Cardiac Transplant Rejection

Michael Pham, Mario C. Deng, Jay Wohlgemuth and Thomas Quertermous

INTRODUCTION

The development of highly parallel assessment of genome-wide patterns of gene expression and the development of statistical and bioinformatics algorithms for evaluation of these large datasets have provided great insight into the molecular basis of physiology and disease. While less widely appreciated, it was apparent early on that large gene expression databases, if collected in a clinically and epidemiologically appropriate fashion, could provide the basis for diagnosis and monitoring tools capable of informing on human disease. Attention has focused on tissue samples obtained through biopsy for cancer profiling and monitoring and on gene expression in circulating leukocytes to gain information about the broad array of immune-associated diseases. Although technically demanding with respect to reproducibility of measuring changes in gene expression and appropriate handling of data, gene expression measurements have nonetheless provided the basis for a small number of clinically useful and recognized tests that are now available to physicians for disease monitoring, augmenting more classical laboratory data to guide patient management decisions.

CARDIAC ALLOTRANSPLANTATION AS A DEFINITIVE THERAPY FOR END-STAGE HEART FAILURE

Heart failure (HF) is a leading cause of morbidity and mortality in the United States. In 2001, approximately five million Americans were affected by this condition, and over half a million new cases are diagnosed annually. The disease accounts for the number one cause of hospitalization for individuals aged 65 or greater. In patients with end-stage HF and severe functional limitation, 1-year mortality approaches 75%, rivaling the effects of most cancers (Rose et al., 2001). Despite major advances in the treatment of this disease over the past decade, a sizable number of patients with terminal or progressive myocardial dysfunction are fated to die or to be severely limited by symptoms. In these patients, biological replacement of the heart with human organs (allotransplantation) has become standard therapy and is widely accepted as a modality for prolonging life and improving its quality in carefully selected patients. Currently, approximately 4000 heart transplants are performed worldwide each year with survival rates of 81%, 74%, and 68% at 1, 3, and 5 years, respectively (Taylor et al., 2006).

THE PROBLEM OF ALLOGRAFT REJECTION

Heart transplantation is the definitive therapy for end-stage HF but is complicated by recipient immune responses to the transplanted heart (allograft), often resulting in cardiac allograft rejection. Different forms of rejection are recognized, including hyperacute rejection (Kemnitz et al., 1991), acute cellular rejection (ACR) (Billingham et al., 1990; Rodriguez, 2003; Stewart et al., 2005; Winters and McManus, 1996; Winters et al., 1998), acute antibody-mediated rejection (AMR), mixed rejection (Book et al., 2003; Michaels et al., 2003a), and chronic rejection, also termed cardiac allograft vasculopathy (CAV). Hyperacute rejection is rare but may occur in the setting of circulating-preformed antibodies to the ABO blood group (in cases of ABO blood group incompatability) or to major histocompatability antigens on the cardiac allograft. This form of rejection manifests as severe graft failure within the first few minutes to hours after transplantation. ACR is the most common form of rejection and occurs in 30–50% of heart transplant recipients in the first year following transplantation (Hershberger et al., 2005). Most episodes occur within the first 3–6 months. This type of rejection is primarily mediated by T-lymphocytes and is characterized by lymphocytic infiltration within the myocardium, direct myocyte damage, and subsequent graft dysfunction. The severity of cellular rejection reflects the distribution and extent of inflammation and the presence or absence of myocyte damage. Acute AMR is mediated by B-lymphocytes and is characterized by antibody deposition on the cardiac allograft microvasculature, complement activation, and graft dysfunction. It is more likely to be associated with hemodynamic compromise compared with ACR, carries a worse prognosis, and is a strong risk factor for the early development of CAV (Michaels et al., 2003b). The prevalence of AMR has been reported to be between 15% and 20%, and it can occur independently of or in combination with ACR (Hammond et al., 1989; Michaels et al., 2003a). Chronic rejection occurs months to years after transplantation and is typically manifested as CAV and late graft failure. The mechanisms of chronic rejection are incompletely understood but may involve a proliferative response to both immunologically and nonimmunologically mediated endothelial injury with progressive intimal thickening within the coronary vessels.

IMMUNOSUPPRESSION STRATEGIES TO PREVENT REJECTION

Most clinically used immunosuppressive regimens consist of a combination of several agents used concurrently and utilize several general principles. The first general principle is that immune reactivity and tendency toward graft rejection are highest early (within the first 3–6 months) after graft implantation and decrease with time. Thus, most regimens employ the highest levels of immunosuppression immediately after transplantation and decrease those levels over the first year, eventually settling on the lowest maintenance levels of immune suppression that are compatible with preventing graft rejection and minimizing drug toxicities. The second general principle is to use low doses of several drugs without overlapping toxicities in preference to higher (and more toxic) doses of fewer drugs whenever feasible. The third principle is that too much or too intense immunosuppression is undesirable, because it leads to a myriad of undesirable effects, such as susceptibility to infection and malignancy. Finding the right balance between over- and under-immunosuppression in an individual patient is truly an art that utilizes science.

Most modern immunosuppressive protocols employ a three-drug regimen consisting of a calcineurin inhibitor (cyclosporine or tacrolimus), an antiproliferative agent (mycophenolate mofetil or azathioprine), and corticosteroids. The calcineurin inhibitors inhibit production of the cytokine interleukin-2, therefore preventing T-lymphocyte differentiation and proliferation. The antiproliferative agents exert their immunosuppressive effects by blocking purine synthesis and inhibiting proliferation of both T- and B-lymphocytes. Corticosteroids are non-specific anti-inflammatory agents that interrupt multiple steps in immune activation, including antigen presentation, cytokine production, and proliferation of lymphocytes. They are used in relatively high doses in the early post-transplant period and are tapered to low doses or discontinued after the first 6–12 months. A new class of agents called proliferation signal inhibitors (sirolimus and everolimus) work by inhibiting both T- and B-lymphocyte proliferation through G1 cell cycle blockade. These newer agents have become increasingly popular over the past 5 years due to their ability to prevent and retard progression of CAV and calcineurin-inhibitor-associated nephrotoxicity.

Significant advances have been made over the past two decades in moving from drugs that provide broad and non-specific immunosuppression to newer agents that provide more targeted immunosuppression through inhibition of lymphocyte activation and proliferation. Although use of these newer agents has decreased the incidence of both rejection and life-threatening infections, modern immunosuppressive regimens are inherently associated with drug- and class-specific toxicities, including metabolic derangements (hypertension, dyslipidemia, diabetes mellitus) and renal dysfunction. Additionally, heart transplant patients continue to have higher risk of developing opportunistic infections and malignancy compared to the general population due to suppression of their immune system. The risk of infection and neoplasm is typically related to the intensity and duration of immunosuppression.

Given the continued inherent toxicity of immunosuppression regimens, the variability of immunosuppression and susceptibility to drug toxicities among different individuals, and the constant aim to find a regimen that provides optimal immunosuppression with minimal side effects, there continues to be a great need for ways of monitoring immune suppression. Better tools for monitoring relative immunosuppression would allow for tailoring of immunosuppressive regimens to individual patients and aid in the development of new therapeutics (Table 27.1).

TABLE 27.1 Immunosuppression therapies

Method	Target	Selectivity
Total body irradiation	Bone marrow	+
Steroids	Lymphocytes/RES	+
Thoracic duct drainage	Lymphocytes	++
Antilymphocyte globuline	Lymphocytes	++
Azathioprine	Lymphocytes	++
Plasmapheresis	Antibodies	++
Cyclophosphamide	B-lymphocytes	++
Antithymocyte globuline	T-lymphocytes	++
Monoclonal CD3 antibodies	CD3+ T-lymphocytes	+++
Monoclonal CD4 antibodies	CD4+ T-lymphocytes	+++
Mycophelonate	De novo purine synthesis in lymphocytes	++++
Cyclosporine	IL2 inhibition in T-lymphocytes	++++
Tacrolimus	IL2 inhibition in T-lymphocytes	++++
Daclizumab	IL2 receptor antibodies	++++

TABLE 27.2 Grading system for endomyocardial biopsy

ISHLT Standardized cardiac biopsy grading
Acute cellular rejection

Old (1990) Grade	Revised (2004) Grade	Description
0	0R	No rejection
1A 1B 2	1R (mild)	Interstitial and/or perivascular mononuclear cell infiltrate with up to one focus of myocyte damage
3A	2R (moderate)	Two or more foci of mononuclear cell infiltrate with associated myocyte damage
3B 4	3R (severe)	Diffuse mononuclear and/or mixed inflammatory cell infiltrates with multiple foci of myocyte damage, with or without edema, hemorrhage, or vasculitis
Antibody-mediated rejection		
AMR 0		Negative for acute AMR
AMR 1		Positive immunofluorescence or immunoperoxidase staining for AMR (positive CD68, C4d).

R denotes "revised" grade. Adapted from Stewart et al. (2005).

CURRENT STRATEGIES FOR MONITORING TRANSPLANT REJECTION

Most patients with acute rejection are asymptomatic and have no clinical findings of cardiac allograft dysfunction. Additionally, the signs and symptoms of rejection, when present, are non-specific and may only manifest in the late stages of rejection. Thus, close surveillance of heart transplant recipients for acute rejection is critical. Patients are typically monitored for rejection using a combination of clinical assessment, imaging and/or quantification of allograft function [echocardiography, multiple gated acquisition (MUGA) scan, measurement of intracardiac pressures and flows], in addition to sampling of the myocardium via the technique of endomyocardial biopsy (EMB). Protocols for the timing of rejection surveillance are variable among transplant programs but are generally chosen to match the observed frequency of rejection episodes, which is clearly highest in the early postoperative period. Most programs perform rejection surveillance on a weekly basis for the first 4–6 postoperative weeks and then with diminishing frequency in a stable patient but at a minimum of every 3 months for the first postoperative year and at 3–6 months intervals after the first year.

The gold standard for diagnosing ACR has remained the EMB. In this procedure, several pieces of heart tissue from the inner portion (endomyocardium) of the right ventricle are removed with a rigid catheter advanced into the heart via a vein in the patient's neck or groin area. The specimens are then evaluated under a microscope for evidence of inflammatory infiltrates and myocyte injury. A uniform and standardized grading scheme for grading of ACR was developed by the International Society of Heart and Lung Transplantation (ISHLT) in 1990 and recently revised in 2004 (Stewart et al., 2005) (Table 27.2). Rejection therapy in the form of augmented immunosuppression is typically given for rejection grades of 3A/2R or higher and for rejection episodes that are associated with allograft dysfunction. The EMB, compared to other modalities of rejection surveillance, has the advantage of identifying rejection prior to the development of cardiac allograft dysfunction. However, the procedure is invasive, expensive, subject to sampling error, inter-observer variability, and causes morbidity (0.5–1.5%) (Nielsen

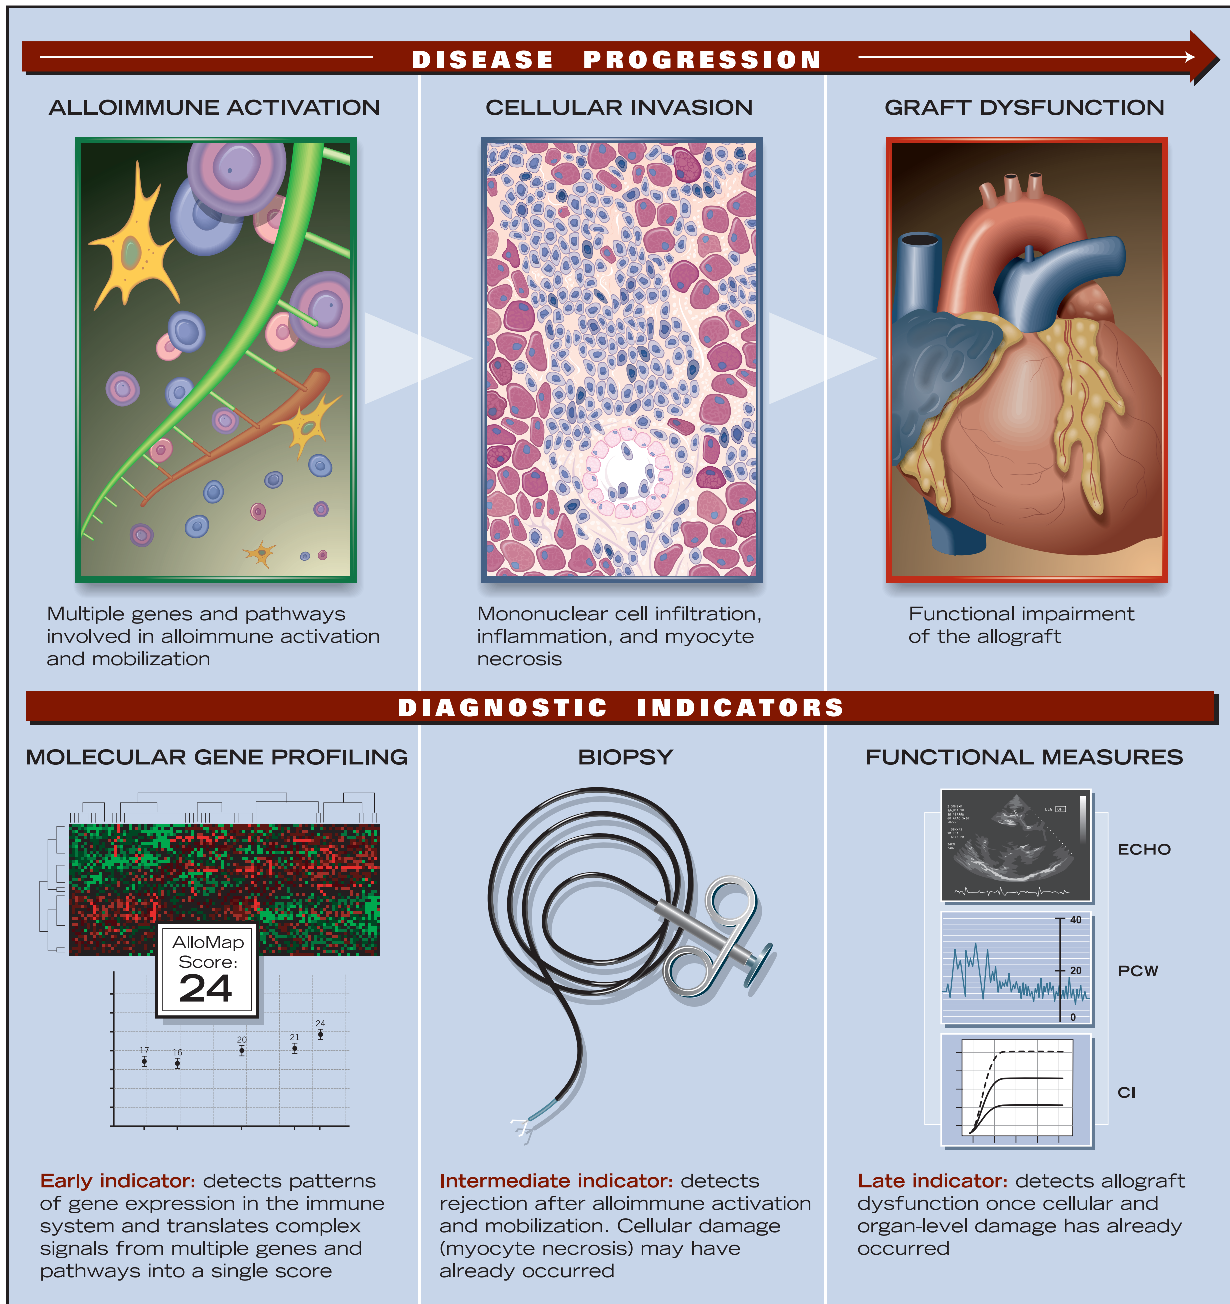

Figure 27.1 Progression and diagnosis of acute cellular rejection within the cardiac allograft.

et al., 1993; Winters and McManus, 1996; Winters et al., 1998). Biopsy-related complications include damage to the tricuspid valve, myocardial perforation, and excessive bleeding. Although non-invasive alternatives to EMB are clearly needed, methods such as echocardiography, ultrasonic myocardial backscatter, radionuclide imaging, magnetic resonance imaging, intra-myocardial electrograms, measurement of serum cardiac markers such as cardiac troponin I and B-type natriuretic peptide, and multiparametric immune monitoring have been difficult to validate and implement (Deng et al., 2005).

Most of the currently employed strategies identify cellular rejection long after immune activation has occurred. In many cases, myocyte injury and allograft dysfunction have already occurred (Figure 27.1). Despite activation of a broad range of immune pathways occurring in rejection, it has not been possible to identify specific molecular clues that inform on the degree of rejection in the transplanted organ. Clearly, greater information regarding the genes and proteins that are specifically activated in relation to transplant rejection is needed to provide a measure of rejection activity. Based on advances in the human

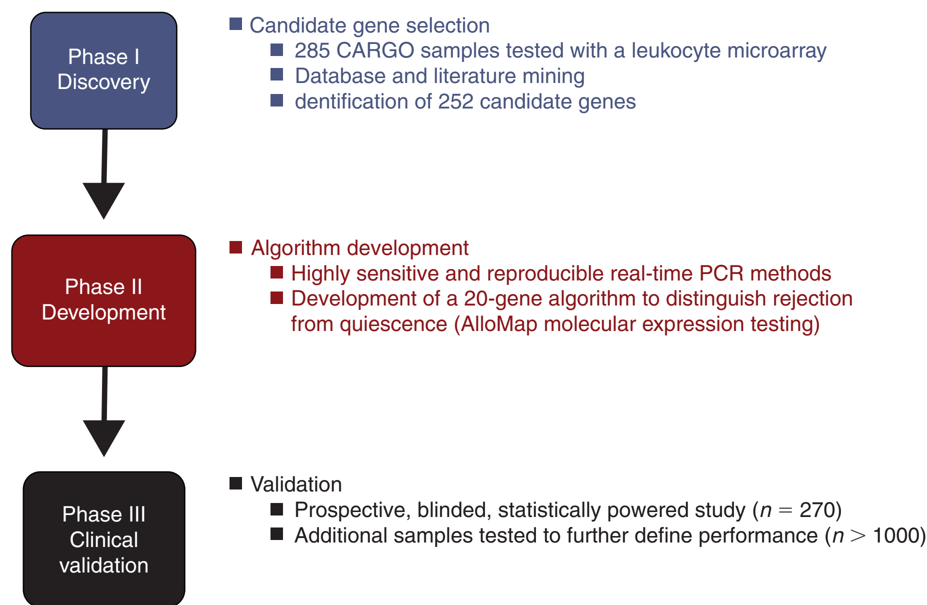

Figure 27.2 Approach to the development of a gene expression profiling test for cardiac transplant rejection.

genome project and based on the development of microarray technology and related computational methodology, a group of clinical and molecular scientists hypothesized that peripheral blood leukocyte expression profiling might reflect differential activity in the two states of acute rejection and quiescence within the allotransplanted heart.

THE CARGO CLINICAL STUDY

As circulating peripheral blood mononuclear cells (PBMC) reflect the status of a host immune system and responses to the allograft, measurement of PBMC gene expression should provide useful diagnostic or prognostic information for cardiac transplant recipients. Based on this hypothesis, studies have now been performed (Deng et al., 2006a; Horwitz et al., 2004; Schoels et al., 2004) to identify genes and pathways predictive of rejection in peripheral blood and to develop a molecular test based on this information. To identify the correlation between gene expression in circulating mononuclear cells and the relative degree of cardiac allograft rejection, a multicenter prospective study called the Cardiac Allograft Rejection Gene Expression Observational (CARGO) was initiated. Based on the genes and pathways identified as correlates of rejection, the CARGO study resulted in the development and validation of a peripheral blood gene expression test for rejection. The test was developed using DNA microarray technology and real-time PCR. The CARGO study had as a primary objective the development of a molecular diagnostic test from PBMC samples to discriminate between a quiescent state (original ISHLT Grade 0 rejection; revised ISHLT Grade 0R) and moderate/severe rejection (original ISHLT Grade >3A; revised ISHLT Grade >2R) in cardiac transplant recipients. Patients at eight heart transplant centers were followed prospectively with blood sampling performed at the time of post-transplant visits. Biopsies were graded by both local pathologists and three independent core pathologists blinded to clinical data. The scheme for gene discovery, test development, and validation from CARGO is shown in Figure 27.2.

DEVELOPMENT OF A GENE EXPRESSION SIGNATURE FOR CARDIAC TRANSPLANT REJECTION

Microarrays were used to identify genes in PBMC samples ($n = 285$) from cardiac transplant recipients that are associated with moderate/severe rejection or the absence of rejection. A set of 252 genes were selected for real-time PCR assay development from the microarray data and from genes in the published literature with known or hypothesized roles in cardiac allograft rejection (knowledge-based genes). While an empirical genomic approach should provide a comprehensive look at the genome, technical limitations of microarray technologies suggested that additional genes from existing knowledge should also be evaluated even if they were not selected from the microarray experiments. The limitations of microarrays include low sensitivity for genes expressed at low levels or in small subsets of circulating cells and nonspecificity of array probes for individual transcripts or splice variants. The 62 genes from the real-time PCR panel found to be reproducibly and differentially expressed between rejection and quiescence states were evaluated in a training set of 145 PBMC samples, and a multigene algorithm was developed using linear discriminant analysis for the ability to classify samples as having no rejection (ISHLT 0R) or moderate/severe rejection (ISHLT >2R). The optimal number of genes required for best classification was determined to be 11, with 9 genes being

included as controls. A gene expression profiling (GEP) test for detecting cardiac allograft rejection was then developed using PCR-based quantification of expression of these genes and their relative contribution to a probability score, based on the classification algorithm (Table 27.2). Finally, a validation cohort of independent samples from CARGO (63 samples from 63 patients) was used to validate the performance of the multigene test. These samples were independent from those used for the gene selection and algorithm development studies described above. This approach is critical for genomic studies that are fraught with false positive results due to the very large excess of genes to samples (Deng et al., 2006a). In this study, the test was shown to accurately detect the absence of moderate/severe rejection and thus identify a state of "quiescence" in the allograft. Using a single, pre-defined threshold of 20 (scores below 20 indicating a low probability of rejection), the test distinguished moderate/severe biopsy-defined rejection from quiescence ($p = 0.0018$) and had an agreement of 84% (95% CI 66–94%) with ISHLT Grade ≥3A/2R rejection compared with EMB. Beyond 1-year post-transplant, patient-GEP scores below the threshold also had a negative predictive value (NPV) for Grade ≥3A/2R rejection of >99%.

Based on these data, the GEP has been commercialized by XDx, Inc., Brisbane, CA. Their AlloMap™ test, which became available in January 2005, employs quantitative PCR of the 20 genes in triplicate and provides a score ranging from 0 to 40, with lower scores being associated with a very low likelihood of moderate/severe cardiac allograft rejection. A score of <30–34 has been used by many heart transplant centers to identify patients with a low probability of acute rejection. Details on development and validation of the GEP test have been published elsewhere (Deng et al., 2006b).

PATHWAYS MONITORED BY THE GEP (AlloMap™) TEST

A total of 62 genes were identified by real-time PCR in the validation phase of the CARGO study as being able to distinguish quiescent cardiac transplant patients from those who had moderate/severe biopsy-defined rejection. Study of the GeneOntology (http://www.geneontology.org) annotations associated with these genes, and in particular the 11 GEP test genes (Deng et al., 2006b), identified several different pathways (Table 27.3) associated with the rejection process. The pathways include T-cell priming, state of immunosuppression, changes in platelet phenotype, and systemic responses to inflammation in the allograft. T-cell receptor chains were upregulated. Another cluster involved hematopoiesis, reflecting an increase in erythroid progenitors, potentially stimulated by circulating byproducts of immune activity in the allograft (Hammer et al., 1998). Alternatively, a certain level of hematopoietic activity may be required to have or sustain an acute rejection response. Down-regulation of several genes was also observed. A number of genes of unknown function showed significant up- or down-regulation with rejection, requiring further work to elucidate their roles. In the context of the phenotypic changes that a naive T-cell acquires when it is primed in the lymph node (Mempel et al., 2004), PDCD1, a negative costimulatory molecule that minimizes the autoreactivity of an aggressive effector T-cell, is one of those candidates in the GEP classifier. Primed T-cells need to be able to traffic into sites of inflammation and acquire new trafficking molecules including ITGA4 (another GEP classifier gene).

TABLE 27.3 Genes and pathways represented in the final GEP (Allomap™) diagnostic test

Genes in AlloMap test	Corresponding pathways
SEMA7A	Macrophage activation/PMNs
IL1R2, FLT3, ITGAM	Steroid responsiveness
PF4, G6B	Platelet production
MIR, WDR40A	RBC production (hematopoiesis)
PDCD1, ITGA4	T-cell activation and regulation
RHOU	Cell morphology

VARIABILITY OF THE BIOPSY GOLD STANDARD AND RELATIONSHIP TO THE GEP (AlloMap™) SCORE

The CARGO study design originally assumed a "gold standard" clinical endpoint of biopsy-based detection of ACR. However, results from CARGO demonstrated that this "gold standard" was limited by considerable inter-observer variability among local pathologists, and use of GEP testing may help reduce the variability of diagnosing ACR inherent in the biopsy (Marboe et al., 2005). Therefore, in the development and evaluation of the GEP test, rejection was defined by a local pathologist's grading and by interpretation by a panel of three experienced, independent, blinded pathologists (central pathologists) who re-read each case. GEP scores were progressively higher, on average, as the rate of concordance among all pathologists' readings increased for identifying Grade >3A/2R rejection. When 1 of 4 pathologists diagnosed Grade ≥3A/2R, the average GEP score was 28.5. When 4 of 4 agreed on Grade ≥3A/2R, the average GEP score was 33 (Marboe et al., 2006).

DISCORDANCE BETWEEN BIOPSY GRADE AND MOLECULAR SCORE

Certainly the situation can arise where the GEP score is discordant from the histologic grading. A "positive" biopsy (ISHLT

Grade ≥3A/2R) and low GEP score (<34) are uncommon but may hypothetically be seen when local pathologists misdiagnose rejection, either overgrading or misinterpreting (e.g., Quilty lesions) the histology (Marboe et al., 2005). Additionally, a subset of focal rejection may be benign; in one study, more than 90% of Grade 3A/2R biopsies with two foci of focal moderate rejection diagnosed after 1-year post-transplant, resolved without therapy (Winters et al., 1995). Finally, molecular testing and biopsy measure different processes which may be discordant (e.g., lagging clearance of infiltrate in "resolving rejection"). In the CARGO study, rates of positive biopsy and low molecular score were low. For example, with a threshold score of 34 beyond 1-year post-transplant, the NPV of the test for Grade ≥2R/3A rejection was 99.2%. Thus, a Grade ≥2R/3A would be expected to occur with a low GEP score in 8 of 1000 tests in a population similar to CARGO. Conversely, a "negative" biopsy and high molecular score may be observed. Several hypotheses may explain this phenomenon, including early or focal rejection that may not be detected on the biopsy due to sampling error, alloimmune activation in the absence of cellular rejection on the biopsy, immune activation relating to conditions other than ACR (e.g., AMR, CAV/chronic rejection, or infection), or a quiescent state in a chronic and clinically stable heart transplant recipient. In the CARGO study, the rate of samples tested that had a negative biopsy with a high GEP score increased with time post-transplantation.

EFFECT OF TIME POST-TRANSPLANTATION ON PERFORMANCE OF THE GEP TEST

Samples from CARGO were used to derive the performance characteristics for the GEP test across a range of scoring thresholds. Since rejection rates and average GEP scores are known to vary with time post-transplant, performance characteristics were reported for defined time intervals (<6, 6–12, and ≥12 months). NPV and positive predictive value (PPV) were calculated for each threshold with respect to Grade ≥3A/2R rejection as defined by both local and central pathologists. The percent above threshold is the estimated overall rate of positive tests for an outpatient population. When interpreting the PPV for the GEP test for Grade ≥3A/2R rejection, it must be recognized that this parameter is highly dependent on the time-dependent prevalence of rejection in this population. In the first 6 months post-transplant, the risk of rejection is significantly higher than in later periods, and the PPV of the GEP test can be as high as 20–40% with high scores. Beyond 1-year post-transplant, the rate of Grade ≥3A/2R rejection drops to low levels (<3% of biopsies in CARGO), and the PPV of the test declines as well. This phenomenon is important to consider when interpreting high scores in patients ≥1 year post-transplant, who are at low risk for rejection. The expectation in the majority of these patients is that they do not have concurrent Grade ≥3A/2R rejection on biopsy. The GEP score associated with quiescence also rises with time post-transplant, probably related to down titration of corticosteroids and overall immunosuppression. Since the risk of rejection decreases with time and the NPV of the GEP score remains high over the range of scores between 30 and 35, the higher GEP score thresholds may be used to identify patients at very low risk for rejection during later periods post-transplant. Thus, implementation guidelines based on early clinical experience with the test recommend that GEP thresholds should vary by time post-transplant (0–6, 6–12, and ≥12 months post-transplant) (Starling et al., 2006).

RELATIONSHIP OF GEP SCORE TO CORTICOSTEROID DOSE

Quiescent GEP scores rise with time post-transplant throughout the first year, with the steepest part of this rise in the first 6 months (Figure 27.3). Corticosteroid dosing is the clinical variable most strongly associated with this pattern (Starling et al., 2005). Expression of a number of genes in the GEP algorithm correlates with steroid dose (*ITGAM*, *IL1R2*, *FLT3*). The pattern of change in expression of these genes with decreasing steroid dose is the same as the pattern observed with rejection. Steroid dosing is rapidly reduced in the first 6 months and progressively lowered during the remainder of the first year and beyond. Available data from the CARGO registry suggest that prednisone doses of <20 mg/day do not significantly influence the GEP score.

PREDICTION OF FUTURE ACR BY MOLECULAR SCORE

Peripheral blood gene expression patterns in 104 clinically stable heart transplant patients without initial histological evidence of acute rejection (ISHLT Grade 0 or 1A/1R) were evaluated in a nested case-control study within CARGO, to assess the ability of the GEP test to predict rejection in the subsequent 12 weeks. The cases included 39 patients who developed subsequently moderate to severe rejection (ISHLT Grade >3A/2R) within 12 weeks, and the controls included the remaining 65 patients who did not experience rejection during this time period. In addition, changes in individual gene expression patterns and their relationship with rejection therapy were studied. The gene expression score was significantly higher in patients with future moderate/severe rejection ($p = 0.01$), and the difference was more statistically significant within 180 days post-transplant ($p = 0.0004$). In this period, no patients with gene expression scores ≤20 developed moderate/severe rejection within 12 weeks, while 58% of patients with gene expression scores ≥30 did go on to develop rejection. Individual genes that most significantly predicted future rejection included *IL1R2* and *FLT3*, both corticosteroid responsive genes that decreased in expression

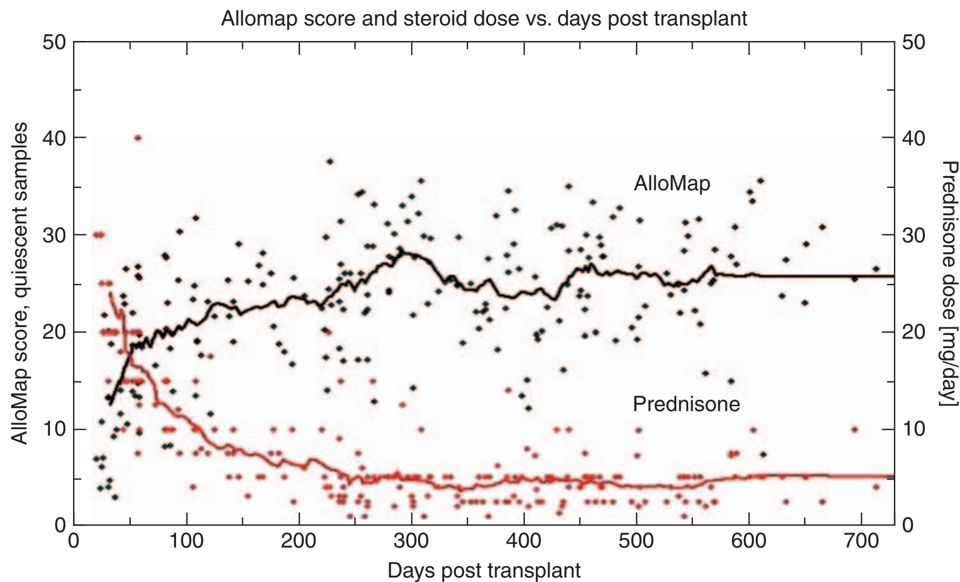

Figure 27.3 The GEP (AlloMap™) score and steroid dose versus days post-transplant.

before rejection, and *PCD1*, a marker of T-cell activation, that increased prior to rejection. Anti-rejection therapy resulted in a significant decrease in gene expression score (p=0.01). These data suggest that peripheral blood gene expression patterns can anticipate future moderate/severe cardiac allograft rejection in advance of EMB and may allow pre-emptive augmentation of baseline immunosuppression (Mehra et al., 2007).

CLINICAL USE OF THE AlloMap™ TEST

AlloMap™ is commercially available through the CLIA-certified XDx reference laboratory for use in heart transplant recipients who are 2 months or beyond post-transplantation and has been used clinically by US transplant centers since January 2005. Experience with rejection surveillance protocols incorporating GEP testing has provided additional insight into the performance characteristics of this test when used in a real-time clinical setting and across a wide spectrum of time periods post-transplantation. To date, transplant centers have used the AlloMap™ test in conjunction with the biopsy or in lieu of the biopsy in patients who are ≥3 months post-transplant. Indications for the GEP test vary according to the time period in which it is used. Centers have used the test within the first year to identify individuals at future risk of rejection and to assist in weaning of corticosteroids and immunosuppression. Beyond the first year post-transplantation, the test is typically used to identify patients at low risk of rejection that may safely be managed without routine biopsies. Finally, the AlloMap™ test has been used to noninvasively exclude rejection in patients with ambiguous signs or symptoms, in patients with inadequate biopsy specimens, and in patients with difficult vascular access.

The pooled data from early clinical implementation of GEP testing at several large US transplant centers (follow-up date March 31, 2006) have been analyzed and reported (Starling et al., 2004). Two hundred and forty-three clinical AlloMap™ measurements were included, 32 (13.2%) during the 6–12-month period, 192 (79.0%) during the 1–5-year period, and 19 (7.8%) during the >5-year period. The most important observation was the CARGO study confirmation of a high NPV (100%) with respect to ISHLT ≥2R/3A biopsy grades. It should be recognized that the mean duration post-transplant in this cohort was longer than the 14.5 months in the CARGO study. The data suggest that the test characteristics, when applied to patients who are ≥6 months post-transplant, are similar to those derived from the CARGO study. However, in this patient population, a higher test threshold (<34), which still maintains excellent NPV of >99%, may be appropriate as the AlloMap™ scores tend to rise with time post-transplant in clinically stable patients with histologically confirmed "quiescence" (Starling et al., 2006). A second important observation derived from clinical experience is that a subset of patients have consistently high longitudinal AlloMap™ scores but yet do not have associated Grade ≥3A/2R rejection on their biopsies. Therefore, some transplant centers have discontinued biopsies or transitioned to non-invasive rejection surveillance protocols in patients with consecutively high scores and quiescent biopsies. When used as part of a non-invasive strategy of rejection surveillance, the GEP test is typically combined with clinical and echocardiographic assessment of graft function to identify patients that may safely be managed without a heart biopsy. A clinical algorithm utilizing GEP testing to noninvasively manage heart transplant patients

who are beyond 1-year post-transplantation has been published (Pham et al., 2007).

While the performance of the AlloMap™ test has been validated in a large number of transplant patients, the clinical outcomes associated with using a gene expression-based strategy to monitor for rejection are currently unknown. A multicenter randomized clinical trial is underway to evaluate a GEP-based strategy, compared to a biopsy-based strategy, for assessing rejection in heart transplant recipients who are >6 months–5 years post-transplant. The "Invasive Monitoring Attenuation through Gene Expression (IMAGE)" will evaluate the impact of these two strategies with respect to clinically meaningful outcomes, such as graft dysfunction, rejection with hemodynamic compromise, and death. Additionally, the study will evaluate the incidence of biopsy-related complications, quality of life, and resource utilization among the two groups of patients.

2009 UPDATE

The AlloMap® Molecular Expression test received clearance by the US Food and Drug Administration (FDA) in August 2008 to aid in the identification of heart transplant recipients with stable allograft function who have a low probability of moderate/severe acute cellular rejection at the time of testing in conjunction with standard clinical assessment (US Food and Drug Administration, 2008). AlloMap® is the third *in vitro* diagnostic multivariate index assay (IVDMIA) cleared by the FDA. An IVDMIA is a test system that employs data from one or more *in vitro* assays, in conjunction with an algorithm, to generate a single, patient-specific result. The other FDA-approved tests under this category include a microarray-based multigene expression test that provides breast cancer prognostic information, as well as another microarray-based test that can help identify the type of cancer in a tumor sample by comparing the gene expression patterns within the sample with known gene expression patterns from malignant tumor types stored in a database.

Clinical studies evaluating the role of the GEP in heart transplantation are ongoing, and their findings should provide additional insight into use of this technology for detecting cardiac allograft rejection and other transplant-related conditions. In addition to detecting acute cellular rejection, small single-center studies have evaluated the role of GEP in identifying antibody-mediated rejection (Cadeiras et al., 2008), cardiac allograft vasculopathy (Yamani et al., 2007b), and post-transplant ischemic injury (Yamani et al., 2007a).

Additionally, the results from several large-scale observational and randomized prospective studies are expected to be announced in 2009–2010. The CARGO II study, involving over 700 heart transplant recipients from 13 European and 4 North American centers, was recently completed. The results of this study, expected in 2009, should provide additional information on the performance characteristics of the AlloMap® test in an international patient population. The IMAGE study, which has now enrolled over 500 heart transplant recipients from 12 large US heart transplant centers, is also expected to be completed in the fourth quarter of 2009 and will directly evaluate the impact of GEP-based versus biopsy-based rejection surveillance strategies on clinical endpoints. Additionally, the combined genetic and clinical information gathered from these studies may help investigators identify unique genetic profiles and mechanisms responsible for antibody-mediated rejection and cardiac allograft vasculopathy, thus potentially expanding the future role of GEP testing in the management of heart transplant recipients.

CHAPTER

Genetics and Genomics of Hypertrophic Cardiomyopathy

J. Martijn Bos, Steve R. Ommen and Michael J. Ackerman

INTRODUCTION

Hypertrophic cardiomyopathy (HCM) is a primary disorder of the myocardium associated with increase in cardiac mass and typically, asymmetric, predominantly left ventricular hypertrophy. Affecting 1 in 500 people, HCM is a disease of profound phenotypic and genotypic heterogeneity. Clinically, HCM can be characterized by a completely asymptomatic course to severe cardiac symptoms or even sudden cardiac death (SCD). In 1989, the molecular underpinnings of HCM were exposed with the discovery of the first locus of familial HCM, which was followed in 1990 with the identification of a mutation in the *MYH7*-encoded beta myosin heavy chain. Since then, hundreds of mutations scattered amongst at least 10 myofilament genes confer the pathogenetic substrate for this "disease of the sarcomere/myofilament." More recently, the genetic spectrum of HCM has expanded to encompass mutations in Z-disc–associated genes (Z-disc HCM). Furthermore, seemingly unexplained cardiac hypertrophy mimicking HCM can be the (primary) feature of some syndromes or metabolic diseases.

However, the underlying genetic mechanism for approximately 30–50% of HCM remains to be elucidated and although many genotype–phenotype relationships have been observed, only few carry enough clinical significance to aid physicians predicting genotype status or course and prognosis of the disease. Current treatment for HCM is mostly aimed at symptom relief, although studies are underway to design pharmacologic treatments for prevention of hypertrophy or individualized treatment based on one's genetic fingerprint.

DEFINITIONS, CLINICAL PRESENTATION, AND DIAGNOSIS

Background

Hypertrophic cardiomyopathy is defined as unexplained left ventricular hypertrophy (LVH) in the absence of precipitating factors such as hypertension or aortic stenosis. HCM is a disease of enormous phenotypic and genotypic heterogeneity. Affecting 1 in 500 people, it is the most prevalent genetic cardiovascular disease, and more importantly the most common cause of SCD in young athletes (Maron, 2002). HCM can manifest with negligible to extreme hypertrophy, minimal to extensive fibrosis and myocyte disarray, absent to severe left ventricular outflow tract obstruction (LVOTO), and distinct patterns of hypertrophy.

Nomenclature

Hypertrophic cardiomyopathy was described fully for the first time by Teare in 1958 as "asymmetrical hypertrophy of the heart in young adults" (Teare, 1958). Over the past half century, HCM has since been known by a confusing array of names, reflecting its clinical heterogeneity and uncommon occurrence in daily

practice. In 1968, WHO defined cardiomyopathies as "diseases of different and often unknown etiology in which the dominant feature is cardiomegaly and heart failure" (Abelmann, 1984). In 1980, cardiomyopathies were newly defined as "heart muscle diseases of unknown cause," thereby differentiating it from specific identified heart muscle diseases of known cause such as myocarditis. Throughout the years, names such as idiopathic hypertrophic subaortic stenosis (IHSS), (Braunwald et al., 1964), muscular subaortic stenosis (Pollick et al., 1982), and hypertrophic obstructive cardiomyopathy (HOCM) (Schoendube et al., 1995) have been used widely and interchangeably to define the same disease. In 1995, the WHO/International Society and Federation of Cardiology Task Force on cardiomyopathies classified the different cardiomyopathies by dominant pathophysiology or, if possible, by etiological/pathogenetic factors (Richardson et al., 1996). The four most important cardiomyopathies – dilated cardiomyopathy (DCM), restrictive cardiomyopathy (RCM), arrhythmogenic right ventricular cardiomyopathy (ARVC), and hypertrophic cardiomyopathy (HCM) – were recognized, next to a number of specific and mostly acquired cardiomyopathies, like ischemic- and inflammatory cardiomyopathies (Richardson et al., 1996). Accordingly, HCM is described as left and/or right ventricular hypertrophy, usually asymmetric and involving the interventricular septum with predominant autosomal dominant inheritance that can be caused by mutations in sarcomeric contractile proteins (Richardson et al., 1996). On a microscopic level, HCM is characterized by the classical triad of cardiomyocyte hypertrophy, fibrosis, and myofibrillar disarray.

Clinical Presentation and Diagnosis

The clinical presentation of HCM is underscored by extreme variability from an asymptomatic course to that of severe heart failure, arrhythmias, and SCD. Many patients remain asymptomatic or only mildly symptomatic throughout the course of life. HCM commonly manifests between the second and the fourth decades of life but can present at the extremes of age. Infants and young children may present with severe hypertrophy leading to heart failure, and these patients have poor prognosis. More often, SCD can be the tragic sentinel event for HCM in children, adolescents, and young adults. The most common symptoms at presentation of disease are exertional dyspnea, chest pain, and syncope or presyncope. Approximately 5% of patients with HCM progress to "end-stage" disease characterized by LV dilatation and heart failure. In such cases cardiac transplantation may be considered. Other serious life-threatening complications include embolic stroke and cardiac arrhythmias.

Echocardiography

Conventional two-dimensional echocardiography is the diagnostic modality of choice for the clinical diagnosis of HCM. The disease is characterized by otherwise unexplained and usually asymmetric, diffuse or segmental hypertrophy associated with a non-dilated left ventricle (LV) independent of presence or absence of LV outflow obstruction. A left ventricular wall thickness of ≤12 mm is typically regarded as normal, with measurements of 13–15 mm labeled as "borderline hypertrophy." A maximal LV end-diastolic wall thickness exceeding 15 mm represents the absolute dimension generally accepted for the clinical diagnosis of HCM in adults (in children, 2 or more standard deviations from the mean relative to body surface area) (Maron et al., 2003). Echocardiography can also provide details of location and degree of hypertrophy. In general, while there are innumerable morphologic appearances of the heart, the following four different morphological subtypes of HCM can be recognized in most cases (Table 28.1, Figure 28.1): sigmoid septum, reverse septal curvature, apical-, and neutral contour variant.

TABLE 28.1 Septal morphologies in HCM

Septal morphology	Description
Sigmoid septum	– Septum concave to cavity with pronounced septal bulge – Ovoid LV cavity
Reverse septal curvature	– Predominant mid-septal convexity toward LV cavity – Crescent-shaped cavity
Apical variant	– Predominant apical distribution of hypertrophy
Neutral variant	– Overall straight or variable convexity, predominantly neither convex nor concave

Dynamic LVOTO is a common feature of HCM but is not required for the diagnosis of HCM. The existence of LVOTO is diagnosed by demonstration of a resting or provocable Doppler gradient of >30 mmHg. LVOTO is produced by the interaction of the hypertrophied septum and systolic anterior motion (SAM) of the mitral valve. The latter results from abnormal blood flow vectors across the valve, and abnormal anterior positioning of the valve and its support structures. Variable severity, posteriorly directed mitral regurgitation is a common finding.

Most patients at presentation manifest some degree of impaired diastolic function ranging from abnormal relaxation to severe myocardial stiffness, elevated left ventricular end-diastolic pressure (LVEDP), elevated atrial pressure, and pulmonary congestion leading to exercise intolerance and fatigue. Systolic cardiac function, as measured by ejection fraction, is usually preserved. It is notable that more elegant measures of systolic performance, such as tissue velocity and strain imaging, suggest a decrease in systolic function in patients with HCM, and may even be present in gene-mutation carriers before hypertrophy can be detected. "End-stage disease" is characterized by LV dilatation, poor systolic function, and heart failure.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) constitutes an important additional diagnostic tool especially in patients with suboptimal echocardiography or unusual segmental involvement of myocardium. Delayed gadolinium enhancement in MRI is an excellent

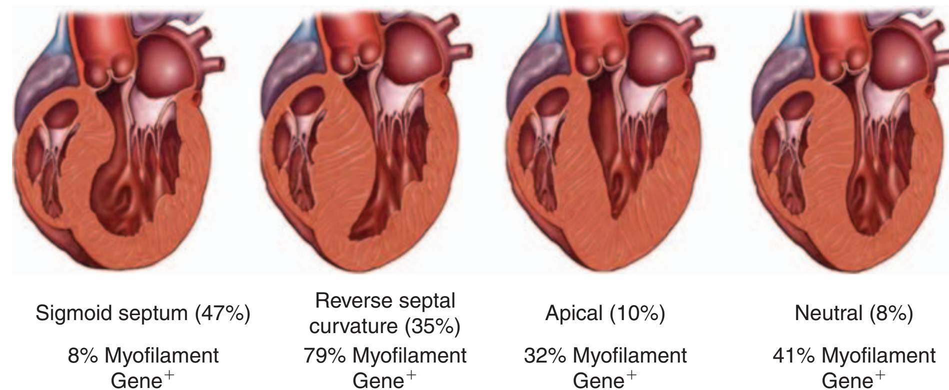

Figure 28.1 Septal morphologies in HCM. Shown are the most common septal morphologies in HCM, their distribution in a large cohort of patients with HCM as well as the yield of genetic testing for each morphological subgroup.

tool to identify areas of scarring, replacement fibrosis, or irreversible myocardial injury. There are some recent reports of higher risk of SCD associated with these finding. In a cohort of 42 patients, myocardial hyper-enhancement was found in 79%. Extent of hyper-enhancement was greater in patients with progressive disease (28.5% versus 8.7%, $p < 0.001$) and in patients with two or more risk factors for SCD (15.7% versus 8.6%, $p = 0.02$) (Moon et al., 2003).

MOLECULAR GENETICS OF HCM

Sarcomeric/Myofilament HCM

Since the sentinel discovery of the first locus for familial HCM on chromosome 14 (1989) and first mutations involving the *MYH7*-encoded beta myosin heavy chain (1990) as the pathogenic basis for HCM (Geisterfer-Lowrance et al., 1990; Jarcho et al., 1989), over 400 mutations scattered among at least 24 genes encoding various sarcomeric proteins (myofilaments and Z-disc–associated proteins) and calcium-handling proteins have been identified (Table 28.2, Figure 28.2). The most common genetically mediated form of HCM is myofilament HCM, with hundreds of disease-associated mutations in eight genes-encoding proteins critical to the sarcomere's thick myofilament (beta myosin heavy chain [*MYH7*] [Geisterfer-Lowrance et al., 1990]; regulatory myosin light chain [*MYL2*] and essential myosin light chain [*MYL3*] [Poetter et al., 1996]), intermediate myofilament (myosin-binding protein C [*MYBPC3*] [Watkins et al., 1995]), and thin myofilament (cardiac troponin T [*TNNT2*], alpha-tropomyosin [*TPM1*] [Thierfelder et al., 1994], cardiac troponin I [*TNNI3*] [Kimura et al., 1997]), troponin C [*TNNC1*] [Landstorm et al., 2008] and actin ([*ACTC*] [Mogensen et al., 1999; Olson et al., 2002a]). Targeted screening of giant sarcomeric *TTN*-encoded titin, which extends throughout half of the sarcomere, has thus far revealed only one mutation (Satoh et al. 1999). More recently, mutations have been described in the myofilament protein alpha myosin heavy chain encoded by *MYH6* (Niimura et al., 2002). The prevalence of mutations in the eight most common myofilament-associated genes, currently comprising the commercially available HCM genetic tests in different international cohorts, ranges from 30% to 61%, leaving still a large number of patients with genetically unexplained disease (Van Driest et al., 2005a).

Z-disc and Calcium-Handling HCM

Over the last few years, the spectrum of HCM-associated genes has expanded outside the myofilament to encompass additional subgroups that could be classified as "Z-disc HCM" and "calcium-handling HCM." Due to its close proximity to the contractile apparatus of the myofilaments and its specific structure–function relationship with regard to cyto-architecture, as well as its role in the stretch-sensor mechanism of the sarcomere, recent attention has been focused on the proteins that comprise the cardiac Z-disc. Initial mutations were described in *CSRP3*-encoded muscle LIM protein (Geier et al., 2003) and *TCAP*-encoded telethonin (Hayashi et al., 2004), an observation replicated in a large cohort of unrelated patients with HCM (Bos et al., 2006). Recently, mutations in patients with HCM have been reported in *LDB3*-encoded LIM domain binding 3, *ACTN2*-encoded alpha-actinin-2, and *VCL*-encoded vinculin/metavinculin (Theis et al., 2006). Interestingly, although the first HCM-associated mutation in vinculin was found in the cardiac-specific insert of the gene, yielding the protein called metavinculin (Vasile et al., 2006a), the follow-up study also identified a mutation in the ubiquitously expressed protein vinculin (Vasile et al., 2006b). In 2007, a mutation in the Z-disc–associated *MYOZ2*-encoded myozenin 2 was reported as a novel gene for HCM (Osio et al., 2007).

As the critical ion in the excitation–contraction coupling of the cardiomyocyte, calcium and proteins involved in calcium-induced calcium release (CICR) have always been of high interest in the pathogenesis of HCM. Although with very low frequency, mutations have been described in the promoter – and coding region of *PLN*-encoded phospholamban – an important

TABLE 28.2 Summary of HCM susceptibility genes

	Gene	Locus	Protein	Estimated frequency (%)
Myofilament HCM				
Giant filament	*TTN*	2q24.3	Titin	<1
Thick filament	*MYH7*[a]	14q11.2–q12	β-myosin heavy chain	15–25
	MYH6	14q11.2–q12	α-myosin heavy chain	<1
	MYL2[a]	12q23–q24.3	Ventricular regulatory myosin light chain	<2
	MYL3[a]	3p21.2–p21.3	Ventricular essential myosin light chain	<1
Intermediate filament	*MYBPC3*[a]	11p11.2	Cardiac myosin-binding protein C	15–25
Thin filament	*TNNT2*[a]	1q32	Cardiac troponin T	<5
	TNNI3[a]	19p13.4	Cardiac troponin I	<5
	TPM1[a]	15q22.1	α-tropomyosin	<5
	ACTC[a]	15q14	α-cardiac actin	<1
	TNNC1[a]	3p21.3–p14.3	Cardiac troponin C	<1
Z-disc HCM				
	LBD3	10q22.2–q23.3	LIM binding domain 3 (alias: ZASP)	1–5
	CSRP3	11p15.1	Muscle LIM protein	<1
	TCAP	17q12–q21.1	Telethonin	<1
	VCL	10q22.1–q23	Vinculin/metavinculin	<1
	ACTN2	1q42–q43	α-actinin 2	<1
	MYOZ2	4q26–q27	Myozenin 2	<1
Calcium-handling HCM				
	RYR2	1q42.1–q43	Cardiac ryanodine receptor	<1
	JPH2	20q12	Junctophilin-2	<1

inhibitor of cardiac muscle sarcoplasmic reticulum Ca(2+)-ATPase (SERCA) (Haghighi et al., 2006; Minamisawa et al., 2003), the *RyR2*-encoded cardiac ryanodine receptor (Fujino et al., 2006), and the *JPH2*-encoded type 2 junctophilin (Landstrom et al., 2007).

Metabolic and Syndromal HCM-mimicry

The last genetic subgroup of unexplained cardiac hypertrophy is the one comprising metabolic and syndromal HCM-mimickers – in which cardiomyopathy is a sometimes sole presenting feature (Table 28.3). In 2001, the first mutations in *PRKAG2*-encoded AMP-activated protein kinase gamma 2, a protein involved in the energy homeostasis of the heart, were described in two families with severe HCM and aberrant AV-conduction in some individuals (Blair et al., 2001). Further studies showed that patients with mutations in this gene lack the HCM characteristics of myocyte – and myofibrillar disarray – but show newly formed vacuoles filled with glycogen-associated granules. This glycogen storage disease therefore seemed to mimic HCM, distinguishing itself by electrophysiological abnormalities, particularly ventricular pre-excitation (Arad et al., 2002, 2005). In 2005, Arad et al. described mutations in lysosome-associated membrane protein2 encoded by *LAMP2* (Danon's syndrome) and protein kinase gamma 2 encoded by *PRKAG2* in glycogen storage disease-associated genes mimicking the clinical phenotype of HCM (Arad et al., 2005). A recent community-based study showed that in 50 healthy individuals with idiopathic LVH, participants with sarcomere gene protein and storage mutations essentially were indistinguishable clinically from those without mutations (Morita et al., 2006).

In 2005, a mutation in *FXN*-encoded frataxin associated with Friedrich ataxia was described in a patient with HCM. Although this patient also harbored a myofilament mutation in *MYBPC3*-encoded myosin binding protein C, functional characterization showed significant influence of the *FXN*-mutant on the phenotype, suggesting that the observed alterations in energetics may act in synergy with the present myofilament mutation (Van Driest et al., 2005b). Akin to PRKAG2 and LAMP2, Fabry's disease can express predominant cardiac features of seemingly unexplained LVH. Over the years, mutations in *GLA*-encoded alpha-galactosidose A have been found in patients with this multisystem disorder (Nakao et al., 1995; Sachdev et al., 2002; Sakuraba et al., 1990).

Genotype–Phenotype Relationships in HCM

For over the past decade, multiple studies have tried to identify phenotypic characteristics most indicative of myofilament HCM to facilitate genetic counseling and strategically direct clinical genetic testing (Ackerman et al., 2002; Richard et al.,

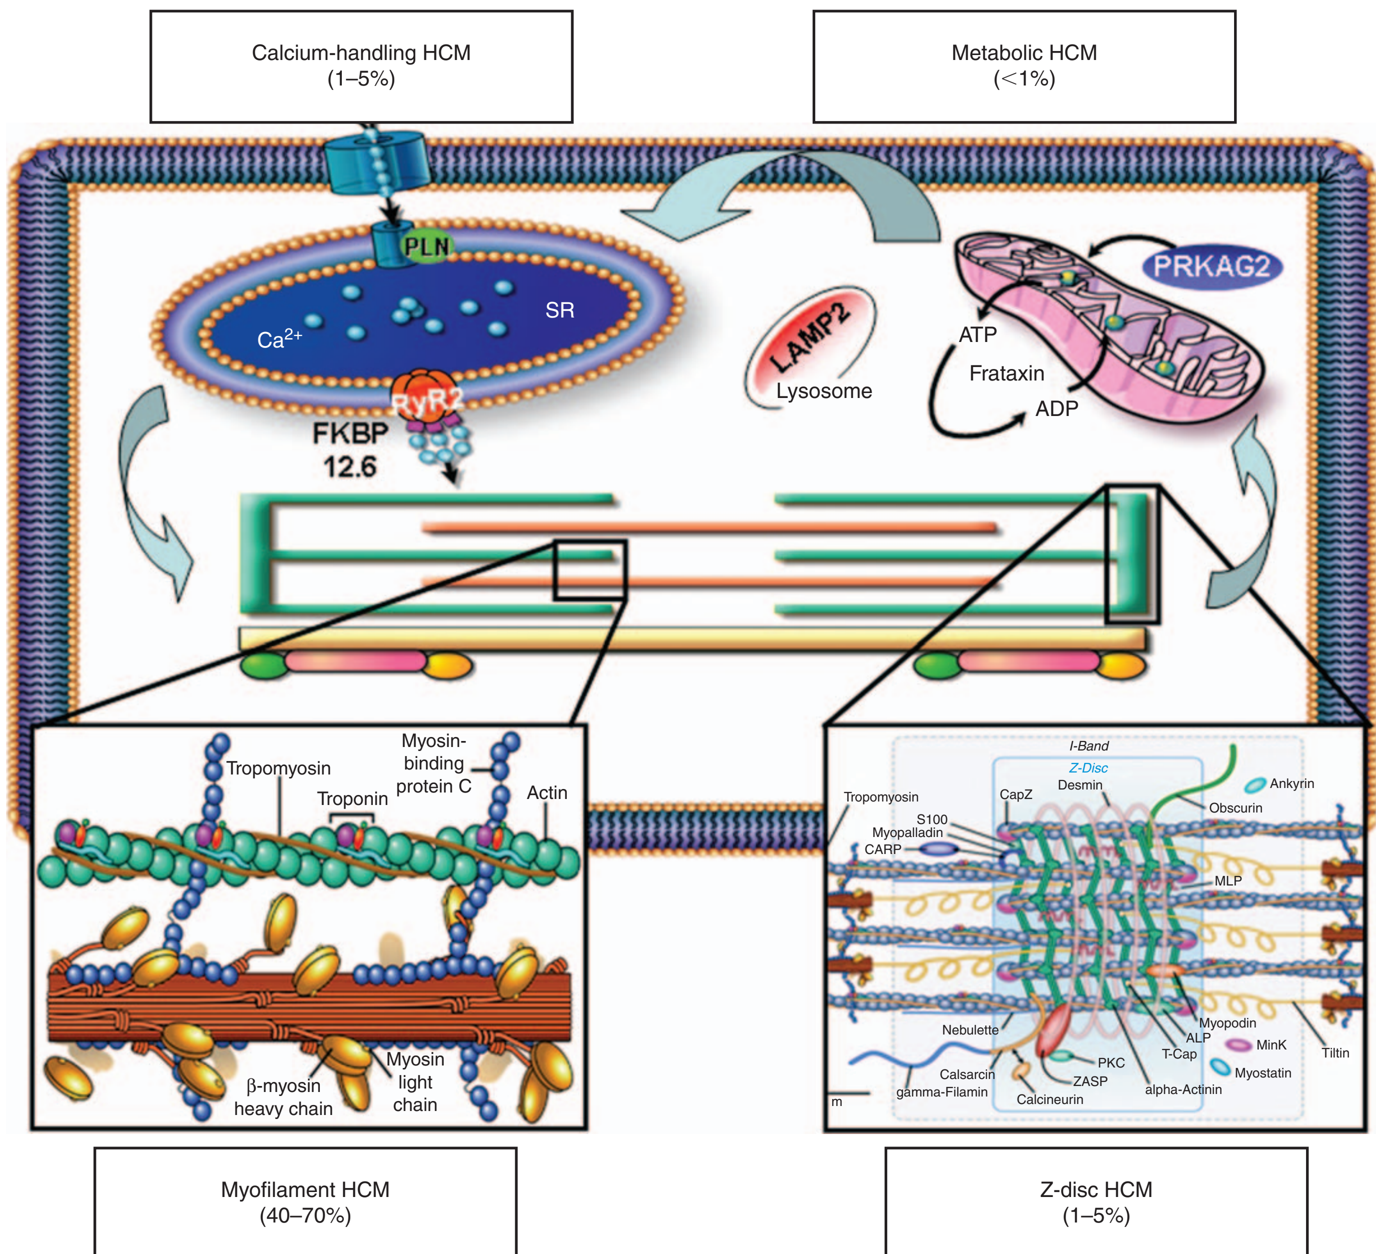

Figure 28.2 Subgroups of genetic HCM. Shown are the most important functional subgroups of genetically mediated HCM. Blue arrows indicate the functional relationship between the different elements.

2003; Van Driest et al., 2002, 2003, 2004a, b; Woo et al., 2003). Up until 2001, it was thought that specific mutations in these myofilament genes were inherently "benign" or "malignant" (Anan et al., 1994; Coviello et al., 1997; Elliott et al., 2000; Moolman et al., 1997; Niimura et al., 2002; Seidman et al., 2001; Varnava et al., 1999; Watkins et al., 1992). However, these studies were based on highly penetrant, single families with HCM, and later genotype–phenotype studies involving a large cohort of unrelated patients have indicated that great caution must be exercised with assigning particular prognostic significance to any particular mutation (Ackerman et al., 2002; Van Driest et al., 2002, 2004b). Furthermore, these studies demonstrated that the two most common forms of genetically mediated HCM – *MYH7*-HCM and *MYBPC3*-HCM – were phenotypically indistinguishable (Van Driest et al., 2004b). While several phenotype–genotype relationships have emerged to enrich the yield of genetic testing, these patient profiles have not been particularly clinically informative on an individual level.

TABLE 28.3 Metabolic and Syndromal-HCM-mimickers

Gene	Locus	Protein	Syndrome
PRKAG2[a]	7q35-q36.36	AMP-activated protein kinase	WPW/HCM
LAMP2[a]	Xq24	Lysosome-associated membrane protein 2	Danon's syndrome
GAA	17q25.2-q25.3	Alpha-1,4-glucosidase deficiency	Pompe's disease
GLA[a]	Xq22	Alpha-galactosidase A	Fabry's disease
FXN	9q13	Frataxin	Friedrich's ataxia
PTPN11[b]	12q24.1	Protein tyrosine phosphatase, non-receptor type 11	Noonan's syndrome

Note: In patients with cardiac hypertrophy secondary to Noonan's syndrome, *PTPN11* mutations are quite uncommon (<10%) compared to >50% yield expected for Noonan's syndrome without LVH.
[a]Available as part of commercially available genetic testing.
[b]*PTPN11* is also associated with LEOPARD syndrome and is allelic to Noonan's syndrome.

Recently, an important discovery, linking the echocardiographically determined septal morphology to the underlying genetic substrate, was made (Binder et al., 2006). The first link to be drawn between septal morphologies was a result of a HCM study by Lever and colleagues in the 1980s, where septal contour (Table 28.1) was found to be age-dependent with a predominance of sigmoidal-HCM noted in the elderly (Lever et al., 1989). In the early 1990s, an early genotype–phenotype observation involving a small number of patients and family members showed that patients with mutations in the beta myosin heavy chain (*MYH7*-HCM) generally had reversed curvature septal contours (reverse curve-HCM) (Solomon et al., 1993).

Analysis of the echocardiograms of 382 previously genotyped and published patients (Van Driest et al., 2003, 2004b, c), revealed that sigmoidal-HCM (47% of cohort) and reverse curve-HCM (35% of cohort) were the two most prevalent anatomical subtypes of HCM and that the septal contour was the strongest predictor for the presence of a myofilament mutation, regardless of age (Binder et al., 2006). In fact, multivariate analysis in this cohort demonstrated that septal morphology was the only, independent predictor of myofilament HCM with an odds ratio of 21 ($p < 0.001$) when reverse curve morphology was present (Figure 28.1; Binder et al., 2006).

The yield from the commercially equivalent HCM genetic research test for myofilament HCM was 79% in reverse curve-HCM but only 8% in patients with sigmoidal-HCM. Of the smaller subgroup of patients with apical HCM, 32% had a mutation in one of the elements of the cardiac myofilament (Binder et al., 2006). These observations may facilitate echo-guided genetic testing by enabling informed genetic counseling about the *a priori* probability of a positive genetic test based on the patient's expressed anatomical phenotype of HCM (Figure 28.1).

With the majority of known myofilament proteins studied, except for a complete analysis of the giant protein *TTN*-encoded titin, recent research has focused on proteins beyond the cardiac myofilaments, especially proteins involved in the cytoarchitecture and cardiac stretch-sensor mechanism of the cardiomyocyte localized to the cardiac Z-disc (Figure 28.2). The Z-disc is an intricate assembly of proteins at the Z-line of the cardiomyocyte sarcomere. Proteins of the Z-disc are important in the structural and mechanical stability of the sarcomere as they appear to serve as a docking station for transcription factors, Ca^{2+} signaling proteins, kinases, and phosphatases (Frank et al., 2006; Pyle et al., 2004). In addition, this assembly of proteins seems to serve as a way station for proteins that regulate transcription by aiding in their controlled translocation between the nucleus and the Z-disc (Frank et al., 2006; Pyle et al., 2004).

A main implication for the Z-disc is its involvement in the cardiomyocyte stretch sensing and response systems (Knoll et al., 2002). Mutations in these proteins have been implicated as HCM (Bos et al., 2006; Geier et al., 2003; Hayashi et al., 2004; Vasile et al., 2006a, b) and DCM susceptibility genes (Bos et al., 2006; Geier et al., 2003; Hayashi et al., 2004; Mohapatra et al., 2003; Olson et al., 2002b; Vasile et al., 2006a). Additionally, it has become appreciated that these divergent cardiomyopathic phenotypes of HCM and DCM are partially allelic disorders with *ACTC*, *MYH7*, *TNNT2*, *TPM1*, *MYBPC3*, *TTN*, *MLP*, *TCAP*, and *VCL* established as both HCM and DCM susceptibility genes (Daehmlow et al., 2002; Geier et al., 2003; Gerull et al., 2002; Hayashi et al., 2004; Kamisago et al., 2000; Mohapatra et al., 2003; Olson et al., 2000, 2001; Vasile et al., 2006a).

Recently, mutations in *ACTN2*-encoded alpha-actinin-2 (ACTN2) and *LDB3*-encoded LIM domain binding 3 (LDB3) as novel HCM susceptibility genes (Theis et al., 2006) were described. Linking reverse curve-HCM to the presence of myofilament mutation, and recognizing that the Z-disc may transduce multiple-signaling pathways during stress, translating into hypertrophic responses, cell growth and remodeling (Frey et al., 2004), it was observed that Z-disc HCM, in contrast to myofilament HCM, is preferentially sigmoidal. In fact, 11 out of 13 patients with Z-disc HCM had a sigmoidal septal contour and no reverse septal curvatures were seen (Theis et al., 2006). It is speculated that Z-disc HCM leads to a hypertrophic response that is expressed in the areas of highest stress (i.e., LVOT) and therefore predisposes to a sigmoidal septal contour.

New Insights and Approaches to Genomics of HCM

Not only in molecular genetics but also in other fields of "-omics," novel pathways underlying the pathophysiology of this heterogeneous disease have been identified using several new techniques to study large-scale transcriptional changes (Churchill, 2002; Holland, 2002; Velculescu et al., 1997). A transcriptomic approach

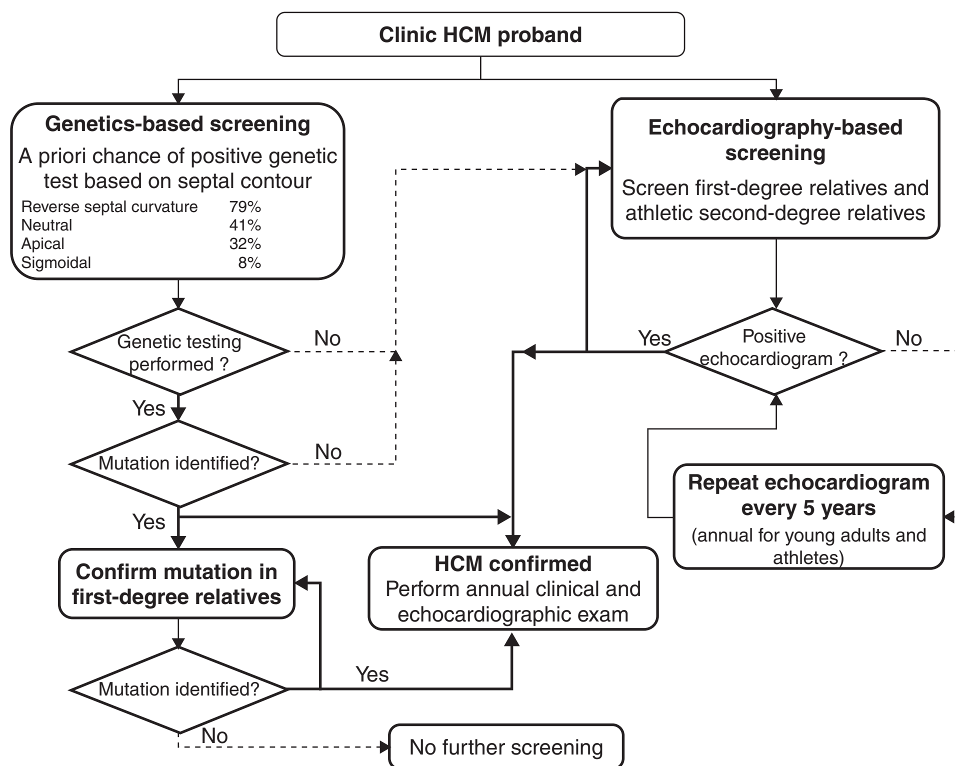

Figure 28.3 Genetic- and echocardiographic-based screening in HCM. Flow-chart showing decision to follow in genetic- and echocardiography-based screening in HCM. Noted are the *a priori* chances for a positive genetic test result based on the echocardiographic-scored septal contour, as well as the steps to follow if a patient chooses not to pursue genetic testing.

using microarray, a technique that enables one to give a snapshot view of gene expression, combined with complex analytic tools, can identify genes that seem to be co-regulated and thereby form a transcriptional network of genes and pathways. Microarray chips can hold over 10,000 genes and can be utilized to compare expression levels in certain disease states with healthy controls. In 2002, Hwang et al. studied RNA from heart failure patients with either HCM or DCM and found 192 genes to be upregulated in both, as well as several genes differentially expressed between the two diseases providing information on different pathways and genes involved in the pathogenesis (Hwang et al., 2002). More recently, Rajan et al. performed microarray analysis on ventricular tissue of two previously developed transgenic HCM mice carrying mutations in alpha-tropomyosin (TPM1). Studying 22,600 genes, they discovered 754 differentially expressed genes between transgenic and non-transgenic mice, of which 266 were differentially regulated between the two different mutant hearts showing most significant changes in genes belonging to the "secreted/extracellular matrix" (upregulation) and "metabolic enzymes" (downregulation) (Rajan et al., 2006).

Microarray techniques were also used by Sayed et al. when they studied the effect of aortic constriction on expression of microRNAs, fundamental regulators consisting of non-coding RNA molecules that silence genes through post-transcriptional regulation first described by Lee et al. in 1993 (Lee et al., 1993). In this recent study, they found that microRNAs, especially microRNA-1 (miR-1), play an important role in the development of cardiac hypertrophy, where downregulation of miR-1 leads to relief of its growth-related target genes, protein synthesis, and increased cell size showing a completely new approach to the -omics of HCM (Sayed et al., 2007).

In 2007, a novel-sensitive messenger RNA (mRNA) profiling technology, PMAGE (polony multiplex analysis of gene expression), which detects mRNAs as rare as one transcript per three cells, was developed (Kim et al., 2007). Using this new technique, early transcriptional changes preceding pathological manifestations were identified in mice with HCM-causing mutations, including low-abundance mRNA encoding signaling molecules and transcription factors that participate in the disease pathogenesis (Kim et al., 2007).

SCREENING AND TREATMENT FOR HCM

Family Screening in HCM

Genetic and clinical screening of family members with HCM plays an important role in the early diagnosis of HCM. Figure 28.3 shows one possible algorithm to follow after diagnosis of a proband with HCM. In general, all first-degree relatives and probably "athletic" second-degree relatives of an index case of HCM

should be screened by an ECG and an echocardiogram. Annual screenings are recommended for young persons (12–25 years) and athletes and thereafter every 5 years. If the HCM-causing mutation is known, first-degree relatives should have confirmatory genetic testing of the mutation in addition to the screening ECG and echocardiogram. Depending on the established familial versus sporadic pattern, confirmatory genetic testing should proceed in concentric circles of relatedness. For example, if the mutation is established in the patient's father, the patient's paternal grandparents should be tested, and if necessary, the paternal aunts and uncles and so forth. If the putative HCM-associated mutation is not found in a phenotype-negative family member, screening can be stopped. However, a decision to cease surveillance for HCM in a relative hinges critically on the certainty of the identified gene/mutation and its causative link as well as the complete absence of any traditional evidence used to diagnose HCM clinically (i.e., asymptomatic and normal echo).

Follow-up and Sports Participation

Intense physical exertion can potentially trigger SCD in individuals with HCM. According to the 2005 Bethesda Conference recommendations, athletes with HCM should be excluded from participation in contact sports as well as most organized competitive sports, with the possible exception of low-intensity sports classified as class IA sports (i.e., golf, bowling, cricket, billiards, and riflery) (Maron et al., 2005). Per the guidelines, the presence of an implantable cardioverter defibrillator (ICD) does not alter these recommendations. This restrictive approach is loosened for the patient with genotype-positive but phenotype-negative HCM. All patients with HCM should undergo, on an annual basis, careful personal and family history record, two-dimensional echocardiography, 12-lead ECG, 24–48-h ambulatory Holter electrocardiogram, and exercise stress testing (for evaluation of exercise tolerance, blood pressure, and ventricular tachyarrhythmias).

Pharmacological Therapy for Obstructive HCM

The primary goal of pharmacologic therapy in obstructive HCM is to decrease symptoms. Understanding the pathophysiology of the LVOTO is crucial to devising appropriate medication recommendations. The LVOTO in HCM is dynamic and highly load-dependent. The obstruction is augmented with decreases in preload (volume status) and afterload (vasodilation) and with increases in contractility. Simple physical exertion such as walking can cause all of these to occur simultaneously. As patients with HCM typically only have symptoms with effort, the goal of medical therapy is to decrease the effort-related augmentation of LVOTO.

Beta Blockers

Due to negative inotropic and negative chronotropic effects, beta blockers are the traditional mainstay of HCM therapy. Beta blockers are used in symptomatic patients with or without obstruction to control heart failure and anginal chest pain. The dose–response relationship of these medications varies significantly from patient to patient. Commonly used beta blockers include propranolol, atenolol, metoprolol, and nadolol (Elliott et al., 2004; Spirito et al., 2006).

Calcium-Blocker Therapy

The calcium channel antagonist verapamil is another drug used in HCM for its negative inotropic effect. It should be avoided in infants and used with caution in patients with heart failure and/or very significant obstruction (Maron et al., 2003). While both verapamil and diltiazem have negative inotropic and negative chronotropic effects, in some patients, vasodilatory action can predominate and paradoxically increase the severity of symptoms. Dihydropyridine-type calcium antagonists are pure vasodilators that should be avoided in patients with HCM.

Disopyramide

Disopyramide is a negative inotrope and type 1-A antiarrhythmic agent, which may help some patients with obstruction. It decreases cardiac output in nonobstructive HCM and is used primarily in patients not responding to beta blocker and/or calcium channel blocker therapy. There are no data that beta blockers, calcium channel blockers, or disopyramide alter the risk of sudden death (Maron et al., 2003).

Drugs to Be Used with Caution in HCM

Angiotensin-converting enzymes inhibitors (ACE inhibitors), angiotensin II blockers, nifedipine, and other pure afterload reducing agents should be used with caution, as afterload reduction may worsen LVOTO (Roberts et al., 2005; Spirito et al., 2006). Beta adrenergic agents like dopamine, dobutamine, or epinephrine and agents with increased inotropic activity may worsen LVOTO (Maron et al., 2003). Likewise, rapid or aggressive diuresis can decrease preload and worsen LVOTO.

Pharmacogenomics

Currently, there is no therapy available specifically designed for specific gene mutations underlying the disease nor a therapy that has been shown to reverse the hypertrophic process. Although polymorphisms in the renin-angiotensin-aldosterone system (RAAS) modify the phenotype of HCM, particularly *MYBPC3*-HCM (Perkins et al., 2005), a direct correlation with genotype-specific drug treatment has not been shown. However, with growing evidence that ACE inhibitors especially combined with low doses of aldosterone receptor blockers can prevent the progression of hypertrophy and fibrosis (Fraccarollo et al., 2003, 2005; Kalkman et al., 1999; Kambara et al., 2003; Monteiro de Resende et al., 2006), one can envision that, with increasing knowledge of the genomic background of HCM, specific therapies will emerge in the near future. In other cases for example, the proper and prompt recognition of an HCM phenocopy such as cardiac Fabry's disease can facilitate gene-specific pharmacotherapy including in this particular example, enzyme-replacement therapy. Albeit rare, such clinical sleuthing can enable early treatment and prevent the progression of the disease.

The Role and Impact of Non-Pharmacological Therapy

Septal Myectomy Surgery

Ventricular septal myectomy remains the gold standard for treating drug refractory, symptomatic obstructive HCM; a procedure during which a piece of hypertrophied septum is removed in order to relieve the obstruction (Maron et al., 2004; Nishimura et al., 2004; Spirito et al., 2006). Surgery is usually indicated in patients with peak instantaneous LVOT Doppler gradient of 50 mmHg or higher under rest or provocation and/or severely symptomatic patients (NYHA class 3 or 4, (Maron et al., 2003, 2004; Spirito et al., 2006). This profile represents approximately 5% of patients with HCM (Elliott et al., 2004). More extensive, extended septal myectomy involving the anterolateral papillary muscle and mitral valvuloplasty may be needed in patients with abnormal papillary muscle apparatus and mitral valve abnormalities (Ommen et al., 2005). The surgical mortality is <1% in most major centers (Maron et al., 2004; Poliac et al., 2006). Long-term survival after surgical myectomy is equal to that observed in the general population (Ommen et al., 2005). Surgery provides long-term improvement in LVOT gradient, mitral valve regurgitation, and symptomatic improvement (Maron et al., 2004; Ommen et al., 2005; Poliac et al., 2006).

Septal Ablation

Alcohol septal ablation technique using ethanol (95% alcohol 1–3 ml) is injected in specific septal branches of the left anterior descending artery producing a controlled septal infarction often providing dramatic symptomatic improvement in some patients (Faber et al., 1998; Gietzen et al., 1999; Kimmelstiel et al., 2004; Knight et al., 1997; Lakkis et al., 1998). The criteria for patient selection for alcohol septal ablation are similar to myectomy with the following *caveat* – the impact of alcohol septal ablation on SCD risk is unknown. Scarring associated with alcohol septal ablation may create a permanent arrhythmogenic substrate (Maron et al., 2003). Complications include complete atrioventricular block requiring permanent pacemakers (5–10% of patients), large myocardial infarction, acute mitral valve regurgitation, ventricular fibrillation (VF), and death (2–4%, Nishimura et al., 2004; Roberts et al., 2005; Spirito et al., 2006). Alcohol septal ablation is not suitable for patients with LVOTO secondary to abnormal mitral valve apparatus and unusual location of hypertrophy away from the area supplied by septal perforator. Given the unknown future risks of alcohol septal ablation, it is not recommended in children or young adults (Maron et al., 2003).

Implantable Cardioverter Defibrillator

The implantable cardiac defibrillator (ICD) plays an important role in primary and secondary prevention of sudden death of patient with HCM. The three main functions of the ICD are detection of arrhythmia; delivery of appropriate electrical therapy; and storage of diagnostic information, including electrocardiograms and details of treated episodes. In a multicenter study of ICDs in patients with HCM, the device intervened appropriately, terminating VT/VF, at a rate of

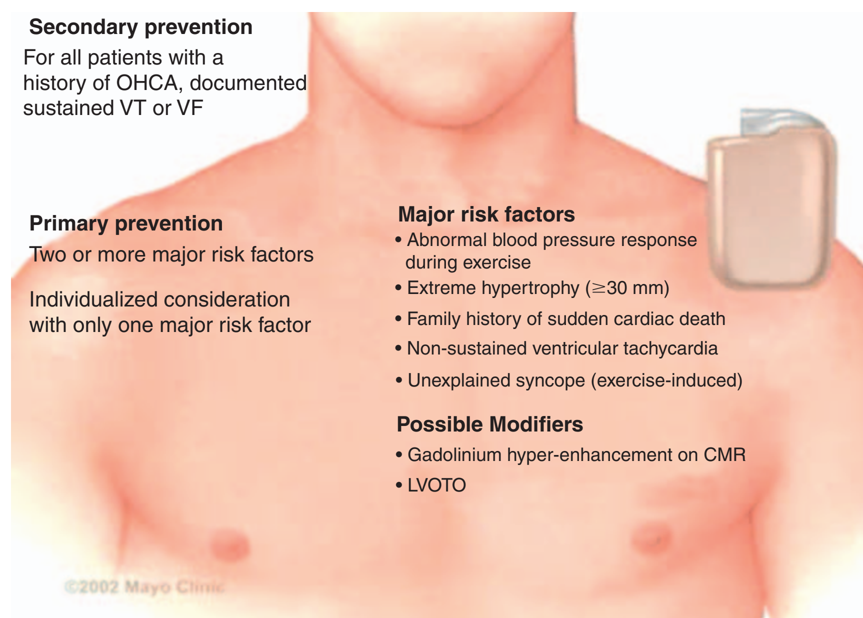

Figure 28.4 The major indications for implantation of an ICD in HCM: secondary prevention or primary prevention, and major risk factors. CMR, cardiac magnetic resonance; LVOTO, left ventricular outflow tract obstruction; OHCA, out of hospital cardiac arrest; VF, ventricular fibrillation; VT, ventricular tachycardia.

5% per year for those patients implanted as primary prevention and 11% per year for secondary prevention, over an average follow-up of 3 years (Maron et al., 2000). The indications for implantation of an ICD are listed in Figure 28.4 and can be summarized as secondary prevention for all patients with a history of out of hospital cardiac arrest (OHCA), documented sustained VT or VF, or as primary prevention in patients with two or more major risk factors.

Dual-Chamber Pacing

There has been a great deal of debate surrounding the use of pacing as a means of relieving ventricular obstruction. Some studies have shown a beneficial effect, while others demonstrated significant placebo effect (Maron et al., 2003). The average decrease in LVOTO gradient with pacing ranged from a modest 25% to 40% and varied substantially (Maron et al., 2003). There is evidence to suggest that appropriately used dual-chamber pacing may decrease LVOT gradient and provide symptomatic relief (Maron et al., 1999). Thus, there may be a limited role of dual-chamber pacing in a select group of patients, for example patients with advanced age (>65 years) and higher surgical risk. There is no evidence to suggest any change in SCD risk or disease progression (Boriani et al., 2004).

Maze Procedures

Surgical Maze procedure combined with myectomy may be a feasible therapeutic option in HCM with LVOTO and atrial fibrillation (AF). There are small case series reporting low operative mortality and morbidity and a high likelihood of patients remaining in sinus rhythm post procedure (Chen et al., 2004). Larger studies with longer follow-up are needed to better define the risks and benefits of surgical Maze procedure in HCM.

2009 UPDATE

With research ongoing and recognizing that approximately 20% of reverse curve-HCM and over 80% of sigmoidal-HCM remains genetically unexplained, novel HCM-susceptibility genes have been discovered recently. In 2007, Arimura et al. found two mutations in one patient with HCM in *OBSCN*-encoded obscurin that altered interaction with the giant myofilament protein titin (Arimura et al., 2007). In a larger study, 3 of 384 patients with HCM were mutation-positive in the *ANKRD1*-encoded cardiac ankyrin repeat protein (Arimura et al., 2009).

The release of the complete human genome sequence and the enormity of variation in individuals show a growing role for modifier genes and the search for effect by genome-wide studies. In 2007, Daw et al. identified multiple loci with suggestive linkage for modifying cardiac hypertrophy. Effect sizes on left ventricular mass on this cohort of 100 patients ranged from an ~8 g shift attributed to one locus for the common allele to 90 g shift for another locus' uncommon allele (Daw et al., 2007). In 2008, sex hormone polymorphisms were shown to modify the HCM phenotype (Lind et al., 2008). Fewer CAG repeats in *AR*-encoded androgen receptor were associated with greater myocardial wall thickness in males ($p=0.008$), and male carriers of the A-allele in the promoter of *ESR1*-encoded estrogen receptor 1 (SNP rs6915267) exhibited a 11% decrease in LV wall thickness ($p=0.047$) compared to GG-homozygote males (Lind et al., 2008). HCM modifier polymorphisms like these could contribute to the clinical differences observed between men and women with HCM (Bos et al., 2008; Olivotto et al., 2005).

A recent longitudinal study in a large cohort of Italian patients with HCM has shown an increased risk of cardiovascular death, nonfatal stroke, or progression to NYHA class III/IV among patients with a positive HCM genetic test involving any of the myofilament genes compared to those patients with a negative genetic test (25% versus 7%, respectively; $p=0.002$). Multivariate analysis showed that myofilament positive HCM (i.e., a positive genetic test) was the strongest predictor of an adverse outcome (hazard ratio 4.27 (CI 1.43 – 12.48, $p=0.008$, Olivotto et al., 2008). Furthermore, patients with a positive genetic test had greater probability of developing severe LV systolic dysfunction ($p=0.021$) and restrictive LV filling ($p=0.018$, Olivotto et al., 2008).

In the emerging field of microRNA's (miR's) and their role in cardiac development and (hypertrophic) heart disease, several new studies linking miR's and hypertrophy have been published. Utilizing two mouse models of pathological hypertrophy – transverse aortic constriction (TAC) and calcineurin transgenic mice – 6 miR's were up-regulated, which *in vitro,* were sufficient to induce hypertrophic growth of cardiomyocytes (van Rooij et al., 2006). A transgenic mouse model over-expressing miR-195 showed that a single miRNA could induce pathological hypertrophy and heart failure (van Rooij et al., 2006). Multiple studies have since been published with miRNA expression profiles in different settings, *in vivo* and *in vitro*, of cardiac hypertrophy demonstrating the potential role of miR's in (hypertrophic) heart disease and possibly HCM (Ikeda et al., 2007; Sayed et al., 2007; Tatsuguchi et al., 2007; Thum et al., 2007; van Rooij et al., 2006, 2007).

CHAPTER

Genetics and Genomics of Arrhythmias

Jeffrey A. Towbin and Matteo Vatta

INTRODUCTION

Arrhythmias typically are thought to occur due to primary or secondary abnormalities in cardiac electrophysiology. These abnormalities can include primary alterations in myocardial conduction and repolarization or those occurring as a result of structural heart disease. A significant portion of the individuals found to have abnormalities of rhythm and conduction are now known to have a genetic basis, with familial inheritance notable. Familial inheritance of arrhythmias and conduction disorders indicates that genetic factors play an integral role in development of these abnormalities. Understanding the underlying genetic defects responsible for these disorders has indeed provided insights into the mechanisms leading to the clinical picture and promises to impact the therapeutic strategies used in the care of these patients. Over the course of the last 15 years, our understanding of the genetic abnormalities in a variety of cardiomyopathies, long QT syndrome (LQTS), Brugada syndrome, catecholaminergic polymorphic ventricular tachycardia (CPVT), and newer disorders has led to general concepts of cardiovascular disease. In this chapter, the clinical features and management of arrhythmia disorders and conduction disease will be discussed and the current understanding of the genetic and genomic abnormalities associated with these disorders will be reviewed.

SPECIFIC CARDIAC ARRHYTHMIAS

The entire cardiac electrical system can be affected by genetic abnormalities, leading to atrial and ventricular tachyarrhythmias, sinus node dysfunction (SND), or atrioventricular block (AV block). Primary and secondary arrhythmias (i.e., those associated with structural heart disease) are discussed below.

PRIMARY ABNORMALITIES IN CARDIAC RHYTHM: VENTRICULAR TACHYARRHYTHMIAS

Long QT Syndromes

The long QT syndromes (LQTS) are primary disorders of cardiac repolarization (Schwartz et al., 2000a) in which prolongation of the QT interval corrected for heart rate (QTc) is seen on the surface electrocardiogram (ECG) along with abnormalities of T-wave morphology and sinus bradycardia (Figure 29.1). Syncope, seizures, and sudden death are the clinical features that are commonly seen, occurring due to ventricular tachycardia (VT), especially polymorphic VT or *torsades de pointes* (Figure 29.2), which can degenerate into ventricular fibrillation (VF). *Torsades de pointes* is common in all forms of LQTS, and is defined as "turning of the points" describing the varying axis of the QRS complex during VT (Schwartz et al., 2000a). This arrhythmia is a subset of polymorphic VT, to be distinguished from monomorphic VT which has a different morphology and mechanism of development (El-Sherif et al., 1997; Viskin et al., 1996). Monomorphic VT usually results from reentrant mechanisms and typically can be induced by programmed electrical stimulation. On the other hand, polymorphic VT cannot be induced using programmed electrical stimulation, suggesting the mechanism is unlikely to be

primary reentry. *Torsades de pointes*, in fact, is thought to be initiated by abnormal automaticity and then maintained by reentrant mechanisms (Antzelevitch, 1999). Development of early afterdepolarizations (EADs) appear to be an important mechanism whereby drug-induced action potential prolongation initiates *torsades* (January and Riddle, 1989; Verduyn et al., 1997). Under normal conditions, the ventricle is activated from subendocardium to epicardium by impulses arising in the subendocardial Purkinje network. Mapping data in animal models support the idea that the initial beat in *torsades* arises in the subendocardium, consistent with a triggered beat arising from an EAD in the Purkinje system (El-Sherif et al., 1996). The conditions that evoke EADs markedly prolong repolarization in the mid-myocardium (M cell region) as well, resulting in a situation where propagation of EAD-related triggered beats from the subendocardium may be blocked in regions where M cell action potentials have become especially long, setting up intramural reentrant excitation with a circuit that varies from beat to beat (Antzelevitch et al., 1995). This perhaps accounts for the distinctive morphology of *torsades de pointes* (Asano et al., 1997; El-Sherif et al., 1997).

Recently, the concept has emerged that defects in currents important for repolarization prolong the action potential but are not directly arrhythmogenic. Rather, action potential duration creates a milieu in which genetically normal, drug-unmodified ion channels or other electrogenic phenomena further prolong repolarization and precipitate arrhythmias.

The LQTS have been classified into acquired and genetically inherited forms. Acquired long QT syndrome (aLQTS) is the most common form of LQTS, with drug-induced LQTS particularly common. Drugs implicated in aLQTS include antiarrhythmic agents such as quinidine or sotalol, tricyclic antidepressants, antibiotics (especially macrolide antibiotics such as erythromycin), antihistamines such as terfenidate, and inhalational anesthetics. Acquired LQTS has also been seen in association with metabolic derangements including hypokalemia, hypomagnesemia, and hypercalcemia. Additionally, aLQTS has been identified in patients with other cardiac diseases such as cardiomyopathies and myocardial ischemia, as well as under circumstances of intracranial disease (i.e., intracranial surgery, subarachnoid hemorrhage, and increased intracranial pressure).

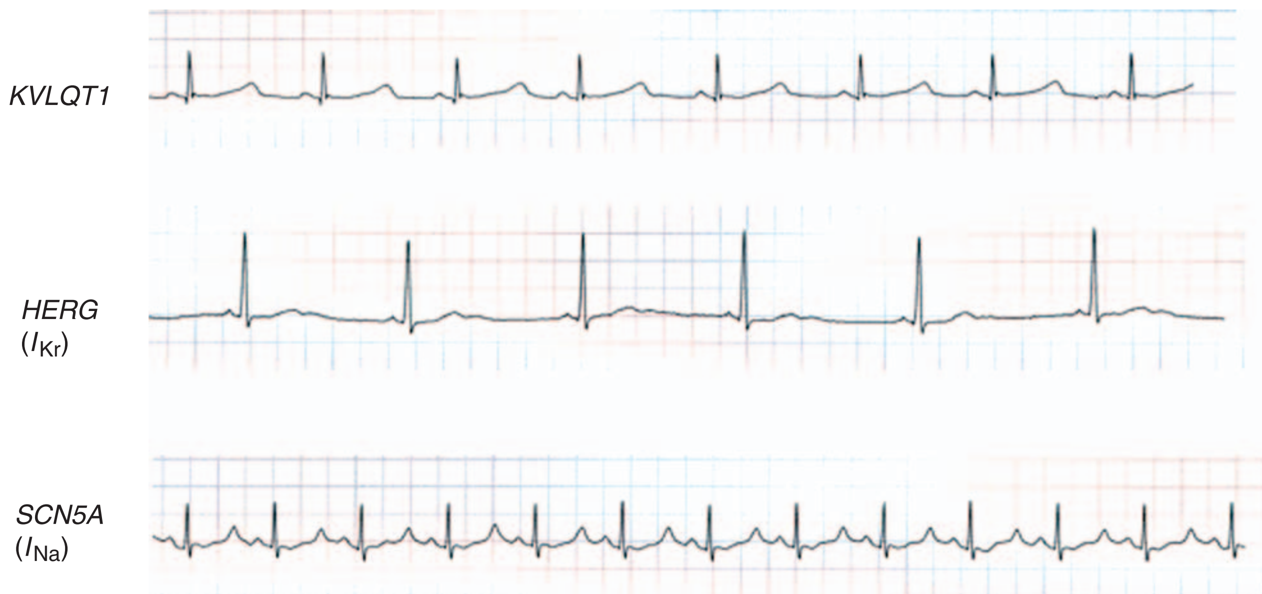

Figure 29.1 Electrocardiograms demonstrating LQTS associated with the three major genes causing LQTS (with permission).

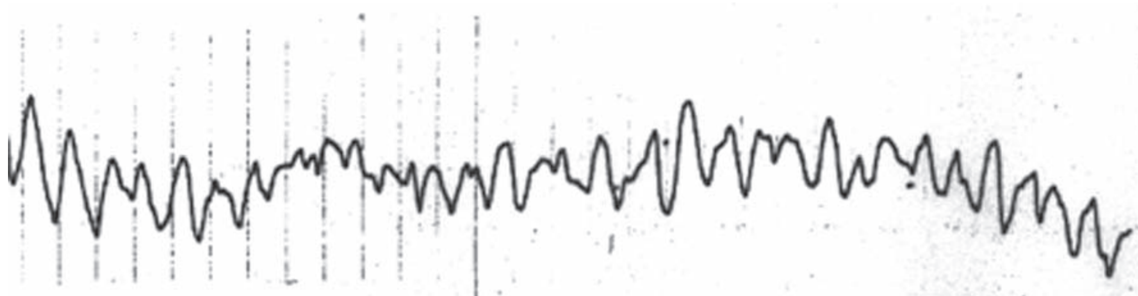

Figure 29.2 *Torsade de pointes* polymorphic ventricular tachycardia.

Four forms of inherited LQTS are known: Romano-Ward LQTS (Romano et al., 1963; Ward, 1964) and Jervell and Lange-Nielsen syndrome (Jervell and Lange-Nielsen, 1957) are the classically described forms of LQTS. More recently, two other disorders, Andersen syndrome (Andersen et al., 1971) and Timothy syndrome (Marks et al., 1995; Splawski et al., 2004) have been described, studied and their underlying causes determined. Another disorder, sudden infant death syndrome (SIDS) has also been found to be "LQTS-like" in some babies (Schwartz et al., 1998).

Table 29.1 Diagnostic criteria in LQTS

Clinical finding	Points
Electrocardiographic findings[a]	
QTc[b]	
>480 $ms^{1/2}$	3
460–470 $ms^{1/2}$	2
450 (male) $ms^{1/2}$	1
Torsades de pointes[c]	2
T-wave alterans	1
Notched T wave in three leads	1
Low heart rate for age[d]	0.5
Clinical history	
Syncope[c]	
With stress	2
Without stress	1
Congenital deafness	0.5
Family history[e]	
Family members with definite LQTS[f]	1
Unexplained sudden cardiac death below age 30 among immediate family members	0.5

Scoring: <1 point = low probability of LQTS; 2–3 points = intermediate probability of LQTS; >4 points = high probability of LQTS.

[a] In the absence of medications or disorders known to affect these ECG features.

[b] QTc calculated by Bazett's formula, where $QTc = QT/\sqrt{RR}$.

[c] Mutually exclusive.

[d] Resting heart rate below the second percentile for age.

[e] The same family member cannot be counted twice.

[f] Definite LQTS is defined by an LQTS score >4.

Romano-Ward syndrome is characterized by autosomal dominant inheritance with reduced penetrance and is the most common inherited form of LQTS, estimated to have an incidence of 1 in 10,000 live births worldwide (Priori et al., 1999a, b; Vatta et al., 2000). Jervell and Lange-Nielsen syndrome is a seemingly rare condition, with an estimated incidence of 1 in 1.6 million live births (Priori et al., 1999a, b; Vatta et al., 2000). This disorder, which is defined as LQTS associated with sensorineural deafness, has been described as having autosomal recessive inheritance since its initial description in 1957 (Jervell and Lange-Nielsen, 1957). In the past decade, molecular genetic studies, have clarified its inheritance, suggesting it to be autosomal dominant LQTS associated with autosomal recessive deafness. Finally, SIDS has been shown to be another presentation of inherited LQTS (Schwartz et al., 1998). Supportive data was provided by the identification of mutations in the cardiac sodium channel gene, *SCN5A*, by Ackerman et al. (2001), followed by identification of *HERG/KCNH2* mutations in other infants with SIDS (Christiansen et al., 2005).

Clinical Features of LQTS

LQTS is typically identified in individuals presenting with syncope, seizures or sudden cardiac death which results from episodic ventricular tachydysrhythmias, particularly *torsades de pointes* and VF (Priori et al., 1999a, b; Schwartz et al., 2000a; Vatta et al., 2000). Cardiac arrhythmias have been reported in up to 24% of cases, but the risk of sudden death has been estimated to be less than 1% per year. These estimates, however, are almost certainly inaccurate, since a significant percentage of the 300,000–400,000 sudden deaths occurring in the United States yearly (Myerburg, 1997) are likely to be the result of this disorder (which goes unrecognized) and many living patients are asymptomatic and can have normal QT intervals on screening ECGs due to reduced penetrance. Today, many asymptomatic family members are being identified via screening ECGs and molecular genetic family screening, and, therefore, better estimates are likely in the future.

Since LQTS may be difficult to diagnose, a set of criteria have been developed by Schwartz et al. (1985, 1993, 2000a). These criteria use a point system in the diagnostic scheme, relying heavily on classic features (Table 29.1). This approach is thought to improve diagnostic accuracy by including major criteria (prolonged QTc >440 ms; stress-induced syncope; family history of LQTS) and minor criteria (congenital deafness; T-wave alternans; relative bradycardia; abnormal ventricular repolarization) (Figure 29.3).

The clinical features of LQTS, which occur due to arrhythmias, are typically associated with triggering events. The most

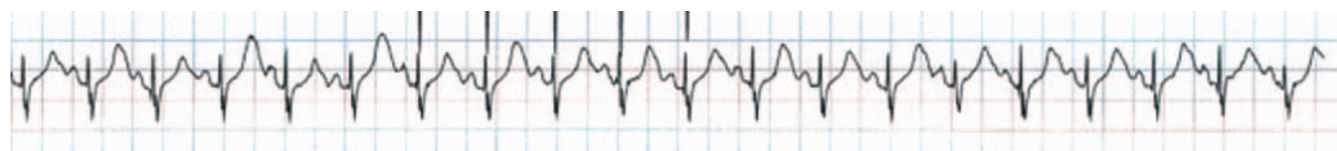

Figure 29.3 T-wave alternans in a child with LQTS.

well described triggers include exercise, anxiety or excitement, auditory events (i.e., telephone or alarm clock ringing), swimming or diving into a pool, and being postpartum. Some patients have events or die during sleep, which is thought to be associated with bradycardia.

In most cases of LQTS, no other abnormalities occur. However, sensorineural deafness is associated with the Jervell and Lange-Nielsen form of LQTS, distinguishing it from the Romano-Ward syndrome. LQTS has been reported to occur in approximately 1% of children with congenital deafness and this has led to the recommendation for screening ECGs in this group of children. A study from Thailand demonstrated a possible prevalence of 0.7% of Jervell and Lange-Nielsen in children with sensorineural deafness at a school for the deaf (Sopontammarak et al., 2003). These children also appear to have more severe ECG abnormalities than Romano-Ward syndrome patients and have a worse prognosis. Other associated abnormalities have rarely been reported in more complex patients with LQTS. Marks et al., (1995) described LQTS patients with syndactyly; in this patient subset, LQTS appears to be quite severe, with a high percentage dying in infancy. In most of these patients, the initial presentation included 2:1 AV block due to marked QT prolongation. These patients were initially found in sporadic cases, with both genders being represented, but more recently families have been identified and a new syndrome termed Timothy syndrome (Splawski et al., 2004), has been labeled (see section on "Timothy Syndrome"). Other patients with LQTS have been described with associated diabetes mellitus or asthma (Bellavere et al., 1988; Rosero et al., 1999), as well as those with potassium-sensitive periodic paralysis, dysmorphic features and skeletal abnormalities termed Andersen syndrome (Andersen et al., 1971).

Genetics of LQTS

As previously noted, four forms of inherited LQTS have been described, including autosomal dominant (Romano-Ward syndrome), autosomal recessive (Jervell and Lange-Nielsen syndrome), and other complex forms (Andersen syndrome and Timothy syndrome), in addition to sporadic cases. Over the past 15 years, the genetic aspects of all four forms of LQTS have been unraveled. In the case of the most common inherited form, Romano-Ward syndrome, the key genes have been identified for all of the mapped subtypes. In 1991, Keating and colleagues identified genetic linkage to the short arm of chromosome 11 (11p15.5) in several families with Romano-Ward syndrome (Keating et al., 1991a, b). Shortly thereafter, we demonstrated genetic heterogeneity and this was confirmed by several laboratories subsequently (Benhorin et al., 1993; Curran et al., 1993; Towbin et al., 1992, 1994). In a collaborative effort (Jiang et al., 1994), linkage was shown for several families to two new loci, the long arm of chromosome 7 (7q35-36) and the short arm of chromosome 3 (3p21). The three loci were later termed *LQT1* (11p15.5), *LQT2* (7q35-56), and *LQT3* (3p21). A fourth locus (*LQT4*) on chromosome 4q (4q25-27) was later described as well (Schott et al., 1995). Two other genes, both located on chromosome 21q22 (*LQT5*, *LQT6*), were later identified (Abbott et al., 1999; Barhanin et al., 1996; Sanguinetti et al., 1996a). More recently, other candidate genes and their loci were also identified (Table 29.2). Penetrance in Romano-Ward syndrome is reduced and in some families Romano-Ward syndrome appears to occur in a recessively inherited pattern (Priori et al., 1998, 1999c).

Gene Identification in Romano-Ward Syndrome: Ion Channel Gene Mutations

KVLQT1 or KCNQ1: The LQT1 Gene

The first of the genes mapped for LQTS, termed *LQT1*, required 5 years from the time that mapping to chromosome 11p15.5 was first reported to gene cloning (Table 29.2). This gene, originally named *KVLQT1*, but more recently called *KCNQ1*, is a potassium channel gene that consists of 16 exons, spans approximately 400 kb, and is widely expressed in human tissues including heart, inner ear, kidney, lung, placenta, and pancreas, but not in skeletal muscle, liver, or brain.

Analysis of the predicted amino acid sequence of KCNQ1 demonstrated that the gene encodes a potassium channel α-subunit (Barhanin et al., 1996; Sanguinetti et al., 1996a; Wang et al., 1996) with a conserved potassium-selective pore-signature sequence flanked by six membrane-spanning segments similar to shaker-type channels (Figure 29.4). A putative voltage sensor is found in the fourth membrane-spanning domains (S4) and the selective pore loop is between the fifth and sixth membrane-spanning domains (S5, S6). Biophysical characterization of the KCNQ1 protein confirmed that KCNQ1 is a voltage-gated potassium channel protein subunit that requires coassembly (Barhanin et al., 1996; Sanguinetti et al., 1996a) with a β-subunit called mink or KCNE1 to function properly (Figure 29.4). Expression of either KCNQ1 or KCNE1 alone results in inefficient (or no) current development. When both subunits are coexpressed in either mammalian cell lines or *Xenopus* oocytes, however, the slowly activating potassium current (I_{Ks}) is developed in cardiac myocytes. Combination of normal and mutant KVLQT1 subunits forms abnormal I_{Ks} channels, and these mutations are believed to act through a dominant-negative mechanism (the mutant form of KVLQT1 interferes with the function of the normal wild-type form through a "poison pill"-type mechanism) or a loss-of-function mechanism (only the mutant form loses activity) (Demolombe et al., 1998; Shalaby et al., 1997; Wollnick et al., 1997). In some cases, the protein is not normally trafficked to the membrane.

The vast majority of mutations in *KCNQ1* are heterozygous mutations in Romano-Ward syndrome patients (Chouabe et al., 1997, 2000; Duggal et al., 1998; Li et al., 1998; Splawski et al., 1997a; Towbin, 2006), and *KCNQ1* appears to be the most commonly mutated gene in LQTS.

HERG or KCNH2: The LQT2 Gene

After the initial localization of LQT2 to chromosome 7q35-36 by Jiang et al. (1994) (Table 29.2), candidate gene screening

Table 29.2 Long QT and related arrhythmia syndromes

Gene	Locus	Syndrome	Protein and subunit	Function and abnormality

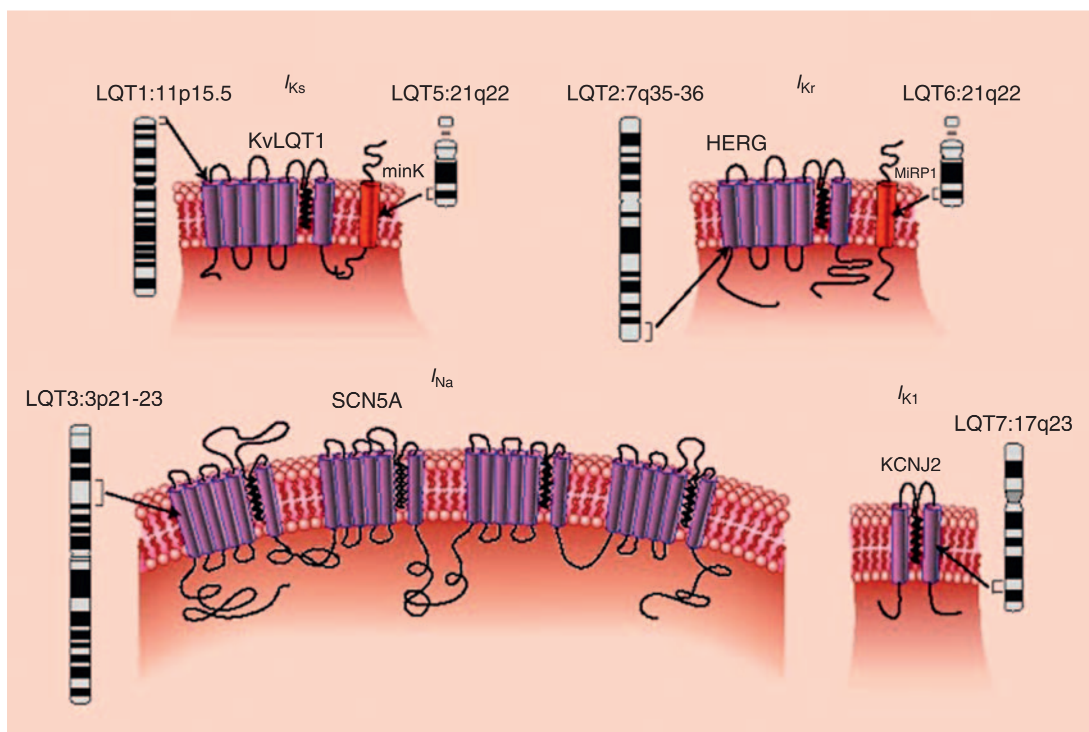

Figure 29.4 Chromosomal loci and genes responsible for LQTS.

identified mutations in *HERG* (human ether-a-go-go-related gene), a cardiac potassium channel gene originally cloned from a brain cDNA library (Warmke and Ganetzky, 1994) and that is expressed in neural crest-derived neurons (Arcangeli et al., 1997), microglia (Pennefather et al., 1998), a wide variety of tumor cell lines (Bianchi et al., 1998), and the heart (Curran et al., 1995).

The *KCNH2* gene consists of 16 exons and spans 55 kb of genomic sequence (Curran et al., 1995). The predicted topology of HERG is shown in Figure 29.4 and is similar to KCNQ1 but, unlike KCNQ1, KCNH2 has extensive intracellular amino- and carboxyl-termini, with a region in the carboxyl-terminal domain having sequence similarity to nucleotide binding domains (NBDs).

Electrophysiologic and biophysical characterization of KCNH2 expressed in *Xenopus* oocytes established that this protein encodes the rapidly activating delayed-rectifier potassium current I_{Kr} (Sanguinetti et al., 1995; Trudeau et al., 1995) and electrophysiologic studies of LQTS-associated mutations demonstrated a loss-of-function or a dominant-negative mechanism (Sanguinetti et al., 1996b) of action. In addition, protein trafficking abnormalities have been shown to occur (Furutani et al., 1999; Zhou et al., 1998). More recently, Zhang et al. (2004) identified an intronic variant in *KCNH2* (T1945 + 6C) in which splicing assay analysis showing downstream intron retention and complementary DNA with the retained intron 7 failed to produce functional channels, consistent with potential disease-causing dysfunction. This finding potentially expands the disease-causing mechanisms in LQTS. This channel has been shown to coassemble with β-subunits for normal function, similar to that seen in I_{Ks}. Abbott et al. (1999) identified MiRP1 (KCNE2) as a β-subunit for KCNH2 (see section on "*MiRP1*: The *LQT6* Gene"). The identification of these initial genes which encoded ion channels, suggested that the "final common pathway" of LQTS is ion channel disruption (Towbin, 2000).

SCN5A: The LQT3 Gene

Utilization of the candidate gene approach established that the gene responsible for chromosome 3-linked LQTS (*LQT3*) (George et al., 1995) is the cardiac sodium channel gene *SCN5A* (Wang et al., 1995a, b) (Table 29.2). SCN5A is highly expressed in human myocardium and brain, but not in skeletal muscle, liver, or uterus (Hartmann et al., 1999; Wang et al., 1995a). It consists of 28 exons that span 80 kb and encodes a protein of 2016 amino acids with a putative structure that consists of four homologous domains (DI to DIV), each of which contains six membrane-spanning segments (S1 to S6) similar to the structure of the potassium channel α-subunits (Figure 29.4) (Gellens et al., 1992). Mutation analysis identified three mutations initially (Wang et al 1995a, b); and when expressed in *Xenopus* oocytes, all mutations generated a late phase of inactivation-resistant, mexiletine- and tetrodotoxin-sensitive whole-cell current via different mechanisms (Bennett et al., 1995; Dumaine et al., 1996). Two of the three mutations showed dispersed reopening after the initial transient, but the other mutation showed both dispersed reopening and long-lasting bursts. These results suggested that SCN5A mutations act through a gain-of-function mechanism (the mutant channel functions normally, but with altered properties such as delayed inactivation) and that the mechanism of chromosome 3-linked LQTS is persistent nonactivated sodium current in the plateau phase of the action potential. An et al. (1998) also showed that not all mutations in SCN5A are associated with persistent current and demonstrated that SCN5A interacted with β-subunits. Other mutations were later identified (Benhorin et al., 1998).

MinK or KCNE1: The LQT5 Gene

The *minK* (IsK or *KCNE1*) gene was initially localized to chromosome 21 (21q22.1) and found to consist of three exons that span approximately 40 kb (Honore et al., 1991). It encodes a short protein consisting of 130 amino acids and has only one transmembrane-spanning segment with small extracellular and intercellular regions (Figure 29.4). When expressed in *Xenopus* oocytes, it produces potassium current that closely resembles the slowly activating delayed-rectifier potassium current I_{Ks} in cardiac cells (Barhanin et al., 1996; Sanguinetti et al., 1996a), but requires coexpression cardiac slowly activating delayed-rectifier I_{Ks} current to develop (Barhanin et al., 1996; Sanguinetti et al., 1996a). Bianchi et al. (1999) also showed that mutant KCNE1 results in abnormalities of I_{Ks} and I_{Kr} and in protein trafficking abnormalities. McDonald et al. (1997) showed that KCNE1 also interacts with KCNH2, regulating I_{Kr}. Splawski et al. (1997b) demonstrated that *KCNE1* mutations cause LQT5 when they identified mutations in two families with LQTS (Table 29.2). In both cases, mutations were identified that reduced I_{Ks} by shifting the voltage dependence of activation and accelerating channel deactivation. This was later confirmed by others (Chouabe et al., 2000; Duggal et al., 1998) and further supported by the fact that a mouse model with mutant *minK* (Vetter et al., 1996) developed a phenotype (that included deafness). The functional consequences of these mutations include delayed cardiac repolarization and hence, an increased risk of arrhythmias (Chouabe et al., 2000; Duggal et al., 1998; Franqueza et al., 1999; Vatta and Towbin, 2006).

MiRP1 or KCNE2: The LQT6 Gene

The *MiRP1* gene (the *minK-related peptide 1* or *KCNE2* gene) is a potassium channel gene encoding a small integral membrane subunit protein that assembles with KCNH2 (LQT2) to alter its function and enable full development of the I_{Kr} current (Figure 29.4). This is 123-amino acid channel protein has a single predicted transmembrane segment similar to that described for KCNE1. Chromosomal localization studies mapped the *KCNE2* gene to chromosome 21q22.1, within 79 kb of *KCNE1* (*minK*) and arrayed in opposite orientation. The open reading frames of these two genes share 34% identity and both are contained in a single exon, suggesting that they are related through gene duplication and divergent evolution (Abbott et al., 1999).

Three missense mutations associated with dysrhythmias were initially identified (Abbott et al., 1999) and biophysical analysis demonstrated that these mutants form channels

that open slowly and close rapidly, thus diminishing potassium currents. Therefore, like KCNE1, this channel protein acts as a β-subunit but, by itself, leads to risk of ventricular arrhythmia when mutated (Table 29.2).

Gene Identification in Romano-Ward Syndrome: Non-Ion Channel-Encoding Genes

Ankyrin-β or ANKβ: The LQT4 Gene

Initially mapped in 1995 to chromosome 4q25-25 by Schott and colleagues in a large French family with autosomal dominant LQTS associated with sinus bradycardia due to SND and atrial fibrillation (AF), the gene remained elusive until 2003. Mohler et al. (2003) identified *ankyrin-β* or *ankyrin-2* (*ANKβ*) as the disease-causing gene (Table 29.2). This gene encodes a protein with three major isoforms with molecular weights ranging from 440, 220, and 150 kDa generated by alternative splicing. The major isoform in the heart is the 220 kDa form. Ankyrins are adapter proteins that link integral membrane proteins to the spectrin-based cytoskeleton (Bennett and Baines, 2001) and contain three functional domains that consist of the membrane binding domain, the spectrin binding domain, and the regulatory domain. These proteins bind to several ion channel proteins, including the voltage-sensitive sodium channel (I_{Na}), anion exchanger (Cl^-/HCD_3 exchanger), sodium–potassium ATPase, sodium–calcium exchanger (NCX or $I_{Na—Ca}$), and calcium release channels including those mediated by the ryanodine receptor (RyR2) and inositol triphosphate (IP_3) receptor. Mutations in *ANKβ* appear to act by a loss-of-function mechanism. It is likely that mutations in this gene cause clinical phenotype by disrupting the cytoskeletal framework which results in compromise of channel function or of the trafficking of channels to their proper locale. A murine model of mutant *ANKβ* results in clinical similarities to that seen in humans and findings indicative of calcium handling abnormalities (Mohler et al., 2003) and sodium channel dysfunction (Chauhan et al., 2000) have been reported.

Caveolin-3 or CAV3: The LQT9 Gene

Caveolae are 50–100-nm omega-shaped microdomains of the plasmalemma which are particularly abundant in the cardiovascular system, including cardiomyocytes, endothelial cells, smooth muscle cells, macrophages, and fibroblasts. These proteins are involved in a variety of functions including vesicular trafficking and serve as platforms to organize and regulate a variety of signal transduction pathways. Caveolins, the principal proteins in caveolae, are found as three different isoforms (CAV1–CAV3) that are encoded by separate genes. Although CAV1 and CAV2 are expressed in most cell types, only CAV3 is specifically expressed in cardiomyocytes and skeletal muscle. Some cardiac ion channels have been specifically localized to caveolae, including the SCN5A-encoded voltage-gated sodium channel ($Na_v1.5$), the voltage-dependent potassium channel ($K_v1.5$), the sodium-calcium exchanger, and the L-type calcium channel. In the heart, a variety of other signaling molecules have been found

TABLE 29.3 Brugada and related arrhythmia syndromes

Gene	Locus	Syndrome	Protein and subunit	Function and abnormality
SCN5A	3p21	BrS1, CoD	$Na_V1.5$ α	I_{Na}↓

SCN5A	3p21	BrS1, SIDS1	$Na_V1.5$ α	I_{Na}↓
SCN5A	3p21	BrS1, CoD, SIDS1	$Na_V1.5$ α	I_{Na}↓

in caveolae, including the β2-adrenergic receptor. Vatta et al. (2006) identified multiple mutations in familial and sporadic cases of LQTS (Table 29.2) and electrophysiological analysis of these mutations demonstrated a two- to three-fold increase in the late sodium current compared with wild-type CAV3. In addition, CAV3 was shown to directly interact with SCN5A, the cardiac sodium channel. This gain-of-function of the cardiac sodium channel induced by mutations in CAV3, is similar to the SCN5A mechanism of disease.

Caveolin-3 is the second non-ion channel protein (after ankyrin-B) implicated in the pathogenesis of congenital LQTS. Consistent with the "final common pathway" hypothesis (Bowles et al., 2000; Towbin, 1998, 2000), genes encoding cardiac channel-interacting proteins, which secondarily disrupt ion channel function, may confer genetic susceptibility for LQTS. Caveolin-3 represents one of a potentially large group of such proteins. In addition, $Na_V1.5$ appears to be disrupted in a variety of arrhythmia-associated disorders, including LQTS and Brugada syndrome (Table 29.3) both possible substrates of SIDS (Ackerman et al., 2001; Towbin and Ackerman, 2001) and AV block (Benson et al., 2003).

SCN4B: The LQT10 Gene

Sodium channel β-subunits are critical regulatory proteins, and four of these β-subunits have been described, β1–β4. These regulatory proteins are encoded by the sodium channel β-subunit gene family known as $Na_{v\beta}$ and the four protein subunits include SCN1B–SCN4B. These β-subunits are all detectable in cardiac tissue and play a crucial role in cell adhesion, signal transduction, channel expression at the sarcolemma, and voltage dependence

of channel gating. These proteins are characterized by an extracellular N-terminal cleaved region, a transmembrane segment, and a cytoplasmic domain with a C-terminal tail. Studies have shown that $Na_{v\beta}$ subunits contain an extracellular Ig-like fold, often found in cell adhesion molecules that target ion channels to the sarcolemma and mediate interactions with signaling molecules. $Na_{v\beta}1$ and $Na_{v\beta}3$ are similar in sequence and associate noncovalently with β-subunits while $Na_{v\beta}2$ and $Na_{v\beta}4$ are related proteins that are disulfide-linked to β-subunits. Immunohistochemical studies in murine hearts indicate that the primary cardiac sodium channel in ventricular myocytes is composed of $Na_v1.5$ (SCN5A) plus β2 and/or β4 subunits. The β4-subunit cytoplasmic tail is thought to interact with the S6-binding site within the inner cavity of $Na_v1.5$. Recently, Madeiros-Domingo et al. (2007) have identified a mutation in the gene encoding the β4-subunit (SCN4B) in a multigenerational family with severe LQTS in several family members (Table 29.2), as well as with reduced penetrance in others. In addition, AV block, sudden cardiac death, and bradycardia were clinically apparent in this family. The authors identified a missense mutation in the family (L179F) which occurred in the transmembrane-spanning region of the protein. Biophysical analysis of this mutation expressed with the SCN5A β-subunit demonstrated an eightfold increase in late sodium current compared with SCN5A alone and threefold increase compared with SCN5A + WT-β4. This is consistent with the LQT3 biophysical phenotype and is similar to that seen in CAV3-related LQTS. Hence, this further confirms the "final common pathway hypothesis" that arrhythmias and conduction system disease occur as a consequence of ion channel dysfunction occurring either directly through ion channel mutations or secondarily due to dysfunction resulting from abnormal binding partner function or other indirect channel abnormality (such as, occurs with drugs) (Bowles et al., 2000; Towbin, 2000).

COMPLEX FORMS OF LQTS

Jervell and Lange-Nielsen Syndrome

Clinical Features

As noted previously, patients with Jervell and Lange-Nielsen syndrome (JLNS) have severe QT interval prolongation, episodic tachydysrhythmias including *torsades de pointes*, syncope and/or sudden death, and sensorineural deafness (Jervell and Lange-Nielsen, 1957; Schwartz et al., 2000). The deafness is autosomal recessive and severe while the LQTS is autosomal dominant (Vatta et al., 2000).

Genetics

Neyroud et al. (1997) reported the first molecular abnormality in patients with JLNS when they reported on two families in which three children were affected by JLNS, finding a novel homozygous deletion–insertion mutation of *KCNQ1* (Table 29.2). A deletion of 7 bp and an insertion of 8 bp at the same location led to premature termination at the C-terminal end of the KVLQT1 channel. At the same time, Splawski et al. (1997a) identified a homozygous insertion of a single nucleotide that caused a frameshift in the coding sequence after the second putative transmembrane domain (S2) of KCNQ1. Together, these data strongly suggested that at least one form of JLNS is caused by homozygous mutations in *KCNQ1*, which was confirmed by others (Chen et al., 1999; Chouabe et al., 1997; Schulze-Bahr et al., 1997; Tyson et al., 1997; Wollnick et al., 1997).

As a general rule, heterozygous mutations in *KCNQ1* cause Romano-Ward syndrome (LQTS only), whereas homozygous (or compound heterozygous) mutations in *KCNQ1* cause JLNS (LQTS and deafness). The hypothetical explanation suggests that although heterozygous KCNQ1 mutations act by a dominant-negative mechanism (Mohammad-Pannah et al., 1999), some functional KCNQ1 potassium channels still exist in the stria vascularis of the inner ear. Therefore, congenital deafness is averted in patients with heterozygous *KCNQ1* mutations. For patients with homozygous mutations, no functional KCNQ1 potassium channels can be formed. It was shown by *in situ* hybridization that KCNQ1 is expressed in the inner ear (Neyroud et al., 1997), suggesting that homozygous *KCNQ1* mutations can cause the dysfunction of potassium secretion in the inner ear and lead to deafness (Vetter et al., 1996). However, it should be noted that incomplete penetrance exists and not all heterozygous or homozygous mutations follow this rule (Priori et al., 1999c).

As with Romano-Ward syndrome, if *KCNQ1* mutations can cause the phenotype, it could be expected that *KCNE1* mutations could also be causative of the phenotype (JLNS). Schulze-Bahr et al. (1997), in fact, showed that mutations in *KCNE1* result in JLNS syndrome as well (Table 29.2), and this was confirmed subsequently (Duggal et al., 1998; Tyson et al., 1997). Hence, abnormal I_{Ks} current, whether it occurs due to homozygous or compound heterozygous mutations in *KCNQ1* or *KCNE1*, results in LQTS and deafness.

Andersen-Tawil Syndrome (LQT7)

Clinical Aspects

Andersen et al. (1971) identified a complex phenotype including ventricular arrhythmias, potassium-sensitive periodic paralysis, and dysmorphic features. The dysmorphisms included hypertelorism, broad nasal root, defects of the soft and hard palate, as well as short stature. More recently, skeletal abnormalities have broadened the phenotype (Andelfinger et al., 2002). These skeletal features include micrognathia, clinodactyly, syndactyly, and scoliosis. The associated cardiac abnormalities include QTc prolongation, VT, VF, and atrial arrhythmias. *Torsades de pointes* and bidirectional VT have been seen. In addition, repolarization abnormalities affecting late repolarization and resembling giant U waves are common. Sudden death has not been reported as a major risk in this disorder. Andelfinger et al. (2002) also reported sex-specific variable expression, as well as other clinical features including unilateral dysplastic kidney and congenital heart disease (bicusopid aortic valve, coarctation of the aorta, valvular pulmonic stenosis).

TABLE 29.4 Ca^{2+} dependent arrhythmia syndromes

Gene	Locus	Syndrome	Protein and subunit	Function and abnormality
CACNA1CA	12p13.3	TS1, ASD	$Ca_V1.2\ \alpha_{1C}$	$I_{Ca,L}\uparrow$

RyR2	1q42-q43	CPVT1, LQTS	RyR2 α	SR Ca^{2+} leak ↑
RyR2	1q42-q43	CPVT1, ARVC2	RyR2 α	SR Ca^{2+} leak ↑

Genetic Aspects

Kir 2.1 or KCNJ2: The LQT7 Gene

Andersen-Tawil syndrome was originally mapped to chromosome 17q23-q24.2 by Plaster et al. (2001) using genome-wide linkage analysis. Candidate gene mutation screening identified mutations in *KCNJ2* (Table 29.2), which encodes an inward rectifier potassium channel called Kir2.1 (Tristani-Firouzi et al., 2002). This channel is highly expressed in the heart and plays a role in phase 4 repolarization and in the resting membrane potential. Multiple gene mutations have been identified to date with relatively high penetrance noted. Functional studies have demonstrated reduction or suppression of I_{K1} by a haploinsufficiency or dominant-negative effect (Tristani-Firouzi et al., 2002; Lange et al., 2003). Lange et al. (2003) generated known *KCNJ2* mutants which did not yield any measurable potassium currents in CHO cells consistent with failure to form functional homomultimeric complexes and non-functional channels. In addition, Bendahhou et al. (2003) demonstrated that defective Kir 2.1 channels may not traffic to the membrane properly. This gene may play a role in developmental signaling pathways as well, which is believed to be the cause of the dysmorphisms (Andelfinger et al., 2002).

Analysis of a variety of *KCNJ2* mutations demonstrated that many of these mutations included residues implicated in binding membrane-associated phoephatidylinositol 4,5-biphosphate (PIP2) (Donaldson et al., 2003). It should be noted that nearly 40% of cases do not segregate with this gene, suggesting that genetic heterogeneity exists (Donaldson et al., 2004).

Timothy Syndrome

Clinical

This complex disorder is characterized by multisystem dysfunction including webbing of fingers and toes (syndactyly), immune deficiency, intermittent hypoglycemia, a cognitive immune deficiency, intermittent hypoglycemia, cognitive abnormalities, autism, dysmorphic features, various forms of congenital heart disease, and lethal arrhythmias associated with LQTS (Marks et al., 1995; Splawski et al., 2004).

Genetics

This autosomal dominant disorder was described initially by Marks et al. (1995), and more recently the genetic basis of this syndrome was described by Splawski et al. (2004). Mutations in Ca(V)1.2, the L-type calcium channel, which is expressed in all affected tissues, was shown to produce maintained inward Ca^{2+} overload in multiple cell types and, in the heart, causes prolonged Ca^{2+} current delaying cardiomyocyte repolarization and increased arrhythmia risk (Table 29.4).

Genotype–Phenotype Correlations in LQTS

Moss et al. (1995) showed that the ECG manifestations of LQTS were in great part determined by which channel is mutated. Different T-wave patterns were clearly evident when comparing tracings from patients with mutations in LQT1, LQT2, and LQT3. More recently, Zareba et al. (1998) showed that the mutated gene may result in a specific clinical phenotype with different triggers and may predict outcome. For instance, these authors suggested that mutations in LQT1 and LQT2 result in early symptoms (i.e., syncope) but the risk of sudden death was relatively low for any event. In contrast, mutations in LQT3 resulted in a paucity of symptoms but when symptoms occurred they were associated with a high likelihood of sudden death. Zareba et al. (2003a) showed that the location of mutations in *KCNQ1* plays no role in clinical course. However, Shimizu et al. (2004) showed mutation site-specific differences in arrhythmic risk and sensitivity to sympathetic stimulation in LQT1 patients with those having transmembrane mutations having a greater risk of early-onset cardiac events and greater sensitivity to sympathetic stimulation compared with patients having C-terminal mutations. Moss and colleagues showed that pore mutations in LQT2 have higher risk effects of age and gender based on genotype were also reported (Zareba et al., 2003b). In this case, Zareba and colleagues showed that during childhood, the risk of cardiac events was significantly higher in LQT1 and LQT3 males than females with no gender-related differences in the risk of cardiac events among LQT2 and LQT3 carriers. In adulthood, LQT2 and LQT1 females had a significantly higher

risk of cardiac events than respective males. The lethality of cardiac events was highest in LQT3 males and females, and higher in LQT1 and LQT2 males than females. Compound mutations, which reportedly occurs in ~8% of subjects, appears to cause longer QTc intervals, worse and more frequent cardiac events and, in general, a more severe phenotype than other mutations and worse disease than expected (Westenskow et al., 2004).

Neonates appear to have gene-specific clinical features as well. Lupoglazoff et al. (2004) studied 23 neonate probands and demonstrated that 2:1 AV block is common and usually associated with LQT2 mutations, with a poor prognosis during the first month of life. In contrast, LQT1 mutations in this patient subgroup appeared correlated with sinus bradycardia and good short-term prognosis with β-blocker therapy. Ackerman et al. (1999) and Moss et al. (1999) showed that swimming is a common trigger for symptoms in LQT1 patients while Wilde et al. (1999) have found auditory triggers to be common in LQT2. LQT3, on the other hand, appears to be associated with sleep-associated symptoms. More recently, Choi et al. (2004) evaluated 388 subjects with LQTS for LQT gene mutations and identified 43 individuals with swimming-related events (11%). Among this group, 65% had mutations in LQT1, with 21% having ryanodine receptor mutations (RyR2), and 5% with LQT2 mutations. Coupled with the findings by Moss and colleagues, it could be suggested that understanding the underlying cause of LQTS in any individual could be used to improve survival by prevention and gene-specific therapy.

Management of LQTS

At present, there are four classical modalities for treatment of LQTS that have withstood the test of time: (1) β-blockers (Moss, 1998, Moss et al., 2000; Priori et al., 2004; Villain et al., 2004;), (2) pacemakers (Eldar et al., 1987; Moss et al., 1991, Viskin, 2000), (3) left cervicothoracic sympathetic ganglionectomy (Moss and McDonald, 1970; Schwartz et al., 1991, 2004), and, most recently, (4) internal cardioverter defibrillator (ICD) (Ten Harkel et al., 2005; Zareba et al., 2003c). The mortality of untreated symptomatic patients with LQTS exceeds 20% in the year after their first syncopal episode and approaches 50% within 10 years of initial presentation (Schwartz, 1985). With institution of the classical therapy, this can be reduced to 2–4% in 5 years after initial presentation (Moss et al., 2000; Schwartz, 1985). Despite the lack of a placebo-controlled, randomized clinical trial, strong evidence supports the use of antiadrenergic interventions as the mainstay of therapy for most patients. The trigger for many life-threatening events appears to involve sudden increases in sympathetic activity (i.e., emotional or physical stress), and therefore, antiadrenergic therapy makes physiological sense. The β-adrenergic blocking agents prevent new syncopal episodes in approximately 65–75% of patients (Moss et al., 2000). Suppression of complex ventricular arrhythmias (i.e., couplets and VT) seems desirable. Villain et al. (2004) showed that a low incidence of cardiac events occur in children with LQTS treated with β-blockers. In the 122 children studied, only 4 deaths occurred. Of these, 111 children (92%) were treated with β-blockers alone, with no deaths and only 5 non-fatal cardiac events (4.5%) noted. None of these children had LQT1 mutations. Priori et al. (2004) studied 335 patients treated with β-blockers for an average of 5 years and found 10% of LQT1 patients, 23% of LQT2 patients, and 32% of LQT3 patients had events while being treated with the highest risk of events in LQT2 and LQT3 patients. Chatrath et al. (2004) found that 25% of LQTS probands had cardiac events, with LQT1 most prevalent. In addition, they found that the highest rate of events occurred during treatment with atenolol while propranolol appeared more protective. The addition of an IB agent (mexiletine) to β-blocker therapy may be helpful, particularly in patients with the LQT3 genotype (Schwartz et al., 1995). High-risk patients with drug resistant, symptomatic VT are referred for left cardiac sympathetic denervation which apparently provides additional protection (Moss and McDonald, 1970; Schwartz et al. 1991, 2004). In addition, the use of cardiac pacing as an adjunct to β-blockers appears to be most rational in patients with evidence of pause-dependent or bradycardia-dependent arrhythmias (Eldar et al., 1987; Moss et al., 1991; Viskin, 2000). Symptomatic bradycardia due to LQTS or induced by β-blocker therapy, should also be considered an indication for elective pacing. Beta-blocker therapy is monitored with treadmill exercise testing with the desired result a blunting of the heart rate response to exercise. However, Kaltman et al. (2003) suggested that little difference occurs between pretreated and treated patients regarding QTc at any phase, QTc dispersion or other QTc measures. Unfortunately, in some patients, this comes at the expense of excessive sinus bradycardia at rest and with minimal levels of exertion. Excessive fatigue, inattentiveness and irritability may result in discontinuance of therapy by the patient. Compliance, especially in the adolescent population, may be enhanced by returning the patient to a relatively normal lifestyle by the elimination of chronotropic incompetence with a pacemaker.

Other less time-tested therapies are also available. In some rare cases, *torsades de pointes* persists despite therapy with the classical modalities. The ICD has been used successfully in this setting (Groh et al., 1996; Platia et al., 1985). Up until recently, it had not been considered to be first-line therapy because shocks from the device can precipitate further emotional stress and set off a circuitous response of persistent malignant arrhythmias. However, the Multicenter Automatic Defibrillator Implantation Trial (MADIT), which demonstrated dramatic superiority of therapy with automatic implantable defibrillators over "best conventional therapy" in patients with coronary disease at high risk for ventricular arrhythmias (Moss et al., 1996), has made this therapeutic approach somewhat appealing. Automatic implantable defibrillators have been used more commonly in LQTS patients due to the results of the MADIT trial. However, whether this is the best approach is still not clear as long-term data is needed to determine the answer to this question. Zareba et al. (2003c) has shown 3-year follow-up analysis with 1.3% death in ICD patients versus 16% non-ICD patients. Reports of efficacy in neonates have been published as well (Ten Harkel et al., 2005).

Another new approach to treating patients with LQTS is the so-called "gene-specific" approach. With the identification of the precise molecular defect in some patients with LQTS, specific mechanism-based therapies have been devised and small therapeutic trials performed. Schwartz et al. (1995) were the first to use this approach when they used the sodium channel blocker mexiletine in patients with mutations in the sodium channel gene *SCN5A* (*LQT3*). In these patients the QTc was dramatically shortened in a statistically significant manner. Patients with potassium channel mutations (*HERG*, *LQT2*) treated with mexiletine had no change in the QTc. However, no data currently exists which demonstrates clinical efficacy of this approach in either decreasing the number of syncopal events or improving survival. Other sodium channel blockers have had similar effects (Rosero et al., 1999). Recently, Benhorin et al. (2000) showed that flecainide shortened the QTc in patients with a D1790G *SCN5A* mutation while lidocaine was ineffective suggesting that allele-specific therapies may be needed. Although the data is intriguing, use of sodium channel blockers alone for patients with *SCN5A* mutations should still be considered experimental. Other gene-specific trials have also been performed with similar results. Compton et al. (1996) used intravenous potassium to elevate the serum potassium to >4.8 in patients with *LQT2* and found significant shortening of the QTc. Again, no data on survival or symptom improvement exists for this therapy, but this has been confirmed (Choy et al., 1997). Etheridge et al. (2003) showed that QTc reduction may be large, QT dispersion and T-wave morphology improved, but outcome data was not available. Potassium channel openers may have the same effect (Shimizu et al., 1998). Other gene-specific therapeutic approaches are currently being developed.

Brugada Syndrome

Clinical Features

This disorder is characterized by ST-segment elevation in the right precordial leads (V1–V3) with or without right bundle branch block (RBBB) (Figure 29.5) and episodic VF (Brugada et al., 2005). The first identification of the ECG pattern of RBBB with ST-elevation in leads V1–V3 was reported by Osher and Wolff (1953). Shortly thereafter, Edeiken (1954) identified persistent ST-elevation without RBBB in 10 asymptomatic males and Levine et al. (1956) described ST-elevation in the right chest leads and conduction block in the right ventricle in patients with severe hyperkalemia. The first association of this ECG pattern with sudden death was described by Martini et al. (1989) and later by Aihara et al. (1990) and further confirmed in 1991 by Pedro and Josep Brugada (1991) who described four patients with sudden death and aborted sudden death with ECGs demonstrating RBBB and persistent ST-elevation in leads V1–V3. In 1992, these authors characterized what they believed to be a distinct clinical and ECG syndrome (Antzelevitch et al., 2003; Brugada et al., 1992, 1997). In some patients the surface ECG appears normal, even in familial cases. Provocation studies in the catheterization laboratory using ajmaline, flecainide, or procainamide

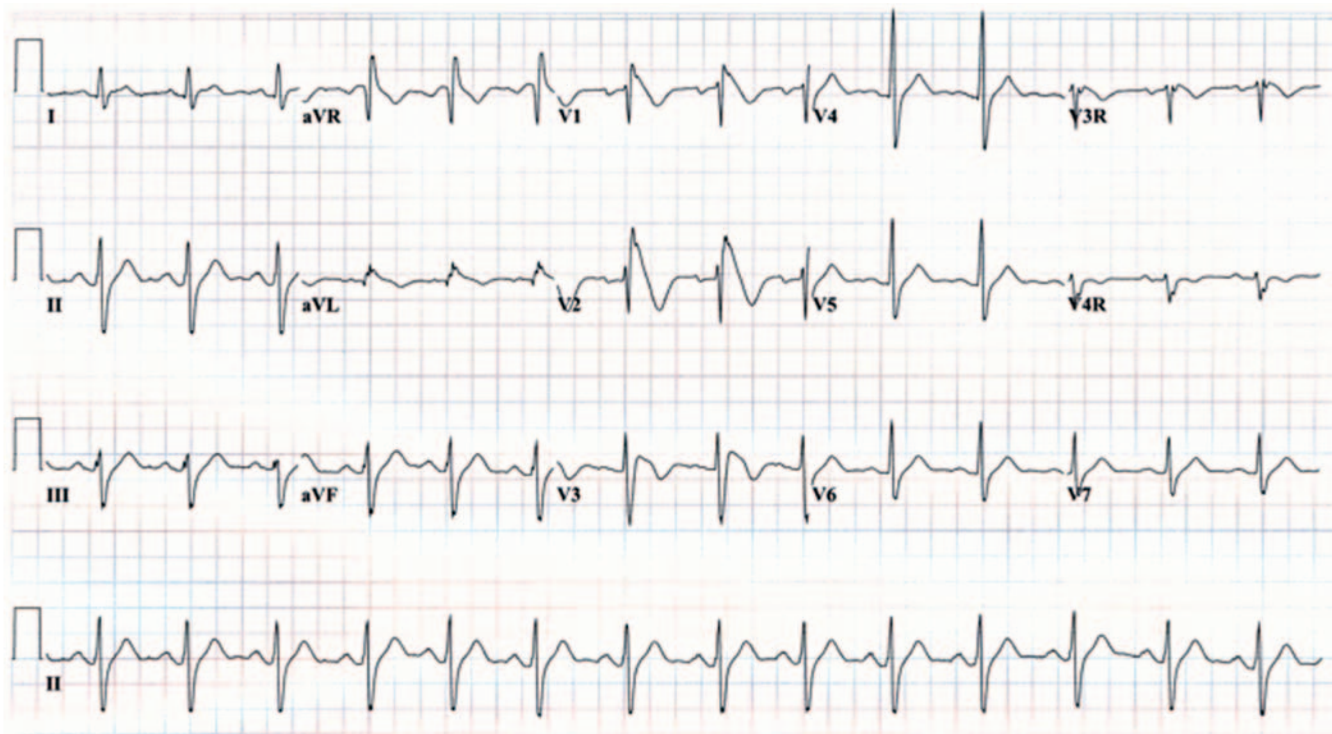

Figure 29.5 Brugada syndrome in a 4-year old. Note the right ventricular conduction delay and ST-segment elevation in leads V1, V2. Procainamide infusion worsened the ST-elevation.

will result in ST-segment elevation in the right precordial leads in affected patients (Brugada et al., 2000, 2003; Hong et al., 2004; Priori et al., 2002a; Rolf et al., 2003). Long term follow-up (Brugada et al., 2002) of patients and families with Brugada syndrome demonstrates sudden death is a persistent risk.

The finding of ST-elevation in the right chest leads has been observed in a variety of clinical and experimental settings and is not unique or diagnostic of Brugada syndrome by itself. Situations in which these ECG findings occur include electrolyte or metabolic disorders, pulmonary or inflammatory diseases, abnormalities of the central or peripheral nervous system. In the absence of these abnormalities, the term idiopathic ST-elevation is often used and may identify Brugada syndrome patients (Antzelevitch, 1999). Two consensus conferences have been held to define the clinical signs, diagnostic approaches, therapies, and diagnostic studies (Antzelevitch et al., 2005; Wilde et al., 2002a,b,c).

The ECG findings and associated sudden and unexpected death has been reported as a common problem in Southeast Asia where it most commonly affects men during sleep (Nademanee et al., 1997). This disorder, known as Sudden and Unexpected Death Syndrome (SUDS) or Sudden Unexpected Nocturnal Death Syndrome (SUNDS), has many names in Southeast Asia including bangungut (to rise and moan in sleep) in the Philippines; non-lai-tai (sleep-death) in Laos; lai-tai (died during sleep) in Thailand; and pokkuri (sudden and unexpectedly ceased phenomena) in Japan (Nademanee et al., 1997; Sangwatanaroj et al., 2002). General characteristics of SUDS include young, healthy males in whom death occurs suddenly with a groan, usually during sleep late at night. No precipitating factors are identified and autopsy findings are generally negative (Gotoh, 1976). Life-threatening ventricular tachydysrhythmias as a primary cause of SUDS have been demonstrated, with VF occurring in most cases (Hayashi et al., 1985).

SHORT QT INTERVAL SYNDROME

Clinical Features

In 2000, Gussak and colleagues identified a new familial clinical syndrome characterized by an abbreviated QTc interval (<300 ms), predisposition to life-threatening arrhythmias and a high rate of sudden death. AF may occur and on electrophysiologic evaluation, short refractory periods may be identified. Age of onset of symptoms may be young (<1 year of age) and in some cases may be responsible for SIDS.

Genetics of Short QT Syndrome

Short QT syndrome (SQT) was initially shown by Gussak et al. (2000) to have autosomal dominant inheritance. Multiple families and sporadic cases have been reported (Bellocq et al., 2004; Brugada et al., 2004; Gaita et al., 2003; Gussak et al., 2000; Priori et al., 2004). Mutations in three ion channel genes (*SQT1*, *HERG/KCNH2*; *SQT2*, *KvLQT1/KCNQ1*; *SQT3*, *Kir 2.1/KCNJ2*; Table 29.5) have been reported to date (Bellocq et al., 2004; Brugada et al., 2004; Priori et al., 2005). In the case of SQT1, mutations dramatically increased I_{Kr}, leading to heterogeneous abbreviation of action potential duration and refractoriness and reduced the affinity of the channels to I_K blockers. Bellocq et al. performed functional studies on the *KCNQ1* mutations which revealed a pronounced shift of the half-activation kinetics which led to a gain-of function of I_{Ks} and repolarization shortening. In the case of the SQT3-causing mutations in *KCNJ2*, whole-cell patch-clamp studies of this inward rectifying potassium channel Kir2.1 (I_{K1}) demonstrated a larger outward I_{K1} than wild type and shifting of peak current, as well as acceleration of the final phase of repolarization leading to shortened action potential duration. Clinically, this leads to tall and asymmetric T waves, a finding that appears to be distinct for SQT3 (Priori et al., 2005).

TABLE 29.5 Short QT syndromes

Gene	Locus	Syndrome	Protein and subunit	Function and abnormality
KCNH2	7q35	SQTS1	K_V11.1 α	*IKr↑HERG*
KCNQ1	11p15.5	SQTS2	K_V7.1 α	*IKs↑KvLQT1*
KCNJ2	17q23	SQTS3	Kir2.1 α	*IK1↑*

Therapy in SQT Syndrome

Since sudden death occurs commonly in this disorder, defibrillator implantation is indicated. Gaita et al. (2004) evaluated the role of medical therapy, testing QTc interval response to flecainide, sotalol, ibutilide, and quinidine with only quinidine producing QTc prolongation (normalization). However, no definitive treatment approaches have been described to date. Wolpert et al. (2005) evaluated the role of quinidine in SQTS due to HERG mutations as well.

FAMILIAL VT/CPVT

Clinical Features

This inherited form of VT was first described in detail by Rubin et al. (1992) and is another form of VT that occurs in the absence of structural heart disease. Clinically, these patients present with frequent runs of nonsustained VT at rest, which may decrease or extinguish with exercise (Rubin et al., 1992; Sacks et al., 1978; Vlay, 1987) and may occur during childhood with episodes of Adams Strokes syndrome (Coumel et al., 1978; Leenhardt et al., 1995). In some cases, salvos of nonsustained VT may be incessant, causing palpitations, dizziness or syncope. The ECG is usually normal during sinus rhythm, with a normal QT interval. Electrophysiologic evaluation may not consistently show inducible VT in these patients, suggesting that the mechanism for this dysrhythmia is not reentry, as with more common forms of VT. Instead, it is believed that this form of inherited dysrhythmia is due to enhanced automaticity (i.e., an increased rate of electrical firing of a ventricular myocyte) or triggering (i.e., results from secondary depolarizations that occur during or immediately after repolarization).

Sumitomo et al. (2003) described the ECG characteristics of CPVT and clinical features in detail. The initial manifestations included young age of presentation (10.3 years, mean age of onset), syncope (79%), cardiac arrest (7%), and family history (14%). ECGs demonstrated sinus bradycardia and normal QTc. The CPVT morphology included polymorphic (62%), polymorphic and bidirectional (21%), bidirectional (10%) or polymorphic with VF (7%). Cohen et al. (1989) demonstrated a sudden death risk with familial bidirectional ventricular tachycardia.

Genetics and Management

This inherited tachyarrhythmia is transmitted as an autosomal dominant trait (Tables 29.2 and 29.4; Glikson et al., 1991; Wren et al., 1990). Mutations in the ryanodine receptor (RyR2) have been identified as causative in CPVT (Laitinen et al., 2001; Marks et al., 2002; Priori et al., 2001, 2002b; Swan et al., 1999). In addition, mutations of the calsequestrin gene have been found in CPVT (Eldar et al., 2003; Lahat et al., 2002; Postma et al., 2002) appears to be relatively uncommon but the incidence and prevalence are not known. The therapy of this disorder appears to rely on the use of β-adrenergic blocking agents, which effectively suppresses this rhythm disturbance. However, Sumitomo showed complete β-blocker control in only 31% of cases (2003). In addition, the use of class I and class III antiarrhythmics have reportedly been successful in treating this disorder. Sumitomo and colleagues also showed calcium channel antagonists partially suppressed CPVT in some familial autosomal dominant cases. The use of ICDs have not been reported in this disorder but this is certainly a likely option in malignant families or difficult cases.

PRIMARY CONDUCTION ABNORMALITIES

Lev-Lenegre Progressive Cardiac Conduction Disease

Clinical Features

This syndrome, also known as progressive cardiac conduction defect (PCCD), is amongst the most common cardiac conduction disorders in the world and represents the major cause for pacemaker implantation worldwide at 0.15 pacemaker implantations per 1000 inhabitants per year in developed countries (Schott et al., 1999). PCCD is characterized by progressive worsening of cardiac conduction through the His-Purkinje system, resulting in right or left bundle branch block and widening of the QRS complex (Lenegre and Moreau, 1963; Lev, 1964; Lev et al., 1970). Patients with this disorder ultimately develop complete AV block (Figure 29.6) and in many instances present with syncope or sudden death. Etiologically, PCCD has been considered to be a primary degenerative disease or an exaggerated age-related process in which sclerosis of the conduction system occurs (Gault et al., 1972; Gazes et al., 1965).

Genetics

The first gene for PCCD was mapped to chromosome 19q13.3 (Table 29.6) in families with autosomal dominantly transmitted disease (Brink et al., 1995; Connor et al., 1959; De Meeus et al., 1995; Waxman et al., 1975). Genetic heterogeneity was identified when Schott et al. (1999) demonstrated linkage to chromosome 3p21 and identified mutations in the cardiac sodium channel gene *SCN5A* (Tables 29.3 and 29.6; Figure 29.7). This gene had previously been shown to cause a form of long QT syndrome (LQT3) as well as Brugada syndrome (Chen et al., 1998; Wang et al., 1995a, b). Other supportive evidence of *SCN5A* mutations causing AV block have been reported. Miura et al. (2003) identified *SCN5A* mutations in congenital LQT and 2:1 AV block while Shirai et al. (2002) showed that mutations in this gene may cause overlapping features of Brugada syndrome and cardiac conduction disease. Tan and colleagues showed that mutations in *SCN5A* results in isolated conduction system disease as well, and this was confirmed by Wang et al. (2002). In addition, Viswanathan et al. (2003) showed that a common *SCN5A* polymorphism (H558R) mitigates the effects of mutations on channel function and its clinical response. Mechanisms responsible for these varying clinical features, patient sudden death, have been speculated to be based on the biophysical responses to the mutations in SCN5A (Towbin, 2001a, b).

Management

Patients with PCCD require pacemaker therapy once bradycardia occurs. In cases where syncope precedes diagnosis, immediate implantation is appropriate. Prior to pacemaker implantation, serial ECGs and Holter monitor studies are necessary for close monitoring.

Sinus Node Dysfunction/Sick Sinus Syndrome

Clinical Features

Congenital absence of sinus rhythm (Surawicz and Hariman, 1988) or SND (Caralis and Varghese, 1976; Spellberg, 1971) occurs in familial forms. The clinical presentation is generally due to symptomatic bradycardia, but it also may be associated with paroxymal AF and other atrial tachydysrhythmias. Histologic data are limited, but one report of a single member of a family who suffered sudden death showed mononuclear cell infiltration of the

sinus node; fibrosis of the sinus, AV nodes, and atrial tissue; and atrophy of the right and left bundle branches (Bharati et al., 1992).

Genetics and Management

The inheritance pattern of familial congenital absence of sinus node function is autosomal dominant with a high degree of penetrance (Table 29.6). The gene for this disorder remains unknown. However, Benson et al. (2003) identified homozygous mutations in the cardiac sodium channel gene *SCN5A* (Figure 29.7) in individuals with SSS.

Treatment consists of permanent pacing for symptomatic bradycardia and, unlike persistent atrial standstill, in which the atria are unable to be paced due to inability to produce electrical excitation, atrial or dual-chamber pacing may be used. If AF is a prominent feature, antiarrhythmic medications and/or chronic anticoagulation may be indicated.

Atrial Fibrillation

Clinical Aspects

Atrial fibrillation (AF), first described in 1906, is a cardiac rhythm disorder characterized by rapid, irregular activation of the atria, resulting in loss of coordinated atrial contraction and therefore reduced ventricular filling and stasis of blood in the atria (Fye, 2006). This predisposes to heart failure and thromboembolic stroke (Albers, 1994; Wang et al., 2003; Wolf et al., 1991). It is currently believed to be the most common sustained cardiac

arrhythmia worldwide, accounting for 15% of all strokes and over 30% of all strokes in subjects 65 years of age or older (Wolf et al., 1991). The prevalence of AF reportedly has a age dependence, ranging from <1% in young adults to approximately 10% in individuals older than 80 years of age (Kannel et al., 1998). In the United States, more than 3 million people are estimated to have persistent AF (Feinberg et al., 1995; Go et al., 2001). AF is an independent risk factor for death, as well (Benjamin et al., 1998).

AF may be classified as paroxysmal, persistent or permanent (Boston Area Anticoagulation Trial, 1990). The paroxysmal form of AF accounts for 35–40% of all AF, and there is a 30–50% chance of paroxysmal AF converting to a permanent form (Boston Area Anticoagulation Trial, 1990). It is frequently observed as a complication of a variety of cardiovascular and systemic disorders, such as hypertension, coronary artery disease, valvular heart disease, various forms of congenital heart disease, as well as cardiomyopathies. Thus, AF is typically considered to be a sporadic, non-genetic form of disease. In approximately 10–20% of cases, however, no underlying associated defect is identified and, therefore, it is termed "idiopathic" or "lone" AF (Brand et al., 1985). In rare occasion, fetal onset has been identified (Tikanoja et al., 1998).

Electrophysiology of AF

Atrial conduction depends on the connections between cells, the structural properties of the atrial wall, and ion flux. Cardiomyocytes link in an end-to-end fashion by intercalated disks and therefore form a syncytium of elongated branching fibers. The structural components of atria are required to function properly for normal electrical activity. Atrial electrophysiology is a complex process which requires coordinated interactions between multiple ionic and structural factors in order to generate normal impulse formation and propagation (Weiss et al., 2005).

Genetics of AF

The first case of apparent inherited AF was described in 1936 and subsequently a small number of families have been published in the literature (Arnar et al., 2006; Bedi et al., 2006; Beyer et al., 1993; Darbar et al., 2003; Ellinor et al., 2005; Fox et al., 2004; Orgain et al., 1936). Over the past decade, it has become apparent that familial aggregation of AF is relatively common and, for this reason, genetic analyses were able to be pursued. The first genetic locus for AF was reported in 1997 by Brugada and colleagues, identifying chromosome 10q22-q24 linkage. A second locus was later identified by Oberti et al. (2004) on chromosome 5p13 in a family with neonatal-onset autosomal recessive AF. Later, Chen et al. (2003) identified linkage in a single family with AF on chromosome 11p15 and, using a candidate gene screening approach, identified a mutation in *KCNQ1*. This was subsequently confirmed in a small number of subjects and appears to be an uncommon cause of AF (Ellinor et al., 2004, 2006; Otway et al., 2007). Another uncommon cause of AF includes mutations in the β-subunits of the cardiac I_{Ks} channel, including KCNE2 and possibly KCNE3 (Yang et al., 2004; Zhang et al., 2005). The *KCNJ2* gene located on chromosome 17q23-q24, which encodes the Kir2.1 protein that forms the α-subunit of the cardiac I_{KI}, has also been identified in a small number of subjects (Xia et al., 2005). A novel and promising gene, *KCNA5*, an atrial-specific gene located on chromosome 12p13, has been reported to be mutated and causative of AF in a single family with AF completes the genes identified to date that cause predominant AF (Olson et al., 2006). An additional group of genes have been found to carry mutations in subjects with combined atrial and ventricular phenotypes, and these include *KCNH2*, *SCN5A*, and *LMNA*. In the case of *KCNH2*, an N588K missense mutation was identified in one family with an overlapping phenotype including AF and SQT syndrome (Hong et al., 2005). This same mutation was identified in two other families only presenting with SQTS alone (Brugada et al., 2004). Similarly, another ion channel-encoding gene that is well known as a cause of arrhythmia disorders, SCN5A, has been shown to cause complex phenotypes that include AF, in particular those associated with dilated cardiomyopathy and conduction system disease (McNair et al., 2004; Olson et al., 2005). Finally, another pleiomorphic gene, *lamin A/C* (*LMNA*), has also been shown to cause AF in patients and families with dilated cardiomyopathy and conduction disease (Fatkin et al., 1999; Sebillon et al., 2003).

Another group of mutations that have been described in subjects are so-called "somatic mutations." This group of abnormalities differs from the germline mutations described above. Typically, genetic-based disorders are inherited in families by transmission of gene mutations in the germ cells. Mutations can also arise *de novo* in discrete cell lineages during embryonic development or postnatally. Germ cell *de novo* mutations can be transmitted to future generations while somatic mutations cannot, but in this case can give rise to mixed populations of mutant and normal cells within specific tissues, known as mosaicism. Mosaic mutations may have variable functional consequences and hence the clinical phenotype that develops may be unpredictable. In AF, somatic mutations have been associated in a small number of studies. Gollob et al. (2006) identified mutations in the *GJA5* gene, encoding the cardiac gap junction protein connexin40, in DNA from atrial tissue from 4 subjects; however, none of these variants were found in DNA extracted from blood. In one other subject, a mutation was identified in DNA extracted from both atrial tissue and blood. Functional studies was performed on the mutations and showed reduction of gap junction formation and/or coupling properties.

Genetic Mechanisms in AF

The majority of mutations in subjects with AF have occurred in genes encoding potassium channels. Mutations in *KCNQ1* and *KCNE2* appear to increase I_{Ks} channel activation while mutations in *KCNJ2* and *KCNH2* lead to increased activation of cardiac I_{KI} and I_{Kr} currents, respectively. These gain-of-function mutations all result in shortening of the action potential duration and effective refractory period, thereby promoting AF by creating an electrical substrate for reentry.

2009 UPDATE

During the past year, several new discoveries have occurred in understanding the genetics of arrhythmias. Two new LQTS-causing genes have been identified, *AKAP9* (LQT11) and *SNTA1* (LQT12). Chen et al. (2007) reported mutations in *AKAP9* (LQT11) that affect the KCNQ1 binding domain and result in functional disturbance of the KCNQ1 potassium channel. Mutations in *SNTA1* (LQT12) were described by Ueda et al. (2008), who reported an A390V variant that affects the SNTA1 link to the neuronal nitric oxide synthase (nNOS) inhibitor plasma membrane Ca-ATPase subtype 4b (PMCA4b), causing the release of inhibition of nNOS. This leads to *S*-nitrosylation of $Na_v1.5$, resulting in an increase in late sodium current. In addition, Wu et al. (2008) identified an A257G variant in *SNTA1* that led to increased peak sodium currents, which negatively shifted the onset and peak currents of the current-voltage relationships and shifted steady-state activation leftward; no change in the voltage-dependent inactivation kinetics and late sodium currents were observed.

In addition to the standard candidate gene approach, novel genetic linkage studies aimed at identifying new disease-causing genes have included genetic association studies (GAS) and genome-wide association studies (GWAS). In the case of GAS, these studies are a form of candidate gene screen that aims to assess the association between disease status and genetic variants (polymorphisms, single nucleotide polymorphisms or SNPs) in a population, while GWAS is an unbiased, hypothesis-free approach that involves large scans of the genome using a dense set of SNPs (up to 500,000 or more) aimed at identifying causal variants (Donohue and Allen, 2005). GWAS studies generate vast datasets, leading to challenges both in primary analysis and meta-analysis (Hirschhorn and Daly, 2005; Visscher et al., 2008; Zintzaras and Lau, 2008).

Over the years, GAS and GWAS studies have come under scrutiny due to the lack of replication of data by independent studies. Major methodological issues that have surfaced include small sample size and insufficient power to detect minor contributing roles of one or more alleles. Other confounding factors may include population stratification and experimental design flaws have been problematic. More recently, many of these challenges have been overcomed and new genes and pathways have been identified using GWAS. However, effect sizes are small in these studies, with relative genotype risks typically <1.5. In the case of quantitative traits, the individual effect sizes are consistent with $<1\%$ of the phenotypic variance being explained by a single polymorphism. Hence, while challenges exist for this approach, successes have been forthcoming and excitement appears to exist in regards to the future impact of these methods.

Reliable information concerning the clinical, ethnic, and genetic background of the subjects under study is essential when performing association studies. In this regard, the Framingham Heart Study represents an extraordinary effort to collect family members throughout multiple generations and includes the recruitment of 5209 individuals from the first generation in 1948, 5124 from the second generation in 1971, and 4095 from the third generation in 2002. Recently, the GWAS approach was applied to the Framingham study population in an attempt to identify genetic factors associated with arrhythmias. Larson et al. (2007) evaluated the Framingham study population and identified linkage to chromosome 9p21 for subjects with major cardiovascular disease, as well as associating linkage of this region with AF. Gudbjartsson et al. (2007) identified variants conferring risk of AF on chromosome 4q25. These and other studies (Ellinor et al., 2008) are quickly focusing new studies for new targets responsible for these phenotypes. More recently, Newton-Cheh et al. (2007) showed, using an Affymetrix 100K GeneChip on 1345 related Framingham Heart Study Original and Offspring cohort participants, that common variants in NOS1AP are associated with prolongation of the QT interval and heart rate variation.

In the case of atrial fibrillation, SNPs in several cardiac ion channel genes have been linked with the disease. In several reports, I_{Ks} channel components have been linked with atrial fibrillation, including KCNE1, KCNE2, and KCNE5 (Chen et al., 2007; Ehrlich et al., 2005; Fatini et al., 2007; Lai et al., 2002; Ravn et al., 2005; Zeng et al., 2007). In addition, SNPs in genes that alter regulation of ion channel function (Bedi et al., 2006; Firouzi et al., 2007; Nyberg et al., 2007; Schreieck et al., 2004), intracellular handling of calcium (Firouzi et al., 2007), gap junction formation (Juang et al., 2007; Yamashita et al., 1997), and activation of the renin-angiotensin system (Fatini et al., 2007; Tsai et al., 2004) have been reported. These associated genes include GNB3 and NOS3, which regulate channel function, and GJA5, which is involved in the formation of gap junctions, amongst others.

CHAPTER

Genetics and Genomics in the Management of Hemostasis and Thrombosis

Richard C. Becker and Felicita Andreotti

INTRODUCTION

Blood coagulation is a cell surface, biochemical event designed not only to stem the loss of blood following vascular injury (hemostasis), but also to provide the necessary molecular, cellular, and protein constituents for growth and repair as well. In addition, coagulation occurring within medium-sized arteries and veins can have detrimental effects, ranging from end-organ damage to death. Conceptually, blood coagulation represents a complex, yet well-coordinated series of events that involve tissue factor-bearing cells and platelets. The initiation and propagation phases of coagulation, under biological conditions are catalyzed by thrombin in small (nM) and large concentrations, respectively (Figures 30.1 and 30.2) (Monroe and Hoffnan, 2006).

The complex catalysts that participate in tissue factor-mediated thrombin generation each consist of a serine protease interacting with a receptor and/or cofactor protein, which collectively are anchored to a specific cellular surface. One must recognize, however, that coagulation is regulated tightly by stoichiometric and dynamic systems of inhibition. Specifically, the tissue factor concentration threshold for thrombin generation is steep, and the resulting product is dependent largely on the concentration of plasma proteins and surface inhibition, including tissue factor pathway inhibitor and antithrombin III. Thus, the blood coagulation proteome can be studied in biochemically quantifiable terms (Mann et al., 2006).

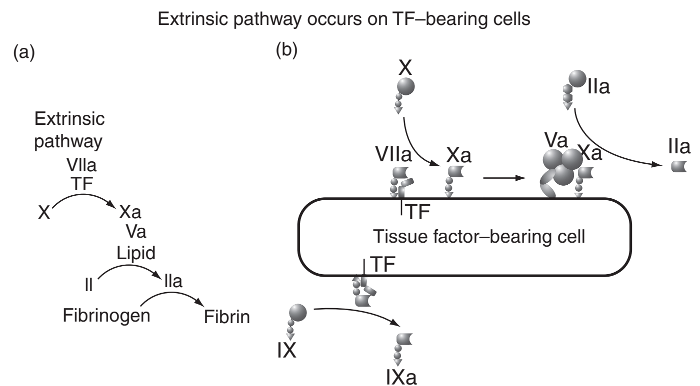

Figure 30.1 Traditional (a) and contemporary (b) paradigms of coagulation highlighting both the biochemical and cell-based components required for thrombin generation. From Monroe and Hoffman (2006).

GENETICS OF COAGULATION

The complex network of integrated biochemical events regulating mammalian coagulation comprises, in essence, five proteases

Essentials of Genomic and Personalized Medicine

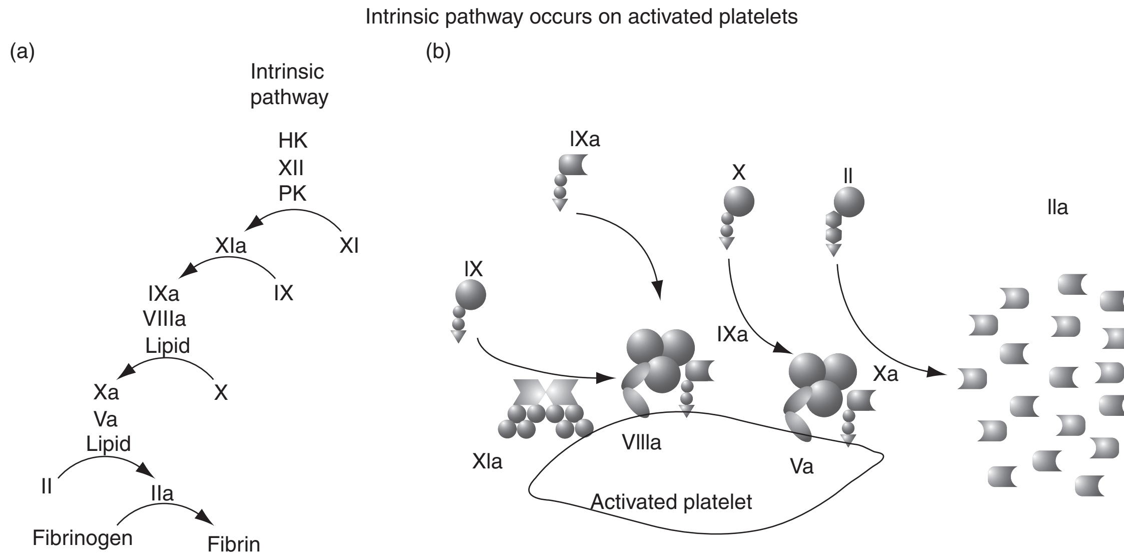

Figure 30.2 The assembly of coagulation proteins on activated platelets leads to a burst of thrombin (IIa) generation – a prerequisite event in thrombus growth and propagations, and fibrin formation. From Monroe and Hoffman (2006).

(fII or prothrombin, f VII, f IX, f X, and protein C) that interact with five cofactors (tissue factor, f VIII, f V, thrombomodulin, and membrane proteins) to generate fibrin (Davidson et al., 2003b). Although each component of the network has unique functional properties, data derived from gene organizations, protein structure, and sequence analysis suggest that coagulation-hemostatic regulatory proteins may have emerged more than 400 million years ago from duplication and diversification of only two gene structures: a vitamin K–dependent serine protease, composed of a γ-carboxylated glutamic acid-epidermal growth factor (EGF)–like domain structure (common to fVII, fIX, fX, and protein C), and the A1-A2-B-A3-C1-C2 domain structure common to f V and f VIII. Prothrombin is also a vitamin K–dependent serine protease; however, it contains kringle domains rather than EGF domains, suggesting a replacement during gene duplication and exon shuffling. Analysis of active-site amino acid residues reveals distinguishing characteristics of thrombin from other serine proteases, supporting its position as the ancestral blood enzyme (Figures 30.3 and 30.4) (Davidson et al., 2003a, b; Krem and Di Cera, 2002; McLysaght et al., 2002; Van Hylckama Vlieg et al., 2003).

There is evidence that large regional or genome duplications have contributed to the overarching structure of mammalian coagulation genomes. Similarly, local duplication and translocation could have contributed to the evaluation of multigene families on separate chromosomal regions (Abi-Rached et al., 2002).

The evolution of complex mammalian coagulation pathways from invertebrate and early vertebrate species is perhaps best illustrated in Zebrafish, whose cDNA/gene orthologues for major coagulant, anticoagulant and fibrinolytic proteins bare striking homology to mammalian sequences (Hanumanthaiah et al., 2002). The only difference, which requires further investigation, is a f VII-like gene in Zebrafish that clusters with f VII and f X genes and functions as a inhibitor (f VIIi) of coagulation. Interestingly, the fVII, fVIIi, and f X gene cluster is homologous to a Drosophilia trypsin gene cluster, supporting a rapid path of evolution from invertebrates to vertebrates, and ultimately, mammals.

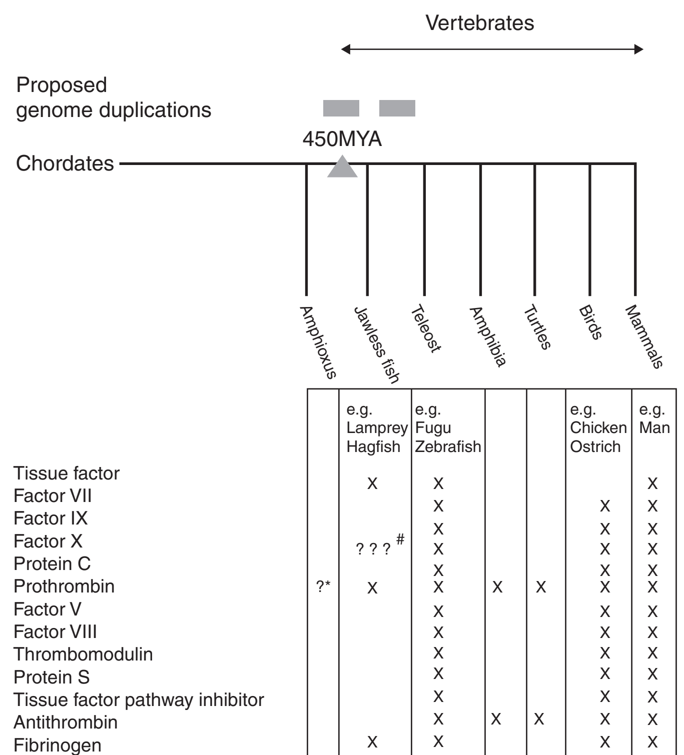

Figure 30.3 Chordate phylogenetic tree illustrating proposed genome duplication and the complement of coagulation proteins identified to date. Reprinted, with permission, from Davidson et al. (2003a, b).

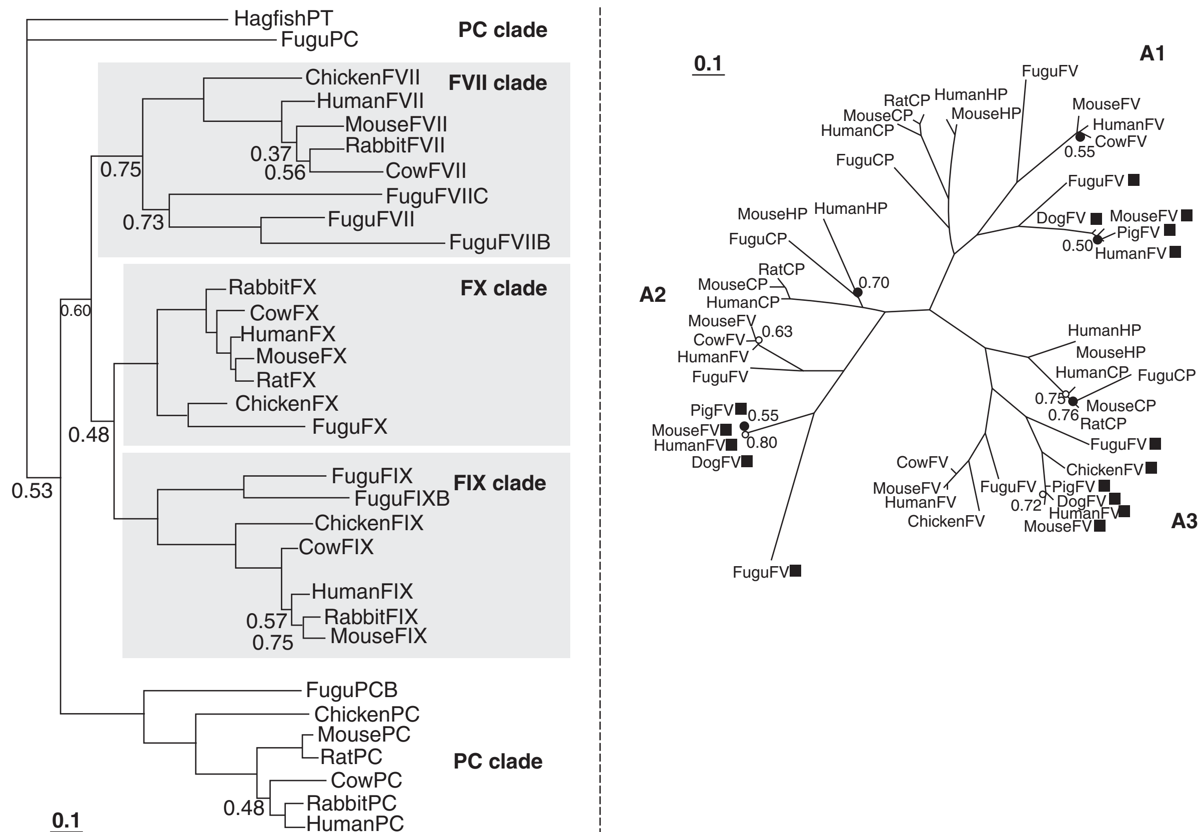

Figure 30.4 Consensus tree illustrating the phylogenetic relationship of vitamin K–dependent proteases and A domain–containing proteins. The number at each internal node represents the posterior probability that the taxa in the corresponding subtree form a clade in the recovered consensus tree. Reprinted, with permission, from Davidson et al. (2003a, b).

HUMAN HEMOSTATIC VARIABILITY

de Lange and colleagues (de Lange et al., 2001) performed a class twin study, including 1002 female twins, 149 pairs of monozygotic and 352 pairs of dizygotic twins. Quantitative genetic model fitting revealed that genetic factors were responsible for 41–75% of the variation in fibrinogen, factor VII, factor VIII, plasminogen activator, factor XIII A-subunit and B-subunit, and von Willebrand factor (vWF). Factor XIII activity showed higher (82%) and factor XII lower (38%) heritability. A higher monozygotic than dizygotic twin correlation was seen for all factors, supporting further the influence of genetics on hemostatic proteins.

Because the genetic contribution to cardiovascular disease and related thrombotic phenotypes decreases with advancing age, the heritability of hemostatic proteins was determined in 130 monozygotic and 155 dizygotic same-sex twin pairs (ages 73–94 years) participating in the Longitudinal Study of Aging of Danish Twins. Genetic factors accounted for 33% (D-dimer) to 71% (Thrombin Activatable Fibrinolysis Inhibitor). In a linage analysis, polymorphisms explained a very small proportion of genetic variations in hemostatic variables (Bladbjerg et al., 2006). Thus, age has a modest effect on hemostatic proteins, explaining anywhere from 1.5% to 14.5% of the variance in plasma concentrations (de Lange et al., 2001).

GENOTYPE–PHENOTYPE INFLUENCES

The work of Rosendaal and colleagues (Van Hylckama Vlieg et al., 2003) underscores the diversity of hemostasis as a biologic system. The structural homologies among coagulation factors suggests similarities in their biosynthesis (transcription, posttranslational processing) and in the mechanisms that govern their plasma levels and clearance. In a group of healthy subjects participating in the Leiden Thrombophilia Study (LETS) (Van Hylckama Vlieg et al., 2003), clustering was found among the plasma concentrations of vitamin K–dependent factors (II, VII, IX, and X) and those of factors XI and XII. Factors V and VIII clustered with fibrinogen and D-dimer (a measure of fibrin formation and its subsequent degradation). The anticoagulant factors (protein C, protein S, and antithrombin III) clustered together, whereas f XIII remained independent. The identification of several independent clusters within the group of procoagulant and anticoagulant factors suggests that the basis for individual fluctuations in plasma levels may lie outside the genes coding for these factors. This example highlights the complexity

of linking genotypes to phenotypes and the relevance of understanding the regulation of gene expression (in particular, the role played by environmental factors) and posttranslational protein modifications (Romualdi et al., 2003).

Completion of the human genome sequence, although one of the most important achievements in science, medicine, and human biology, highlights the importance of proteins in determining biological function and disease (reviewed in reference [Loscalzo, 2003]). Indeed, gene sequences cannot fully predict the complex quaternary structure of proteins (nor their function or dysfunction). The regulation of proteins, in fact, escapes genetic control through posttranslational modifications and protein–protein interactions. Proteomics is defined as the identification and functional characterization of complete sets of proteins expressed by complex biological systems.

Posttranslational modifications of proteins, including proteolysis, oxidation, phosphorylation, nitrosylation, glycation, and sulfuration may well participate in the development and clinical expression of thrombophilias. Many of these modifications are the consequence of environmental influences on gene expression (reviewed in reference [Loscalzo, 2003]). Examples include the correlation between the oxidative state of plasma proteins (determined by measurement of carbonyl content) and several markers of thrombin generation and activity (De Cristofaro et al., 2002); oxidation of thrombomodulin at methionine 388, which reduces its capacity to down-regulate coagulation (through activated protein C), but not its capacity to inhibit fibrinolysis [through Thrombin Activatable Fibrinolysis Inhibitor (Nesheim, 2001)]; oxidation of low-density lipoprotein, a process that involves modification of the amino acid side chain of apoprotein B, which changes the protein moiety's identity, rendering it prothrombotic (Vlassara et al., 1995); nonenzymatic glycation of protein and lipid macromolecules and their condensation to advanced glycation end products (AGEs), which promote atherothrombosis (Loscalzo, 2003); and, the mixed disulfide-bond formation between cysteinyl side chains of proteins and homocysteine, which may induce protein modifications that favor vascular injury and thrombosis (Van Hylckama Vlieg et al., 2003).

The Framingham investigators (Wang et al., 2006) measured 10 biomarkers in 3209 participants attending a routine examination cycle of the Framingham Heart Study. During a median follow-up of 7.4 years, 207 participants died and 169 had a first major cardiovascular event. Neither fibrinogen, D-dimer or plasminogen activator inhibitor type 1 strongly predicted death or major cardiovascular events by Cox proportional hazards models adjusted for conventional risk factors, suggesting that protein modifications, to include their metabolic byproducts, may represent more accurately, pathobiological events and provide more direct links between genotype and phenotype.

TABLE 30.1 Variants of fibrinogen and factor XIII

Variants	Function	Relation to disease
Splice variants		
Fibrinogen γ′	Binds thrombin and f XIII; reduces fiber diameter	Increases risk for MI
Fibrinogen $A\alpha_E C$	Unknown	None?
Noncoding polymorphisms		
Fibrinogen Aα Taq1	–	–
Fibrinogen Bβ Bcl1	Increases fibrinogen level	More common in CAD
Fibrinogen Bβ-148C/T	–	–
Fibrinogen Bβ-448G/A	Alters nuclear protein binding	More common in CAD
Coding polymorphisms		
Fibrinogen Aα Thr312Ala	Changes fibrin structure/ function and FXIII cross-linking	Atrial fibrillation/ pulmonary embolism
Fibrinogen BβArg448Lys	Changes fibrin structure/function	Macrovascular disease
Factor XIIIA Val34Leu	Changes FXIII activation rate and fibrin structure/function	MI, Deep vein thrombosis (DVT)
Factor XIIIB His95Arg	Unknown	MI

From Scott et al. (2004).
MI = myocardial infarction; CAD = coronary artery disease.

GENE-ENVIRONMENT INFLUENCES ON HEMOSTASIS

Fibrin, as summarized previously, is the predominant protein constituent of blood clots formed from fibrinogen, a large glycoprotein present within the circulation. Because fibrin clot architecture plays an important role in hemostasis and vascular repair, variations have important clinical implications. In turn, variability in fibrin strand width, branch points, mass-to-length ratio, density and cross-linking among healthy individuals, as well as those with atherosclerosis, metabolic disorders, and other prothrombotic disease states, support both genetic and environmental influences (Table 30.1) (Scott et al., 2004). Alterations in gene expression and coding function, splice variants, and posttranslational modifications each influence fibrin structure and functionality.

Vascular Bed–Specific Hemostasis and Thrombosis

A well-recognized feature of thrombophilias, whether inherited or acquired (or both), is the focal and vascular bed–specific

TABLE 30.2 Vascular bed–specific thrombosis

	Organ bed				
	Heart	**Lung**	**Spleen**	**Kidney**	**Brain**
Clinical disorders/ associated syndromes	Myocardial infarction Acute coronary syndromes	Pulmonary hypertension Pulmonary embolism/infarction	Splenic infarction	Nephropathy Renal thrombosis	Stroke
Clinically associated factors	Activated factor IX peptide, factor XIIa Fibrinogen Plasminogen activator inhibitor-1 Tissue-type plasminogen activator antigen von Willebrand factor	Fibrinopeptide A Hereditary spherocytosis Soluble thrombomodulin	Protein C Sickle cell anemia	Factor V Leiden Homocysteine Plasminogen activator inhibitor-1 4G/4G	Antithrombin III Factor V Leiden Homocysteinuria

From Edelberg et al. (2001) with permission.

expression of thrombosis. This distinct feature suggests that local regulatory pathways and intrinsic vessel-determined responses to prothrombotic stimuli are distinguishing factors (Mackman, 2005). Moreover, from the clinical perspective, it argues strongly in favor of a patient/vascular bed–specific approach to screening, diagnostic testing, and management rather than a more generalized strategy (Table 30.2) (Edelberg et al., 2001).

The regulation of platelet–vessel wall interactions, coagulation proteases, and fibrinolytic factors takes place on the endothelial surface, suggesting strongly that overall hemostatic regulation and the heterogeneity of clinical expression observed under conditions favoring thrombosis, is based on site-specific differences in endothelial cell structure, functionality, and molecular responsiveness to both biologic and rheologic conditions (Bavendiek et al., 2002; Braddock et al., 1998; Chien et al., 1998; Lin et al., 1997; Sokabe et al., 2004).

Endothelial cells derived from venous, arterial, and microvascular beds exhibit distinct phenotypes in mitosis rates (Beekhuizen and van Furth, 1994), growth responses (Rupnick et al., 1988), signaling pathways (Chang et al., 2000), and expression of nitric oxide synthase (Guillot et al., 2000), vWF (Edelberg et al., 1998), and tissue-type plasminogen activator (Christie, 1999; Rosenberg, 1999). In addition, the functional relationship between vascular endothelial cells and surrounding tissues (cortex, myocardium, myometrium, connective tissue/skeletal muscle) and hemostatic regulation, may be particularly important in "site-specific" responses to prothrombotic stimuli (Christie et al., 1999; Le Flem et al., 1999; Nishida et al., 1993; Tabrizi et al., 1999). An area of considerable interest and relevance to the subject of thrombophilias and vascular bed–specific thrombotic potential is endothelial cell repair and death (apoptosis). An ability to restore endothelial integrity (structural and functional) following injury and the prompt regulation of apoptotic cell–mediated prothrombotic activity may, in fact, be the most critical part of the biologic equation (Figure 30.5).

The clear distinction between vascular beds in response to injury, regulation of coagulation and perhaps thromboprophylaxis with antithrombotic drugs has implications for investigation of medical genomics in general, and the impact of disease predisposition attributable to traditional risk factors in particular. Indeed, the major risk factors for clinical atherosclerosis, including dyslipidemia, hypertension, glucose intolerance, adiposity, cigarette smoking, sedentary life style, inflammatory markers and, to a lesser degree, hemostatic factors accounted for 85% of the cardiovascular disease arising within the Framingham population (Kannel and Wolf, 2006).

CIRCULATING CELLULAR AND PROTEIN INFLUENCES ON HEMOSTASIS AND THROMBOSIS

A traditionally held view that thrombosis, particularly involving the arterial circulatory system, is governed solely by factors intrinsic to the vessel wall at sites of injury requires reconsideration. Tissue factor is found in high concentrations within atherosclerotic plaques, activated endothelial cells, fibroblasts, macrophages, and vascular smooth muscle cells; however, tissue factor antigen is also present within the circulating blood of patients with coronary artery disease or with hematologic disorders characterized by heightened thrombogenicity (Falciani et al., 1998). Tissue factor–containing neutrophils, monocytes, and microparticles (Giesen et al., 1999), circulating in peripheral blood, can be delivered to sites of vascular injury where they contribute directly to both the initiation of thrombus formation and its subsequent propagation. This evolving construct emphasizes an important interface between leukocytes and activated endothelial cells, activated platelets, and the vessel wall, where essential substrate for thrombin generation already exists (Giesen et al., 1999; McEver, 2001). Adherent leukocytes enhance fibrin deposition by

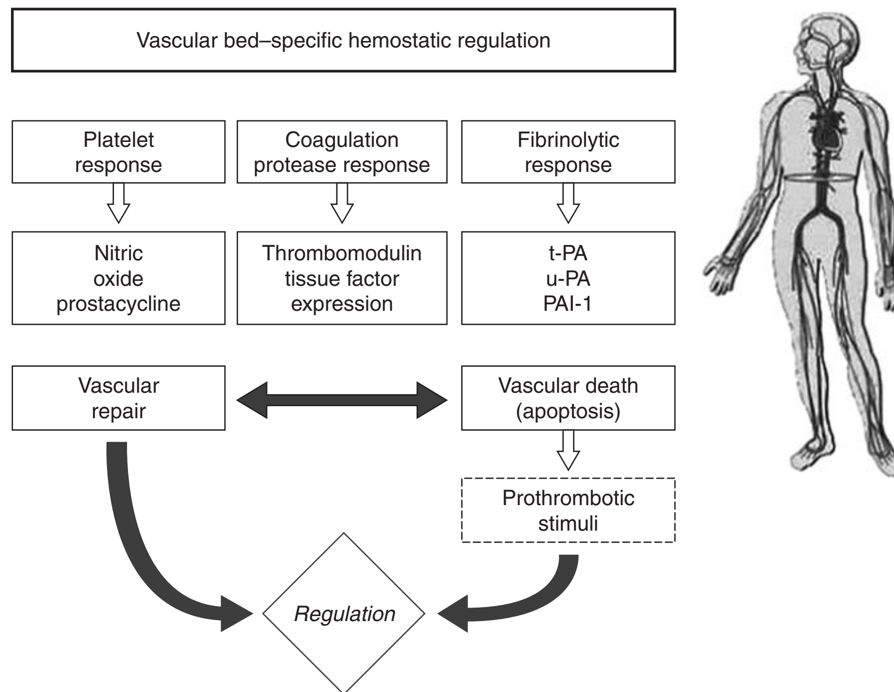

Figure 30.5 Vascular bed–specific hemostasis and thrombosis is regulated by endothelial cell-based vascular responses to prothrombotic stimuli involving platelets, coagulation proteases, and fibrin. Cell–cell and cell–protein interactions, coupled with programmed cellular events, play a particularly important role in vascular repair.

CD18-dependent capture of fibrin protofibrils that are flowing in plasma, and by f XII–dependent thrombin generation. They also activate platelets, providing a fully functional platform for fibrin formation under flow conditions (Goel and Diamond, 2001).

A blood-borne propensity for thrombosis, not entirely dependent on vascular pathology, provides a biology-based explanation for the observed disparities between "degree" or "extent" of atherosclerosis and risk of thrombotic events of the arterial vascular bed (Karnicki et al., 2002), as well as for the propensity toward venous thrombosis with malignancy and following trauma or major surgery.

LINKAGE STUDIES IN THROMBOSIS

Linkage studies differ from association studies by their dependence on transmission from parents to offspring (of a gene marker) and functional genetic variant. Accordingly, linkage investigation requires sibling pairs, nuclear families or extended families (Souto, 2003). Unlike association studies that are prone to false positive and false negative (failure to identify the candidate gene despite the identification of polymorphisms [unrelated to the phenotype in question]) results, linkage studies are more technically challenging but critical to uncovering new genes that causally influence the observed phenotype.

In the Genetic Analysis of Idiopathic Thrombosis (GAIT) family-based study, an additive genetic heritability of 60% for thrombosis was estimated, suggesting the gene mutations would represent the single largest causal mechanism in the pathobiology of disease (Blangero et al., 2003).

Genome-wide scans were carried out using 325 pedigrees with 1144 individuals participating in the Framingham Heart Study (Lin et al., 2007). Using variance-component linkage methods, heritabilities were estimated at greater than 50% for red blood cell count, mean corpuscular volume and mean corpuscular hemoglobin. For red blood cell count, a maximum LOD score of 3.2 on chromosome 19 was identified in close proximity to several genes known to influence cellular differentiation and possibly thrombogenicity-erythropoietin and erythroid Kruppel-like factor.

A variance-component linkage analysis of C-reactive protein (CRP), IL-6, MCP-1, and soluble ICAM was performed in 304 extended families from the Framingham Heart Study (Dupuis et al., 2005). Heritability estimates ranged from 14% to 44%. A significant linkage to MCP-1 was found on chromosome 1 (LOD 4.27), in a region containing several candidate genes, including E-selectin, P-selectin, and CRP. The findings suggest that genes on chromosome 1 may influence inflammation and may have a potential role in atherothrombosis.

Based on available information derived from investigations among individuals with thrombotic disorders, a preferred approach is to utilize linkage studies for gene identification, followed by association studies to further examine polymorphisms in the positional candidate genes (Broeckel et al., 2002; Cooper et al., 2002). If prior linkage studies have not been performed,

candidate genes, at the very least, should be based on known functionality.

ASSOCIATION STUDIES IN THROMBOSIS

The study of complex diseases to include venous and, perhaps to an even greater extent, arterial thrombosis has taken several unique paths. Association studies, conducted among unrelated subjects are undertaken with a basic premise that genetic variants are either related directly to a predetermined phenotype or closely linked to a causative variant. Using either a cohort or case-control approach, the association between genotype and phenotype can be examined. Although population admixture is a potential confounder in genetic association studies, careful selection of a "control" population may address the problem (Wacholder et al., 2000). In contrast, the generalizability and discovery of intermediate phenotypes that can then be used to identify candidate gene or tested in linkage studies is a potential strength of association studies.

A linkage disequilibrium-based genetic approach was utilized to investigate common gene sequence variance in five thrombosis-related genes and related plasma hemostatic proteins among 1811 unrelated Framingham Heart Study participants (Kathiresan et al., 2006). Forty-one tag single nucleotide polymorphisms (SNPs) were genotyped and revealed associations between a fibrinogen-beta SNPs with circulating fibrinogen levels and 7 fVII SNPs and plasma fVII levels. In a step-wise analysis, a single fibrinogen-beta variant explained 1% of the residual variance in fibrinogen levels, and 2 fVII SNPs together explained 10% of the residual variance in fVII levels.

The availability of genome-wide surveys of genetic variants and decreasing cost of genotyping provides an ideal environment for using association studies to unravel complex human conditions. Programs in biostatistical methods and informatics will undoubtedly play a critical role in realizing the full potential of this technique (Lin et al., 2006).

HERITABILITY AND THROMBOSIS: EXISTING COMPLEXITIES

Heritability, defined as the proportion of the total phenotypic variation within a population, is attributed to genetic variance – also referred to as shared variance. The challenge in complex diseases, including thrombotic disorders, is driven by a lack of independence for genetic and environmental components. In many cases, there is an interaction between the two, with one or more environmental factors modifying the genetic effect.

A common illustration is an individual with an inherited thrombophilia who experiences trauma or undergoes major surgery. Under these circumstances, an existing predisposition, coupled with an acquired risk may culminate in a thrombotic event.

There are several subtypes of genetic variance: additive (variance resulting from individual alleles and best represented in parent–offspring studies); dominance (variance stemming from pairs of homologous alleles as determined in twin studies); and epistasis (variance from genes that affect the expression of other genes). Accordingly, heritability is itself complex and may be most suitable for detecting the presence (or absence) of genetic variance (van Asselt et al., 2006).

A PERSONALIZED APPROACH TO HEMOSTASIS AND THROMBOSIS

A recognized priority area for thrombosis-related investigation is identifying patients who will ultimately experience the clinical phenotype. This knowledge allows a clear distinction between individuals in whom treatment is required to prevent life-altering or life-threatening events, and those who potentially incur undue risk from antithrombotics with little likelihood of benefit.

Numerous studies have demonstrated the ability of gene-expression profiles to identify subtle distinctions that define important clinical phenotypes. In a study performed at Duke University Medical Center, Potti and colleagues (Potti et al., 2006) identified gene-expression profiles that predicted thrombotic events among patients with anticardiolipin antibodies (Figures 30.6 and 30.7). An analysis of 50 genes who expression patterns provided the power to discriminate and predict thrombosis included APOE, coagulation factor X, thomboxane, matrix metalloproteinase 19, interleukin 22 receptor, and hematopoietic progenitor cell antigen (CD34) precursor.

An ability to identify polymophisms in high-porosity genes may, in turn, lead to novel diagnostic tools for determining patients at risk, and intervening prior to a clinical event.

PATIENT SCREENING: A TRADITIONAL PARADIGM

Whom to Investigate

In patients with arterial thrombosis, the search for an underlying thrombophilic condition is justified in the presence of at least one of the following: (1) recurrent thromboembolic event; (2) young age (≤50 years if male, ≤55 years if female); (3) lack of significant arterial stenosis at angiography; (4) age ≤55 years if male or ≤60 years if female and no apparent cause (i.e., lack of traditional cardiovascular risk factors, systemic illnesses, malignancies, offending drugs); or (5) age ≤55 years if male or ≤60 years if female and strong family history of thrombosis (Table 30.3) (Figure 30.8) (Andreotti and Becker, 2005). A venous thromboembolic (VTE) event should prompt further evaluation in the following individuals: age <50 years, thrombosis at unusual sites (cerebral, mesenteric, hepatic, portal veins), recurrent venous thrombosis, venous thrombosis and a strong family history of thrombotic disease, women with recurring miscarriages and/or puerperal complications. A targeted approach to testing

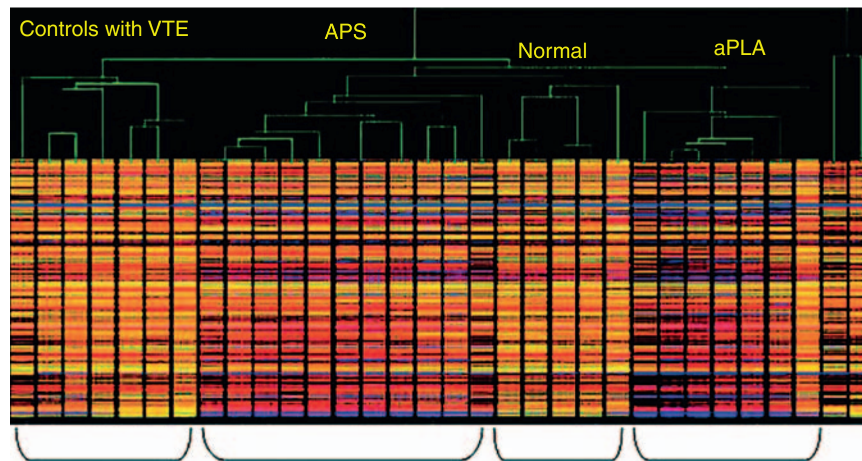

Figure 30.6 Patterns of gene expression that characterize clinical phenotypes. Hierarchal clustering of the initial patient samples based on gene-expression patterns. Each gene is represented by a single row, and each sample is represented by a single column. The color heat map represents genes in a graded fashion along a spectrum of activation, extending from strongly upregulated genes in red to the down-regulated in blue. VTE, venous thromboembolism; APS, antiphospholipid antibody syndromes; aPLA, antiphospholipid antibody. From Potti et al. (2006) with permission.

influences strongly the likelihood of detecting an inherited mutation with biological linkage (Table 30.4) (Seligsohn and Lubetsky, 2001). The importance of gathering a family history, a simple and frequently underutilized tool available to all and useful in assessing the risk for common complex diseases, has been stressed by the Centers for Disease Control and Prevention, Office of Genomics and Disease Prevention (Yoon et al., 2003). Selective testing for common inherited thrombophilias is more cost-effective than universal screening (Wu, 2006).

What and When to Investigate

The tests summarized in Figure 30.8 may be performed during hospitalization, even during the initial stages of a thrombotic episode. Evaluations for an acquired thrombophilia, including those associated with underlying malignancy, systemic disorders, and drug-induced prothrombotic states, should also begin without delay. A definitive diagnosis of myeloproliferative disorder or the search for occult malignancy may require serial office visits and carefully selected imaging studies.

Implications for Treatment

The approaches to inherited and acquired thrombophilias differ at several levels. The former raises questions of susceptibility to recurrent events, treatment duration, and whether to perform testing among related family members (who may themselves carry the trait) (Seligsohn and Lubetsky, 2001). The latter is based on concomitant illnesses and identification of offending drugs or conditions in which diagnosis and treatment of the predisposing disorder have a major impact on the overall thrombotic risk.

PATIENT SCREENING: A COMPREHENSIVE AND POPULATION-BASED APPROACH

Individuals who have experienced an initial VTE event incur a significant risk for recurrence. Traditional risk factors including stasis (from immobility and surgery), vascular injury and either inherited or acquired thrombophilias contribute to sustained risk. In the last 10–15 years it has become apparent that there are number of genetic mutations that are present variably within populations that predispose some individuals to recurring events. Accordingly, attention to personal and family history of thrombosis, with testing according to established guidelines is recommended.

A thrombosis risk intake system, modeled for use in a community setting, is summarized in Figure 30.9. The algorithm and targeted risk management recommendations ideally should be based on the ACMG and CAP consensus statements with respect to genetic testing for thrombophilias and expert opinion. There should be shared decision made before proceeding with the test, as well as education posttest. This particular approach is based on existing concern for patients with inherited thrombophilias. A recent study specifically investigated the knowledge and education needs of individuals with the factor V Leiden mutation (Hellmann et al., 2003). Several observations are worthy of careful consideration: 79% incorrectly estimated their thrombosis risk (2–8 years posttesting); 64% stated that they were given little information about factor V Leiden (pre-or posttesting); 68% had remaining questions at the time of the survey; 53% believed their health care providers to be inadequately informed about the test implications; and 88% preferred knowing the results (of genetic testing).

PROGNOSTIC CONSIDERATIONS

The most prevalent phenotype of a thrombophilia is venous thromboembolism – a continuum from deep vein thrombosis (DVT) to pulmonary embolism (PE). The annual incidence of venous thromboembolism is approximately 1 in 1000 patients, similar to the annual incidence of stroke. The mortality of PE is particularly high with approximately one in six cases resulting in death. As previously described, individuals who have experienced an initial VTE event have a significant risk of recurrence even after an initial course of treatment. The declining risk over time suggests that concomitant illness and factors related to the thrombus itself contribute.

Recent data, based on patients with unprovoked (spontaneous or idiopathic) VTE, suggest a 10–15% rate of recurrence. The incidence is particularly high following a PE (Gonzalez-Porras

et al., 2006). Although the presence of an inherited thrombophilia is associated with increased risk, common mutations such as factor V Leiden, prothrombin 20210, and methylene tetrahydrofolate reductase (MTHFR), pose the greatest concern when combined (double defects), or exist as homozygous or double heterozygous forms.

The case fatality rates for recurrent PE during anticoagulant therapy vary from 8% to as high as 26%. Recurrence after a course of therapy, on average for 3–6 months, is fatal in approximately 5% of cases (Gonzalez-Porras et al., 2006).

The risk of recurrent arterial thrombosis is determined by several factors, include age, vascular bed origin, coexisting disease in other vascular beds, concomitant risk factors, the presence of a defined thrombophilia, and the use and associated effectiveness of existing treatments (that may included percutaneous and/or surgical interventions).

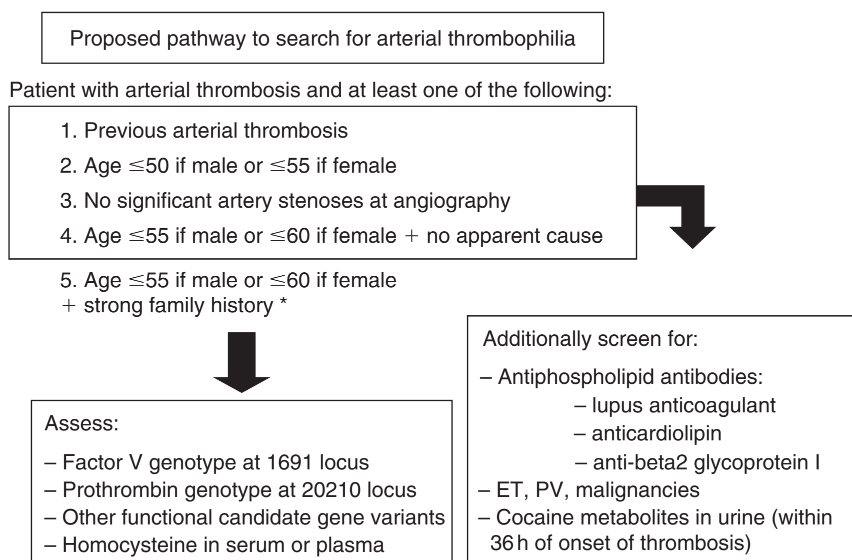

Figure 30.8 Proposed criteria for the selection of patients in whom it may be justified to perform a number of nonroutine tests for underlying thrombophilic conditions. Selected patients, age less than 50, a family history of venous thrombosis, a history of recurrent events, and the absence of acquired risk factors except pregnancy of the use of oral contraceptives. Adapted from Seligsohn (2001).

EMERGING PLATFORM FOR HEMOSTASIS AND THROMBOSIS RESEARCH

Scientific advances have provided a strong knowledge base for research agendas in the fields of hemostasis and thrombosis. Coupled with great strides in molecular biology, the next decade promises many opportunities to translate fundamental science to patient care. Several emerging platforms will be instrumental and include: proteomic analysis capabilities for defining signaling cascades in platelets (Garcia, 2006), systems-based models of individual pro- and anticoagulant factor levels, and related *in silico* prediction models of thrombotic capacity (hemostatic proteome) (Brummel-Ziedins et al., 2005), expression profiles of circulating blood components (Potti et al., 2006) and thrombus modulation achieved through inhibition of cellular adhesive events (Jackson et al., 2005).

A pyrosequencing-based genotype platform that analyzes common prothrombotic, hemostatic, and treatment-modulating mutations may represent an optimized diagnostic strategy for analysis (Holmberg et al., 2005), with potential application in both epidemiologic studies and clinical diagnosis (Mooser et al., 2003).

Pharmacogenomics

Antithrombotic therapy has improved patient outcomes across a broad range of thrombotic disorders; however, not all patients in all clinical settings respond favorably. Accordingly, efforts must be undertaken to better distinguish "good responders" from "bad responders" or "non-responders." Pharmacogenomics represents an important part of an emerging paradigm for drug

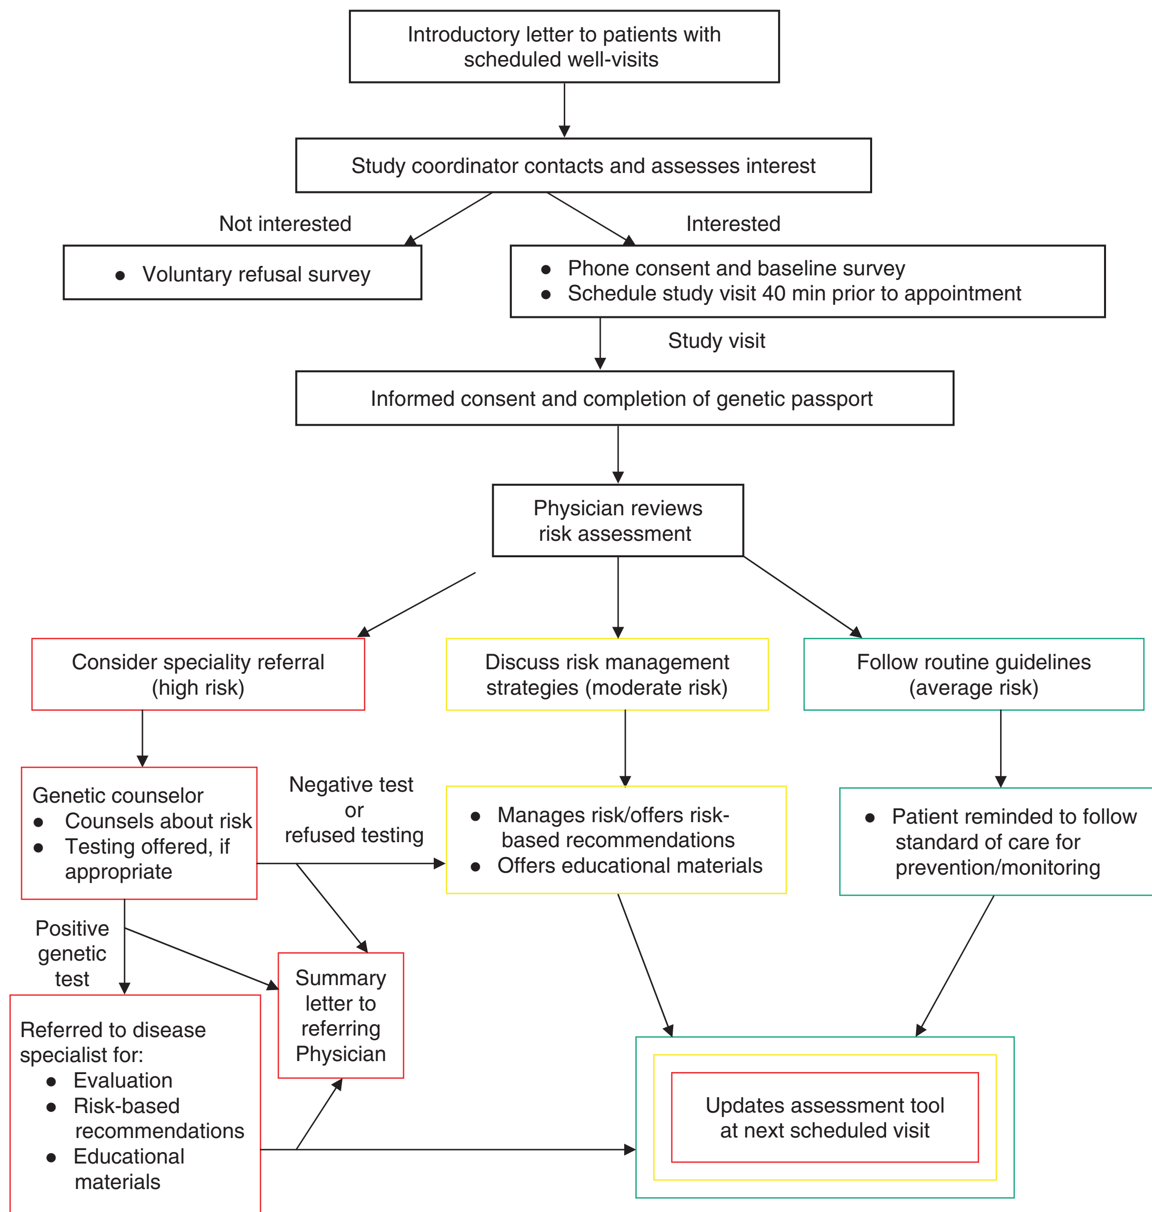

Figure 30.9 A population-based approach to thrombophilias emphasizes family and patient history of thrombotic events, carefully selected tests, genetic counseling when appropriate and educated disease management.

treatment given gene-based influences on enzymes, transporters, and receptors involved with several fundamental properties, including drug absorption, metabolism, excretion, mechanism of action, and toxicity (reviewed in reference [Palkimas et al., 2003]). An illustration of pharmacogenomics as a platform for patient care is well represented with the anticoagulant warfarin (a vitamin K antagonists used widely in the management of thrombotic disorders). Genetic variations in the hepatic metabolism of S-warfarin, the more potent isomer that accounts for 70% of the overall anticoagulant response, by P450 2C9 have important implications in drug dose requirements and risk of bleeding (reviewed in reference [Aithal et al., 1999]) (Table 30.5) (Dang et al., 2005; Higashi et al., 2002; Loebstein et al., 2001; Tabrizi et al., 2002; Taube et al., 2000). Although the prevalence of 2C9 polymorphisms varies among ethnic groups, this may not fully explain differences in warfarin dose requirements (Dang et al., 2005). One must acknowledge, despite the likely importance of pharmacogenomics in clinical practice, that the role of genetic testing in therapy decisions must be defined through carefully designed clinical trials.

The Bloodomics project at Cambridge University, financed by the European Community, has a primary objective to

Table 30.5 Genetics of warfarin metabolism

discover genetic markers within platelets that predict arterial thrombosis risk. An overarching plan is to identify and catalog SNPs in 300 genes, and establish a basis for population genetics (reviewed in reference [Nurden, 2006]).

Polymorphisms in platelet receptors, coagulation proteins and fibrin; coupled with concomitant genetic polymorphisms affecting the metabolism, disposition, transporter proteins, and target binding of antithrombotic drugs emphasizes the importance of ongoing pharmacogenomic research within clinical trials. Application of bioinformatics, genomics, and pharmacogenomics will play a critical role in the unraveling of complex interactions (Iqbal and Fareed, 2006).

2009 UPDATE

The field of genomics as it relates to coagulation and thrombosis is evolving rapidly in three major areas: genetic predisposition to venous thrombosis, genetic predisposition to drug-induced, malignancy-associated venous thromboembolism, and the pharmacogenomics of antithrombotic therapy for thrombotic disorders of the coronary arterial circulatory system.

While an inherited predisposition to venous thrombosis is detectable in upward of 50% of selected patients, the remaining patients lack an identifiable thrombotic mutation, even under conditions in which multiple family members or several generations have the clinical phenotype. The employment of large population data sets, including the LETS and multiple environmental and genetic assessment (MEGA) of Risk Factors for Venous Thromboembolism Study provided a powerful resource for assessing fundamental questions of thrombotic risk and common inherited variations (Bezemer et al., 2008).

Malignancy is a common acquired thrombophilia that poses a strong risk for venous thromboembolism. In some instances, chemotherapy itself may heighten the inherent risk, creating unique challenges for both clinicians and patients. Large-scale clinical trials and established networks have recently provided an opportunity to investigate genomic associations for thrombosis. Using patients and controls from the Medical Research Council (MRC) Myeloma IX, Hovon-50, and Eastern Cooperative Oncology Group (ECOG) studies, Johnson and Colleagues identified a set of SNPs, associated with thalidomide-related venous thromboembolism, that were enriched in genes and pathways important in drug transport/metabolism, DNA repair, and cytokine synthesis. (Johnson et al., 2008). The fundamental question that requires further investigation is whether the relationship exists at the tumor level, tumor-related microenvironment, or the vascular endothelium. Further studies will be required to identify those patients who are at increased risk for thromboembolism in the setting of malignancy.

The opportunity for translation of pharmacogenomics to patient care in coronary arterial thrombotic disorders is well illustrated in two recent studies (Mega et al., 2008; Simon et al., 2008). In the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel (TRITON) Study (Mega et al., 2008), 1477 subjects with acute coronary syndromes treated with clopidogrel – who were carriers of at least one CYP2C19 reduced-function allele (27.1% of the study population) – were at significantly higher risk for death from cardiovascular causes, MI, or stroke than noncarriers (12.1% versus 8.0%; hazard ratio, 1.53; 95% CI 1.07–2.19; $p = 0.01$). The risk of stent thrombosis in carriers of a reduced-function allele was threefold higher than noncarriers (2.6% versus 0.08%; hazard ratio, 3.09; 95% CI, 1.19–8.00; $p = 0.02$). The presence of at least one copy of the *2 allele for CYP2C19 accounted for 95% of the subjects classified as carriers of a reduced-function allele. In a study of healthy subjects with the CYP gene variant, carriers had a relative reduction of 32.4% in plasma exposure to clopidogrel's active metabolite, and a diminished pharmacodynamic response, with an absolute change in maximal platelet aggregation in response to clopidogrel that was 9% points less than noncarriers (Mega et al., 2008).

The French Registry of Acute ST-elevation and non ST-elevation Myocardial Infarction (FAST-MI) investigators (Simon et al., 2008) assessed the relation of allelic variants in genes modulating clopidogrel absorption (ABCB1), metabolic activation (CYP3A5, CYP2C19), and biologic activity ($P2RY_{12}$, ITGB3) to the risk of death (all cause), MI, or nonfatal stroke during one year of follow-up in 2208 patients. Patients with two variant alleles of ABCB1 had a higher rate of cardiovascular events than those with the wild-type genotype (15.5% versus 10.7% adjusted hazard ratio 1.72; 95% CI, 1.20–2.47). Patients carrying any two CYP2C19 loss-of-function alleles (*2,*3, *4, or *5) had a higher event rate than patients without gene variants (21.5% versus 13.3%; adjusted hazard ratio 1.98, 95% CI 1.10–3.58). The event rates were particularly high among patients with CYP2C19 loss-of-function alleles who underwent PCI during initial hospitalization (3.58fold higher; 95% CI, 1.71–7.51). The presence of at least one ABCB1 variant allele and two CYP2C19 alleles was associated with the highest hazard for events (5.31; 95% CI, 1.71–7.51; $p = 0.005$).

The CYP2C19 gene variant was also a determinant for prognosis in patients less than 45 years of age who were receiving clopidogrel after treatment for a first acute myocardial infarction (Collet et al., 2008). Clearly, determination of CYP2C19 status will soon be part of the standard evaluation of patients who are candidates for clopidogrel in the near future.

CHAPTER

Genomics of Congenital Heart Disease

Jessie H. Conta and Roger E. Breitbart

INTRODUCTION

Congenital heart disease (CHD) refers to structural malformations of the heart and great vessels that result from abnormal embryonic and fetal development. They comprise a broad spectrum of anatomic and clinical severity, ranging from relatively simple lesions such as atrial and ventricular septal defects to highly complex malformations of the cardiac chambers and their venous and arterial connections. As a group, cardiovascular malformations are the most common form of major birth defect, occurring at a frequency of 8 per 1000 live births (excluding bicuspid aortic valve, which has an estimated prevalence of 2% to 3%). They are also among the most frequent causes of death in infants beyond the neonatal period.

The genetic basis of CHD has been the subject of intense investigation and increasing understanding in the past decade. CHD has long been recognized as a key feature of certain genetic syndromes, a prime example being Down syndrome (trisomy 21). In contrast, the importance of genetic mutation in non-syndromic CHD has emerged relatively recently through the elucidation of single gene defects in certain families with inherited CHD. This work, undertaken largely before the completion of the Human Genome Project, has relied principally on conventional genetic approaches, that is linkage analysis and positional cloning, as well as candidate gene sequencing. As it happens, however, families with mendelian transmission of CHD are actually quite rare. Non-mendelian patterns with variable penetrance and expressivity are more the rule in families with manifestly inherited CHD. Furthermore, most cases of CHD are, or at least appear to be, sporadic, occurring in patients with no known family history of CHD. On this basis there is growing expectation that the bulk of CHD will ultimately be attributed to more complex genetics involving polymorphisms, modifying loci, and gene-gene and gene-environment interactions. Ongoing investigation of these mechanisms relies necessarily on genomic approaches.

This chapter reviews the current knowledge of the molecular genetics and genomics of CHD. Future directions for this research, and the associated challenges, are also considered. Recommendations for genetic evaluation of patients and families with CHD are offered, including screening, molecular diagnosis, and counseling. Of note, the genetics of cardiac arrhythmias and of the cardiomyopathies, both also affecting children, are beyond the scope of this chapter but are addressed elsewhere in this volume (see Chapters 28 and 29).

CHD GENE DISCOVERY BY CONVENTIONAL GENETICS

Salient human genes with established roles in the etiology of CHD are summarized in Table 31.1. This list includes the most well studied and illustrative examples of CHD genes but is by no means exhaustive. Indeed, a search of the Online Mendelian Inheritance in Man database (www.ncbi.nlm.nih.gov/omim/) yields more than 900 additional genes or loci linked to a range of CHD at this writing. CHD genes have been identified largely through conventional genetic approaches including linkage

[a]TF, transcription factor; CS, cell signaling factor; EM, extracellular matrix protein.

[b]ASD, atrial septal defect; VSD, ventricular septal defect; TOF, tetralogy of Fallot; PDA, patent ductus arteriosus; PS, pulmonary stenosis; HCM, hypertrophic cardiomyopathy; MVP, mitral valve prolapse; AD, aortic dilation; SVAS, supravalvar aortic stenosis.

analysis, positional cloning, and candidate gene sequencing. Some were discovered in the context of clinical genetic syndromes that include CHD phenotypes while others have been found in families with non-syndromic CHD. Re-sequencing of candidate genes has also demonstrated mutations or polymorphisms associated with sporadic CHD.

Transcription Factor Genes

Among the fourteen CHD genes in Table 31.1, eight encode nuclear transcription factors. Five of these, Tbx5, *Nkx2-5*, *GATA4*, *Zfpm2/Fog2*, and *Sall4*, have been demonstrated to interact cooperatively with each other to regulate gene expression during cardiac embryogenesis.

TBX5 (Holt-Oram Syndrome)

Holt-Oram syndrome is an autosomal dominant disorder characterized by skeletal malformations of the upper extremities and CHD, most commonly secundum atrial septal defects but also ventricular septal defects and tetralogy of Fallot. *TBX5*, encoding a T-box nuclear transcription factor, was identified as the disease gene using linkage analysis and detailed positional cloning, and several missense and nonsense mutations were identified in multiple affected families (Basson et al., 1997; Li et al., 1997b). *TBX5* was found expressed in embryonic human heart and limb, and targeted deletion of *Tbx5* in the mouse resulted in defective cardiac development, supporting the conclusion that human *TBX5* mutation is responsible for the CHD in Holt-Oram patients (Basson et al., 1997; Bruneau et al., 2001; Li et al., 1997b).

TBX1 (DiGeorge Syndrome)

DiGeorge syndrome, now synonymous with velo-cardio-facial syndrome, Shprintzen syndrome, and CATCH22, involves a range of variable clinical phenotypes including CHD, neonatal hypocalcemia, cellular immune deficiency, palatal defects, characteristic facies, and cognitive and psychiatric disorders. The cardiac defects are typically conotruncal or outflow tract malformations associated with defective neural crest migration, including interrupted aortic arch, truncus arteriosus, and tetralogy of Fallot, especially tetralogy with pulmonary atresia (McDonald-McGinn et al., 1999). This is a well established contiguous gene syndrome caused by microdeletion of a critical region located at chromosome 22q11.2 (a minority of DiGeorge patients have an alternate deletion at 10p14–13). The human *TBX1* gene,

encoding another T-box transcription factor and expressed in neural crest and the developing cardiac outflow tract (conotruncus), was mapped to the center of the DiGeorge critical region (Chieffo et al., 1997). Mice with targeted heterozygous *Tbx1* deletion developed cardiac outflow tract malformations and certain extra-cardiac phenotypes characteristic of human DiGeorge syndrome (Jerome and Papaioannou, 2001; Lindsay et al., 2001; Merscher et al., 2001). Furthermore, both the cardiac and extracardiac phenotypes could be rescued by the introduction of an extrachromosomal copy of *Tbx1*. These findings lend strong support to the hypothesis that human *TBX1* mutations may be sufficient to cause the cardiac defects that are characteristic DiGeorge syndrome and, indeed, similar lesions in patients who do not have the syndrome. However, rather surprisingly, isolated *TBX1* mutations or deletions have not been found in large numbers of non-deleted patients with conotruncal malformations (Conti et al., 2003; Gong et al., 2001). There is a sole report of *TBX1* frameshift and missense mutations in a small kindred and two unrelated individuals with DiGeorge-like phenotypes and no 22q11.2 deletion (Yagi et al., 2003). Thus, a role for *TBX1* mutation in non-syndromic conotruncal malformations seems very likely but awaits more definitive proof.

NKX2-5

The mammalian homeobox transcription factor Nkx2-5 was first identified as a homolog of the Drosophila *tinman* gene, essential for specification of heart muscle progenitors (Bodmer, 1993; Komuro and Izumo, 1993). Targeted disruption of *Nkx2-5* in the mouse was found to cause arrested cardiac development at the linear heart tube stage (Lyons et al., 1995). Subsequent studies showed that Nkx2-5 interacts with Tbx5, the Holt-Oram factor, to promote cardiomyocyte differentiation (Hiroi et al., 2001). Human *NKX2-5* was recognized as a likely candidate gene in the linked region on chromosome 5q35 following genome-wide scans in families with non-syndromic, multigenerational CHD (Schott et al., 1998). Direct sequencing identified a series of mutations that segregated with the CHD. Subsequently, re-sequencing in large cohorts of CHD patients has revealed an appreciable frequency of *NKX2-5* mutations or polymorphisms in association with sporadic, apparently non-familial CHD involving a broad range of cardiac defects (Benson et al., 1999; Elliott et al., 2003; Goldmuntz et al., 2001; McElhinney et al., 2003). Somatic mutations of *NKX2-5* have also been identified in the hearts of patients with cardiac malformations although causation has not been established (Reamon-Buettner et al., 2004).

GATA-4

GATA-4, one of a family of closely related zinc-finger transcription factors, is expressed in the developing heart. Targeted homozygous deletion of *Gata4* in the mouse abrogated normal formation of the primitive heart tube in the early embryo (Kuo et al., 1997; Molkentin et al., 1997), while haploinsufficiency and conditional myocardial deletion resulted in a range of cardiac malformations (Pu et al., 2004; Zeisberg et al., 2005). Human *GATA4* was identified as a candidate gene in an interval at 8p22–23 that was linked to CHD, principally atrial septal defects, in a genome-wide scan in a large multigenerational kindred (Garg et al., 2003). Direct sequencing identified mutations that segregated with non-syndromic CHD in this and a second independent kindred. GATA4 interacts with Tbx5, the Holt-Oram factor, and with Nkx2-5 to regulate cardiac gene expression, and disease-causing mutations abrogate these interactions (Durocher et al., 1997; Garg et al., 2003). Somatic mutations of *GATA4* have also been identified in the hearts of patients with cardiac malformations although again causation has not been established (Reamon-Buettner and Borlak, 2005).

ZFPM2/FOG2

FOG2 or ZFPM2, one of a family of zinc finger transcription factors, is expressed in the embryonic and adult heart, co-localizes with GATA-4, and interacts physically with GATA-4 to downregulate its activity (Svensson et al., 1999). Mice with targeted homozygous deletion of *Zfpm2/Fog2* develop cardiac lesions including tetralogy of Fallot, complete atrioventricular canal, and tricuspid atresia (Svensson et al., 2000; Tevosian et al., 2000). In a candidate gene approach, two missense mutations in *ZFPM2/FOG2* were identified in two of 47 patients with non-syndromic tetralogy of Fallot (Pizzuti et al., 2003). However, these mutations had at most a slight effect on protein function *in vitro* and, moreover, co-existing mutations in either *GATA-4* or *NKX2-5* were not excluded. Additional investigation will be required if *ZFPM2/FOG2* is to be implicated more definitively in CHD.

SALL4 (Okihiro Syndrome)

Okihiro syndrome is an autosomal dominant disorder involving multiple congenital anomalies including a characteristic eye movement disorder (Duane anomaly), forelimb defects, deafness, and CHD, typically atrial septal defects, ventricular septal defects, or tetralogy of Fallot. Linkage analysis in three affected pedigrees mapped the disease gene to a 21.6 cM region on chromosome 20 containing *SALL4*, a novel member of a zinc finger transcription factor family, in which nonsense and frameshift mutations were identified (Al-Baradie et al., 2002). Another group, working contemporaneously, also identified *SALL4* as the Okihiro disease locus using a candidate gene approach when they recognized certain non-cardiac phenotypic similarities between Okihiro syndrome and another syndrome caused by mutations in *SALL1* (Kohlhase et al., 2002). Recent work has shown that in the developing mouse, *Sall4* expression is regulated by *Tbx5*, the Holt-Oram gene, and the two interact in cardiac and forelimb patterning (Koshiba-Takeuchi et al., 2006).

ZIC3 (Heterotaxy)

Heterotaxy refers to ambiguous visceral situs in which the positions of normally asymmetric organs such as the liver and spleen are disordered with respect to the midline. Cardiac lesions associated with heterotaxy are often among the most severe

encountered, including complex malformations of the atria and ventricles and their venous and arterial connections. Many cases of heterotaxy appear to be sporadic but familial cases, notably with X-linked transmission, have been described. Linkage analysis in one such family mapped the heterotaxy phenotype to a locus at Xq24-q27.1 (Casey et al., 1993), and mutation in the gene *ZIC3*, a zinc finger transcription factor, was identified by positional cloning (Gebbia et al., 1997). Subsequently, additional *ZIC3* mutations have been identified by re-sequencing in other heterotaxy kindreds and isolated individuals with similar CHD phenotypes (Ware et al., 2004).

TFAP2B (Char Syndrome)

Char syndrome is an autosomal dominant disorder comprising facial dysmorphism, hand anomalies, and patent ductus arteriosus. Linkage analysis in two large multigenerational kindreds mapped the phenotype to a 3.1 cM region on chromosome 6 (Satoda et al., 1999). Candidate gene analysis then revealed missense mutations in *TFAP2B*, encoding a transcription factor expressed in neural crest, a contributor to the embryogenesis of the ductus arteriosus (Satoda et al., 2000). Examination of genotype–phenotype correlations among several *TFAP2B* mutations revealed that those in the DNA-binding domain of the protein produce the full Char phenotype while one in the trans-activation domain is associated with patent ductus arteriosus but only mild facial and no limb abnormalities (Zhao et al., 2001).

Cell Signaling Genes

Four CHD genes in Table 31.1 encode proteins involved in cell signal transduction, three of which are in the Notch pathways that regulate cell fate decisions during embryonic development.

JAG1 and *NOTCH2* (Alagille Syndrome)

Alagille syndrome is an autosomal dominant disorder comprising hepatic, cardiac, ocular, and vertebral abnormalities in addition to a characteristic facial appearance (Alagille et al., 1987). The cardiac defects are typically right-sided, with valvar pulmonary stenosis the single most common finding and tetralogy of Fallot the most common complex lesion. Linkage analysis and positional cloning in a series of affected families led to the definition of a locus on chromosome 20p12 that included *JAG1*, encoding a Notch ligand, in which a series of mutations were identified (Li et al., 1997a; Oda et al., 1997). Analysis of *JAG1* during mammalian embryogenesis showed expression in the developing heart and vessels, consistent with a critical role in patterning of the right heart and pulmonary vasculature (Loomes et al., 1999). Subsequently, in a candidate gene approach, a *JAG1* missense mutation was identified as the cause of non-Alagille autosomal dominant tetralogy of Fallot segregating in a large kindred, shown in Figure 31.1 (Eldadah et al., 2001). This finding further validated the hypothesis that genes associated with certain cardiac phenotypes in genetic syndromes may also be found to be mutated in non-syndromic patients with similar cardiac defects. Recently, in a candidate gene approach, mutations in the JAG1 receptor *NOTCH2* were found to segregate with cardiac and other phenotypes in two rare Alagille families without JAG1 mutations, strengthening the understanding that these phenotypes are attributable to defective Notch pathway signaling (McDaniell et al., 2006).

NOTCH1 (Bicuspid Aortic Valve)

Bicuspid (two-leaflet) aortic valve is the most prevalent congenital cardiac malformation, estimated to occur in as many as 2–3% of individuals. It is inconsequential in many children, but associated with stenosis of the valve in others. Further, bicuspid valves have a predilection to calcify in later life leading to progressive aortic stenosis and regurgitation. Although most cases appear to be sporadic, families with autosomal dominant bicuspid aortic valve have been identified. Whole genome linkage analysis in one such family and additional studies in other kindreds led to the identification of mutations in the *NOTCH1* transmembrane receptor that appear to be responsible both for the congenital valve deformity and later de-repression of osteoblast calcium deposition in these valves (Garg et al., 2005).

PTPN11 (Noonan Syndrome)

Noonan syndrome is an autosomal dominant disorder comprising dysmorphic facial features, skeletal malformations, short stature, and cardiac abnormalities of which pulmonary stenosis and hypertrophic cardiomyopathy are most characteristic. Genome-wide linkage analysis in a large kindred mapped the Noonan locus to the long arm of chromosome 12 (Jamieson et al., 1994). *PTPN11*, encoding the SHP-2 intracellular protein tyrosine phosphatase, was identified in this region and, in a candidate gene approach, was found to be mutated in approximately 50% of Noonan cases (Tartaglia et al., 2001); a locus or loci for the remaining cases remains to be mapped. Genotype-phenotype analyses showed that pulmonary stenosis was seen more frequently, and hypertrophic cardiomyopathy less frequently, in Noonan patients with *PTPN11* mutations compared to those without (Tartaglia et al., 2002).

Extracellular Matrix Protein Genes

Mutations in two genes encoding extracellular matrix proteins cause congenital syndromes involving arteriopathies of different forms.

FIBRILLIN-1 (Marfan Syndrome)

Marfan syndrome is an autosomal dominant disease of connective tissue principally involving the cardiovascular, skeletal, and ocular systems. Cardiovascular manifestations include mitral valve prolapse and regurgitation, presenting in infancy in the most severe cases, and progressive aneurismal dilation of the aortic root with the potential for catastrophic aortic dissection and rupture. Marfan syndrome was first mapped to chromosome 15 using traditional genetic linkage analysis (Dietz et al., 1991b; Kainulainen et al., 1990). At about the same time, immunohistochemical studies performed on skin and dermal fibroblasts from Marfan patients revealed that abnormal microfibrils were

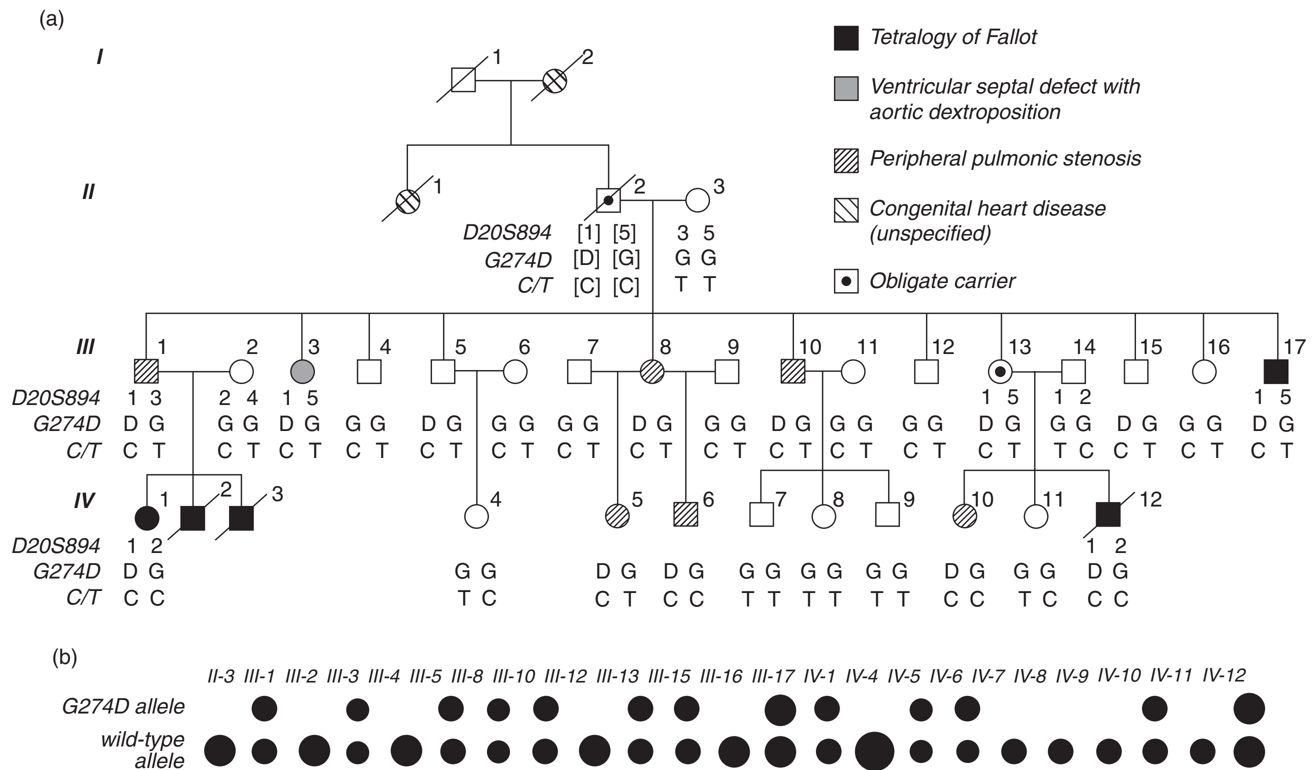

Figure 31.1 Alagille kindred. (a) Pedigree of four generations of a family with Alagille syndrome. Haplotypes include marker alleles of *D20S894* (1–5), glycine (G) or aspartic acid (D) at the mutation site (G274D), and cytosine (C) or thymidine (T) at nucleotide 765, a silent polymorphism (information in brackets was inferred). All individuals with a clinical phenotype inherited the D274 allele. (b) Genomic DNA from the indicated individuals was hybridized with radiolabeled probes specific for the mutant G274D and wild-type coding sequences. (Reprinted, with permission, from Eldadah et al., 2001.)

deficient in the protein fibrillin (Hollister et al., 1990). Then, taking a candidate gene approach, it was possible to localize *FIBRILLIN-1* to 15q21.1 (Magenis et al., 1991) and to demonstrate conclusively that mutations in this gene were tightly linked to the Marfan phenotype in several affected families (Dietz et al., 1991a; Lee et al., 1991). Recognizing this, fibrillin has long been assumed to be critical in the aortic wall and other connective tissues as a structural protein. However, recent work has revealed that fibrillin has a regulatory role in TGF-β signaling and dysregulation of this pathway may instead underlie Marfan pathogenesis (Habashi et al., 2006; Neptune et al., 2003).

ELASTIN (Williams Syndrome)

Williams or Williams-Beuren syndrome is a contiguous gene syndrome involving a 1.5–2 Mb microdeletion of chromosome 7q11.23. The phenotype comprises characteristic endocrine, cognitive, and facial features in association with areas of arterial narrowing, most typically supravalvar aortic stenosis (SVAS). SVAS is a constriction of the proximal aorta above the valve that increases the pressure work of the left ventricle, leading potentially to ventricular hypertrophy and congestive heart failure. On histopathological examination the architecture of the aortic wall elastic lamina is disrupted. The specific gene responsible for SVAS in Williams syndrome remained unknown until a non-syndromic form of autosomal dominant SVAS was recognized in a number of families. Linkage studies and candidate gene analysis in one such kindred identified *ELASTIN* as the disease gene in non-syndromic SVAS (Ewart et al., 1993). As this gene resides in the Williams critical region on 7q11.23, *ELASTIN* hemizygosity appears to underlie the characteristic arteriopathy of Williams syndrome.

Chromosomal Aneuploidies Associated with CHD

Down syndrome (trisomy 21) is the most prevalent genetic syndrome causing congenital heart malformations. It is most closely associated with endocardial cushion defects such as complete atrioventricular canal. The gene or genes on chromosome 21 that underlie the predilection for cardiac defects in Down syndrome are the subject of ongoing intense investigation (Reeves, 2006). Putative cardiac genes for trisomy 13 and trisomy 18, much less common than trisomy 21 but also involving heart defects, similarly remain to be elucidated. In Turner syndrome (45,XO), haploinsufficiency of one or more as yet unidentified genes on the X chromosome is inferred to cause coarctation of the aorta, the cardiovascular lesion most frequently associated with this condition.

GENOMIC STRATEGIES FOR CHD GENE DISCOVERY

It is evident from the foregoing overview that conventional genetic methods have been effective tools in the discovery of CHD genes and mutations. However, these methods are limited to the extent that they allow, in general, for the study of only one or a few genes at a time. The advent of genomic technologies has afforded opportunities in CHD, as in other fields, to analyze thousands of genes if not the entire genome simultaneously with the promise of accelerated discovery.

Large Scale cDNA Sequencing

The first systematic effort to sequence large numbers of cardiac cDNAs was pioneered in the early 1990s by Liew and coworkers (Hwang et al., 1994; Liew et al., 1994). A cDNA library was constructed from human fetal heart and more than 3000 clones identified, nearly half of which were novel at the time by comparison to existing public databases. Early experiments in array transcription profiling, in the form of dot blot filters, demonstrated differential fetal versus adult expression of some of these genes. These investigators expanded their analysis to encompass multiple cardiac libraries and found more than 43,000 expressed sequence tags using automated sequencing; an additional 41,000 were culled *in silico* from existing databases (Hwang et al., 1997). Further bioinformatics analyses allowed for the identification of potential tissue-, developmental stage-, and disease-specific expression of subsets of these genes.

Subtractive Hybridization and Differential Display

Understanding that developmental stage-specific genes are crucial to cardiac morphogenesis, additional genomic strategies have been brought to bear to identify them. Srivastava and coworkers developed a novel subtractive hybridization technique, termed subtractive and selective PCR amplification, to select genes expressed specifically in the earliest embryonic cardiac precursor cells (Gottlieb et al., 2002). Among these was *Bop*, a transcriptional repressor that they then showed to be necessary for normal development of the right ventricle, potentially through regulation of the HAND2 transcription factor, also critical for formation of the right ventricle (Srivastava et al., 1997). These and other investigators also used subtractive and differential display techniques to compare gene expression in *Hand2*$^{-/-}$ versus wild-type mice and elucidate cardiac molecular pathways downstream of HAND2 (Yamagishi et al., 1999). One such pathway gene mapped to human chromosome 10p13-p14, which is deleted in patients with a variant of DiGeorge syndrome that also includes cardiac malformations (Villanueva et al., 2002).

Microarray Transcriptional Profiling

More recently microarray technology has been used to study gene expression patterns related to CHD. Some of these experiments have focused on regional differences in cardiac gene expression in the early vertebrate embryo or in the adult heart (Afrakhte and Schultheiss, 2004; Zhao et al., 2002). Quertermous and coworkers undertook a comprehensive analysis of gene expression patterns in the four chambers and interventricular septum of the mouse heart using a 42,300 element mouse cDNA microarray representing more than 25,000 unique genes and expressed sequence tags (Tabibiazar et al., 2003). This strategy yielded large sets of chamber-specific genes, some in gene families well established to be involved in cardiac development and others more novel.

In the first genome-wide array analysis comparing normal and congenitally malformed human hearts, Sperling and coworkers hybridized human unigene cDNA arrays with right ventricular and/or right atrial RNA probes prepared from normal donors and from patients with simple ventricular septal defects, tetralogy of Fallot, and other defects leading to right ventricular hypertrophy (Kaynak et al., 2003). As represented in Figure 31.2, the levels and probability values for the differentially expressed genes constitute lesion- and chamber-specific genomic fingerprints. Similar microarray analyses of gene expression in tetralogy of Fallot and other lesions producing right ventricular outflow obstruction have followed (Konstantinov et al., 2004; Sharma et al., 2006). The identification of transcriptional patterns associated with particular congenital malformations is intriguing. The extent to which these reflect the primary genetic etiologies of these lesions versus secondary perturbations – due to cyanosis, pressure overload, volume overload, chamber interactions, for example – merits further investigation.

Microarray analysis is an increasingly important tool for the elucidation of molecular pathways that lie downstream of key transcriptional regulators of cardiac development and CHD, including Nkx2-5, Tbx5, and GATA6. In a study of gene expression in the myopathic ventricles of conditional *Nkx2-5*$^{-/-}$ knockout mice, genes associated with myocardial cell proliferation and trabeculation were markedly dysregulated (Pashmforoush et al., 2004). Among these was a gene previously established to lie downstream of *Nkx2-5*, as well as a series of others newly associated with this pathway. Other investigators have profiled gene expression in a mouse model of DiGeorge syndrome with *Tbx1* haploinsufficiency (Prescott et al., 2005) and in cardiac-derived cell lines with or without overexpression of *TBX5* or *GATA6*, revealing multiple putative downstream target genes in each pathway (Plageman and Yutzey, 2006; Alexandrovich et al., 2006).

Mutagenesis and Phenotypic Screens

Genomic strategies for CHD gene discovery are complemented by "phenomic" approaches in the mouse. The Jackson Laboratory has undertaken a phenotype-driven project to identify new murine mutations leading to the development of cardiovascular disease (Svenson et al., 2003). In collaboration with the Laboratory of Developmental Biology at the National Heart Lung and Blood Institute, non-invasive two-dimensional and Doppler echocardiography was used to screen 7546 mouse fetuses from

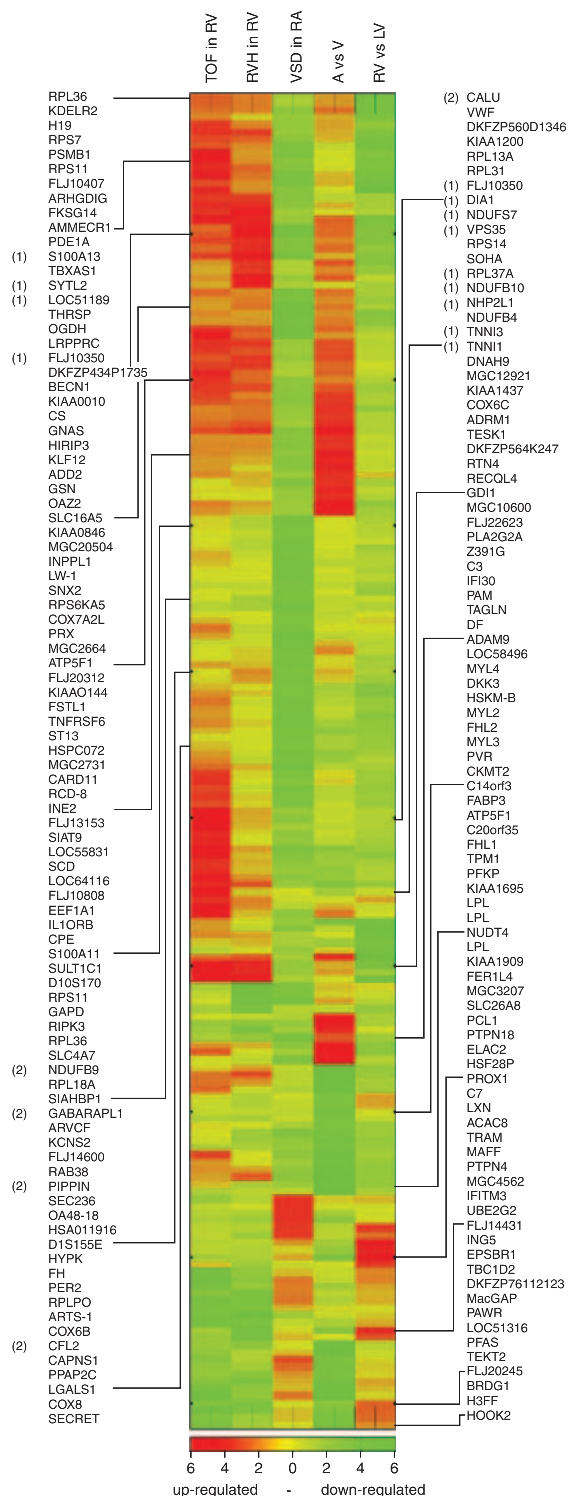

Figure 31.2 Transcription profiling. Graphic display of gene expression levels and probability values profiled across several cardiac phenotypes using microarray analysis. Gene names are listed. Each comparison is represented by a column and each gene by a row. The $-\log_{10}(P)$ for each gene in each comparison is color coded in yellow-to-red for upregulated and yellow-to-green for down-regulated genes, for example a value of 2 represents $P=0.01$ and is color coded in red if the gene is upregulated. (Reprinted, with permission, from Kaynak et al., 2003.)

262 chemically (*N*-ethyl-*N*-nitrosourea) mutagenized families (Yu et al., 2004). Remarkably, congenital heart defects were identified in 124 of these families, among them several with virtual phenocopies of human genetic syndromes including Holt–Oram and DiGeorge syndromes. Chromosomal localization of these mutations using polymorphic microsatellite markers revealed that they mapped to loci other than *Tbx5* and *Tbx1*, the genes previously linked respectively to these syndromes. Thus it is likely that novel CHD genes, some in established molecular pathways and others in entirely new pathways, will be discovered in these and other chemically mutagenized mouse models.

CYTOGENETIC AND MOLECULAR GENETIC TESTING

Cytogenetic and molecular techniques used in the discovery of genes associated with CHD also have practical utility when evaluating the underlying cause of CHD in a patient. Table 31.2 provides a comparison of available diagnostic genetic testing platforms and their applications in CHD.

Structural chromosome anomalies may explain a finding of CHD in conjunction with other congenital anomalies or developmental issues. A standard metaphase karyotype (450–550 bands) is useful for identifying extra or missing chromosomes, whereas high-resolution banding (550–800 bands) is effective at identifying more subtle structural abnormalities including deletions, duplications, translocations, and inversions.

Fluorescence *in situ* hybridization (FISH), another cytogenetic technique, has greater specificity and resolution for identification of microdeletions or duplications that could be missed in a karyotype analysis. FISH is routinely used to detect microdeletion syndromes that are associated with CHD including velocardiofacial syndrome (deletion of 22q11.2) and Williams–Beuren syndrome (deletion of 7q11.23).

Array-based comparative genomic hybridization (CGH) is increasingly performed as an adjunct to standard high-resolution karyotype analysis. Array-CGH can detect abnormalities as small as 80 kb whereas high-resolution chromosome analysis has a minimum resolution of 5 mb. Array-CGH typically includes subtelomeric evaluation to analyze the most distal ends of the chromosomes. Array-CGH cannot detect balanced rearrangements or abnormalities in the genome that are not covered by the selected DNA segments in the microarray. However, array-CGH may be a useful means of evaluating a patient with CHD for multiple genetic abnormalities at once.

Lastly, targeted mutation analysis of a known gene, whether by sequencing, array hybridization, or multiplex ligation-dependent probe amplification (MLPA), can be useful in confirming a clinical diagnosis in a patient whose features are highly suggestive of a particular genetic syndrome. Targeted mutation analysis is complicated by locus heterogeneity, where it is likely that other causal genes exist but have not been discovered. Thus,

TABLE 31.2 Cytogenetic and molecular diagnostic testing in CHD

Assay platform	Genetic abnormality	Resolution	Examples
Standard metaphase karyotype (450–550 bands)	Aneuploidies (monosomies, trisomies)	5–10 Mb	Trisomy 13, 18, 21
Karyotype with high-resolution banding (550–850 bands)	Chromosome structural anomalies: duplications, translocations, interstitial or terminal deletions	3–5 Mb	Trisomy 13, 18, 21, other chromosome structural anomaly syndromes
Fluorescence *in situ* hybridization (FISH)	Subtle chromosome structural anomalies: microdeletions, microduplications, subtle translocations	30–40 kb in clinical setting; as small as 1 kb in research setting	Deletion syndromes such as Velocardiofacial Syndrome (del22q11.2), Williams-Beuren Syndrome (del7q11.23), some instances of Noonan syndrome (*PTPN11*)
Array comparative genomic hybridization (array-CGH)	Identifies deletions and duplications in regions of the genome that are represented on the microarray	~80 kb clinical setting, smaller in research setting	Ability to evaluate multiple deletion/duplication syndromes simultaneously
Multiplex ligation-dependent probe amplification (MLPA)	Detects very small genetic aberrations, to the level of a single nucleotide change	Single base pair alterations	Small deletions below level of detection by FISH
Targeted DNA mutation detection (sequencing)	Single gene mutations, including point mutations, deletions, duplications within the gene	Single base pair alterations	Holt-Oram syndrome (*TBX5*), Alagille syndrome (*JAG1*), Char syndrome (*TFAP2B*), Noonan syndrome (*PTPN11*)

a negative test does not rule out the condition and provides limited recurrence risk information to the family.

MEDICAL EVALUATION AND COUNSELING RECOMMENDATIONS

A thorough medical evaluation, including family history, physical exam, and genetic testing, can aid in distinguishing isolated or sporadic CHD from syndromic CHD. This distinction can provide critical information for cardiac management as well as screening for extra-cardiac issues. Identification of an underlying genetic cause provides answers to the family and aids in recurrence risk counseling. Lastly, given the variability in phenotypic expression of many of the genetic syndromes associated with CHD, knowing the genetic cause and inheritance pattern helps identify at-risk relatives who may need cardiac evaluation and potential intervention. The following approach is recommended to the treating clinician, also outlined in Figure 31.3.

Family history: A three-generation family history can help to direct genetic testing. Documentation of details related to CHD in other family members is critical. It may be useful to request cardiac evaluations of other family members to rule out subtle cardiac defects. Additionally, it is important to document any history of other birth defects, learning disabilities, mental retardation, multiple miscarriages, and still births.

Physical exam and clinical imaging: During the physical exam, attention should be paid to subtle dysmorphic facial features, as well as the involvement of other organ systems. The exam should also focus on ear and eye abnormalities, skeletal issues such as limb reduction defects, gastrointestinal and urologic defects. Standard radiological studies may provide unique diagnostic clues; spine anomalies, aortic arch anomalies, and stomach situs can often be seen in a routine chest radiograph. For example, a right aortic arch, in combination with the diagnosis of tetralogy of Fallot and a family history of learning disabilities is suggestive of velocardiofacial syndrome.

Genetic testing: If the diagnosis of CHD was made prenatally, the patient may have had a standard karyotype performed via amniocentesis to rule out obvious chromosomal abnormalities. It is reasonable to order a high-resolution chromosome analysis if this has not been done, particularly if the infant or child has dysmorphic features or other congenital anomalies. If a chromosome abnormality is detected, it is recommended that the family consult with a genetic specialist for counseling and evaluation of other family members.

Genetic counseling: In the case of syndromic CHD, the clinician can provide referrals to appropriate specialists who can help evaluate and manage non-cardiac manifestations. A discussion about the genetic cause, inheritance pattern and available genetic testing for at-risk family members is imperative, as well as options for prenatal diagnosis in future pregnancies.

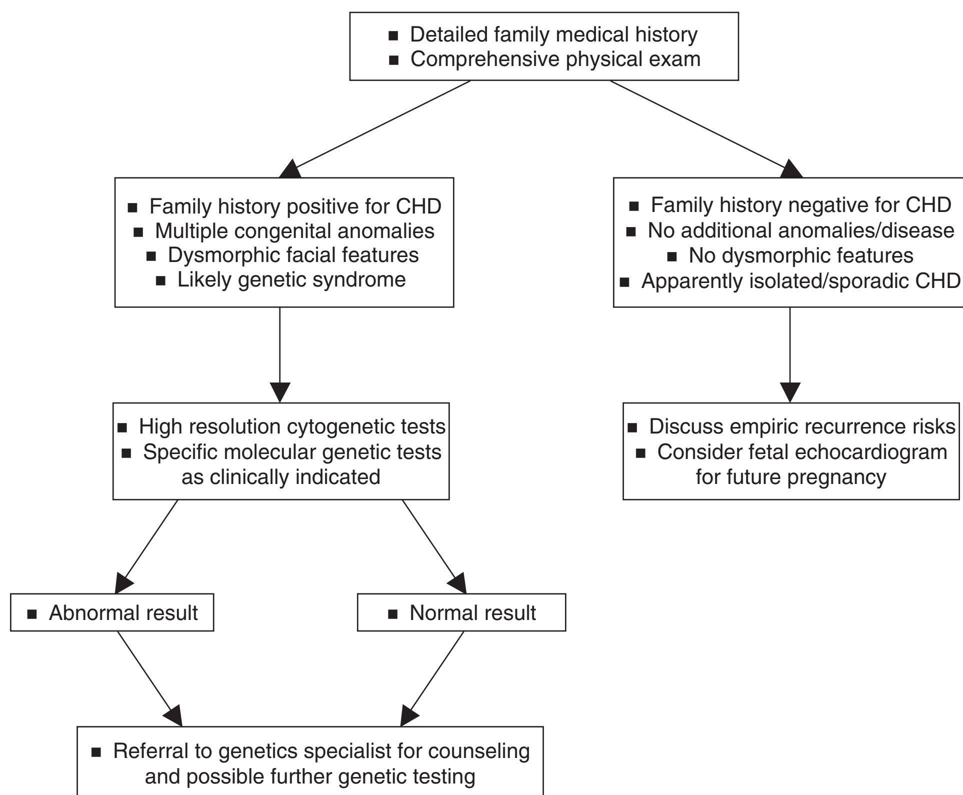

Figure 31.3 Strategy for genetic evaluation of patient with CHD.

A referral to a genetics specialist may be valuable in addressing the various questions and concerns of these families. If the family history is not indicative of familial CHD and the individual does not have features that are suggestive of a syndromic cause, the clinician is encouraged to discuss empiric evidence of an increased risk of CHD in subsequent children. The family can also be informed about fetal echocardiography to monitor future pregnancies.

2009 UPDATE

Genomic studies in humans and model organisms have continued to yield new knowledge of the genetic underpinnings of CHD, as well as the molecular pathways that ensue. A third T-box transcription factor, TBX20, known for some time to play a key role in murine cardiac development via interaction with NKX2-5 and GATA-4, has now been implicated in human cardiac malformations. Germline missense and nonsense *TBX20* mutations are associated with familial CHD, comprising a spectrum of septation, chamber, and valvular abnormalities (Kirk et al., 2007). *TBX20* mutations have subsequently been identified in sporadic cases of tetralogy of Fallot, atrial septal defect, and total anomalous pulmonary venous connection (Liu et al., 2008). *TBX20* transcripts are upregulated in cardiac biopsies of patients with tetralogy of Fallot hearts as compared with simple ventricular septal defects and normal controls (Hammer et al., 2008).

Further studies of GATA-4 in murine models and human CHD have also been revealing (Rajagopal et al., 2007). Mice with heterozygous *GATA-4* mutation developed a range of cardiac phenotypes including atrial and ventricular septal defects, endocardial cushion defects, and right ventricular hypoplasia. In human candidate gene analyses, *GATA-4* mutations were found associated with an overlapping spectrum of cardiac malformations including atrial septal defects, endocardial cushion defects, and right ventricular hypoplasia with double-inlet left ventricle. These mutations were absent in a large control cohort and resulted in nonconservative amino acid substitutions in key protein domains, strengthening the assertion that these are indeed causative CHD mutations.

Novel sequence variants in *CFC1*, encoding a cofactor for NODAL-related signaling in early embryogenesis and

previously associated with laterality defects, have recently been identified in heterotaxy patients with associated cardiac malformations including double-outlet right ventricle (Selamet Tierney et al., 2007). Transmission of some of these variant alleles from unaffected parents, and the presence of others in unaffected controls, indicates incomplete penetrance and suggests a role for other factors in the development of these phenotypes. The importance of complex genetic interactions has been highlighted by functional genomics investigation of the NODAL pathway comprising *FOXH1*, *SMAD2*, *GDF1*, and *TDGF1*, in addition to *CFC1* and *NODAL* itself (Roessler et al., 2008). Sequence variants in several of these component genes combine to reduce NODAL signaling strength. Further, loss-of-function mutations of *GDF1* alone have been associated with human CHD (Karkera et al., 2007).

The discovery of chromosomal rearrangements associated with CHD provides a key opportunity to identify potential new CHD genes at translocation, duplication, and deletion breakpoints (Behjati et al., 2008; Mefford et al., 2008). In addition to conventional cytogenetic analysis, the technique of array comparative genomic hybridization has revealed heretofore undetected submicroscopic chromosomal aberrations in patients with CHD and other birth defects (Erdogan et al., 2008, Lu et al., 2008; Richards et al., 2008).

The next phase of genomic research in CHD resides in large measure in the elucidation of complex genetic and epigenetic interactions. The effects of complex genetics are evident in mice with *GATA-4* mutation in which the cardiac phenotype is strongly influenced by the genetic background in different lines (Rajagopal et al., 2007). It is likely that such interactions are responsible for the incomplete penetrance and variable expressivity that characterize nearly all known CHD mutations, including *TBX20*, *GATA-4*, and *CFC-1* (Kirk et al., 2007; Rajagopal et al., 2007; Selamet Tierney et al., 2007).

Several informative reviews of CHD genetics have been published recently (Andelfinger, 2008; Bruneau, 2008; Pierpont et al., 2007).

ACKNOWLEDGEMENTS

The authors thank Christine Seidman and Jon Seidman for helpful discussions and Kristin Tassinari for expert administrative assistance. This work was supported in part by NIH P50 HL074734 and by the Boston Children's Heart Foundation. The authors have no conflicts of interest related to this publication.

CHAPTER

Genomics in the Management of Lymphomas

Lisa Rimsza

INTRODUCTION

"Lymphoma" is not a single disease but a general term encompassing nearly 40 different types of lymphoid malignancies broadly divided into Hodgkin and non-Hodgkin categories, the latter including precursor B or T-cell neoplasms and mature B or T-cell neoplasms, as well as rare natural killer (NK) cell neoplasms. Each type of lymphoma has unique histogenesis. In other words, each type of lymphoma has been derived from a particular lymphocyte subset defined by stage of differentiation, immune compartment, function, activation status, and/or exposure to antigens. The diversity of the immune system is reflected by the many types of lymphoma ranging from indolent to aggressive, highly curable to almost invariably lethal diseases. Any age, race, or sex of patients can be affected, as can any location in the body. Lymphoid neoplasms including lymphoma (non-Hodgkin and Hodgkin lymphoma), chronic lymphocytic leukemia and multiple myeloma accounted for 93,420 new cases and 38,000 deaths in the United States in 2005. Over one-half of new cases are non-Hodgkin lymphoma (Morton et al., 2006). The incidence of lymphoma has increased 50% from 1970 to 1990, although the rate of increase appears to be slowing. Increased lymphoma incidence is partly attributable to the AIDS epidemic and increased numbers of immunocompromised patients and partly unexplained. The cause of the increased incidence in non-immunocompromised patients is unknown but thought to be due to unidentified factors in the environment such as viral or other infections, or exposure to toxins. Table 32.1 contains a list of Hodgkin and non-Hodgkin lymphoma types according to the World Health Organization (Jaffe et al., 2001).

Predisposition

Certain groups of patients are more likely to get lymphoma than others. In general, lymphoma is a disease of adults. As mentioned above, immunocompromised patients, either due to congenital immune deficiency, HIV infection, or iatrogenic immunosuppression (for the purpose of preventing organ or tissue rejection or for treatment of autoimmune and other types of disease) are at increased risk. Presumably, in immunosuppressed states, immunosurveillance by T-cells is compromised, allowing growth of a malignant lymphoid clone. Other risk factors include genetic diseases that promote genomic instability, exposure to ionizing radiation or chemotherapy, and exposure to certain infectious agents. Epstein-Barr virus (EBV) is particularly associated with Burkitt lymphoma (BL), Hodgkin lymphoma, and lymphomas in immunocompromised patients. Human T-cell leukemia virus-1 (HTLV1) is highly associated with adult T-cell leukemia/lymphoma. Kaposi's Sarcoma Human Virus-8 (KSHV8) is associated with primary effusion lymphoma (PEL). Chronic bacterial infections such as *Helicobacter pylori* in the stomach or *Borrelia burgdorferi* in the skin can create situations of

TABLE 32.1 Lymphoma disease categories, characteristic chromosomal aberrations, and involved genes

Lymphoma	Characteristic chromosome aberrations	Involved genes
B-cell		
Lymphoplasmacytic/Waldenstrom's macroglobulinemia	t(9;14)(p13;q32)	*PAX5, IgH*
Splenic Marginal Zone	Loss of 7q21-32	
Extranodal marginal zone (MALT)	t(11;18)(q21;q21) t(14;18)(q32;q21) t(1;14)(p22;q21) 5(1;2)(p22;p12)	*AP12, MALT1* *MALT1, IgH* *BCL-10, IgH BCL-10, Igκ*
Nodal marginal zone		
Follicular	t(14;18)(q32;q21)	*BCL-2, IgH*
Mantle cell	t(11;14)(q13;q32)	*CCND1* (cyclin D1), *IgH*
Diffuse large B cell	t(14;18)(q32;q21) t(3;14)(q27;q32) t(3;22)(q27;q11) t(2;3)(p12;q27) 2p13–15 amplification	*BCL-2, IgH* *BCL-6, IgH* *BCL-6, Igλ BCL-6, Igκ* *REL* amplification
Mediastinal (thymic) large B cell	Gains at 9p	*JAK* amplification
Intravascular large B cell		
Primary effusion		
Burkitt	t(8;14)(q24;q32) t(8:22) (q24;q11) t(2;8) (p11;q24)	*C-MYC, IgH* *C-MYC, Igλ* *C-MYC, Igκ*
Lymphomatoid granulomatosis		
T/NK cell		
Adult T-cell leukemia/lymphoma		
Extranodal NK/T-cell, nasal type		
Enteropathy-type T-cell		
Hepatosplenic T-cell	Isochromosome 7q	
Subcutaneous panniculitis-like T-cell		
Blastic NK-cell		
Mycosis fungoides/Sezary syndrome		
Primary cutaneous CD30-positive T-cell lymphoproliferative disorders		
Angioimmunoblastic T-cell		
Peripheral T-cell, unspecified		
Anaplastic large cell	t(2;5)(p23;q35) other translocations involving ALK	*ALK, NPM* *ALK*, others
Hodgkin		
Nodular lymphocyte predominant		
Nodular sclerosis		
Mixed cellularity		
Lymphocyte rich		
Lymphocyte depleted		
Immunodeficiency associated lymphoproliferative disorders		
Primary immune disorder-related		
Human immunodeficiency virus-related		
Post-transplant		
Methotrexate-associated		

chronic inflammation which in turn lead to lymphoid proliferation and an increased risk of lymphoma (Aster, 2005).

Diagnosis

The diagnosis of lymphoma is a highly specialized branch of medicine practiced by pathologists, often with subspecialty training (hematopathologists). The diagnosis of lymphoma, and even lymphoma type, can be suspected based on clinical history, laboratory data, or imaging studies, but the definitive diagnosis can only be made from a tissue biopsy. The histologic appearance of the biopsy alone is frequently insufficient for current classification of lymphoma. Additional studies to determine the lineage and subtype of the malignant lymphoid cells as well as any characteristic genetic changes are often necessary. These studies may include immunophenotyping by flow cytometry or immunohistochemistry, cytogenetics, molecular studies such as Southern blot, PCR, RT-PCR, or FISH to assess lymphoid clonality or to discover characteristic chromosomal aberrations. Molecular diagnostic techniques are almost routine in the medical diagnosis of hematopoietic neoplasms. Table 32.1 includes a description of the most common known genetic changes in lymphomas identified by karyotyping or FISH, summarized from a recent review article (Spagnolo et al., 2004). Because of the extreme complexity of diagnosis in lymphomas and the present need to integrate information from numerous different testing modalities, a search for a single unifying technique for diagnosis is particularly appealing. Gene expression profiling (GEP) is therefore being used extensively in studies aimed at establishing a precise clinical diagnosis of particular lymphoma subtypes based on characteristic GEP patterns or "signatures."

Prognosis

In a patient with a recent diagnosis of lymphoma, prognosis is the next question to be considered. It is imperative to know what type of clinical course the patient might be facing in order to plan therapy. Therapy for lymphoma can range from careful observation without treatment, to local radiation, immunomodulation, chemotherapy, and even hematopoietic stem cell transplant. The International Prognostic Index (IPI) is commonly used in patients with diffuse large B-cell lymphoma (DLBCL) to determine the likely clinical outcome of the patient (Shipp et al., 1993). This IPI score includes age, serum lactate dehydrogenase (LDH) level, performance status, stage of disease, and number of extra-nodal sites. Patients with high IPI scores usually have a worse outcome and may be selected for more aggressive or alternative therapies. However, even within groups of patients with similar IPI scores, the outcome is variable (from cure to death). Thus, there are clearly additional factors about each patient's tumor which influence the course of the disease. GEP has been recently used to identify gene expression patterns that have additional prognostic information for an individual patient independent of the clinical IPI score (Rosenwald et al., 2002; Shipp et al., 2002).

Novel and Emerging Therapeutics

After the questions of diagnosis and prognosis, a search for therapeutic targets has been the next information sought in lymphoma GEP studies. As stated previously, even within groups of patients with the same diagnosis and with similar IPI scores, there is still variability in patient outcome. Many of the known disease subtypes have a dismal prognosis. Therefore, a search for new therapeutic targets is a pressing concern. Recent studies have identified the NF-κB pathway (Lam et al., 2005), PKCβ, MAPK (Elenitoba-Johnson et al., 2003), or immune modulation (Dave et al., 2004; Rimsza et al., 2004) as likely targets.

GEP in Lymphoma Research

Lymphoma and leukemia are particularly amenable to GEP analysis due to the relative homogeneity of tissue compared to solid tumors and to the lack of strong cohesion between the cells which makes homogenization of tissue samples relatively easy. Because of these factors, the early use of cytogenetics helped to define the genetic basis of the different diseases. The cytogenetics of these diseases in turn led to development of PCR, RT-PCR, and FISH tests to identify the characteristic genomic changes with more sensitivity and with shorter turnaround time to test completion. Consequently, acquisition of fresh tissue for flow cytometry and/or snap freezing became standard practice for hematologic malignancies in many medical centers, which stands in contrast to most of the non-hematologic solid tumors for which tissue biopsy specimens are immediately placed in fixatives to preserve tissue appearance under the microscope after paraffin embedding and staining. Therefore, when GEP was developed as a new technique, research groups interested in lymphoma had access to high quality frozen tissue. Many groups also had experience performing molecular techniques such as flow sorting, RNA/DNA extraction and qualitative or quantitative PCR and RT-PCR for diagnostic purposes. This eased the way for lymphoma researchers to apply GEP in their studies. In 1998, after completion of the Human Genome Project with a draft of the entire human DNA sequence, Dr. Robert Klausner, then director of the National Institutes of Health (NIH), announced the Director's Challenge Program to establish the molecular diagnosis of cancer. The Leukemia and Lymphoma Molecular Profiling Project (LLMPP) got underway immediately with the development of the "LymphoChip." This chip was a spotted oligonucleotide microarray containing numerous elements known to represent genes expressed by B or T lymphoid cells, genes involved in the immune response, or genes expressed by lymphoma and leukemia cell lines. These genes included cytokines, chemokines, chemokine receptors, adhesion molecules, cell surface differentiation molecules, signal transduction molecules, transcription factors, cell cycle regulators, apoptosis genes, tumor suppressor genes, oncogenes, viral genes, and genes induced/repressed during the immune response (Alizadeh et al., 1999). Under the NIH Director's Challenge Program, this group examined a series of snap frozen lymph node biopsies from different types of lymphomas and benign tissues. The results demonstrated the striking differences in GEP of the several lymphomas from each other and from benign tissues (Alizadeh et al., 2000). This was the first demonstration of the potential of GEP in the investigation of lymphoma. Other papers by the LLMPP

and other research groups, which will be detailed under particular disease subtypes in the following chapters, soon followed. Besides the Lymphochip, other groups have used different array platforms including high density oligonucleotide arrays with focused gene sets (sub-genomic) such as HY6800 or U95 chips and later on total genome chips such as U133A + B (all from the Affymetrix corporation, Santa Clara, CA). Subsequent studies have also used tumor samples (sorted, unsorted, or microdissected) or cell lines representing different types of lymphomas with a focus on diagnosis, identification of genes involved in lymphomagenesis, discovery of new subtypes, prognostically relevant genes, and therapeutic targets. The different diseases, techniques, analysis strategies, specimen sources and questions asked have led to an explosive amount of information over the last 5 years. The major advances in the most common diseases or findings illustrating a general principle will be discussed in the sections below.

DIFFUSE LARGE B-CELL LYMPHOMA

DLBCL is the most common of the aggressive lymphomas, accounting for nearly 40% of lymphomas overall. With multi-agent chemotherapy, the overall survival is approximately 50% at 5 years including some patients who are completely cured and some who die of initial or relapsed disease. The clinical IPI score for DLBCL, described above, helps to stratify patients into risk categories based on clinical features. However, even within categories, patient outcome is variable. There are three common chromosomal alterations in DLBCL. The first involves translocations of the *BCL-6* gene at the 3q27 locus with the immunoglobulin heavy chain (*IgH*) or light chain (*Igκ* or *Igλ*) genes (see Table 32.1). Since *BCL-6* is a critical gene in germinal center formation, alterations in *BCL-6* fundamentally influence the developmental program of the B-cells. Secondly, the t(14;18)(q32;q21) translocation places the anti-apoptotic gene *BCL-2* under the regulation of IgH enhancers possibly leading to increased anti-apoptosis signals. Thirdly, amplification of chromosomal region 2p13–15 leads to amplification of the *REL* gene which is a member of the NF-κB family. DLBCL can occur at any anatomic location and is characterized histologically by sheets of large B-lymphocytes which may have a variety of cytologic appearances. Several subtypes have been described based on histologic appearance (centroblastic, immunoblastic, anaplastic) or sites of presentation (immune-privileged sites, intravascular) (Jaffe et al., 2001). Because of the variable patient outcome, it has long been suspected that other biologically relevant subtypes may exist.

Diagnosis and Histogenesis

In the first GEP paper published on lymphoma, the investigators used the Lymphochip to analyze 96 samples of several subtypes of lymphoid malignancies including DLBCL, benign lymphoid cell samples, and DLBCL cell lines. They discovered that in otherwise histologically indistinguishable cases, there were at least two different subtypes of DLBCL termed the germinal center B-cell (GCB) and activated B-cell (ABC) subtypes with better and worse survival respectively. This was the first documentation that DLBCL tumors with the same appearance could have unique gene expression signatures which yielded prognostically useful information. Other researchers used Affymetrix HU6800 oligonucleotide arrays to differentiate DLBCL from follicular lymphoma (FL). DLBCL had increased expression of LDH and transferrin (known prognostic markers in lymphoma) as well as increased cellular proliferation genes, invasion and metastasis genes (cathep-sins B and D), myc-targeted genes, hematopoietic cell kinases (induced with CD44 signaling) and apoptosis inhibitors. The GCB subtype was later found to correlate with the presence of the t(14;18)(q32;q21) translocation (23–35% of the cases) which made intuitive sense because the GCB subtype of DLBCL is of follicular cell origin and may share the translocation as an early pathogenic event similar to FL in which the t(14;18) is the characteristic genetic abnormality. These findings lent credence to the importance of the GCB and ABC distinction since these subtypes could be related to a previously well known prognostically important genetic translocation (Huang et al., 2002; Iqbal et al., 2004). A short panel of only 3 immunohistochemical stains was then developed from the GEP signatures, which was capable of dividing DLBCL into GCB and non-GCB subtypes yielding similar prognostic information to the GEP analysis (Chang et al., 2004; Hans et al., 2004). This latter study demonstrated that the strength and complexity of GEP analysis is reducible into a format which can be put into immediate clinical use for patient diagnosis.

Prognosis

The LLMPP group then expanded on the initial set of 40 DLBCL cases with a follow-up study of 240 cases of untreated, untransformed DLBCL with an emphasis on gene expression patterns related to prognosis. They discovered four key gene expression signatures that were highly related to patient survival: "germinal center," "major histocompatibility (MHC) class II," "lymph node," and "proliferation." Two of the four signatures, "MHC Class II" and "lymph node," contain antigen presenting molecules, T-cell-associated genes, inflammatory genes, and stromal genes, which directly reflect the critical role of tumor immunosurveillance and host response in relation to patient outcome. Representative genes from these four signatures with the addition of the gene *BMP6* were used to create a 17-gene outcome predictor score, which provide additional prognostic value independent of the clinical IPI score. A follow-up study on the same cases used comparative genomic hybridization (CGH) to assess chromosomal losses, gains, or amplifications and found that this added prognostic information to the GEP results. In particular, chromosomal gains involving 3p11–12 correlated with a worse outcome and were related to decreased MHC Class II signature while loss at 6q21 also correlated with worse outcome but with increased proliferation signature (Bea et al., 2005). Shipp

and colleagues, however, found no prognostic significance based on the cell-of-origin (GCB versus ABC) in their data using the HU6800 chip or in their re-analysis of the Lymphochip data. However, they did find that the Lymphochip data confirmed the prognostic significance of the PKC-β2A isoform. Since these two datasets appeared to have different conclusions, the LLMPP investigators downloaded and re-analyzed the Shipp dataset. Using a different analysis technique, they were able to reconcile somewhat the two different datasets and conclusions (Wright et al., 2003). This exercise emphasizes the importance of making GEP data available to the research community for interactive re-analysis to validate scientific conclusions. It also underscores that different conclusions can be reached as a result of different technology (gene arrays, samples) and analysis strategies. The Shipp research group then used the Affymetrix total genome chip (U133A + B) on 175 DLBCL cases and identified three distinct GEP-defined subgroups termed "oxidative-phosphorylation (Ox-Phos)," "B-cell receptor/proliferation" and "host response." The "B-cell receptor/proliferation" cluster is characterized by increased expression of genes related to not only signaling and proliferation but also replication, DNA repair, and transcription factors. The "host response" cluster showed high expression of T-cell, dendritic cell, macrophage, and antigen presentation genes which may reflect the prominent inflammatory background seen in some types of DLBCL (T-cell/histiocyte rich large B-cell lymphoma). The "Ox-Phos" cluster included genes related to oxidative-phosphorylation, mitochondrial function, and the electron transport chain (Monti et al., 2005). Comparison of the consensus clusters identified in this study with the GCB and ABC cell-of-origin signatures described by Rosenwald et al. indicated that these two classification schema identify different aspects of tumor biology. Some overlap of gene expression patterns was identified in that there was enrichment of genes from the "lymph node" signature in the "host response" consensus cluster as well as increased "proliferation" signature genes in the "B-cell receptor/signaling" consensus cluster. Furthermore, the "B-cell receptor/signaling" consensus cluster genes were enriched in the ABC subtype while the "Ox-Phos" consensus cluster genes were enriched in the GCB subtype.

The importance of the loss of the "MHC Class II" gene expression signature as reported by Rosenwald et al. was further documented by a reanalysis of the LLMPP dataset. This analysis revealed that for every incremental decrease in MHC Class II expression, there was an incremental increase in the hazard ratio of death and that loss of MHC Class II expression was associated with a decreased percentage of tumor infiltrating lymphocytes. The same investigators later used GEP data to create a positional expressional profiling map which used gene expression data organized by chromosomal position to create a "virtual" CGH with implications about the genetic structure of the MHC Class II region. These "virtual" results correlated well with actual laboratory CGH results demonstrating that complete mRNA data can be used assess the possibility of DNA alterations (Rimsza et al., 2006).

In order to create a more practical platform for outcome prediction in DLBCL, Lossos and co-workers analyzed 66 cases using quantitative real-time RT-PCR to assess mRNA levels of 36 genes identified by univariate analysis in either the Shipp or LLMPP GEP data or in previous studies reported in the literature using a variety of investigational methods. These investigators identified six genes (*LM02*, *BCL-6*, *FN1*, *CCND2*, *SCYA3*, and *BCL-2*) as most important to overall survival. Using these six genes, they created a multivariate model with prognostic predictive ability independent of the clinical IPI score (Lossos et al., 2004). This work again demonstrated that GEP data can be reduced to a small number of gene analyses that might be quickly applicable in the clinical laboratory setting to determine patient prognosis.

Additional Subtypes

Other investigators have used GEP to investigate phenotypically different subtypes of DLBCL in order to determine whether these represent different diseases. One group focused on DLBCL which either does or does not express the usually T-cell associated antigen CD5 (Kobayashi et al., 2003). A second group of investigators compared site-specific DLBCL either involving or outside of the central nervous system (Fujii et al., 2005). Both of these groups discovered GEP patterns suggesting that there were additional DLBCL subtypes yet to be identified. Another group analyzed cases of DLBCL with primary involvement of the skin. There has been a long debate over whether those cases of cutaneous DLBCL which involve the lower leg were a different disease from those involving other areas of the skin. These investigators discovered that those tumors involving the leg were frequently of the ABC subtype while those tumors involving other areas of the skin were generally related to the GCB subtype (Hoefnagel et al., 2005). Their results correlated well with the known worse outcome in DLBCL of the leg compared to other sites. Why the ABC subtype of cutaneous DLBCL would involve the lower leg more frequently than other skin locations is currently a matter for speculation.

Therapeutic Targets

Using the GEP data on the ABC subtype of DLBCL, the LLMPP group identified activation of the NFκB pathway as a potential therapeutic target not typically seen in the GCB subtype of lymphoma. They then treated ABC and GCB DLBCL cell lines with IκB kinase inhibitors and demonstrated toxicity only in the ABC cell lines. This work mined the GEP data, identified an abnormal pathway, and demonstrated the *in vitro* effects of targeting that pathway, illustrating the strength of GEP for identification of new therapeutic targets.

PRIMARY MEDIASTINAL LARGE B-CELL LYMPHOMA

Primary Mediastinal Large B-Cell Lymphoma (PMBCL) has been a controversial entity that was originally thought to be
